VOLUME 1

SECTION I
GENERAL ISSUES IN CLINICAL MICROBIOLOGY / 1
VOLUME EDITOR: JAMES H. JORGENSEN
SECTION EDITOR: MELVIN P. WEINSTEIN

1 Introduction to the Ninth Edition of the *Manual of Clinical Microbiology* / 3
PATRICK R. MURRAY

2 Laboratory Management / 4
W. MICHAEL DUNNE, JR., AND MARK T. LAROCCO

3 Laboratory Design / 20
MICHAEL L. WILSON AND L. BARTH RELLER

4 Laboratory Consultation, Communication, and Information Systems / 30
JOSEPH M. CAMPOS

5 General Principles of Specimen Collection and Handling / 43
J. MICHAEL MILLER, KAREN KRISHER, AND HARVEY T. HOLMES

6 Procedures for the Storage of Microorganisms / 55
CATHY A. PETTI, KAREN C. CARROLL, AND LARRY G. REIMER

SECTION II
THE CLINICAL MICROBIOLOGY LABORATORY IN INFECTION DETECTION, PREVENTION, AND CONTROL / 63
VOLUME EDITOR: MICHAEL A. PFALLER
SECTION EDITOR: LOREEN A. HERWALDT

7 Decontamination, Disinfection, and Sterilization / 65
ANDREAS F. WIDMER AND RENO FREI

8 Prevention and Control of Laboratory-Acquired Infections / 97
MICHAEL A. NOBLE

9 Laboratory Detection of Potential Agents of Bioterrorism / 107
ROSEMARY HUMES AND JAMES W. SNYDER

10 Infection Control Epidemiology and Clinical Microbiology / 118
DANIEL J. DIEKEMA AND MICHAEL A. PFALLER

11 Laboratory Procedures for the Epidemiological Analysis of Microorganisms / 129
DAVID R. SOLL, CLAUDE PUJOL, AND SHAWN R. LOCKHART

12 Investigation of Foodborne and Waterborne Disease Outbreaks / 152
TIMOTHY F. JONES

SECTION III

DIAGNOSTIC TECHNOLOGIES IN CLINICAL MICROBIOLOGY / 171
VOLUME EDITOR: JAMES H. JORGENSEN
SECTION EDITOR: MELVIN P. WEINSTEIN

13 Microscopy / 173
DANNY L. WIEDBRAUK

14 Principles of Stains and Media / 182
KIMBERLE C. CHAPIN

15 Manual and Automated Systems for Detection and Identification of Microorganisms / 192
KAREN C. CARROLL AND MELVIN P. WEINSTEIN

16 Molecular Detection and Identification of Microorganisms / 218
FREDERICK S. NOLTE AND ANGELA M. CALIENDO

17 Susceptibility Testing Instrumentation and Computerized Expert Systems for Data Analysis and Interpretation / 245
SANDRA S. RICHTER AND MARY JANE FERRARO

18 Immunoassays for the Diagnosis of Infectious Diseases / 257
A. BETTS CARPENTER

SECTION IV

BACTERIOLOGY / 272
VOLUME EDITOR: ELLEN JO BARON
SECTION EDITORS: J. STEPHEN DUMLER, GUIDO FUNKE, J. MICHAEL JANDA, IRVING NACHAMKIN, AND JAMES VERSALOVIC

GENERAL

19 Taxonomy and Classification of Bacteria / 275
PETER A. R. VANDAMME

20 Specimen Collection, Transport, and Processing: Bacteriology / 291
RICHARD B. THOMSON, JR.

21 Reagents, Stains, and Media: Bacteriology / 334
KIMBERLE C. CHAPIN AND TSAI-LING LAUDERDALE

22 Algorithm for Identification of Aerobic Gram-Positive Cocci / 365
KATHRYN L. RUOFF

23 Algorithm for Identification of Aerobic Gram-Positive Rods / 368
GUIDO FUNKE

24 Algorithms for Identification of Aerobic Gram-Negative Bacteria / 371
PAUL C. SCHRECKENBERGER AND DAVID LINDQUIST

25 Algorithm for Identification of Anaerobic Bacteria / 377
DIANE M. CITRON

26 Algorithms for Identification of Curved and Spiral-Shaped Gram-Negative Rods / 379
IRVING NACHAMKIN

27 Algorithms for Identification of *Mycoplasma, Ureaplasma*, and Obligate Intracellular Bacteria / 384
J. STEPHEN DUMLER

GRAM-POSITIVE COCCI

28 *Staphylococcus, Micrococcus*, and Other Catalase-Positive Cocci / 390
TAMMY L. BANNERMAN AND SHARON J. PEACOCK

29 *Streptococcus* / 412
BARBARA SPELLERBERG AND CLAUDIA BRANDT

30 *Enterococcus* / 430
LÚCIA MARTINS TEIXEIRA, MARIA DA GLÓRIA SIQUEIRA CARVALHO, AND RICHARD R. FACKLAM

31 *Aerococcus, Abiotrophia*, and Other Aerobic Catalase-Negative, Gram-Positive Cocci / 443
KATHRYN L. RUOFF

GRAM-POSITIVE RODS

32 *Bacillus* and Other Aerobic Endospore-Forming Bacteria / 455
NIALL A. LOGAN, TANJA POPOVIC, AND ALEX HOFFMASTER

33 *Listeria* and *Erysipelothrix* / 474
JACQUES BILLE

34 Coryneform Gram-Positive Rods / 485
GUIDO FUNKE AND KATHRYN A. BERNARD

35 *Nocardia, Rhodococcus, Gordonia, Actinomadura, Streptomyces*, and Other Aerobic Actinomycetes / 515
PATRICIA S. CONVILLE AND FRANK G. WITEBSKY

36 *Mycobacterium:* General Characteristics, Laboratory Detection, and Staining Procedures / 543
GABY E. PFYFFER

37 *Mycobacterium:* Laboratory Characteristics of Slowly Growing Mycobacteria / 573
VÉRONIQUE VINCENT AND M. CRISTINA GUTIÉRREZ

38 *Mycobacterium:* Clinical and Laboratory Characteristics of Rapidly Growing Mycobacteria / 589
BARBARA A. BROWN-ELLIOTT AND RICHARD J. WALLACE, JR.

GRAM-NEGATIVE BACTERIA

39 *Neisseria* / 601
WILLIAM M. JANDA AND CHARLOTTE A. GAYDOS

40 *Actinobacillus, Capnocytophaga, Eikenella, Kingella, Pasteurella*, and Other Fastidious or Rarely Encountered Gram-Negative Rods / 621
ALEXANDER VON GRAEVENITZ, REINHARD ZBINDEN, AND REINIER MUTTERS

41 *Haemophilus* / 636
MOGENS KILIAN

42 *Enterobacteriaceae:* Introduction and Identification / 649
J. J. FARMER III, K. D. BOATWRIGHT, AND J. MICHAEL JANDA

43 *Escherichia, Shigella*, and *Salmonella* / 670
JAMES P. NATARO, CHERYL A. BOPP, PATRICIA I. FIELDS, JAMES B. KAPER, AND NANCY A. STROCKBINE

44 *Yersinia* / 688
AUDREY WANGER

45 *Klebsiella, Enterobacter, Citrobacter, Serratia, Plesiomonas,* and Other *Enterobacteriaceae* / 698
SHARON L. ABBOTT

46 *Aeromonas* / 716
AMY J. HORNEMAN, AFSAR ALI, AND SHARON L. ABBOTT

47 *Vibrio* and Related Organisms / 723
SHARON L. ABBOTT, J. MICHAEL JANDA, JUDITH A. JOHNSON, AND J. J. FARMER III

48 *Pseudomonas* / 734
EDITH BLONDEL-HILL, DEBORAH A. HENRY, AND DAVID P. SPEERT

49 *Burkholderia, Stenotrophomonas, Ralstonia, Cupriavidus, Pandoraea, Brevundimonas, Comamonas, Delftia,* and *Acidovorax* / 749
JOHN J. LiPUMA, BART J. CURRIE, GARY D. LUM, AND PETER A. R. VANDAMME

50 *Acinetobacter, Achromobacter, Chryseobacterium, Moraxella,* and Other Nonfermentative Gram-Negative Rods / 770
PAUL C. SCHRECKENBERGER, MARYAM I. DANESHVAR, AND DANNIE G. HOLLIS

51 *Bordetella* / 803
MICHAEL J. LOEFFELHOLZ AND GARY N. SANDEN

52 *Francisella* and *Brucella* / 815
DAVID LINDQUIST, MAY C. CHU, AND WILL S. PROBERT

53 *Legionella* / 835
PAUL H. EDELSTEIN

54 *Bartonella* / 850
BRUNO B. CHOMEL AND JEAN MARC ROLAIN

ANAEROBIC BACTERIA

55 *Peptostreptococcus, Finegoldia, Anaerococcus, Peptoniphilus, Veillonella,* and Other Anaerobic Cocci / 862
YULI SONG AND SYDNEY M. FINEGOLD

56 *Propionibacterium, Lactobacillus, Actinomyces,* and Other Non-Spore-Forming Anaerobic Gram-Positive Rods / 872
EIJA KÖNÖNEN AND WILLIAM G. WADE

57 *Clostridium* / 889
ERIC A. JOHNSON, PAULA SUMMANEN, AND SYDNEY M. FINEGOLD

58 *Bacteroides, Porphyromonas, Prevotella, Fusobacterium,* and Other Anaerobic Gram-Negative Rods / 911
DIANE M. CITRON, IAN R. POXTON, AND ELLEN JO BARON

CURVED AND SPIRAL-SHAPED GRAM-NEGATIVE RODS

59 *Campylobacter* and *Arcobacter* / 933
COLLETTE FITZGERALD AND IRVING NACHAMKIN

60 *Helicobacter* / 947
JAMES G. FOX AND FRANCIS MEGRAUD

61 *Leptospira* / 963
PAUL N. LEVETT

62 *Borrelia* / 971
BETTINA WILSKE, BARBARA J. B. JOHNSON, AND MARTIN E. SCHRIEFER

63 *Treponema* and Other Human Host-Associated Spirochetes / 987
VICTORIA POPE, STEVEN J. NORRIS, AND ROBERT E. JOHNSON

MYCOPLASMAS AND OBLIGATE INTRACELLULAR BACTERIA

64 *Mycoplasma* and *Ureaplasma* / 1004
KEN B. WAITES AND DAVID TAYLOR-ROBINSON

65 *Chlamydia* and *Chlamydophila* / 1021
ANDREAS ESSIG

66 *Rickettsia* and *Orientia* / 1036
DAVID H. WALKER AND DONALD H. BOUYER

67 *Ehrlichia, Anaplasma,* and Related Intracellular Bacteria / 1046
JUAN P. OLANO AND MARIA E. AGUERO-ROSENFELD

68 *Coxiella* / 1062
PHILIPPE BROUQUI, THOMAS MARRIE, AND DIDIER RAOULT

69 *Tropheryma* / 1070
DIDIER RAOULT, FLORENCE FENOLLAR, AND DAVID RELMAN

SECTION V
ANTIBACTERIAL AGENTS AND SUSCEPTIBILITY TEST METHODS / 1075
VOLUME EDITOR: JAMES H. JORGENSEN
SECTION EDITORS: MARY JANE FERRARO AND JOHN D. TURNIDGE

70 Antibacterial Agents / 1077
JOSEPH D. C. YAO AND ROBERT C. MOELLERING, JR.

71 Mechanisms of Resistance to Antibacterial Agents / 1114
LOUIS B. RICE AND ROBERT A. BONOMO

72 Susceptibility Test Methods: General Considerations / 1146
JOHN D. TURNIDGE, MARY JANE FERRARO, AND JAMES H. JORGENSEN

73 Susceptibility Test Methods: Dilution and Disk Diffusion Methods / 1152
JAMES H. JORGENSEN AND JOHN D. TURNIDGE

74 Special Phenotypic Methods for Detecting Antibacterial Resistance / 1173
JANA M. SWENSON, JEAN B. PATEL, AND JAMES H. JORGENSEN

75 Susceptibility Test Methods: Fastidious Bacteria / 1193
JANET FICK HINDLER AND JEAN B. PATEL

76 Susceptibility Test Methods: Anaerobic Bacteria / 1214
DIANE M. CITRON AND DAVID W. HECHT

77 Susceptibility Test Methods: Mycobacteria, *Nocardia,* and Other Actinomycetes / 1223
GAIL L. WOODS, NANCY G. WARREN, AND CLARK B. INDERLIED

78 Detection and Characterization of Antimicrobial Resistance Genes in Pathogenic Bacteria / 1248
J. KAMILE RASHEED, FRANKLIN COCKERILL, AND FRED C. TENOVER

VOLUME 2

SECTION VI
VIROLOGY / 1270
VOLUME EDITOR: MARIE LOUISE LANDRY
SECTION EDITORS: ANGELA M. CALIENDO, YI-WEI TANG, AND ALEXANDRA VALSAMAKIS

GENERAL

79 Taxonomy and Classification of Viruses / 1273
CORNELIA BÜCHEN-OSMOND

80 Specimen Collection, Transport, and Processing: Virology / 1284
MICHAEL S. FORMAN AND ALEXANDRA VALSAMAKIS

81 Reagents, Stains, Media, and Cell Lines: Virology / 1297
KIMBERLE C. CHAPIN

82 Algorithms for Detection and Identification of Viruses / 1304
MARIE LOUISE LANDRY, ANGELA M. CALIENDO, YI-WEI TANG, AND ALEXANDRA VALSAMAKIS

RNA VIRUSES

83 Human Immunodeficiency Viruses / 1308
BRIGITTE P. GRIFFITH, SHELDON CAMPBELL, AND DONALD R. MAYO

84 Human T-Cell Lymphotropic Virus Types 1 and 2 / 1330
ANTOINE GESSAIN, CHARLENE S. DEZZUTTI, ELLIOT P. COWAN, AND RENU B. LAL

85 Influenza Viruses / 1340
ROBERT L. ATMAR

86 Parainfluenza and Mumps Viruses / 1352
DIANE S. LELAND

87 Respiratory Syncytial Virus and Human Metapneumovirus / 1361
YI-WEI TANG AND JAMES E. CROWE, JR.

88 Measles and Rubella Viruses / 1378
WILLIAM J. BELLINI AND JOSEPH P. ICENOGLE

89 Enteroviruses and Parechoviruses / 1392
JOSÉ R. ROMERO

90 Rhinoviruses / 1405
MARIE LOUISE LANDRY

91 Coronaviruses / 1414
JAMES B. MAHONY

92 Hepatitis A and E Viruses / 1424
DAVID A. ANDERSON

93 Hepatitis C and G Viruses / 1437
JOHN D. SCOTT AND DAVID R. GRETCH

94 Rotaviruses, Caliciviruses, Astroviruses, Enteric Adenoviruses, and Other Diarrheic Viruses / 1453
TIBOR FARKAS AND XI JIANG

95 Rabies Virus / 1470
LILLIAN A. ORCIARI AND CHARLES E. RUPPRECHT

96 Hendra and Nipah Viruses / 1478
PIERRE E. ROLLIN, PAUL ROTA, SHERIF ZAKI, AND THOMAS G. KSIAZEK

97 Arboviruses / 1486
ROBERT S. LANCIOTTI AND THEODORE F. TSAI

98 Hantaviruses / 1501
CHARLES F. FULHORST AND MICHAEL D. BOWEN

99 Arenaviruses and Filoviruses / 1510
PIERRE E. ROLLIN, STUART T. NICHOL, SHERIF ZAKI, AND THOMAS G. KSIAZEK

DNA VIRUSES

100 Herpes Simplex Viruses and Herpes B Virus / 1523
KEITH R. JEROME AND RHODA ASHLEY MORROW

101 Varicella-Zoster Virus / 1537
ANNE A. GERSHON, JINGXIAN CHEN, PHILIP LaRUSSA, AND SHARON P. STEINBERG

102 Human Cytomegalovirus / 1549
RICHARD L. HODINKA

103 Epstein-Barr Virus / 1564
ANNIKA LINDE AND KERSTIN I. FALK

104 Human Herpesviruses 6, 7, and 8 / 1574
PHILIP E. PELLETT AND GRAHAM TIPPLES

105 Adenoviruses / 1589
CHRISTINE ROBINSON AND MARCELA ECHAVARRIA

106 Human Papillomaviruses / 1601
BRUCE K. PATTERSON

107 Human Polyomaviruses / 1612
EUGENE O. MAJOR, CAROLINE RYSCHKEWITSCH, ALEXANDRA VALSAMAKIS, AND JEAN HOU

108 Human Parvoviruses / 1622
JEANNE A. JORDAN

109 Poxviruses / 1631
INGER K. DAMON

110 Hepatitis B and D Viruses / 1641
REBECCA T. HORVAT AND GARY E. TEGTMEIER

SUBVIRAL AGENTS

111 Transmissible Spongiform Encephalopathies / 1660
ADRIANO AGUZZI AND MARKUS GLATZEL

SECTION VII
ANTIVIRAL AGENTS AND SUSCEPTIBILITY TEST METHODS / 1667
VOLUME EDITOR: JAMES H. JORGENSEN
SECTION EDITOR: JOHN D. TURNIDGE

112 Antiviral Agents / 1669
NELL S. LURAIN AND KENNETH D. THOMPSON

113 Mechanisms of Resistance to Antiviral Agents / 1689
ROBERT W. SHAFER, SHIRIT EINAV, AND SUNWEN CHOU

114 Susceptibility Test Methods: Viruses / 1705
MAX Q. ARENS AND ELLA M. SWIERKOSZ

SECTION VIII
MYCOLOGY / 1719
VOLUME EDITOR: MICHAEL A. PFALLER
SECTION EDITOR: DAVID W. WARNOCK

GENERAL

115 Taxonomy and Classification of Fungi / 1721
DAVID W. WARNOCK

116 Specimen Collection, Transport, and Processing: Mycology / 1728
DEANNA A. SUTTON

117 Reagents, Stains, and Media: Mycology / 1737
MARK T. LAROCCO

118 Algorithms for Detection and Identification of Fungi / 1745
YVONNE R. SHEA

FUNGI

119 *Candida*, *Cryptococcus*, and Other Yeasts of Medical Importance / 1762
KEVIN C. HAZEN AND SUSAN A. HOWELL

120 *Pneumocystis* / 1789
MELANIE T. CUSHION

121 *Aspergillus*, *Fusarium*, and Other Opportunistic Moniliaceous Fungi / 1802
PAUL E. VERWEIJ AND MARY E. BRANDT

122 *Rhizopus*, *Rhizomucor*, *Absidia*, and Other Agents of Systemic and Subcutaneous Zygomycoses / 1839
MALCOLM D. RICHARDSON AND PIRKKO KOUKILA-KÄHKÖLÄ

123 *Histoplasma*, *Blastomyces*, *Coccidioides*, and Other Dimorphic Fungi Causing Systemic Mycoses / 1857
MARY E. BRANDT AND DAVID W. WARNOCK

124 *Trichophyton*, *Microsporum*, *Epidermophyton*, and Agents of Superficial Mycoses / 1874
RICHARD C. SUMMERBELL, IRENE WEITZMAN, AND ARVIND A. PADHYE

125 *Bipolaris*, *Exophiala*, *Scedosporium*, *Sporothrix*, and Other Dematiaceous Fungi / 1898
G. SYBREN DE HOOG AND ROXANA G. VITALE

126 Fungi Causing Eumycotic Mycetoma / 1918
G. SYBREN DE HOOG, ABDALLA O. A. AHMED, MICHAEL R. MCGINNIS, AND ARVIND A. PADHYE

127 Mycotoxins / 1928
WILLIAM J. HALSALL, NANCY C. ISHAM, AND MAHMOUD A. GHANNOUM

128 *Lacazia, Pythium*, and *Rhinosporidium* / 1936
LEONEL MENDOZA

SECTION IX
ANTIFUNGAL AGENTS AND SUSCEPTIBILITY TEST METHODS / 1947
VOLUME EDITOR: JAMES H. JORGENSEN
SECTION EDITOR: JOHN D. TURNIDGE

129 Antifungal Agents / 1949
SEVTAP ARIKAN AND JOHN H. REX

130 Mechanisms of Resistance to Antifungal Agents / 1961
THEODORE C. WHITE

131 Susceptibility Test Methods: Yeasts and Filamentous Fungi / 1972
ANA V. ESPINEL-INGROFF AND MICHAEL A. PFALLER

SECTION X
PARASITOLOGY / 1987
VOLUME EDITOR: MICHAEL A. PFALLER
SECTION EDITOR: LYNNE S. GARCIA

GENERAL

132 Taxonomy and Classification of Human Parasites / 1989
FRANCIS E. G. COX

133 Specimen Collection, Transport, and Processing: Parasitology / 1995
PETER DEPLAZES, LYNNE S. GARCIA, AND ROBYN Y. SHIMIZU

134 Reagents, Stains, and Media: Parasitology / 2013
SUSAN E. SHARP

135 Algorithms for Detection and Identification of Parasites / 2020
LYNNE S. GARCIA, ROBYN Y. SHIMIZU, AND GRAEME P. PALTRIDGE

PARASITES

136 *Plasmodium* and *Babesia* / 2040
WILLIAM O. ROGERS

137 *Leishmania* and *Trypanosoma* / 2057
DAVID A. BRUCKNER AND JAIME A. LABARCA

138 *Toxoplasma* / 2070
MARIANNA WILSON, JEFFERY L. JONES, AND JAMES B. McAULEY

139 Pathogenic and Opportunistic Free-Living Amebae / 2082
GOVINDA S. VISVESVARA

140 Intestinal and Urogenital Amebae, Flagellates, and Ciliates / 2092
AMY L. LEBER AND SUSAN NOVAK-WEEKLEY

141 *Isospora, Cyclospora,* and *Sarcocystis* / 2113
DAVID S. LINDSAY, STEVE J. UPTON, AND LOUIS M. WEISS

142 *Cryptosporidium* / 2122
LIHUA XIAO AND VITALIANO CAMA

143 Microsporidia / 2133
RAINER WEBER, ALEXANDER MATHIS, AND PETER DEPLAZES

144 Nematodes / 2144
HARSHA SHEOREY, BEVERLEY-ANN BIGGS, AND PETER TRAYNOR

145 Filarial Nematodes / 2156
TESS McPHERSON AND THOMAS B. NUTMAN

146 Cestodes / 2166
HECTOR H. GARCIA, JUAN A. JIMENEZ, AND HERMES ESCALANTE

147 Trematodes / 2175
MALCOLM K. JONES AND DONALD P. McMANUS

148 Less Common Helminths / 2188
GARY W. PROCOP AND RONALD C. NEAFIE

149 Arthropods of Medical Importance / 2199
SAM R. TELFORD III

SECTION XI
ANTIPARASITIC AGENTS AND SUSCEPTIBILITY TEST METHODS / 2219
VOLUME EDITOR: JAMES H. JORGENSEN
SECTION EDITOR: MARY JANE FERRARO

150 Antiparasitic Agents / 2221
KARIN LEDER AND PETER F. WELLER

151 Mechanisms of Resistance to Antiparasitic Agents / 2240
W. EVAN SECOR AND PHUC NGUYEN-DINH

152 Susceptibility Test Methods: Parasites / 2250
PHUC NGUYEN-DINH AND W. EVAN SECOR

Author Index / xxvii

Subject Index / xxix

Centre National de Référence Listeria, Institut de Microbiologie, Rue de Bugnon 48, CH-1011 Lausanne, Switzerland

EDITH BLONDEL-HILL
Department of Pathology and Laboratory Medicine, British Columbia Children's Hospital, 2G5, 4500 Oak Street, Vancouver, British Columbia, Canada V6H 3N1

K. D. BOATWRIGHT
Infectious Diseases Division, Medical University of South Carolina, 100 Doughty Street, Room 210BA, Charleston, SC 29425

ROBERT A. BONOMO
Medical Service 111(W), Louis Stokes Cleveland VA Medical Center, 10701 East Boulevard, and Department of Medicine, Case Western Reserve University, Cleveland, OH 44106

CHERYL A. BOPP
Foodborne and Diarrheal Diseases Laboratory Section, Foodborne and Diarrheal Diseases Branch, Division of Bacterial and Mycotic Diseases, National Center for Infectious Diseases, Centers for Disease Control and Prevention, Atlanta, GA 30333

DONALD H. BOUYER
Department of Pathology, University of Texas Medical Branch, 301 University Boulevard, Keiller Building, Galveston, TX 77555-0609

MICHAEL D. BOWEN
Bioterrorism Rapid Response and Advanced Technology Laboratory, Bioterrorism Preparedness and Response Program, Centers for Disease Control and Prevention, MS G42, 1600 Clifton Road, N.E., Atlanta, GA 30333

CLAUDIA BRANDT
Institute of Medical Microbiology, Johann Wolfgang Goethe University, Paul Ehrlich Strasse 40, 60596 Frankfurt, Germany

MARY E. BRANDT
Mycotic Diseases Branch, Division of Bacterial and Mycotic Diseases, National Center for Infectious Diseases, Centers for Disease Control and Prevention, 1600 Clifton Road, N.E., Mailstop G-11, Atlanta, GA 30333

PHILIPPE BROUQUI
Unité des Rickettsies, IFR 48, CNRS UMR 6020, Faculté de Médecine, 27 Boulevard Jean Moulin, 13385 Marseille Cedex 5, and Service des Maladies Infectieuses et Tropicales, CHU Nord, 13015 Marseille, France

BARBARA A. BROWN-ELLIOTT
Department of Microbiology, The University of Texas Health Center at Tyler, 11937 US Highway 271, Tyler, TX 75708

DAVID A. BRUCKNER
Department of Pathology and Laboratory Medicine, David Geffen School of Medicine at UCLA, P.O. Box 951713, Los Angeles, CA 90095-1713

CORNELIA BÜCHEN-OSMOND
Jerome L. and Dawn Greene Infectious Disease Laboratory, Mailman School of Public Health, Department of Epidemiology—Lipkin, 722 W. 168th Street, New York, NY 10032

ANGELA M. CALIENDO
Department of Pathology and Laboratory Medicine, Emory University School of Medicine, 1364 Clifton Road, N.E., Atlanta, GA 30322

VITALIANO CAMA
Division of Parasitic Diseases, Centers for Disease Control and Prevention, 4770 Buford Highway, Atlanta, GA 30341

SHELDON CAMPBELL
Pathology and Laboratory Service, VA Connecticut Healthcare System, 950 Campbell Avenue, West Haven, CT 06516, and Department of Laboratory Medicine, Yale University School of Medicine, New Haven, CT 06520

JOSEPH M. CAMPOS
Department of Laboratory Medicine, Children's National Medical Center, Washington, DC 20010, and Departments of Pediatrics, Pathology, and Microbiology/Tropical Medicine, George Washington University Medical Center, Washington, DC 20037

A. BETTS CARPENTER
Department of Pathology, Joan C. Edwards School of Medicine, Marshall University, 1542 Spring Valley Drive, Huntington, WV 25704

KAREN C. CARROLL
Department of Pathology, The Johns Hopkins University School of Medicine, 600 North Wolfe Street, Baltimore, MD 21287

MARIA DA GLÓRIA SIQUEIRA CARVALHO
Streptococcus Laboratory, Respiratory Diseases Branch, Division of Bacterial Diseases, Centers for Disease Control and Prevention, Mail Stop C0-2, Atlanta, GA 30333

KIMBERLE C. CHAPIN
Department of Pathology and Laboratory Medicine, Rhode Island Hospital, Providence, RI 02903

JINGXIAN CHEN
Department of Pathology, Columbia University College of Physicians & Surgeons, 650 W. 168th Street, New York, NY 10032

BRUNO B. CHOMEL
Department of Population Health and Reproduction, School of Veterinary Medicine, University of California, Davis, CA 95616

SUNWEN CHOU
Department of Medicine, Oregon Health and Sciences University, Portland, OR 97239

MAY C. CHU
Emerging and Dangerous Pathogens Alert and Response Operations, CSR/CDS/WHO, Avenue Appia 20, CH-1211 Geneva, Switzerland

DIANE M. CITRON
R. M. Alden Research Laboratory, 2001 Santa Monica Boulevard, Suite 685W, Santa Monica, CA 90404, and Microbial Research Laboratory, Los Angeles County-University of Southern California Medical Center, 1801 E. Marengo Street, Los Angeles, CA 90033

FRANKLIN COCKERILL
Department of Laboratory Medicine, Mayo Clinic, Rochester, MN 55905

PATRICIA S. CONVILLE
Microbiology Service, Department of Laboratory Medicine, Clinical Center, National Institutes of Health, Building 10, Room 2C-385, 10 Center Drive MSC 1508, Bethesda, MD 20892-1508

ELLIOT P. COWAN
Center for Biologics Evaluation and Research, U.S. Food and Drug Administration, Rockville, MD 20852

FRANCIS E. G. COX
Department of Infectious and Tropical Diseases, London School of Hygiene and Tropical Medicine, London WC1E 7HT, United Kingdom

JAMES E. CROWE, JR.
Departments of Pediatrics and Microbiology and Immunology, Vanderbilt University School of Medicine, T-2220 MCN, 1161 21st Avenue, South, Nashville, TN 37232-2905

BART J. CURRIE
Tropical and Emerging Infectious Diseases Division, Menzies School of Health Research, Charles Darwin University, Darwin 0810, Northern Territory, Australia

MELANIE T. CUSHION
Department of Internal Medicine, Division of Infectious Diseases, University of Cincinnati College of Medicine, 231 Albert Sabin Way, Cincinnati, OH 45267-0560

INGER K. DAMON
Poxvirus Program, Division of Viral and Rickettsial Diseases, National Center for Infectious Diseases, Centers for Disease Control and Prevention, 1600 Clifton Road, Mailstop G43, Atlanta, GA 30333

MARYAM I. DANESHVAR
Centers for Disease Control and Prevention, Atlanta, GA 30333

G. SYBREN DE HOOG
Centraalbureau voor Schimmelcultures, P.O. Box 85167, NL-3508 AD The Netherlands

PETER DEPLAZES
Institute of Parasitology, University of Zurich, Winterthurerstrasse 266a, CH-8057 Zurich, Switzerland

CHARLENE S. DEZZUTTI
Laboratory Branch, Division of HIV/AIDS Prevention, National Center for HIV, STD, and TB Prevention, Centers for Disease Control and Prevention, Atlanta, GA 30333

DANIEL J. DIEKEMA
Division of Medical Microbiology, Department of Pathology, University of Iowa College of Medicine, Iowa City, IA 52242

J. STEPHEN DUMLER
Division of Medical Microbiology, Department of Pathology, The Johns Hopkins University School of Medicine, 720 Rutland Avenue, Ross 624, Baltimore, MD 21205

W. MICHAEL DUNNE, JR.
Departments of Pathology and Immunology, and Molecular Microbiology, Washington University School of Medicine, and Microbiology Laboratory, Barnes-Jewish Hospital, St. Louis, MO 63110

MARCELA ECHAVARRIA
Clinical Virology Laboratory, Center for Medical Education and Clinical Research, University Hospital, Buenos Aires C1431FWO, Argentina

PAUL H. EDELSTEIN
Clinical Microbiology Laboratory, 4th Floor, Gates Building, Hospital of the University of Pennsylvania, 3400 Spruce Street, Philadelphia, PA 19104-4283

SHIRIT EINAV
Department of Medicine, Stanford University, Stanford, CA 94305

HERMES ESCALANTE
Department of Microbiology, School of Biological Sciences, Universidad Nacional de Trujillo, Av. Juan Pablo II S/N, Ciudad Universitaria, Trujillo, Peru

ANA V. ESPINEL-INGROFF
Medical Mycology Research Laboratory, Division of Infectious Diseases, VCU Medical Center, 1101 East Marshall Street, Sanger Hall Room 7-049, Richmond, VA 23298-0049

ANDREAS ESSIG
Department of Medical Microbiology and Hygiene, University Hospital Ulm, D-89081 Ulm, Germany

RICHARD R. FACKLAM
Streptococcus Laboratory, Respiratory Diseases Branch, Division of Bacterial Diseases, Centers for Disease Control and Prevention, Mail Stop C0-2, Atlanta, GA 30333

KERSTIN I. FALK
Centre for Microbiological Preparedness, Swedish Institute for Infectious Disease Control, SE-171 82 Solna, Sweden

TIBOR FARKAS
Division of Infectious Diseases, Department of Pediatrics, Cincinnati Children's Hospital Medical Center, University of Cincinnati College of Medicine, 3333 Burnet Avenue, Cincinnati, OH 45229-3039

J. J. FARMER III
United States Public Health Service (retired), 1781 Silver Hill Road, Stone Mountain, GA 30087-2212

FLORENCE FENOLLAR
Unité des Rickettsies, IFR 48, CNRS UMR 6020, Faculté de Médecine, 27 Boulevard Jean Moulin, 13385 Marseille Cedex 5, France

MARY JANE FERRARO
Clinical Microbiology Laboratory, Massachusetts General Hospital, and Harvard Medical School, Boston, MA 02114

PATRICIA I. FIELDS
Foodborne and Diarrheal Diseases Laboratory Section, Foodborne and Diarrheal Diseases Branch, Division of Bacterial and Mycotic Diseases, National Center for Infectious Diseases, Centers for Disease Control and Prevention, Atlanta, GA 30333

SYDNEY M. FINEGOLD
Infectious Diseases Section, VA Medical Center West Los Angeles, Los Angeles, CA 90073, and Department of Medicine and Department of Microbiology, Immunology, and Molecular Genetics, University of California at Los Angeles School of Medicine, Los Angeles, CA 90025

COLLETTE FITZGERALD
National *Campylobacter* and *Helicobacter* Reference Laboratory, Foodborne and Diarrheal Diseases Branch, Centers for Disease Control and Prevention, Atlanta, GA 30333

MICHAEL S. FORMAN
Department of Pathology, Johns Hopkins Medicine, 600 North Wolfe Street, Meyer B1-193, Baltimore, MD 21287

JAMES G. FOX
Division of Comparative Medicine, Massachusetts Institute of Technology, 77 Massachusetts Avenue, Building 16, Room 825C, Cambridge, MA 02139

RENO FREI
Microbiology Laboratory, University Hospital Basel, Petersgraben 4, 4031 Basel, Switzerland

CHARLES F. FULHORST
Department of Pathology, University of Texas Medical Branch, 301 University Boulevard, Route 0609, Galveston, TX 77555-0609

GUIDO FUNKE
Department of Medical Microbiology and Hygiene, Gärtner & Colleagues Laboratories, D-88212 Ravensburg, Germany

HECTOR H. GARCIA
Department of Microbiology, School of Sciences, Universidad Peruana Cayetano Heredia, Av. Honorio Delgado 430, SMP, Lima 31, Peru, and Cysticercosis Unit, Instituto de Ciencias Neurologicas, Lima, Peru

LYNNE S. GARCIA
LSG & Associates, 512-12th Street, Santa Monica, CA 90402-2908

CHARLOTTE A. GAYDOS
Division of Infectious Diseases and Medicine, Johns Hopkins University, 1159 Ross Building, 720 Rutland Avenue, Baltimore, MD 21205

ANNE A. GERSHON
Department of Pediatrics, Columbia University College of Physicians & Surgeons, 650 W. 168th Street, New York, NY 10032

ANTOINE GESSAIN
EPVO Unit, EEMI Department, Institut Pasteur, Paris 75015, France

MAHMOUD A. GHANNOUM
Center for Medical Mycology, Department of Dermatology, University Hospitals/Case Western Reserve University, 11100 Euclid Avenue, Cleveland, OH 44106

MARKUS GLATZEL
University Hospital Zürich, Institute of Neuropathology, Schmelzbergstrasse 12, CH-8091 Zürich, Switzerland

DAVID R. GRETCH
Viral Hepatitis Laboratory, University of Washington Harborview Medical Center, 325 Ninth Avenue, Box 359690, Seattle, WA 98104

BRIGITTE P. GRIFFITH
Virology Reference Laboratory, VA Connecticut Healthcare System, 950 Campbell Avenue, West Haven, CT 06516, and Department of Laboratory Medicine, Yale University School of Medicine, New Haven, CT 06520

M. CRISTINA GUTIÉRREZ
Reference Laboratory for Mycobacteria, Institut Pasteur, 25 rue du Docteur Roux, 75015 Paris, France

WILLIAM J. HALSALL
Center for Medical Mycology, Department of Dermatology, University Hospitals/Case Western Reserve University, 11100 Euclid Avenue, Cleveland, OH 44106

KEVIN C. HAZEN
Division of Clinical Microbiology, Department of Pathology, University of Virginia Health System, P.O. Box 800255, Charlottesville, VA 22908-0255

DAVID W. HECHT
Department of Medicine, Division of Infectious Diseases, Loyola University Medical Center, 2160 S. First Avenue, Building 54-149, Maywood, IL 60153, and Hines Veterans Administration Hospital, Hines, IL 60141

DEBORAH A. HENRY
Child and Family Research Institute, 950 West 28th Avenue, Room 370, Vancouver, British Columbia, Canada V5Z 4H4

JANET FICK HINDLER
Department of Pathology and Laboratory Medicine, UCLA Medical Center, Los Angeles, CA 90095-1713

RICHARD L. HODINKA
Departments of Pediatrics and Anatomic Pathology and Clinical Laboratories, Clinical Virology Laboratory, Children's Hospital of Philadelphia and University of Pennsylvania School of Medicine, Philadelphia, PA 19104

ALEX HOFFMASTER
Meningitis and Special Pathogens Branch, Division of Bacterial and Mycotic Diseases, National Center for Infectious Diseases, Centers for Disease Control and Prevention, 1600 Clifton Road, MS G34, Atlanta, GA 30333

DANNIE G. HOLLIS
Centers for Disease Control and Prevention, Atlanta, GA 30333

HARVEY T. HOLMES
Laboratory Response Branch, National Center for Infectious Diseases, Centers for Disease Control and Prevention, Atlanta, GA 30333

AMY J. HORNEMAN (formerly Martin-Carnahan)
Department of Epidemiology and Preventive Medicine, University of Maryland School of Medicine, 10 South Pine Street, MSTF 900D, Baltimore, MD 21201

REBECCA T. HORVAT
Department of Pathology and Laboratory Medicine, University of Kansas School of Medicine, 3901 Rainbow Boulevard, Mail Stop 4045, Kansas City, KS 66160

JEAN HOU
Laboratory of Molecular Medicine and Neuroscience, National Institute of Neurological Disorders and Stroke, 10 Center Drive, MSC 1296, Building 10, Room 3B14A, Bethesda, MD 20892-1296

SUSAN A. HOWELL
King's College London, Mycology, St. Johns Institute of Dermatology, Guy's and St. Thomas' NHS Foundation Trust, London SE1 7EH, Great Britain

ROSEMARY HUMES
Association of Public Health Laboratories, 8515 Georgia Avenue, Silver Spring, MD 20910

JOSEPH P. ICENOGLE
Measles, Mumps, Rubella, and Herpesviruses Branch, Division of Viral Diseases, National Center for Immunizations and Respiratory Diseases, Centers for Disease Control and Prevention, Mail Stop C-22, 1600 Clifton Road, NE, Atlanta, GA 30333

CLARK B. INDERLIED
Department of Pathology, Keck School of Medicine, University of Southern California, Los Angeles, CA 90033, and Department of Pathology & Laboratory Medicine, Childrens Hospital Los Angeles, 4650 Sunset Boulevard, Mail Stop #32, Los Angeles, CA 90027

NANCY C. ISHAM
Center for Medical Mycology, Department of Dermatology, University Hospitals/Case Western Reserve University, 11100 Euclid Avenue, Cleveland, OH 44106

J. MICHAEL JANDA
Microbial Diseases Laboratory, California State Department of Health Services, 850 Marina Bay Parkway, Room E164, Richmond, CA 94804

WILLIAM M. JANDA
Clinical Microbiology Laboratory, Department of Pathology, M/C 750, University of Illinois Medical Center, 840 S. Wood Street, Chicago, IL 60612

KEITH R. JEROME
Department of Laboratory Medicine, University of Washington, and Program in Infectious Diseases, Fred Hutchinson Cancer Research Center, 1100 Fairview Avenue N., D3-100, Seattle, WA 98109

XI JIANG
Division of Infectious Diseases, Department of Pediatrics, Cincinnati Children's Hospital Medical Center, University of Cincinnati College of Medicine, 3333 Burnet Avenue, Cincinnati, OH 45229-3039

JUAN A. JIMENEZ
Cysticercosis Unit, Instituto de Ciencias Neurologicas, Jr Ancash 1271, Lima 1, Peru

BARBARA J. B. JOHNSON
Division of Vector-Borne Infectious Diseases, Centers for Disease Control and Prevention, Rampart Road, Foothills Campus, Fort Collins, CO 80522

ERIC A. JOHNSON
Department of Food Microbiology and Toxicology, University of Wisconsin, 1925 Willow Drive, Madison, WI 53706-1187

JUDITH A. JOHNSON
VA Medical Center, 10 North Greene Street, Room 4D-150, Baltimore, MD 21201

ROBERT E. JOHNSON
National Center for HIV, STD, and TB Prevention, E-02, Centers for Disease Control and Prevention, 1600 Clifton Road, NE, Atlanta, GA 30333

JEFFERY L. JONES
Parasitic Diseases Branch, Division of Parasitic Diseases, National Center for Infectious Diseases, Centers for Disease Control and Prevention, MS F-22, 4770 Buford Highway, Atlanta, GA 30341

MALCOLM K. JONES
Molecular Parasitology Laboratory, Queensland Institute of Medical Research, 300 Herston Road, Herston, Queensland 4006, Australia

TIMOTHY F. JONES
Communicable and Environmental Disease Services, Tennessee Department of Health, 4th Floor, Cordell Hull Building, 425 5th Avenue N., Nashville, TN 37247

JEANNE A. JORDAN
Department of Pathology, University of Pittsburgh, Magee-Women's Hospital, 204 Craft Avenue, Pittsburgh, PA 15213

JAMES H. JORGENSEN
Department of Pathology, The University of Texas Health Science Center, 7703 Floyd Curl Drive, San Antonio, TX 78229-3700

JAMES B. KAPER
Center for Vaccine Development and Department of Microbiology & Immunology, University of Maryland School of Medicine, 685 West Baltimore Street, Baltimore, MD 21201

MOGENS KILIAN
Department of Medical Microbiology and Immunology, Bartholin Building, University of Aarhus, DK-8000 Aarhus C, Denmark

EIJA KÖNÖNEN
Anaerobe Reference Laboratory, Department of Bacterial and Inflammatory Diseases, National Public Health Insititute (KTL), FIN-00300 Helsinki, Finland

PIRKKO KOUKILA-KÄHKÖLÄ
HUS Diagnostics, Mycology Laboratory, Helsinki University Central Hospital, Helsinki, Finland

KAREN KRISHER
Detroit Medical Center University Laboratories, 4201 St. Antoine, Detroit, MI 48201

THOMAS G. KSIAZEK
Special Pathogens Branch, MS G-14, Centers for Disease Control and Prevention, 1600 Clifton Road, Atlanta, GA 30333

JAIME A. LABARCA
Department of Medicine, Facultad de Medicine, Pontificia Universidad Catolica de Chile, Lira 44, Santiago, Chile

RENU B. LAL
Epidemiology Branch, Division of HIV/AIDS Prevention, National Center for HIV, STD and TB Prevention, Centers for Disease Control and Prevention, Atlanta, GA 30333

ROBERT S. LANCIOTTI
Diagnostic and Reference Laboratory, Arbovirus Diseases Branch, Centers for Disease Control and Prevention, Fort Collins, CO 80521

MARIE LOUISE LANDRY
Department of Laboratory Medicine, Yale University School of Medicine, P.O. Box 208035, New Haven, CT 06520-8035

MARK T. LaROCCO
Department of Pathology, St. Luke's Episcopal Health System, Houston, TX 77030

PHILIP LaRUSSA
Department of Pediatrics, Columbia University College of Physicians & Surgeons, 650 W. 168th Street, New York, NY 10032

TSAI-LING LAUDERDALE
Division of Clinical Research, National Health Research Institutes, Taipei 11529, Taiwan, Republic of China

AMY L. LEBER
Quest Diagnostics, Nichols Institute, 33608 Ortega Highway, San Juan Capistrano, CA 92690

KARIN LEDER
Infectious Disease Epidemiology Unit, Department of Epidemiology and Preventive Medicine, Monash Medical School, Alfred Hospital, Commercial Road, Prahran, Victoria 3181, Australia

DIANE S. LELAND
Indiana University School of Medicine, 350 W. 11th Street, Indianapolis, IN 46202

PAUL N. LEVETT
Provincial Laboratory, Saskatchewan Health, 3211 Albert Street, Regina, Saskatchewan, S4S 5W6 Canada

ANNIKA LINDE
Department of Epidemiology, Swedish Institute for Infectious Disease Control, SE-171 82 Solna, Sweden

DAVID LINDQUIST
Microbial Diseases Laboratory, California Department of Health Services, 850 Marina Bay Parkway, Richmond, CA 94804

DAVID S. LINDSAY
Center for Molecular Medicine and Infectious Diseases, Department of Biomedical Sciences and Pathobiology, Virginia-Maryland Regional College of Veterinary Medicine, Virginia Tech, 1410 Prices Fork Road, Blacksburg, VA 24061-0342

JOHN J. LiPUMA
Department of Pediatrics and Communicable Diseases, University of Michigan Medical School, 1150 W. Medical Center Drive, 8323 MSRB III, 0646, Ann Arbor, MI 48109

SHAWN R. LOCKHART
Department of Biological Sciences, University of Iowa, Iowa City, IA 52242

MICHAEL J. LOEFFELHOLZ
Viromed Laboratories, 6101 Blue Circle Drive, Minnetonka, MN 55343

NIALL A. LOGAN
Department of Biological and Biomedical Sciences, School of Life Sciences, Glasgow Caledonian University, Cowcaddens Road, Glasgow G4 0BA, United Kingdom

GARY D. LUM
Pathology Administration, Northern Territory Government Pathology Service, PO Box 41326, Casuarina NT 0811, Australia

NELL S. LURAIN
Department of Immunology/Microbiology, Rush University Medical Center, 1653 West Congress Parkway, Chicago, IL 60612

JAMES B. MAHONY
Department of Pathology and Molecular Medicine, McMaster University, and Regional Virology and Chlamydiology Laboratory, St. Joseph's Healthcare, 50 Charlton Avenue East, Hamilton, Ontario L8N 4A6, Canada

EUGENE O. MAJOR
Laboratory of Molecular Medicine and Neuroscience, National Institute of Neurological Disorders and Stroke, 10 Center Drive, MSC 1296, Building 10, Room 3B14A, Bethesda, MD 20892-1296

THOMAS MARRIE
Faculty of Medicine and Dentistry, 2J2.01 Walter C. Mackenzie Health Sciences Center, 8440 112th Street, Edmonton, Alberta, Canada T6G 2R7

ALEXANDER MATHIS
Institute of Parasitology, University of Zurich, Winterthurerstrasse 266a, CH-8057 Zurich, Switzerland

DONALD R. MAYO
Virology Reference Laboratory, VA Connecticut Healthcare System, 950 Campbell Avenue, West Haven, CT 06516, and Department of Laboratory Medicine, Yale University School of Medicine, New Haven, CT 06520

JAMES B. McAULEY
Rush University, 1725 W. Harrison Street, Chicago, IL 60612

MICHAEL R. McGINNIS
Medical Mycology Research Center, Center for Tropic Diseases, University of Texas Medical Branch, 301 University Boulevard, Galveston, TX 77555-0609

DONALD P. McMANUS
Molecular Parasitology Laboratory, Queensland Institute of Medical Research, 300 Herston Road, Herston, Queensland 4006, Australia

TESS McPHERSON
Laboratory of Parasitic Diseases, National Institute of Allergy and Infectious Diseases, National Institutes of Health, 4 Center Drive, Bethesda, MD 20892

FRANCIS MEGRAUD
INSERM ERI 10, Laboratoire de Bactériologie, Université Victor Segalen Bordeaux 2, 33076 Bordeaux Cedex, France

LEONEL MENDOZA
Medical Technology Program, Department of Microbiology and Molecular Genetics, Michigan State University, 322 North Kedzie Hall, East Lansing, MI 48824-1031

J. MICHAEL MILLER
Laboratory Response Branch, National Center for Infectious Diseases, Centers for Disease Control and Prevention, Atlanta, GA 30333

ROBERT C. MOELLERING, JR.
Department of Medicine, Beth Israel Deaconess Medical Center, and Harvard Medical School, Boston, MA 02215

RHODA ASHLEY MORROW
Department of Laboratory Medicine, University of Washington, and Program in Infectious Diseases, Fred Hutchinson Cancer Research Center, 1100 Fairview Avenue N., LE-500, Seattle, WA 98109

PATRICK R. MURRAY
Clinical Center, National Institutes of Health, Bethesda, MD 20892-1508

REINIER MUTTERS
Institute of Medical Microbiology and Hospital Hygiene, Philipps University, D-35037 Marburg, Germany

IRVING NACHAMKIN
Department of Pathology and Laboratory Medicine, University of Pennsylvania School of Medicine, 4th Floor, Gates Building, 3400 Spruce Street, Philadelphia, PA 19104-4283

JAMES P. NATARO
Center for Vaccine Development and Department of Microbiology & Immunology, University of Maryland School of Medicine, 685 West Baltimore Street, Baltimore, MD 21201

RONALD C. NEAFIE
Parasitic Infectious Disease Pathology Branch, The Armed Forces Institute of Pathology, 6825 16th Street, N.W., Washington, DC 20306

PHUC NGUYEN-DINH
Division of Parasitic Diseases, MS F-22, Centers for Disease Control and Prevention, 4770 Buford Highway, N.E., Atlanta, GA 30341

STUART T. NICHOL
Special Pathogens Branch, MS G-14, Centers for Disease Control and Prevention, 1600 Clifton Road, Atlanta, GA 30333

MICHAEL A. NOBLE
Department of Pathology and Laboratory Medicine, University of British Columbia, Room 328A, 2733 Heather Street, Vancouver, British Columbia V5Z 1M9, Canada

FREDERICK S. NOLTE
Department of Pathology and Laboratory Medicine, Emory University School of Medicine, 1364 Clifton Road, N.E., Atlanta, GA 30322

STEVEN J. NORRIS
Department of Pathology and Laboratory Medicine, University of Texas Medical School at Houston, P.O. Box 20708, Houston, TX 77225

SUSAN NOVAK-WEEKLEY
Microbiology Services, Kaiser Permanente Regional Reference Laboratories, 11668 Sherman Way, North Hollywood, CA 91605

THOMAS B. NUTMAN
Laboratory of Parasitic Diseases, National Institute of Allergy and Infectious Diseases, National Institutes of Health, 4 Center Drive, Room B1-03, Bethesda, MD 20892

JUAN P. OLANO
Department of Pathology, University of Texas Medical Branch, Galveston, TX 77555-0609

LILLIAN A. ORCIARI
Poxvirus and Rabies Branch, Division of Viral and Rickettsial Diseases, National Center for Zoonotic, Vector-Borne, and Enteric Diseases, Coordinating Center for Infectious Diseases, Centers for Disease Control and Prevention, Mailstop G-33, Atlanta, GA 30333

ARVIND A. PADHYE
Mycotic Disease Branch, Division of Bacterial and Mycotic Diseases, National Center for Infectious Diseases, Centers

for Disease Control and Prevention, Mail Stop G-11, Atlanta, GA 30333

GRAEME P. PALTRIDGE
Bacteriology and Parasitology Laboratory, Canterbury Health Laboratories, Christchurch, New Zealand

JEAN B. PATEL
Epidemiology and Laboratory Branch, Division of Healthcare Quality Promotion, Centers for Disease Control and Prevention, 1600 Clifton Road, Atlanta, GA 30333

BRUCE K. PATTERSON
Department of Pathology and Medicine, Division of Infectious Diseases and Geographic Medicine, Stanford University Medical School, 300 Pasteur Drive, Room H1537J, M/C 5629, Stanford, CA 94305-5629

SHARON J. PEACOCK
Wellcome Trust-Mahidol University-Oxford Tropical Medicine Research Program, Faculty of Tropical Medicine, Mahidol University, 420/6 Rajvithi Road, Bangkok 10400, Thailand

PHILIP E. PELLETT
Lerner Research Institute, Cleveland Clinic Foundation, 9500 Euclid Avenue, NN10, Cleveland, OH 44106

CATHY A. PETTI
Departments of Pathology and Medicine, University of Utah School of Medicine, Salt Lake City, UT 84132, and Associated Regional and University Pathologists, Salt Lake City, UT 84108

MICHAEL A. PFALLER
Division of Medical Microbiology, Department of Pathology, University of Iowa College of Medicine, Iowa City, IA 52242

GABY E. PFYFFER
Department of Medical Microbiology, Center for Laboratory Medicine, Kantonsspital Luzern, CH-6000 Luzern 16, Switzerland

VICTORIA POPE
National Center for HIV, STD, and TB Prevention, A-12, Centers for Disease Control and Prevention, 1600 Clifton Road, NE, Atlanta, GA 30333 (retired)

TANJA POPOVIC
Centers for Disease Control and Prevention, 1600 Clifton Road, MS D50, Atlanta, GA 30333

IAN R. POXTON
Medical Microbiology, Centre for Infectious Diseases, University of Edinburgh College of Medicine and Veterinary Medicine, The Chancellor's Building, 49, Little France Crescent, Edinburgh EH16 4SB, Scotland

WILL S. PROBERT
Microbial Diseases Laboratory, California Department of Health Services, 850 Marina Bay Parkway, Richmond, CA 94804

GARY W. PROCOP
Miller School of Medicine, The University of Miami, Miami, FL 33136

CLAUDE PUJOL
Department of Biological Sciences, University of Iowa, Iowa City, IA 52242

DIDIER RAOULT
Unité des Rickettsies, IFR 48, CNRS UMR 6020, Faculté de Médecine, 27 Boulevard Jean Moulin, 13385 Marseille Cedex 5, France

J. KAMILE RASHEED
Division of Healthcare Quality Promotion (G-08), National Center for Infectious Diseases, Centers for Disease Control and Prevention, 1600 Clifton Road, Atlanta, GA 30333

LARRY G. REIMER
Departments of Pathology and Medicine, University of Utah School of Medicine, Salt Lake City, UT 84132, and Associated Regional and University Pathologists, Salt Lake City, UT 84108

L. BARTH RELLER
Clinical Microbiology Laboratory, Duke University Medical Center, and Departments of Pathology and Medicine, Duke University School of Medicine, Durham, NC 27710

DAVID RELMAN
Departments of Microbiology & Immunology, and Medicine, Stanford University, and Veterans Affairs Palo Alto Health Care System, Palo Alto, CA 94304

JOHN H. REX
AstraZeneca, Alderley House, Alderley Park, Macclesfield, Cheshire, United Kingdom, and Division of Infectious Diseases, Department of Internal Medicine, Center for the Study of Emerging and Reemerging Pathogens, University of Texas Medical School—Houston, Houston, TX 77030

LOUIS B. RICE
Medical Service 111(W), Louis Stokes Cleveland VA Medical Center, 10701 East Boulevard, and Department of Medicine, Case Western Reserve University, Cleveland, OH 44106

MALCOLM D. RICHARDSON
Mycology Unit, Department of Bacteriology and Immunology, University of Helsinki, Haartman Institute, Haartmaninkatu 3, P.O. Box 21, 00014 Helsinki, Finland

SANDRA S. RICHTER

Acknowledgment of Previous Contributors

The *Manual of Clinical Microbiology* is by its nature a continuously revised work which refines and extends the contributions of previous editions. Since its first edition in 1970, many eminent scientists have contributed to this important reference work. The American Society for Microbiology and its Publications Board gratefully acknowledge the contributions of all of these generous authors over the life of this Manual.

Preface

It seems that much of my professional career has revolved around the *Manual of Clinical Microbiology*, first as an author, then as a section editor, and finally for the last four editions as the editor in chief. I have learned a great deal from this experience, although I must confess that I have forgotten far more science than I have retained. My most valuable lesson has been to rely on my fellow editors. I have been privileged to have worked on all four editions with Ellen Jo Baron and Mike Pfaller, with Jim Jorgensen for the last two editions, and with Marie Landry, who ably filled Bob Yolken's shoes, for this edition. I have also relied on the help of 29 section editors, including 7 new editors for this edition, and hundreds of authors. Almost 40% of the authors of the ninth edition of the *Manual of Clinical Microbiology* (MCM9) are new. For each edition I have purposely selected new editors and authors with the conviction that they will bring a new perspective to their assignment. I have systematically added non-U.S. authors, representing almost 30% of the authors of this edition, so that this Manual will be truly international in scope. These changes have not come without difficulties. My fellow editors and I have frequently had to curtail our authors' "creativity" for the sake of consistency, taught them that eloquence can equate to brevity, and reminded them that deadlines are not the fantasies of publishers. Many unpopular decisions are made in the creation of any work as comprehensive as MCM9, so I must thank the editors and authors for their understanding. If I have offended anyone in the process, it was unintentional.

I am very proud of what we have accomplished with MCM9, and I hope that this feeling is shared by the entire editorial board and all the authors. Although the field of clinical microbiology is undergoing dramatic changes with the confluence of traditional techniques and exciting advances in genomics and proteomics, I believe that the *Manual of Clinical Microbiology* should form the road map for our understanding of this evolving scientific discipline. I hope that the readers share the opinion of the authors and editors that MCM9 successfully meets this goal. An additional feature for the ninth edition is a CD-ROM with close to 500 illustrations from the book. It is available for purchase through ASM Press.

I would be remiss if I did not acknowledge the wisdom and guidance provided by Susan Birch, the ASM Press Production Manager whose name should more appropriately be listed on the cover of MCM9, and Jeff Holtmeier, the director of ASM Press who makes everyone's job a little easier and more pleasant. The entire staff at ASM Press was very supportive and helpful during the process of preparing this edition of the Manual.

PATRICK R. MURRAY

Introduction to the Ninth Edition of the *Manual of Clinical Microbiology*

PATRICK R. MURRAY

1

The eighth edition of the *Manual of Clinical Microbiology* (MCM8) was a dramatic change from previous editions, growing from one to two volumes and increasing in length by more than 20%. Even though the changes in the ninth edition of the *Manual of Clinical Microbiology* (MCM9) are not as obvious, they are no less substantial. One new volume editor, Marie Louise Landry, and seven new section editors joined the editorial board. Of the 269 authors, almost 40% are new and 28% represent 22 non-U.S. countries. Although we retained the same 11 sections that were introduced in MCM8 and the algorithm chapters that have proved to be practical identification tools, we have expanded the chapters from 141 to 152. The MCM8 chapter "Pathogenic and Indigenous Microorganisms of Humans" was removed in MCM9 because we believed that this topic could not be satisfactorily covered in a limited chapter. To compensate for this deletion, the discussion of the topic was expanded in the individual organism chapters. A new chapter, "Microscopy," was added to section III, Diagnostic Technologies in Clinical Microbiology. This topic was covered in the sixth edition of the Manual but not in subsequent editions, a decision that the editorial board felt should be rectified. Section IV, Bacteriology, was increased by three chapters—coverage of mycobacteria was expanded from two chapters to three; coverage of anaerobes was expanded from three chapters to four; and *Tropheryma* was assigned to a new chapter, chapter 69. The most significant changes in MCM9 occurred in section VI, Virology, reflecting the influence of a new volume editor and three new section editors. The discussion of hepatitis A and hepatitis E viruses was consolidated into one chapter, and three new chapters were added—chapter 91, "Coronaviruses"; chapter 96, "Hendra and Nipah Viruses"; and chapter 98, "Hantaviruses." Coverage in other chapters was expanded to include metapneumoviruses and parechoviruses. Two new chapters were added to section VIII, Mycology—chapter 127, "Mycotoxins"; and chapter 128, "*Lacazia, Pythium*, and *Rhinosporidium*." Finally, section X, Parasitology, was reorganized with the addition of four new chapters. *Cryptosporidium* was transferred to a new chapter, chapter 142, and the coverage of helminths was expanded from two to five chapters.

All chapters in MCM9 were updated with the most current taxonomic and diagnostic information, which is not an insignificant feat in this era of molecular classification and diagnostic tools. Nearly 4,000 of the literature citations in MCM9 were published after the last edition went to press. Despite these efforts, we recognize that by the time that MCM9 will be published, some data will be dated and some statements will be inaccurate. This occurs despite the best efforts of the authors, editors, and ASM staff and is the unfortunate reality of publishing a major reference text. We ask for your understanding, as well as for your help in remedying the inaccuracies. If you discover an error, please contact ASM Press. A system will be established to post both the error and the corrections for the readership. The editorial board hopes that through the efforts of our authors and your careful review of the text, MCM9 will be an accurate, valuable reference source.

Laboratory Management*

W. MICHAEL DUNNE, JR., AND MARK T. LAROCCO

2

The diagnostic microbiology laboratory, regardless of demographics, is a business and needs to be managed with the same basic principles and tenets used by businesses. True, the products provided by microbiology laboratories belong to the service industry, but the day-to-day management of resources, productivity, finances, quality, and clients is no different. Whether the laboratory is for profit, not for profit, academic, or community based, it needs to follow the same financial rules and standards that businesses do. To develop a primer for medical microbiologists on the basics of business theory, economics, financial accounting, organizational behavior, and marketing, etc., within the confines of this chapter is impractical given the wealth of excellent contemporary reference materials currently available (9, 25, 31). Rather, this chapter will highlight four major management issues: operations, finance, personnel, and regulations.

OPERATIONS

The efficient operation of a clinical microbiology laboratory and effective delivery of diagnostic services to clinicians and their patients are vitally dependent on the management and communication skills of laboratory directors, managers, supervisors, and technologists. Quality laboratory services result directly from the performance of competent laboratory scientists, but the key element lies in the delivery of these services, a highly complex management activity. The clinical microbiology manager's task is to integrate and coordinate laboratory resources so that quality laboratory services can be provided as effectively and efficiently as possible. Laboratory management may be described in terms of four basic functions: planning, organization, direction, and control. In practice, the boundaries between these functions are often obscure because of the interdependence of the functions for effective management.

Strategic Planning

Strategic planning is the process of deciding on objectives for the organization that fulfill its mission, selecting and allocating the resources needed to obtain those objectives, and assigning responsibilities and accountabilities to those involved in the process. The microbiology laboratory will likely be included in the strategic plan of the overall department that in turn embraces the plan of the hospital or other parent organization. Nonetheless, the microbiology director or manager should have an appreciation of key features of the hospital's strategic plan.

A mission statement is a concise description of the overall goals and values of the organization. A mission statement may be thought of as the hospital's credo on which all of its actions are based. In a sense, the mission statement serves as the cornerstone of the organization's strategic plan as it represents the highest level of success that the organization hopes to achieve.

Planning at the department level is an essential requirement of laboratory management. Each section of the laboratory should establish a set of goals and objectives, formulate policies to carry out those objectives, develop intermediate and short-range plans to implement policies, and develop detailed procedures for implementing each plan. During the planning process, managers must be aware of any changes that occur in the operational environment because such awareness keeps decisions realistic and expectations achievable (37). An analysis of the operational environment can be accomplished by conducting an objective assessment of the laboratory's strengths, weaknesses, opportunities, and threats (SWOT analysis). Let's say, for example, that the microbiology laboratory is asked to develop a strategic plan to incorporate molecular diagnostic testing into its service offerings. A preliminary SWOT analysis may reveal the following.

Strengths

1. Strong technical leadership in the laboratory facilitates the implementation of new technologies.
2. The hospital supports a solid-organ and stem cell transplant program with patients that will likely produce a high demand for the service.
3. A teaching affiliation with a regional school of medical technology provides recruitment opportunities for trained technologists.

Weaknesses

1. The skill sets of most of the current staff do not include molecular diagnostics.

* This chapter contains information presented in chapter 2 by David L. Sewell and James D. MacLowry in the eighth edition of this Manual.

2. Having no record of performance in molecular diagnostics may place the laboratory at a marketing disadvantage.
3. The lack of experience with managing a molecular diagnostic service in the context of the overall laboratory budget.

Opportunities

1. A new academic affiliation will immediately provide resources (space, personnel, and equipment) for supporting a molecular diagnostic service.
2. There is a paucity of facilities in your geographic area that offer molecular diagnostic testing, and physicians are not happy with the service provided by a regional commercial laboratory. The potential for developing outreach volume is high.

Threats

1. Inappropriate utilization of the technology may create a financial hardship for the laboratory.
2. Competition from other commercial laboratories that call on physicians' offices directly.

Specific goals and objectives provide laboratory management with a clear direction before the planning process begins. When policies are set with these goals and objectives in mind, constraints are in place to guide the planning strategies prior to the major plan development stage. A few examples of goals and objectives for the clinical microbiology laboratory may be as follows.

1. Ensure the quality of diagnostic microbiology services by monitoring key functions and processes to determine improvements for quality and cost.
2. Support research and development by reviewing and testing new methods and equipment.
3. Expand volume by researching new markets for outpatient business.
4. Act as consultants to medical staff and outcomes managers to ensure that the most appropriate diagnostic tests are ordered.
5. Communicate, through results, a philosophy of customer service to patients, physicians, family members, and coworkers.
6. Support the strategic plans of the hospital through the laboratory services provided.
7. Employ personnel who are responsive to the needs of patients, physicians, clients, guests, and coworkers.
8. Provide for the future of laboratory service by participating in educational and training programs for medical technology.

Once a goal is identified, a plan for completion of the project and short-term interim plans are needed. Finally, the details necessary for implementation and the expectations of performance are defined. High performance cannot be achieved, however, without accountability. When there is a lack of accountability, needed information may be missed, decisions are not made when action is required, and people do not receive guidance or support when faced with new challenges. Accountability means that people can count on one another to keep performance commitments and communication agreements. It is the basis for an environment of trust, support, and dedication to excellence (27).

During implementation of any department plan, it is important to periodically measure success. Such an exercise affords management the opportunity to step back and revisit elements of the planning strategy while at the same time providing staff with appropriate feedback and motivation to see a difficult project through to its conclusion.

Organization

Organization in the clinical laboratory refers to both structure and process. Structure exemplifies stated relationships or framework, and process deals with interaction. There are three key elements of organization: the tasks to be performed, the individuals who are to perform the tasks, and the clinical laboratory as a workplace.

A scope of services document provides a detailed list of services provided by the microbiology laboratory. The document should contain general information on the hours of laboratory operation and on staffing. It may also include test-specific information such as specimen collection and transport requirements, reference ranges, locations of testing, (in-house versus reference laboratories), and cutoff times for receipt of specimens. The scope of services provided by the laboratory is often a reflection of the type of hospital or facility it serves.

Organizational charts are common to most business structures as they provide a visualization of who is doing what and the chain of command. Although nobody likes to think of oneself as being below other people, these charts can serve a useful purpose in the clinical laboratory by defining the relationships among tasks, individuals, and the workplace. The organizational chart attempts to show relationships between line and staff. A line position is one in which a superior exercises direct supervision over a subordinate. A staff position is advisory, supportive, or auxiliary. These terms were defined in industry, and health care institutions seldom use the same connotation. When laboratory managers speak of staff, they are usually referring to technologists who are, in fact, serving in line positions.

Written policies and procedures, displayed in printed manuals or made available electronically, are an essential component of the clinical microbiology laboratory. Every procedure should be clear, easy to follow, and consistent in its content and organization. These documents provide direction for the many day-to-day tasks performed by the staff, serve as a teaching tool for students and new employees, and provide information to inspectors from accrediting agencies. The Clinical and Laboratory Standards Institute (formerly NCCLS) has a published guideline, GP2-A4, for writing laboratory procedures (23). The guideline provides instructions and recommendations for writing procedures for the full scope of the laboratory's workflow. The document also contains information about organizing procedure manuals, archiving and managing documents, and using manufacturers' procedures for automated purposes. As a testament to the document's universal acceptance, the College of American Pathologists requires that all written laboratory procedures closely follow the GP2-A4 format.

As defined by Brown (4), process design is a broad plan that is developed to provide a blueprint for completing work or a task at hand. Process design in the clinical microbiology laboratory involves an analysis of size and setting, laboratory design, equipment, test methodology, regulations, and staffing. How the work transitions through the laboratory is defined as workflow, and although workflow analysis is part of process design, it is more detailed. Policies and procedures are developed during workflow analysis (4). Workflow can be divided into three phases of the test cycle: preanalytical, analytical, and postanalytical. The preanalytical phase consists of events that occur prior to actual testing, such as selection, collection, transport, and accessioning of specimens. The analytical phase

involves the actual testing. The postanalytical phase consists of events that occur after testing is completed, such as results reporting and interpretation. The preanalytical phase is often the most critical aspect of the test cycle and can be the hardest part of workflow to control.

Strategies to effectively manage and minimize variances associated with the three phases of the test cycle should be included in the clinical laboratory's quality management plan. Quality management is a system for continuously analyzing, improving, and reexamining resources, processes, and services within an organization to produce the best possible outcome (28). Microbiologists have, for many years, concerned themselves with the quality of events that take place within the clinical microbiology laboratory. These events include such things as ensuring the performance of equipment, reagents, stains, and media and monitoring the accuracy of tests performed in the laboratory. These activities fall under the category of quality control (QC). Quality assurance (QA) broadens the scope of traditional QC to encompass processes and events in the preanalytical and postanalytical phases. QA includes such things as determining specimen quality and evaluating the competency and training of personnel. Both QC and QA can be considered aspects of quality management that also includes quality improvement (QI) or quality enhancement. Although applied successfully in industry for many years, QI and quality enhancement are relatively recent concepts in the clinical laboratory setting. Instead of focusing on inspection, identifying poor performance, and taking corrective action, as in traditional QC and QA programs, QI programs emphasize thorough training and prevention and view the system for improvement opportunities rather than the people (8). Continuous QI (CQI), sometimes referred to as total quality management, is an organized, systematic approach to productivity improvement that uses objective methods and a team approach toward improving the quality of all processes, products, and services. The origin of CQI-total quality management is industry based. The approach was promulgated by W. Edwards Deming and grew out of his experience with Japan's industrial reconstruction after World War II. Central to CQI philosophy is the premise that improvement in quality leads to increased productivity, increased customer and employee satisfaction, and decreased cost. The CQI approach is to examine process performance, not people performance, and utilize specific methods of analysis (tools) to better understand and improve those processes. It is a top-down style of QI that requires management commitment and support and involves the participation of all employees. Finally, CQI is viewed as an ongoing initiative.

While these broad definitions may suggest that CQI would be an ideal QI technique for the clinical laboratory, its implementation in clinical laboratories has not been easy. This is due, in part, to the additional time and resource requirements associated with CQI, at least initially, but also relates to an insufficient understanding of how to properly apply CQI to laboratory testing. CQI requires innovative thinking; the traditional internal quality monitors familiar to most laboratories cannot simply be shoehorned into a CQI format. Above all, do not lose sight of the fundamental objective: to improve patient care.

One way for laboratories to avoid this pitfall is to design a CQI program that strives to connect process improvement to clinically relevant patient outcome measures. Outcomes measurement has emerged from the health services research community in response to the changing economic environment in medicine, beginning with the advent of diagnosis-related group (DRG) classifications, and more recently as an important aspect of managed care delivery. Outcomes measurement identifies variations that may adversely affect patient care and can sometimes determine corrective actions for minimizing those variations. Although patient outcomes come in many forms, measurements relevant to laboratory testing generally involve the length of stay, cost, and customer satisfaction, with the customer being both the patient and the physician. Changes in laboratory services and policies that decrease lengths of patient stays, reduce cost, or increase customer satisfaction should be the focus of a laboratory CQI program. Those that have the most impact on outcome measures should be selected for process improvement.

A process is a set of activities that transforms inputs into outputs. Inputs include the needs of patients and physicians, the skill of laboratory personnel, equipment, supplies, and financial resources. Outputs involve laboratory data, diagnoses, and management decisions that are associated with outcomes realized by patients and physicians. Process analysis is often accomplished with techniques such as flowcharting and the use of cause-and-effect diagrams (fishbones), i.e., the tools of CQI, but it is important to remember that the goal of process analysis is to design strategies whereby modifications of the process lead to a measurable improvement in outcome. In clinical microbiology, elements of processes that may be selected for analysis and improvement include specimen rejection criteria, appropriateness of testing, and turnaround times for smear results that acutely affect patient management. Process analysis should include events related to the patient from the time of presentation to the end of an episode of care. For the laboratory, this requires an understanding of how multiple processes related to patient care, including those external to the laboratory, are connected (the output of one process may be the input of another). Failure to understand the interactive dynamic between processes will likely blunt the impact of laboratory improvement initiatives on patient outcomes.

A critical feature of the CQI paradigm is the need to carefully construct and assess any improvement modality before implementing costly changes in policies or procedures on a large scale. Referred to as the Plan-Do-Study-Act cycle for improvement (5, 17), the steps include first stating a specific aim and identifying criteria that will be used to determine if the change represents an improvement. After selection of a change that is practical and most predictive of a positive effect, a plan for evaluating the change in the form of a small pilot study is put forth. The results of the pilot study are assessed for their effect on performance, and then action is taken in the form of process redesign, or if needed, additional pilot studies are conducted. These never-ending cycles of improvement, gradually built into the daily workflow, represent the "meat and potatoes" of a proactive CQI program.

Selection and Implementation of New Equipment and Procedures

As laboratory managers are directly responsible for the quality and productivity of their departments, they must constantly evaluate new technology and equipment for applicability and practicality. Managers must also assess the impact of any new technology on patient care by focusing on attributes such as turnaround time, productivity, and cost. There are several steps involved in this process, including the performance of a needs assessment, research of available technology, and evaluation of performance and cost data gathered before making a decision on implementing a new

procedure or making a new instrument purchase (3). This process is discussed in greater detail elsewhere in the Manual (see chapter 15).

FINANCE

Medicare, Medicaid, prospective payment, DRGs, preferred-provider organizations (PPOs), health care maintenance organizations (HMOs), managed care, fixed versus variable costs, return on investment—the financial side of the health care industry possesses a vocabulary that in many cases is as mind-boggling to the clinical microbiologist as real-time PCR is to the hospital financial officer. In order to be successful, however, clinical microbiology laboratory managers must be able to speak both languages and be as concerned about positive cash flow, cost control, and budget variance as they are about QA and procedural controls.

Laboratory Reimbursement

Medicare Part A provides reimbursement for hospital services related to an inpatient stay. Payment is made based on DRG classifications, a prospective payment system (PPS) of reimbursement. The Centers for Medicare and Medicaid Services (CMS) assign a weight to each DRG based on the severity of the diagnosis, the type of procedure, the number of laboratory and other diagnostic tests, the number and types of drugs prescribed, and the presence of complications or comorbid conditions (6).

Based on this method of payment, hospitals are able to determine how much reimbursement they will receive for Medicare patients and will make a profit if they can manage these patients at a cost below the reimbursed amount. This fixed reimbursement system and incentive to reduce the cost of care has put pressure on hospital support services such as the laboratory to lower expenses.

Medicare Part B covers physician services and outpatient ancillary health care services including clinical laboratory testing. In July 2000, Medicare introduced a new PPS for the outpatient setting and developed ambulatory payment classifications as a basis for reimbursement for outpatient services. The ambulatory payment classification system provides payment predictability and promotes efficiency; however, at this time clinical laboratory tests are excluded from the outpatient PPS. Instead, laboratory tests performed on outpatients are paid for from the Medicare Part B laboratory fee schedule. Fees are assigned based on current procedural terminology (CPT-4) or health care common procedure coding system (HCPCS) codes established for each procedure. The actual Medicare payment is the lowest of either the actual charge, the fee schedule amount set by the contractor, or the national fee cap termed the national limitation amount (la).

Private insurers, also affected by increasing health care costs, have also undergone revision in their reimbursement methodologies. Managed care is defined as a means of providing health care services within a network of service providers (6). Although there are a variety of managed care plans, they usually all require that insured individuals see a physician who is part of the plan or else pay a higher copayment. The most common type of managed care plan is the HMO. Reimbursement under managed care plans can occur in several ways. Capitation, usually applied to physician reimbursement, pays a certain amount per patient per month. Payment can cover the cost of all services related to the member's outpatient care, including any necessary diagnostic or therapeutic tests. The physician can make a profit or lose money depending on the numbers of visits with and tests performed on each patient. Inpatient care costs may be reimbursed on a per diem, or per-day, basis. Under this arrangement, the hospital negotiates with insurers a set amount of reimbursement per day during the patient's hospitalization. The hospital staff will use the cost of care per day to help set the per diem rates and can increase the profit margins if they can decrease costs without compromising patient care. Reimbursement per case, similar to the Medicare PPS, is based on a set reimbursement rate for specific diagnoses or procedures. In some instances where hospitals offer specialized procedures or unique types of care, there may be "carve-outs" whereby reimbursement occurs separately from the per diem or per-case rate, usually on a fee-for-service basis.

In all of this discussion, the key message for the laboratory manager is the focus on cost control. In the hospital's financial landscape, the laboratory is considered a cost center. Although it may produce revenue from its outpatient and outreach workload, the reality is that it represents a necessary but significant expense on the hospital's overall balance sheet. Thus, laboratories that focus on providing high-quality service in a cost-effective and efficient manner will be valued by the organization and those that do not will likely be targeted for redesign.

Laboratory Compliance Programs

In 1998 the Office of the Inspector General, in response to costly and at times fraudulent billing errors on the part of some laboratories, issued compliance program guidance for clinical laboratories. Its purpose was to instruct laboratories on how to conduct their business in a lawful and ethical manner. The guidance document requires that every laboratory have a formal compliance program that addresses several essential elements (2). At a minimum, the laboratory compliance program should (i) develop and promote standards of conduct for employees, (ii) promote a commitment to zero tolerance of fraud and abuse, (iii) designate members of a laboratory compliance committee, (iv) identify education and training programs available to employees, (v) promote communication with employees to ensure that the program is effective, (vi) outline monitoring activities to ensure that the program is effective, and (vii) describe the potential disciplinary measures for those violating standards of conduct and compliance procedures.

The laboratory compliance committee has the responsibility to oversee compliance with standards of conduct and other procedures as they relate to lawful and ethical business practices. The membership of the committee should consist of the medical director, the administrative director, section managers or supervisors, a laboratory information systems (LIS) manager, and the manager of outpatient services if one exists. The duties of the compliance committee are to effectively communicate the standards of conduct to all employees and to implement monitoring systems to detect any possible illegal or unethical conduct as it may relate to medical necessity or billing issues. The committee should also be available to employees who believe that they are aware of unethical or illegal activities that violate the standards of conduct and ensure that the enforcement of these standards is consistently done through appropriate disciplinary mechanisms. On a routine basis, the compliance committee should review any appropriate fraud alerts as periodically issued by the Office of the Inspector General and inform and educate employees appropriately as well as keep current with legal and regulatory compliance issues and revise compliance policy as needed.

The laboratory should communicate regularly with the institution's financial services, governmental reporting, and medical records departments regarding coding and billing

issues. Laboratory managers are expected to take every reasonable precaution to ensure that the CPT-4 codes for laboratory tests accurately describe the tests that were ordered and performed and to choose the code that most accurately describes the ordered and performed test. Intentional up coding, the selection of a code to maximize reimbursement when such a code is not the most appropriate descriptor of the service, is not allowed. A complete review of CPT-4 codes should be performed at least annually to update codes and descriptions, delete obsolete codes, and validate reference lab coding using the American Medical Association's *Current Procedural Terminology* manual (1) and updates from carrier and fiscal intermediary bulletins.

The laboratory should encourage that physicians order only tests that are medically necessary. Diagnostic information for each test should be submitted by the ordering physician or authorized representative in narrative form or codes provided through the International Classification of Diseases, 9th Revision, Clinical Modification (ICD-9-CM). Laboratory employees should never suggest or supply ICD-9-CM codes. As a means to ensure physician knowledge of compliance issues, the laboratory should disseminate a "notice to physicians" to physician clients on an annual basis. The notice should outline the individual component of every laboratory profile that includes a multichannel test or other automated multiple test result and the CPT-4 codes that the laboratory uses to bill Medicare for each such profile. Physicians should also be told that when ordering tests for which Medicare, Medicaid, or other federally funded reimbursement is sought, they should order only those tests which they believe are medically necessary.

Costs

Operating expenditures in the laboratory may be divided into broad categories of fixed and variable costs. These terms reflect the sensitivity of costs to increases or decreases in test volume. A cost that changes more or less in proportion to the test volume is variable. A cost that remains unchanged for some period of time despite volume fluctuations is fixed. Examples of variable costs include technologist salaries, costs of reagents and supplies, and costs on printed requisition forms. Salaries for nonexempt employees, benefits, and the cost of depreciation of equipment are examples of fixed costs. Costs are also classified as either direct or indirect. Costs that can be specifically linked to a test are considered direct costs. These include technologist salaries, costs of clerical support and overtime, courier fees, and costs of reagents and bacteriological media. Costs that cannot be directly traced to a test but are still part of the laboratory's expenses are indirect costs. Examples of indirect costs include those of depreciation, building and equipment maintenance, and utilities. Laboratory managers are more often concerned about unit costs when making financial decisions because understanding how costs fluctuate in producing a specific unit of service (usually defined as a test) permits measurement of productivity. Unit costs are also divided into fixed and variable categories that behave differently as volume changes. Variable costs remain the same per unit regardless of volume, and fixed costs are reduced per unit when volume increases because the total fixed cost is spread over a larger number of tests. A busy clinical laboratory benefits from economies of scale. In general, variable and direct costs are subject to some degree of management control and fixed and indirect costs are much less so. Regardless of cost classifications, laboratory managers must be continually looking for opportunities to control any and all costs. Accurate cost accounting is an imperative for financial decision making, and in today's managed care environment, correct cost information ensures participation in profitable contracts. The laboratory manager must be efficient in defining and itemizing costs associated with the testing services provided by the laboratory. Moreover, accurate test cost analysis provides the manager with a rational mechanism for selecting the most cost-effective testing method among several new procedures whose suppliers each claim that their test is the least expensive to use. Finally, laboratory budgeting becomes more effective with a reliable cost analysis system in place. A simple test cost analysis worksheet is shown in Appendix 1.

Operating Budgets

The development of an operating budget for the hospital is highly dependent upon clearly stated institutional goals and objectives within which the laboratory has a known role and upon which it can base its own specific objectives. The manager should expect to receive, either directly or indirectly from the hospital administration, budget guidelines that include expected inpatient and outpatient census information for the budget year and any anticipated changes in the total service program of the organization. Clinical service line managers, in particular, should communicate new program plans to support service managers, including laboratory managers, because support services may be impacted by these new programs. If, for example, the hospital has plans to begin performing human stem cell transplants, then the microbiology laboratory needs to budget for the additional volume and specialized testing that patients receiving these transplants will require. In return, managers may be required to provide the laboratory and/or hospital administration with information related to program changes anticipated in their areas that arise because of changes in technology or clinical practice. Examples of such changes include procedures that may diminish in volume because of obsolescence or physician education and increasing volume estimates for newly implemented procedures such as those of molecular diagnostics.

There are several types of operating budgets (18). A fixed budget assumes a single level of output or activity and builds the budget around that level. A fixed budget, however, cannot be used to monitor and control resources during changes in test volumes that the laboratory may experience during the year. A flexible budget reflects expected laboratory revenue and expenses and anticipates the impact of volume changes on both. In this type of budget, some of the expenses are fixed and some are variable. The flexible budget recognizes the difficulty of establishing a flat level of expenditure and provides a tool for controlling costs. Quite simply, a flexible budget allocates dollars for resources based on volumes of tests performed. The accuracy of the flexible budget as a predictive tool, however, is only as good as the test component cost analysis performed during the budget's construction. A program budget is based on a specific program matrix. The matrix includes all proposed services and the resources required to deliver them. The program can include a set of activities, services, staffing, and equipment. It is often used for short-term planning purposes when new programs are launched. A zero-based budget calls for management to reevaluate all activities to decide if they should be re-funded for the next budget cycle. Each manager is required to justify the entire budget for their area of responsibility as if all of its activities were entirely new.

Although there is no single formula for the budgetary process, there are some basic elements that will help ensure

success (18). First, establish clear goals and objectives to guide resource allocation. Second, obtain detailed data on existing and potential clients. Third, establish a defined budget period and procedures for development of the budget. Fourth, compile reports with financial and statistical information for comparison with budget information and for variance analysis. Furthermore, when planning a budget, managers should remember the following principles: (i) expenses are charged to the department or cost center that incurs them, (ii) every item of expense must be under the control of someone in the organization, (iii) managers responsible for complying with a budget should participate in the budget's preparation, (iv) managers should not be held accountable for expenditures over which they have no control, and (v) ordinarily, unused funds do not carry over from one budget year to the next.

Variance Analysis

Once the operating budget is established and approved, the extent to which the actual revenues and expenses differ from the budget represents a variance. Controllable variances can be resolved by appropriate management action (32). Salary variances can be addressed by reviewing time cards for excessive overtime. Supply cost variances may prompt an examination of inventory par levels. Suppliers may be approached for deeper discounts, or alternative vendors may be sought. Some variances are not controllable. These often result from unanticipated volume increases due to higher-than-expected numbers of patient admissions, unanticipated (and unbudgeted) price increases, unplanned repair expenses, or an unusual increase in the number of tests requested. A good example of the latter would be an unanticipated epidemic of influenza's producing a large increase in the number of requests for rapid flu testing and the need for the laboratory to purchase an excessive number of kits within a short span of time. As discussed above, a flexible budget should account for month-to-month fluctuations in test volumes and test complexity if properly constructed. Managers may be periodically called upon to communicate their budget performance to the laboratory administration and should be able to accurately record and explain budget variances on a line-by-line basis in their monthly financial statements.

Capital Budgeting

In addition to the operations budget, there must be a process for allocating monies for major investments in facilities and equipment. In accounting terms, a capital item is generally any fixed asset expected to provide service for more than 1 year and has a minimal expense, usually between $500 and $1,000. Items that qualify as capital include new space or renovation of existing space, replacement of equipment, purchase or lease of new equipment, and information technology (hardware, licensing fees, and interfaces, etc.). Capital acquisitions represent a significant investment for the organization and, as such, should be evaluated and justified by a budgetary process. Generally, a fixed amount of funds available for capital is established each fiscal year by the institution. Invariably, the total dollar amount requested for competing capital projects will far exceed the total of funds available. The capital budget process must therefore winnow, select, and prioritize; it is an enormously complex and politically charged task if not handled correctly. But by using a team approach whereby the management maintains focus on the goals and objectives of the organization, the capital budget process can be a successful and rewarding experience.

Prior to the budget process, the pool of total capital dollars available may be divided into smaller pools designed to support different aspects of the institution. For example, a $50 million capital budget may be allocated to allow $5 million for strategic projects, $10 million for information technology, $15 million for patient care, $10 million for facility improvements, and $10 million for ancillary services. If the laboratory is considered part of ancillary services, then the numbers of available dollars is much lower than the overall budget and the laboratory will likely be competing with several other departments for this lesser amount. The evaluation process will seek to classify capital projects in different ways, and managers should be aware of how to appropriately categorize and describe any project submitted for consideration. For example, some projects may represent new or incremental business, some may enhance quality, and some may reduce cost. Finally, capital requests may be prioritized according to need. A nondiscretionary project is a project that must be funded to keep the facility operating. An example would be a renovation project to make the laboratory compliant with regulatory and accreditation mandates. Levels of priority then follow, with level I projects being most critical.

Generally, capital projects of $10,000 or less need minimal analysis. All that is normally required is a brief description of the project and its intended use (new item or replacement, etc.) and the requested dollar amount. Projects with costs exceeding the minimum dollar amount require a higher level of analysis and more detailed documentation supporting the request. In addition to a description of the project and its intended use, proposals for these projects should include an estimate of the life span of the item, an estimate of all costs associated with acquisition, an estimate of yearly incremental cash outflows, and an estimate of yearly incremental cash inflows or savings. Depreciation expense must also be considered. Straight-line depreciation analysis is the most commonly used method of determining the expense of a fixed asset. In this method, the estimated useful life span of the item is divided by the cost of acquisition. A piece of equipment costing $100,000 with a useful life expectancy of 5 years would have a depreciation expense of $20,000 per year.

The financial analysis of large capital projects may have several elements. An illustrative case study follows. Suppose a clinical microbiology laboratory that has historically performed manual bacterial identifications and disk susceptibility tests wishes to purchase an automated system because a new outreach program will significantly increase test volumes. First, a pay-back analysis reveals that with a purchase price of $125,000 and a net cash flow of $137,000 after 3 years, the pay-back period is calculated at 2.68 years. The pay-back method does not take into account the time value of money but serves as a crude measure of risk because it favors projects with a short pay-back horizon. The average rate of return is calculated by dividing the average annual return by the amount of the initial investment. Projects with a higher average rate of return may be rated more favorably, but the method also fails to recognize the impact of time. The concept of present value is very important for capital investment analyses because it takes into account the increase or decrease in the value of a capital investment over time.

The most common method used in the financial analysis of a capital proposal that accounts for the time value of money is the calculation of net present value (NPV). NPV is the present value of all cash flows minus the initial investment. If the NPV is positive or zero, the project is usually considered financially acceptable. This is because all future cash flow has been converted into current dollars, with the use of an expected rate of return (usually set by the institution's

financial department), and has been compared with the initial investment. However, projects with a small negative NPV may still be worthwhile since other factors may be considered, such as the size of the initial investment and the benefit to patients. A favorable NPV for any capital proposal may result in a ranking higher than those for projects with similar costs. Laboratory managers would be well advised to support their capital project proposals with sound financial as well as clinical justification. In the end, it may make the difference between getting the equipment the laboratory needs and limping along for another year without it.

Financial Bench Marking

Increasing economic pressures on today's laboratory operations have created the need for managers to be aware of their financial performance in comparison to some internal or external bench mark. Financial bench marking is but one of many tools that the laboratory employs to improve performance, focus on customers, survive, and thrive in an environment with limited resources (39). In selecting indicators for bench marking, the use of ratios is much preferred over the use of raw numbers because the data are viewed in terms of a common denominator, usually some unit of service. The typical unit of service for the laboratory is the billed test because most financial systems are capturing volumes according to CPT codes that have standardized characteristics. A denominator that is often used outside the laboratory is patient-days or patient discharges. Ratios can be used to assess performance in a number of ways. For example, laboratory workload may be measured by calculating the total number of billed tests per calendar day, per patient-day, or per patient discharge, and examining the number of billed tests per full time equivalent reveals service intensity. Labor productivity can be determined from the number of hours worked per 100 billed tests or per patient discharge. Lastly, important cost data may be ascertained from ratios such as labor and supply expenses per 100 billed tests.

The simplest method of bench marking is to use your own laboratory as the standard and measure performance over time. This type of internal bench marking provides consistency of measurement over time and gives managers control over assumptions. In effect, it affords managers a means to continuously monitor performance and make improvements in productivity and cost on an ongoing basis. External bench marking involves a comparison of the laboratory's performance with that of a peer group. The composition of the peer group is critical. Members of the peer group should be alike in as many critical characteristics as possible. Otherwise, whatever performance expectations are placed on an individual laboratory being compared to the peer group may be unreasonable. Sometimes, voluntary agreements are established with other institutions to share productivity and cost information. This arrangement allows control of the size and composition of the peer group and ensures a fair comparison of whatever characteristics are being measured. There are a number of commercial companies that provide bench-marking products, some specific for the laboratory (see http://www.chisolutionsinc.com) and others more broadly applicable to the institution but with drill-down capability for the laboratory (see http://www.solucient.com).

Now that cost efficiency is a watchword in most health care environments, a comprehensive financial management system is an imperative, rather than an option, for laboratory management. Managers who set goals, measure progress, and identify trouble spots will utilize their limited resources more intelligently than those who do not.

PERSONNEL ISSUES

The study of organizational behavior encompasses all of the human factors encountered in the workplace, including motivation, leadership, organizational models, and responsibilities (31). Organizational behavior is defined as the actions and attitudes of people in organizations. When it comes to personnel issues, most diagnostic microbiology laboratories will fall under the auspices of the human resources department (HR) of the parent institution. In that regard, directors, managers, supervisors, technologists, and laboratory assistants alike are obligated to become familiar with and follow institutional policies relative to hiring and firing practices, compensation and benefits, job descriptions, organizational structure, and grievance procedures, etc., and of course to be compliant with federal, state, and local labor laws.

Hiring

Needs Assessment

Before the microbiology manager goes through the expense and time required to hire a full-time employee, he or she should determine whether that position can be eliminated without compromising service and quality expectations. Could the work be redistributed among existing staff? The solution may involve creative management in terms of subdividing assignments among other stations or individuals (or even among different laboratories), but this approach may not be practical in areas such as specimen processing where the workload is constant and could not be easily transferred elsewhere. It may be possible, however, to rearrange schedules such that individuals are transferred into high-volume work areas during times of peak utilization.

A second option may include the use of temporary or part-time employees to fill the shortage. This alternative can be quite attractive from a convenience standpoint but may be more expensive depending on training and agency costs. An excellent source of part-time help may include previous employees who have left the full-time ranks for alternative pursuits and would like to supplement their income. Finally, the hiring process may present an opportune time to examine laboratory productivity. A number of consultant firms are available to perform bench-marking analysis with laboratories having similar workloads and demographics to determine efficiency.

Analysis, Design, and Description

The job description is a summary of two administrative processes: job analysis and job design. Whereas the analytical and design phases involve proactive evaluation and/or reconfiguration of the nature of the work to be performed, the written job description is a document that defines the required skills, functions, conditions, and hierarchy associated with a specific position (35). Poor job analysis and design will lead to a flawed job description.

A job analysis should be comprehensive and detailed such that the nature of the work to be performed is clearly understood. The information required to complete the analysis can be gained through a structured process that measures and documents the number of tasks performed and the time required to complete those tasks, or informally through observation (10). One can also hire consultants to perform job analysis, request input from current staff, or contact laboratory administrators from demographically similar facilities. Job analysis and design should focus on the essential elements of the position, including the array of duties, the workflow and volume, the technological skills required, the

degree of employee interaction, the reporting relationships, and the working conditions. This, in turn, will make it easier to define minimum education, experience, and personal attributes appropriate for the job. If done properly, job analysis and design will drive the completion of a formal job description. As an example, consider the following scenario. The microbiology manager is allowed to fill a vacancy for a laboratory assistant on the evening shift. The primary responsibilities of that position are specimen processing and reagent preparation. The manager could use the existing job description to recruit for the position. After careful analysis, however, the manager finds that most laboratory assistants on that shift complete their assigned duties nearly 2 h before the shift ends. At the same time, the volume of *Clostridium difficile* toxin testing by enzyme immunoassay on the day shift has exceeded capacity for months, necessitating overtime for qualified technologists. If the new position was expanded to a technologist level, it would allow for testing of excess *C. difficile* specimens on the evening shift without the loss of sample processing capacity at a fraction of the overtime costs alone.

The job description serves to define the specifics of the position and the requirements for the prospective employee (10). It also provides a tool for communication between the employer and the prospective employee and serves as a recruiting tool (35). It can be used to schedule and set staffing requirements, to assess employee performance and competency, to define wage and salary structure, and to act as a template for future corrective actions (35). It should be flexible to allow for future growth of the position and focus on minimum requirements to prevent the loss of high-end applicants (16). There are no rules to writing a good job description unless institutional guidelines are in place. At the very least, the job description should include the items listed in Table 1 (10, 35). Optional information that can be added includes exempt status (time clock or salaried position), personnel and payroll codes (but not actual dollar ranges), and U.S. Department of Labor (DOL) occupational codes and/or U.S. Employment Service functional job analysis codes (34). Bear in mind that the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88; see below) established only six categories for laboratory personnel; director, technical consultant, clinical consultant, technical or general supervisor, testing personnel, and cytotechnologist. The laboratory can expand on the qualifications required for each of these positions but not reduce them below the minimum requirements as outlined in CLIA '88. All job descriptions on file should be reviewed at least annually in conjunction with the employee's performance review or when the position is vacated and a replacement is sought.

Recruiting, Interviews, and Hiring

Once a job description has been drafted and approved, the recruitment and hiring process can begin. As before, it is best to coordinate activities with the organization's HR personnel, who are more familiar with local, state, and federal regulations pertaining to recruitment and hiring. HR can also provide valuable services such as background checks and validation of a candidate's credentials (14).

The job description should be abstracted to provide the essentials for a classified advertisement. The advertisement should contain the job title, minimum education and licensing requirements, a brief summary of the duties, and if desired, the salary ranges (15, 16, 35, 38). The laboratory has basically two candidate pools to choose from: internal and external. The former is usually an attractive source because current employees have already received system orientation and are familiar with general corporate policies and culture. Mobilization of internal candidates usually takes less time because job listings can be posted in organizational newsletters or on institutional websites. Overall, internal hires are generally less costly, but external candidates can infuse the laboratory with new ideas, experiences, and skills. Generally, external searches take longer and may require the use of recruitment bonuses, employment agencies, the Internet, or advertising in trade magazines such as *ASM News*/*Microbe* or *Medical Laboratory Observer*. Other possible external recruitment sources include professional schools and organizations such as the American Society for Clinical Pathology, the Canadian College of Microbiologists, and the American College of Microbiology (the certification and training

TABLE 1 Components of a job description

Items	Example[a]
Organization	Central States Medical Center
Department	Microbiology
Position	Microbiologist, day shift
Education	B.S., medical technology or microbiology
Certification	M.T. (ASCP); SM, NRM, or equivalent
Responsibilities	Responsible for processing of specimens, interpretation of culture and susceptibility results, participation in quality management program, and teaching of medical technology students, laboratory medicine residents, and fellows; nonsupervisory position
Competency	Requires semiannual (first year) and annual (thereafter) competency assessment via departmental program
Working conditions/exposure hazards	Modern clinical microbiology laboratory; no heavy lifting; potential exposure to human specimens, including blood and body fluids, and work with BSL 1–3 agents
Pay code	5, Nonexempt

[a] M.T., Medical Technologist; ASCP, American Society for Clinical Pathologists; SM, Specialist Microbiology; NRM, National Registry of Microbiologists; BSL 1–3, biological safety levels 1–3.

branch of the American Society for Microbiology [ASM]). Parent institutions can also use online automated recruitment web pages for both internal and external candidate searches. By logging on to a website, potential candidates can review job openings within the system and create a personal profile that can be used by HR for reviewing qualifications or for matching individuals with future positions as they become available. The ultimate goal is to provide the microbiology administrator with a qualified pool of candidates while trying to maintain workforce diversity according to a U.S. DOL directive (http://www.dol.gov/dol/compliance/comp-eeo.htm). For individuals applying for supervisory or higher positions, a search committee should be convened to expand the sources of potential candidates. Once a candidate pool of qualified individuals has been identified, it is time to begin the interview process.

The interview is a means of allowing the employer and candidate to determine whether they are suited for each other. It is a very important process because a badly conducted interview may scare off a highly qualified candidate. This is also the part of the hiring process in which the unskilled interviewer may pose a liability and one that requires close attention to regulations. There are several questions shown in Table 2 that the Equal Employment Opportunity Commission prevents an employer from asking a potential employee (14, 16, 35, 38). The interview should be organized and standardized to permit a fair evaluation of each candidate. There are three basic formats for an interview: structured, in which the format is predetermined with a list of questions and a review form; unstructured, in which a set panel of questions is not used but the interview consists primarily of a running conversation with the candidate; and pressurized, in which the candidate is asked to provide analysis of various job-related scenarios or to solve a series of hypothetical problems (34). The interview can be a combination of all three and can be conducted individually or by a panel of interviewers. In some organizations, HR conducts a preliminary interview to screen candidates before the microbiology administration conducts final interviews. The ultimate goals are to meet the candidate, check credentials (usually an HR responsibility), collect additional information not provided on the application form, and gather a sense of personality fit. In management, we tend to think of the interview process from one side only. Holland (14) provides an overview of how to prepare for an interview from both the employer's and the employee's perspectives. If there is an evaluation form to be completed, it should be done immediately after the interview so that impressions are not lost with time. Documentation of the search, selection, interview, and orientation processes should be kept on file for at least 4 years should any improprieties be called into question.

Employee-Related Activities

Orientation

Once a candidate is hired, the next phase involves the assimilation of the new employee into the microbiology workforce. The orientation process must be organized and synchronized to keep the new hire active and engaged.

According to Vernadoe (34), there are three basic aspects of employee orientation. The first is at the organizational level to familiarize the new employee with institutional policies, procedures, and benefits. The second focuses on department-specific policies and codes of conduct. The final aspect concentrates on the microbiology laboratory and addresses job responsibilities, reporting structure, and working relationships that exist therein. There are at least four basic approaches to conducting orientation (16, 34). These include (i) formal meetings and training sessions, usually conducted at the institutional level by HR (these cover such topics as risk management, fire and chemical safety, benefits, and infection control); (ii) microbiology supervisor-led sessions to discuss laboratory-specific issues such as competency assessment, biological safety protocols, dress code, telephone conduct, breaks, and scheduling; (iii) a checklist approach; and (iv) a mentor-driven process.

In addition to a systemwide, general orientation program, many microbiology managers choose to develop a stepwise laboratory-specific orientation process that is checklist driven. First is the preorientation checklist, which is preparatory in nature. It allows the microbiology supervisory staff to organize all the materials that the new employee will receive during orientation. The training orientation checklist guides the assigned mentor and trainee through the basic components of orientation. The specific elements of the microbiology laboratory are covered by a series of modules that may include topics such as scheduling orientation, trainer and trainee expectations, supervisor's review procedures, a special shift rotation checklist, and a LIS orientation, to name a few. The entire process is completed with a postorientation checklist to ensure that each component has been covered and entered into the employee's personnel file.

Above all, the orientation period is the process of welcoming. For this reason, the choice of mentors selected to provide training should be carefully considered and limited to individuals with a great deal of experience and respect.

TABLE 2 Topics to be avoided during a hiring interview

Topic	Examples
Age	Date of birth, year of high school graduation
Weight	Waist size, dietary habits
Financial history	Outstanding loans or debts, bankruptcy
Citizenship	Country of origin, immigration status, parental ancestry
Marital status	Maiden name, number of children
Criminal and military records	Military discharge status, court convictions
Organization memberships	Religious or political groups
Mental/medical/physical disabilities	Current medications, therapy, workman's compensation benefits, missed workdays secondary to disabilities

Staffing and Scheduling

The process of adequately staffing a microbiology laboratory and scheduling individuals with widely ranging abilities to provide maximum coverage on each shift is one part science and one part art. It requires advanced planning, and no one strategy works for every facility because peak activity levels, workloads, and the technical complexity of testing differ significantly. Poor planning can lead to low productivity and high labor costs when staffing is excessive. Inadequate staffing may generate high productivity but also lead to increased overtime and employee burnout (21). To avoid these extremes, a number of good guidelines on staffing and scheduling are available for review (4, 36).

Scheduling is simply the process of assigning work responsibilities to a group of individuals and requires the right number of employees and skill levels to complete the work. Most medical laboratories work under the 8/80 rule for full-time employees, i.e., employees work a total of 8 h per day and 10 days over a 2-week pay period. This plan limits the number of hours to be worked in a day but permits the employee to work more consecutive days and is unique to medical facilities. A 40-h work week permits an employee to work any number of hours per day but not to exceed 40 h per week. Other scheduling systems include the use of part- or variable-time help, job sharing, self-directed work teams, and exempted employees (21, 36). In designing a schedule, it is important to choose a plan or combination of plans to provide the greatest degree of flexibility. A mixture of employees on the 8/80 plan and the 40 plan can be used, but a single employee must choose only one option.

The scheduler must know workload patterns and future trends. This is most often done retrospectively by reviewing LIS-generated billing for an estimate of test volume and plotting these data over time for trend analysis for each shift. Recording workload units periodically over time can also provide a helpful bench mark of test volume. However, keeping pace with method advancement is also necessary for projecting future labor needs. The development of molecular and amplification technology has greatly streamlined a number of processes in the microbiology laboratory—most significantly in clinical virology. Armed with this information, the laboratory manager must calculate how many people for each shift and skill set will accommodate the mean test volume, not peak or trough volumes of work (4). From here, the scheduler starts with a rough draft based on ideal staffing levels by using a matrix for each shift where rows correspond with the services to be provided and columns represent the days of the pay period. With the 8/80 plan, a shift is 8 h times 14 days or 112 h per pay period. Full-time employees can cover 80 of these hours (8 h times 10 days), while part-time staff can be used to fill in the balance (generally 24 h per week or less). Once a rough schedule has been outlined, it can be fine tuned by naming the individuals who will fill each slot and the work assigned. From this working draft, the schedule can be modified to accommodate vacations, family leave, illness, earned time off, and shift switching. Schedulers and managers must also remember that work schedules affect employee families and morale (30). Part-time and variable-time employees can be used to fill in gaps, or cross shift coverage can be applied to relieve peak workload stress. A detailed description of this process can be found elsewhere (4, 30, 36). During new employee orientation, a review of the scheduling process should be included so that there are no surprises when the individual is eventually assigned duties.

Winn and Westenfeld (41) provide an excellent summary of scheduling do's and don'ts as follows: (i) define the absolute minimum number of employees required for each situation (weekends, routine, and holidays); (ii) strictly define the duties for each of the positions required for every type of shift, and if a position is open, try to fill it with existing personnel based on the duties assigned to that slot; (iii) allow scheduling to be orchestrated by a coordinator with input from the staff; (iv) solicit vacation requests well in advance (>6 months) and be clear that not all preferences can be accommodated; (v) publish work schedules in advance to allow for personal adjustments; (vi) if allowed, use earned time off instead of overtime; and (vii) fill empty slots with volunteers or part-time help, with a draft as a last resort. In this context, certain laboratories have developed a rotational "hit list" among staff to cover for open slots on the work schedule. The next person up on the list is informed of their standing and allowed one deferral or may switch their obligation with another employee.

In a situation in which the microbiology workload is high or increasing and staffing is static or decreasing, there are a few options left to the administration to relieve the pressure. The first of these is outsourcing, such as finding reference laboratories to perform a variety of low-volume, esoteric, or technically complex testing, e.g., forwarding all mycobacterial identifications with the exception of probe-confirmed identification of *Mycobacterium tuberculosis* and *Mycobacterium avium* complex organisms to a public health mycobacteriology laboratory. Elimination of low-volume testing may not necessarily prove to be cost efficient but maintaining proficiency when the frequency of testing is low should also factor into outsourcing decisions.

Microbiology laboratories can even outsource testing to other laboratories within their own system. For example, automated blood culture systems can be physically located near a rapid-response laboratory. Signal-positive blood cultures can then be removed during all shifts to be subcultured and stained. Gram stains can be read by trained rapid-response technologists, and cultures can be evaluated during the next microbiology shift.

The second option is to examine the extent of evaluation. In many instances, microbiology laboratories can get into the bad habit of providing too much information, such as identifying isolated organisms that are unlikely pathogens in a disease process. This process not only generates an unnecessary workload but may also give the clinician a false sense of importance.

Unfortunately, staffing and scheduling often go hand in hand with absenteeism. As a result, each facility should have a well-defined absentee policy and management plan that are neither onerous to the employee nor subjective and that can be fairly applied. A laboratory policy on absenteeism requires a working definition, equitable and realistic standards (e.g., less than one unscheduled absence per month), and a management plan that uses the same organizational framework for corrective action for issues such as behavioral or performance problems (36). Absenteeism can be chronic, high frequency, and/or patterned (e.g., Mondays, Fridays, or the day after payday). If not addressed and corrected, chronic absenteeism can generate poor morale among other microbiology staff.

Performance Appraisal

A job description defines the duties of an employee and how the employee's success will be measured. The performance appraisal, on the other hand, asks how the employee is succeeding. A performance appraisal has at least five ingredients: (i) an employee with a job description and appropriate qualifications, (ii) a series of clearly defined goals and

performance standards, (iii) an objective way of measuring achievements, (iv) someone trained to evaluate the employee's performance, and (v) a feedback loop to gain input from the employee (38). The standards used to judge performance must be outlined in the job description and should be objective and consistent with those used to evaluate other employees. Basically, four markers can be measured either alone or in combination to generate a performance appraisal: results, behavior, skills, and peer comparison (33). However, objectivity in performance appraisal is often difficult to achieve. We all have a tendency to rate individuals we like highly and those we do not like less highly. The actual data recorded in the performance appraisal should include employee information, a list of goals and objectives from the previous and for the next review, a scoring system, a place for the employee to provide his or her own feedback, and a summary section that allows for the appraiser to recommend promotions and salary adjustments and that includes a date for the next appraisal and signatures (11, 33). When complete, the form should become an official part of the employee's personal file (22).

If the parent organization permits, there are a number of alternatives to performance appraisals, including feedback sessions, team or section appraisals, self-appraisal, and process improvement sessions, all of which would require some form of documentation.

Competency Assessment

The directive for competency assessment of laboratory personnel was written into CLIA '88. This legislation was signed into law in 1992 and has been revised five times to provide the final ruling in 2003. It mandates that all laboratories falling under the jurisdiction of the CLIA '88 guidelines must develop a program to document the competency of each laboratory employee in every aspect of the employee's assigned duties. As is the case with many pieces of federal legislation, CLIA '88 did not define how this process is to be accomplished nor did they suggest which core competencies should be monitored. They did, however, place the responsibility for establishing a program and documenting competency assessment squarely on the shoulders of the laboratory director and technical consultant or technical supervisor (11). Fortunately, the Clinical and Laboratory Standards Institute (formerly NCCLS) has published a clear and logical approach to the design of a laboratory-based training and competency assessment program that provides a wealth of sample documents used in the process (22). CLIA '88 clearly define the frequency of personnel assessment: semiannually for new employees and annually thereafter unless changes in procedures and protocols occur. At that point, competency for and familiarity with the new protocol must be documented. All agencies approved by the CMS for the purpose of laboratory accreditation have a competency assessment module included in the review process. These agencies include the College of American Pathologists, the Joint Commission on Accreditation of Healthcare Organizations, and the Commission on Office Laboratory Accreditation. For more details on the history and evolution of competency assessment, please refer to the fine review by Sharp and Elder (29).

The final CLIA rule (2003) consolidates commercially marketed in vitro diagnostic assays into two functional categories, waived and nonwaived. When it comes to competency assessment, however, nonwaived testing is subdivided into moderate- and high-complexity tests for the purpose of defining the educational background and training requirements of those individuals performing the testing (40).

CLIA '88 go so far as to define a choice of methods to be used in the evaluation process (13, 29). These include but are not limited to (i) directly observing an individual performing laboratory functions including testing, plating, culture evaluation, and instrument operation and maintenance; (ii) verifying the accuracy of transcribed test results; (iii) checking the integrity of data entered by the employee for QC records, proficiency tests, preventive maintenance charts, and preliminary patient test results; (iv) challenging the employee with internal and external proficiency series; and (v) evaluating an individual's ability to solve laboratory-related dilemmas. Hundreds of individual skills need to be mastered before a technologist-level employee can be considered a competent microbiologist, and there is no way that each of these can be pinpointed let alone evaluated in a year's time. That being said, there are at least three excellent publications outlining a competency assessment program specifically for the microbiology laboratory, and any of these could be used as a template for design (19, 20, 29). General laboratory-wide plans are also available for review (16, 22). In one model, a database in a spreadsheet format (e.g., an Excel file) is established for each active employee upon hire. All of the potential competencies that the job description encompasses are listed in the first column of the spreadsheet (*y* axis), and the first row (*x* axis) indicates the year of review. Each new employee begins with a series of X's in each competency cell for which training has not yet been conducted or in the cells corresponding to competencies not included in the job description. As training for a particular skill is accomplished, the X is removed and the method of measurement, the date, and the initials of the trainer or observer are recorded in the cell. Methods of measurement can be coded as DO for direct observation, Q for quiz, DR for document review, PT for proficiency test (internal or external), PM for preventive maintenance review, and QC for quality control review, etc. By using the spreadsheet approach, the competency assessment report for each employee is readily available for review and update and can also be used as an orientation tool. A copy of each report can be printed on a yearly basis and added to the employee's personal file.

Continuing Education

The Clinical and Laboratory Standards Institute guidelines on training and competence assessment distinguish between training and education in the following way (22). Education is "schooling for the purposes of gaining knowledge," and training is defined as the acquisition of "a set of skills for the purpose of being able to put the knowledge to a practical use." For the purpose of this chapter, however, continuing education will be defined as the extended process of gaining knowledge and improving skill sets. Continuing education constitutes one of the mandatory requirements for competency assessment and professional development dictated by CLIA '88 and necessary for the maintenance of professional licensure by most accreditation agencies. How can microbiology personnel maintain yearly continuing education requirements under the pressure of reduced operating budgets? A number of opportunities are available to satisfy these requirements, including attendance at local meetings such as branch meetings of the ASM. ASM branches usually sponsor at least one annual educational meeting, and the location and time of each are posted on each branch's website (http://www.asm.org/MemberShip/index.asp?bid=1914). In some cities, local microbiologists have formed clubs that meet during the year and invite guest speakers (usually sponsored) to present topics of interest for continuing education

credits. Many medical centers provide weekly opportunities for continuing education purposes such as grand rounds, clinical pathology conferences, infectious diseases case conferences, and microbiology rounds. At one author's facility (W.M.D.), the microbiology laboratory sponsors a weekly case conference open to technologists, infectious diseases staff, and pharmacy personnel. At the organization level, many health centers provide tuition reimbursement for college courses that pertain to the profession of the health care worker.

Other organized microbiological programs for continuing education include teleconferences, workshops, self-assessment materials such as Tech Sample and Check Sample (American Society for Clinical Pathology; http://www.ascp.org/index.asp), and ASM-organized wet laboratory demonstrations, online lectures, and audio lecture series that are available for purchase or subscription (http://www.asm.org).

Termination

Termination refers to the end of a formal business relationship between an employer and employee and can be either voluntary or involuntary (16). The departure of an employee from the workplace can be either amicable or contentious. In any case, procedures are usually developed by HR for employee separation that reflect the situation. For voluntary and amicable termination, the process may include documentation of the date of departure and a forwarding address; discontinuation of payroll, benefits, and parking privileges; and the return of security materials. HR may also wish to conduct an exit interview with the employee to gain insight on laboratory operations and administration (34).

There are good reasons to support the involuntary termination of an employee, including incompetence, chronic absences, violent behavior or verbal abuse, falsification of resume, theft, and insubordination (16). A fair employer will make every reasonable attempt to correct the problem prior to taking disciplinary actions. Detriments to job performance including substance abuse of any kind, stress-related illness, mental illness, or physical disabilities secondary to job activities fall under the auspices of the Americans with Disabilities Act (http://www.usdoj.gov/crt/ada/adahom1.htm) and are not acceptable causes for dismissal (16). A number of variations in the process of progressive disciplinary action have been described for laboratory managers, and each is designed to allow sufficient time for the employee in question to mend his or her ways and for the employer to adequately assess the true nature of the situation (16, 34, 38). The steps generally include (i) verbal counseling, (ii) written counseling, (iii) a penalty phase, and (iv) dismissal. A number of variations on the theme exist. Walters (38) outlines a more creative approach to the resolution or termination process that includes five phases: forewarning, investigation, proof, reflection, and penalty. Importantly, though, employees have the right to representation during any disciplinary process as determined by the National Labor Relations Act (http://www.nlrb.gov/nlrb/legal/manuals/rules/act.asp). If the conclusions of the progressive disciplinary action lead to employee dismissal, the process is usually handled by HR to ensure that all legal steps are followed and documented (16). It is also wise for the employer to retain the personnel file of the departing employee for future reference. Likewise, the departing employee should be informed of the Consolidated Omnibus Budget Reconciliation Act. This act gives workers and their families who lose health benefits the right to continue group health care provided by their current plan for limited periods of time under certain circumstances (http://www.dol.gov/dol/topic/health-plans/cobra.htm).

REGULATIONS

This section will serve as a brief review of those regulations and regulatory agencies that have the most profound effects on the operation of the clinical microbiology laboratory. A more extensive review of laboratory regulations is available in the works of Roseff et al. (26), Walters (38), and Ehrmeyer and Laessig (7).

CLIA '88

CLIA '88 (or simply CLIA) establish baseline performance standards for all U.S. laboratories involved in the testing of human materials for the diagnosis, prevention, or treatment of disease (7). The intention is to ensure the accuracy, reliability, and timeliness of test results no matter which laboratory is performing the testing. They were signed into law in 1988 (12), but five successive final revisions of the initial legislation have been published since, the last of which appeared in the *Federal Register* in 2003 (13, 34). In the first final version of CLIA, laboratory testing was divided into three complexity levels that established the expertise level of personnel performing those tests. Those levels were waived, moderate complexity (including provider-performed microscopy), and high complexity. In the most recent final version of CLIA, testing is now lumped into waived and nonwaived tests (most of the latter were high complexity). However, relative to the qualifications of testing personnel, CLIA still recognize moderate- and high-complexity levels (7, 40).

The administration and implementation of CLIA are under the purview of the CMS (http://www.cms.hhs.gov) in collaboration with the Centers for Disease Control and Prevention (http://www.cdc.gov). The U.S. Food and Drug Administration (http://www.fda.gov) is responsible for classifying the complexity of laboratory testing protocols and the CMS set fee schedules for laboratories providing services to Medicare.

U.S. laboratories wishing to perform and receive compensation for testing of human specimens must apply for a CLIA certificate in one of three complexity categories. If the laboratory meets compliance criteria as judged by the CMS or by one of the recognized professional accreditation agencies, it receives a permanent certificate of compliance or accreditation and becomes subject to the rules, regulations, and inspections of the agency issuing the certification. Organizations that the CMS have deemed suitable for CLIA accreditation of laboratories include the Joint Commission on Accreditation of Healthcare Organizations (http://www.jcaho.org), the Laboratory Accreditation Program of the College of American Pathologists (http://www.cap.org/apps/cap.portal), and the Commission on Office Laboratory Accreditation (http://www.cola.org/).

CLIA lay the foundation for laboratory participation in a proficiency testing program, qualifications of and competency assessment of laboratory personnel, and, establishment of a QC and QA program and ensure the integrity of laboratory testing through all phases of testing. They also call for routine inspection of certified laboratories and the enforcement of penalties for laboratories found to be noncompliant. CLIA dictate that outside or reference laboratories to which specimens are referred from a U.S. health care institution also be CLIA certified or the equivalent. Those wishing to review CLIA '88 in their entirety or to query individual components of the amendments can do so at http://www.phppo.cdc.gov/clia/regs/toc.aspx or http://www.cms.hhs.gov/clia/default.asp. A general description of the program is available at http://www.cms.hhs.gov/clia/progdesc.asp.

HIPAA

Public law 104-191, or the Health Insurance Portability and Accountability Act (HIPAA, Title I) of 1996, was originally written "to improve portability and continuity of health insurance coverage in the group and individual markets, to combat waste, fraud, and abuse in health insurance and health care delivery, to promote the use of medical savings accounts, improve access to long-term care services and coverage, to simplify the administration of health insurance, and for other purposes." However, in 2002, the Department of Health and Human Services issued the HIPAA Privacy Rule (Title II) that set highly restrictive standards on the use and protection of individual demographics and health information (protected health information [PHI]) contained in patient medical records (24). Details are available at http://www.hhs.gov/ocr/hipaa/finalreg.html. The Privacy Rule dictates that all "covered entities" including health insurance plans and health care institutions and providers must obtain written permission from a patient to use or disclose PHI and that the patients must be notified of their right to restrict the use of or disclose PHI (24). Covered entities must also make every attempt to limit PHI disclosure to only that required for any given purpose. From the standpoint of the microbiology laboratory, this means that the release of any PHI attached to bacterial or fungal isolates sent for research or surveillance purposes that can be traced in any way to the patient requires disclosure and consent unless waived by the human studies committee of the institution. The Privacy Rule does not supersede the federal "Common Rule" (see also http://www.hhs.gov/ohrp/humansubjects/guidance/45cfr46.htm) that mandates Institutional Review Board approval of research studies conducted under its auspices (24). As with CLIA '88, the CMS are charged with the responsibility of administering the provisions of HIPAA. For a summary of the HIPAA health insurance reform (Title I) or the HIPAA administrative simplification (Title II), one can access the CMS website at http://www.cms.hhs.gov/hipaa.

Laws Covering Equal Pay and Compensation Discrimination

Several laws have been passed over the past half century to guarantee employees freedom from discrimination in the workplace with regard to wages, compensation, and working conditions. Collectively, these laws are enforced by the U.S. Equal Employment Opportunity Commission and include the Equal Pay Act of 1963, Title VII of the Civil Rights Act of 1964, the Age Discrimination Act of 1967, and Title I of the Americans with Disabilities Act of 1960.

Equal Employment Opportunity Commission

The Equal Employment Opportunity Commission is a federal agency created in 1965 to enforce the Civil Rights Act of 1964 (26). As of 1999, the agency had published new guidelines to further define unlawful harassment in the workplace (including sexual harassment) against the same groups protected by the Civil Rights Act (26, 38; http://www.eeoc.gov). To avoid risk, laboratories and/or HR of the parent institution should have a training module on unlawful harassment in place for employees and supervisory personnel, avenues for rapid reporting and investigation of complaints, and a documentation process for each of these.

Equal Pay Act of 1963

The Equal Pay Act is part of the Fair Labor Standards Act and makes unlawful the practice of wage discrimination between men and women performing the same duties at the same institution in a similar work environment. This act is directed and enforced by the Equal Employment Opportunity Commission and is gender neutral such that it protects males and females equally (38).

Title VII of the Civil Rights Act of 1964

Title VII of the Civil Rights Act of 1964 prohibits the use of race, color, creed, religion, nationality, and sex as a basis for the discharge of or failure to hire an employee, for segregation or classification that would deprive an employee of opportunities or advancement, for the failure or refusal of an employment agency to refer an individual for employment, or for the limitation of training or retraining of an employee.

Age Discrimination in Employment Act of 1967

The Age Discrimination in Employment Act of 1967 applies to individuals 40 years of age and older and, like the Civil Rights Act, prohibits the use of age as a reason for discrimination in the workplace. Interestingly, this law also applies when two candidates over the age of 40 apply for the same job and the younger of the two is hired if the employer has used older age as a negative factor in the selection process (38).

Americans with Disabilities Act

The Americans with Disabilities Act was passed in 1990 and forbids discrimination against an individual who has or has had a disability, is thought to have a disability, or associates with another disabled individual. According to the Americans with Disabilities Act, a disability is a physical or mental deficiency that affects a life function such as walking, talking, employability, and hygiene (38). The Americans with Disabilities Act mandates that an employer reasonably accommodate the needs of any qualified candidate so that he or she can perform the job. For example, the current dimensions of bench tops, shelving, and foot wells in the microbiology laboratory may not be appropriate for wheelchair access by a wheelchair-bound microbiologist and, therefore, require modification. Acceptable dimensions for work-related desk surfaces and shelving are provided in the Americans with Disabilities Act standards for design (http://www.usdoj.gov/crt/ada/stdspdf.htm).

Other Regulations Related to the Workplace

Family and Medical Leave Act

Passed in 1993, the Family and Medical Leave Act provides allowances to eligible employees of an eligible employer to take up to 12 months of unpaid leave during any 12-month period for one or more of the following situations: (i) birth and care of the employee's newborn child, (ii) placement with the employee of a child for adoption or foster care, (iii) care of an immediate family member (spouse, parent, or child) with a serious health problem, and (iv) medical leave secondary to the employee's own serious health problem. The Family and Medical Leave Act falls under the auspices of the U.S. DOL, and definitions of which employers are covered by this act and which employees are eligible can be found at http://www.dol.gov/esa/whd/fmla/.

Fair Labor Standards Act

The DOL also administers the Fair Labor Standards Act, which is legislation that sets basic minimum wage and overtime pay schedules. These regulations are enforced by the

Wage and Hour Division of the DOL, which is a program of the Employment Standards Administration. Pay for overtime (defined as work in excess of 40 h in a work week) is set at a rate of not less than one and one-half times the regular rate of pay. Certain exemptions apply to specific types of businesses or specific types of work. This act does not set requirements for severance pay, sick leave, vacations, or holidays. For more details, one can consult the DOL website at http://www.dol.gov/dol/topic/wages/index.htm.

Affirmative Action

An executive order was issued in 1965 that prohibits contractors engaged in federal contract work exceeding $10,000 from discriminating in hiring decisions against the same protected groups included in the Civil Rights Act. This order has since become known as affirmative action and was updated in 2000 by the Office of Federal Contract Compliance Program of the DOL. In addition, contractors securing more than $50,000 in government business and having more than 50 employees must write and regularly update an affirmative action plan to reflect current guidelines (38). Affirmative action guidelines would apply to many health care institutions and laboratories meeting the criteria defined above because of their participation in federal contracts for care provided to Medicare and Medicaid patients. However, many institutions that do not meet the qualifications outlined in this executive order have chosen to develop a voluntary affirmative action plan. The Office of Federal Contract Compliance Program maintains a website at http://www.dol.gov/esa/regs/compliance/ofccp/faqs/faapfaqs.htm.

Laboratory Design

MICHAEL L. WILSON AND L. BARTH RELLER

3

A well-designed laboratory is a safe, pleasant, and efficient place in which to work, as well as an enjoyable place to visit. When a new laboratory is being designed or renovation of an existing one is being planned, the design must meet the needs of laboratory staff who spend all or most of their working time there, the needs of workers who spend part of their time there, and the needs of visitors who have to interact with the staff. Above all other considerations, a clinical laboratory must be a safe place. No other aspect of laboratory design carries a higher priority, both for the staff and for visitors. A pleasant environment improves staff morale and productivity, minimizes unnecessary distractions (thereby reducing laboratory errors), and enhances employee recruitment and retention. An efficient clinical laboratory helps to improve productivity, to reduce errors, and to improve patient care by shortening laboratory test turnaround time (TAT). An efficient laboratory also helps to improve staff morale and contributes significantly to a pleasant work environment.

Good laboratory design is based on the concept that form follows function, so the unique functions of a clinical microbiology laboratory (CML) should be reflected in the laboratory design. When designing a CML, it should be remembered that there are three key differences between a CML and other types of clinical laboratories. First, clinical microbiology involves the isolation, propagation, and handling of pathogenic microorganisms that pose a risk to laboratory personnel. To minimize this risk, the entire CML must have the facilities and processes necessary to meet biosafety level 2 criteria and, depending upon the extent and scope of services provided, all or part of the laboratory must also meet the requirements necessary to meet biosafety level 3 criteria (4, 15). Second, the interpretation of cultures and other microbiologic test results is based on the ability of the laboratory to isolate pathogenic microorganisms while minimizing microbial contaminants. Again, the laboratory design must be such that the necessary precautions can be taken to minimize contaminants. Third, laboratory design must accommodate specialized equipment used only in microbiology laboratories.

This chapter is intended to be an introduction to the processes of laboratory design, construction, and renovation. Reading this chapter should enable the microbiologist who is beginning a construction or renovation project to communicate with all of the parties who are involved. The informed microbiologist not only will understand the terminology of design and construction, but also will be able to make better decisions as the processes unfold. Being well informed also reduces the likelihood of costly mistakes. Not everything can or should be learned by experience.

GENERAL DESIGN PRINCIPLES

The needs of each laboratory will change over time, often many times between the initial construction of the laboratory and any subsequent renovations. Thus, the best approach to designing is to use the most generic design possible, minimizing features that are unique to current circumstances. Not only does a more generic design facilitate the changing needs of the laboratory, but also it reduces the costs of construction, renovations, and ongoing maintenance. Moreover, a generic design is the most flexible one. As stated by Crane and Richmond (5), "the biggest challenge to the laboratory design team is to keep the design simple, not to overdesign the laboratory. . . ." Meeting this challenge requires strong leadership by the laboratory administration and the architect. In particular, leading a design project for either new construction or renovation requires the ability to say "no" to requests for special design features.

Laboratory Location

CMLs providing services for a hospital must be fully integrated with the main hospital laboratory (7, 11, 13). This is a critical factor in providing adequate staffing, ensuring proper specimen processing and handling, reducing errors, and increasing efficiency and productivity. While it is true that off-site reference laboratories serve a useful role in providing esoteric testing and/or routine microbiology services for outpatient clinics and physician offices, we believe that there are important reasons why off-site microbiology laboratories do not serve hospitals well. First, use of off-site laboratories may result in delayed specimen processing, which can adversely affect microbial recovery and timely reporting of results. Second, use of off-site laboratories decreases interaction between microbiologists and clinicians. This is of particular concern when there is a lack of clinician input into specimen processing, which directly affects the clinical interpretation of microbiological tests. Third, as previously mentioned, loss of integration with the rest of the clinical

laboratory, particularly specimen receipt and processing areas, increases the risk of incorrect specimen processing and medical errors. Fourth, laboratory staff members in different laboratory sections are unable to interact on a frequent basis, provide coverage for one another, and act as a cohesive unit. Fifth, added complexity and cost are associated with off-site laboratories (e.g., reliable, timely transport of specimens). Sixth, location of the CML close to the main laboratory facilitates access during off-hours and simplifies security. A laboratory that is remote to the main laboratory is unlikely to be visited by clinicians during off-hours, if ever. Last, location of a CML distant to the site of patient care precludes meaningful training of clinical microbiologists, infectious disease physicians, and other health care professionals (7, 11).

Laboratory Size

Only broad generalizations can be made regarding laboratory size. As a general rule, each bench technologist needs a minimum of 50 ft^2 in which to work, excluding space for large pieces of equipment, walls, corridors, storage, lockers, and offices. Areas such as that used for specimen processing require ample space to accommodate the necessary equipment, the specimen receiving bench itself, and foot traffic. Laboratory sections such as mycobacteriology, mycology, and virology require a larger amount of space relative to the number of technologists who work there. Areas such as a dedicated autoclave room or medium preparation room require additional space. If the number of technologists and supervisors is proportional to the test volume and the laboratory is well designed with little wasted space, the space allocated for the laboratory should be between 150 and 200 ft^2 per staff member.

Laboratories should be designed with more space than is needed for current workloads and types of services provided. This serves three purposes. First, an efficient laboratory always has the space needed to accommodate short-term expansion of the types and volumes of services provided by that laboratory. Second, extra space (often referred to as swing space) can be used when part of the laboratory is being renovated or repaired. Third, extra space can be used for future expansion of services. It is unwise to design and build a laboratory to meet current needs only.

Transportation

As with other laboratory sections, an effective transportation system is crucial for providing clinical microbiology services. A variety of transportation systems are in use in hospitals today, including manual transportation, robotic systems, and pneumatic tube systems. Manual systems are notoriously unreliable, particularly in large medical centers, and the associated personnel costs make this approach one of the most expensive. While the capital costs of robotic and pneumatic tube systems are high, over time these costs may be less than those associated with a manual transportation system. Robotic systems are not as widely used as pneumatic tube systems for transportation throughout hospitals. Pneumatic tube systems are widely used in hospitals and have been proven to be an effective method for transporting some types of specimens to clinical laboratories. If they are well designed and maintained, they can play an important role in reducing the costs of transportation, decreasing the number of lost or delayed specimens, and reducing test TAT. In general, however, dedicated pneumatic tube systems are not as useful for CMLs as they are for chemistry and hematology laboratories. This is because most microbiologic tests do not have the same expectation for test TAT, many pneumatic tube systems cannot transport specimens as heavy as full blood culture bottles, and containers used to collect specimens such as urine are prone to leakage when shipped through pneumatic tube systems. Other automated transportation systems are available, but, as with pneumatic tube systems, any benefit to a CML is not as great as it is for other clinical laboratory sections.

Building Codes and Architectural Standards

Laboratorians who have never been involved in the construction or renovation of a laboratory are often unaware of building codes and architectural standards (1). Although it is the responsibility of the architects and engineers to ensure that the plan meets the appropriate codes and standards, laboratory staff members who are involved in a project should understand these issues sufficiently to avoid making requests that are not in compliance with codes and standards. There are definite and specific limits to the way a laboratory can be built.

Interior Design

The design of laboratories that are part of health care systems often involves meeting organization design standards. In some organizations, the types of materials that are used for construction, color schemes, and many other architectural details are specified from the outset. For some organizations this makes a great deal of sense, as a standard interior design lends a sense of continuity throughout the organization. In many instances it also reduces construction and renovation costs, as the organization can purchase materials in large quantities. For other organizations, however, it makes little sense to adopt interior design schemes developed for one part of the organization for a laboratory. Moreover, not all design schemes are successful, so an organization should not be reluctant to abandon one scheme in favor of a better one. At all costs, one should avoid trendy interior design schemes, as they are less likely to please a large number of employees, become dated more quickly than do more traditional design schemes, and tend to be more expensive. It should always be remembered that one might have to live with a laboratory or office for many years.

Technology

Much of the same logic that applies to interior design also applies to the use of advanced technology in a laboratory. Laboratorians, architects, engineers, and designers are all enamored with technology, and there is a strong temptation to use the most advanced technology in a new laboratory or when renovating an existing one (5). Nonetheless, one should assess carefully the cost of advanced technology versus less advanced but proven technology, evidence that advanced technology has been used successfully in comparable laboratories, and any evidence of long-term durability. Advanced technological products may or may not be better than traditional ones, but the newer they are, the less experience there is with them. Moreover, some advanced technology products are trendy and should therefore be avoided for the same reasons that trendy interior design schemes should be avoided. There are reasons why traditional built-in laboratory casework continues to be used widely and why certain commercial products and vendors have been around for decades.

SPECIFIC DESIGN ISSUES

Laboratory Layout

The laboratory layout is crucial for achieving the goals set forth in the introduction to this chapter. The overall layout of a clinical laboratory is determined by the types of services provided, the numbers and types of specimens that are processed, the physical constraints of the building, and the resources that are available for the construction or renovation project. A laboratory that provides only patient care services has needs that are different from those of one engaged in teaching and/or research. Busy clinical laboratories must be efficient to maximize specimen throughput and to minimize test TAT. Laboratories that support teaching and research missions also need to be efficient but must have the space and facilities to support the broader missions. Decisions regarding the overall layout of the laboratory should be made first and should be immutable during the design process.

Most CMLs are divided into sections according to the way that specimens are handled in those laboratories (e.g., a bench devoted to urine cultures, another to blood cultures, and so on) and/or by discipline (e.g., a mycology section). There are obviously many different ways to organize a laboratory. As noted above, the best approach is to use a generic design so that equipment, staff, and processes can be moved as necessary. Areas that require biosafety level 3 conditions cannot be easily moved, so the laboratory staff should take extra care in choosing a location for these areas.

Specimen Preparation Area

All CMLs need an area to receive and process specimens. This area should be located near the laboratory entrance so that other laboratory staff and couriers do not need to enter the rest of the laboratory to drop off specimens. The area should have ample benchtop space for receiving specimens, for any necessary equipment, and for the handling of specimen requisitions. This area should have one or more class II biological safety cabinets (BSC) to accommodate all initial specimen processing. All necessary information technology (IT) infrastructure and telecommunications equipment should be provided. This area should have a sink for handwashing and for performing Gram's stain and other direct examinations. Some laboratories place a microscope in this area for reading stains, whereas others place microscopes in a separate area of the laboratory. A refrigerator should be located in the specimen preparation area to hold specimens and media. Some laboratories do not have separate incubators for the specimen processing area, opting to place inoculated media directly in the main laboratory incubators, but unless specimens can be placed in these incubators quickly, a holding incubator should be located in the processing area.

The specific design of a specimen preparation area needs to be tailored to the number of specimens that are received, as well as to the types of microbiologic tests that are performed. There is no single design that is optimal for all laboratories. For this reason, and because this is often one of the busiest areas of any microbiology laboratory, the specimen preparation area should receive emphasis during the design phase of the project. The perspective and wishes of experienced technologists are especially important here. Function should drive design.

General Laboratory Bench Space

Work Areas

Many laboratories are constructed on the basis of U-shaped modules or linear benches. Modules typically measure 10 by 10 ft and can accommodate two or three persons. Advantages to the modular approach include minimized foot traffic in work areas, generous countertop and storage space, corner space that is available for computer workstations (corners otherwise are wasted space), an increased sense of privacy for workers, and use of less floor space for aisles and corridors. Advantages to the linear bench approach include ease of cleaning, ease of moving about the laboratory, a subjective sense of less clutter, easier location of large pieces of equipment such as incubators and refrigerators, ease of moving modular casework, and lower design, construction, and renovation costs. Some laboratories use a combination of modules and linear benches. In many cases, the physical layout and constraints of the building determine which approach is best for a given laboratory.

The space surrounding workbenches should be sufficient to accommodate ample waste containers, both for paper and for biohazardous waste. It is inefficient for laboratory staff and housekeepers to empty trash containers more often than is necessary. Ample space should be provided so that aisles are unobstructed and free of clutter, yet aisles that are too wide merely waste space.

The laboratory should contain space for storing completed cultures, stock cultures, reference books, and teaching materials (e.g., parasitology slides). It is most efficient for completed cultures and reference materials to be located close to workbenches. The principle applies to frozen, lyophilized, or viable cultures.

Casework

Laboratory casework can be built-in (custom) or modular. The type of casework selected for a laboratory is, to a large degree, determined by the size of the laboratory. It is expensive to install custom built-in casework in a large laboratory; vendors are able to give better pricing for installing modular furniture in larger facilities. Thus, larger laboratories almost always find it to be more economical to buy commercial modular furniture. Smaller laboratories, on the other hand, may find the opposite to be true. Before making a decision, one needs to be familiar with the advantages and disadvantages of each type of casework.

Built-in casework typically is less expensive to install, can be made from a wider variety of building materials to suit individual tastes, can be very strong, and is durable. It is not unusual to see built-in laboratory casework that is decades old but is still functional and aesthetically pleasing. The disadvantages to built-in casework are that it cannot be moved easily, repairs tend to be more difficult and expensive, modifications (e.g., adding additional power and communication lines) also are more difficult and expensive, and, for the most part, it cannot be reused once it is disassembled. From an interior design standpoint, it has the disadvantage of requiring users to live with the aesthetic choices of predecessors and those characteristic of previous eras.

Modular furniture has been, in part, designed to overcome the disadvantages associated with built-in casework. Specifically, some parts of it can be moved easily, repairs and replacements are easy, modifications are easy and less expensive, and entire units can be disassembled and moved to another location. The converse, however, is equally true: many of the advantages associated with built-in casework are not found in modular furniture. Specifically, modular furniture tends to be more expensive (unless one is buying large quantities, decreasing the unit cost), there is a smaller selection of building materials and colors to suit individual aesthetic tastes, and it tends to be less strong and durable.

It should be noted that one of the main advantages to modular furniture, the ability to move it around, tends to be overstated. This is because the stanchions that support the casework are bolted to the floor, plumbing and drains for sinks are not easily moved, and there are practical limits to moving the electrical power supply and IT and telecommunication cables. In fact, with some commercial modular casework systems, only the cabinets, shelves, and countertops can be moved, and even they can be moved only within the confines of the supporting stanchions.

Air, Gas, and Vacuum Supplies

Most modern laboratories have little need for compressed air, gas, and vacuum supplies, except as needed for specific purposes. Use of open flames should be prohibited, so there is no need for a flammable gas supply. Most health care facilities do not have central systems to supply the types of gases used in microbiological incubators. These should be included within the laboratory facility.

A generous amount of space should be allocated for incubators, refrigerators, freezers, floor-model centrifuges, and floor-model diagnostic equipment (e.g., continuous-monitoring blood culture systems). Electrical power, water supply, telecommunications ports, and other features necessary to support such equipment should be part of the design. The load capacity of the facility should be such that it can support the weight of this equipment, particularly if most of it is to be located in one part of the laboratory.

Special Laboratory Bench Space

Anaerobic Bacteriology

The anaerobic bacteriology capacities needed by most hospital-based CMLs can be accommodated by countertop jars. For larger laboratories, or those with a special interest in anaerobic bacteriology, sufficient space should be allocated to accommodate an anaerobic chamber and gas supply. Countertop models have replaced most of the floor-model anaerobic tents that once were common in laboratories. Some gas-liquid chromatographs require a dedicated exhaust system for discharged gases. Most of the other equipment needed for anaerobic bacteriology does not require special design features.

Mycobacteriology, Mycology, and Virology

An important design requirement for many mycobacteriology, mycology, and virology laboratories is that the facility should meet biosafety level 3 criteria, as described in the following section, in order for the staff to safely handle pathogenic microorganisms such as *Mycobacterium tuberculosis*. In addition to biosafety issues, these laboratories require special equipment not used elsewhere in the CML, such as refrigerated centrifuges, special diagnostic equipment, and the incubators required to hold specimens at various temperatures. Equipment for performing tissue cultures may also be needed. Mycology and mycobacteriology laboratories must have a certified class II BSC.

Biosafety Level 2 and 3 Conditions

Most routine clinical microbiology procedures can be performed safely under biosafety level 2 conditions (15). Even though biosafety level 2 conditions can be met without use of a BSC, use of a BSC protects laboratory workers from laboratory-acquired infections and protects specimens from contamination (8, 16). Moreover, laboratory staff do not always receive sufficient information with specimen requisition forms to know which specimens are likely to contain pathogens that are risky to process (3). Therefore, it is strongly recommended that all specimen processing be done in a class II BSC. Isolates or cultures that are known or likely to contain high-risk microorganisms should be processed only in a class II BSC, particularly fungal and mycobacterial cultures (3, 15). If possible, positive blood and cerebrospinal fluid cultures should also be processed in a class II BSC. Adequate space, power, and ventilation should be provided for each BSC.

Biosafety level 2 conditions are met largely via use of standard microbiological practices (15). In addition to these practices, biosafety level 2 conditions require that (i) laboratory personnel have specific training in handling pathogenic agents, (ii) personnel be directed by competent scientists, (iii) laboratory access be limited when work is being conducted, (iv) extreme precautions be taken in handling contaminated sharp items, and (v) procedures likely to generate infectious aerosols or splashes be conducted in either a class II BSC or other physical containment equipment (15).

Biosafety level 3 conditions include all of the requirements for biosafety level 2 conditions plus special facilities, equipment, and procedures for handling "pathogenic and potentially lethal agents" (15). For those CMLs that do not have the facilities specified for biosafety level 3 conditions, routine microbiologic procedures should be done using biosafety level 2 conditions. Biosafety level 3 practices and protective equipment should be used when handling agents that pose a risk of serious or lethal infection. The specific requirements needed to meet biosafety level 3 conditions are given in reference 15. In brief, these include (i) limited laboratory access; (ii) written policies and procedures for handling agents; (iii) adequate training, proficiency, and competency for handling agents; (iv) use of a class II BSC for handling highly infectious agents; (v) use of adequate face and respiratory protection for procedures done outside a BSC; and (vi) written policies and procedures for handling spills. The facility requirements are given in reference 16. In brief, these include (i) a separate area with access through two sets of self-closing doors; (ii) sealed floors, walls, and ceilings to facilitate decontamination; (iii) a waste disposal system that is available within the area; (iv) a ducted air system that draws clean air from outside the area, with all of the exhaust air (i.e., none of the air is recirculated) discharged to the outside; and (v) the use of HEPA filters in the exhaust of BSCs, in vacuum lines, and in equipment or devices that may produce aerosols or splashes (e.g., centrifuges).

Molecular Microbiology

As for the general microbiology laboratory, planning for a molecular diagnostics laboratory should optimize workspace flexibility, since this technology is rapidly changing and new equipment, methods, and applications will be available in the next few years (6, 12, 14). Prior to establishment of molecular testing, thought must be given to the type of services planned. For example, if the laboratory staff plans to perform only Food and Drug Administration-approved and commercially available kit-based assays, then minimal space and equipment may be all that is needed. Alternatively, if the laboratory staff plans to develop and perform in-house assays, then a significantly greater investment in space, equipment, and technical expertise will be required. In addition, consideration must be given to the specific assays that will be performed, as space and equipment needs vary considerably for different types of assays.

If the laboratory staff plans to perform only commercial amplification kit-based assays, bench space will be needed to accommodate a hood-type work enclosure with a UV light source, an amplification and detection apparatus(es), and a few other pieces of equipment, such as a water bath and a microcentrifuge. As little as 15 linear feet of bench space is needed. To reduce the risk of contamination, two geographically separated work areas are needed. Most commercial kit-based assays include methods to prevent carryover amplification, and automated equipment also may reduce the possibility of carryover, both of which minimize the amount of space that is needed. According to the manufacturers of some commercial diagnostic molecular assays, certain assays can now be performed in a single area and with only minimal need for special handling. Experience will show whether this is an acceptable approach, but it is likely that as the technology of molecular diagnosis changes, there will be a decreasing need for separate areas. As this occurs, laboratories will be able to fully integrate diagnostic molecular assays with the rest of the CML.

Development, validation, and performance of in-house methods that involve amplifying nucleic acids require a more elaborate laboratory. A minimum of 500 ft^2 is required for a small molecular diagnostics laboratory, with three separate workspaces. The three work areas include one for reagent preparation, one for specimen preparation, and a third for amplification. General analysis of DNA or RNA requires an assortment of basic laboratory equipment, as well as specialized equipment. Sources of high-grade deionized water, wet ice, and dry ice are needed, as is an autoclave. A fume hood and storage cabinet for solvents and flammables are also needed. Access to a darkroom is advantageous.

The reagent preparation area is the cleanest of the three work areas and can be located in a separate room, in a hood with the fan turned off to minimize aerosolization, or in an enclosed countertop hood or box. This area is used for the preparation of the master mix and other necessary reagents. To minimize contamination, patient samples, prepared DNA, and amplified products must never be brought into this area. Since equipment can become contaminated with DNA, it is imperative that dedicated equipment be used and stored within this area. Reagents should be stored in a refrigerator free of DNA (and especially amplicons), and disposable items such as tubes, tips, and gloves should also be stored in a manner to prevent their contamination. Staff should wear a designated clean laboratory coat along with clean gloves; staff should leave transportable items (e.g., pens, tape, and scissors) in this area.

The second area is the specimen preparation area. In this area, tubes containing the aliquoted master mix should be brought for the addition of nucleic acid; these tubes should not be returned to the reagent preparation area. Specimen preparation activities can be performed in the open laboratory on a bench but might also be performed in an enclosed space such as a benchtop hood or containment box. After nucleic acid is added to the reaction tubes in this area, the tubes are sealed and placed in the thermocycler for amplification. When removed, the tubes should be taken unopened to the third area for product detection.

The third area is the most contaminated of the three work areas. Laboratory staff should take extreme caution to ensure that laboratory coats, gloves, tube racks, and other equipment are never moved back into the reagent or specimen preparation areas. Some laboratories have opted for separate areas for a darkroom/gel electrophoresis room, a room for processing of radioactive samples, and a room for other functions.

Work Flow

Efficient laboratories are designed so that specimens flow in one direction. Traditional microbiologic testing follows a pathway of specimen receipt and plating, incubation, isolate identification, antimicrobial susceptibility testing, and result reporting. Because this sequence is by its nature linear, CMLs benefit from unidirectional work flow. Unidirectional work flow is also important in molecular microbiology laboratories. In this case, the issue is not so much one of efficiency but rather one of minimizing the risk of amplicon carryover and specimen contamination. While much of this can be accomplished by designing unidirectional work processes, the laboratory facility must accommodate the needs of those processes.

Laboratory Storage

Storage space should be adequate but not excessive. Insufficient storage space makes for a cluttered laboratory; unused storage space makes for a dusty one. Short-term storage capacity should meet the daily needs of the staff and no more. Long-term storage of supplies should be in the main laboratory storage room; there is no reason for long-term storage in the CML itself. Storage space, whether on shelves, in overhead cabinets, or in drawers, should be designed so that workers have most of what they need during the day within arm's reach. Storage space should be designed so that it can be cleaned easily.

Incubators, Refrigerators, and Centrifuges

CMLs should have ample space for large floor-model incubators, refrigerators, and centrifuges. Sufficient aisle space should be allocated next to large units so that the aisle remains unobstructed when a door is opened. Adequate electrical power should be incorporated into the area housing these units, as well as any necessary gas or water supplies. The location of these units should help maximize laboratory efficiency and ensure a unidirectional work flow. As a general rule, a refrigerator and centrifuge should be located in the specimen processing area. Although some CMLs have adopted the principle of scattering incubators and refrigerators throughout the laboratory, with the rationale of minimizing the distance from workbenches, a more efficient use of space is to have a separate area in the laboratory for these large pieces of equipment. This is because these units almost always are wider than countertops are deep, so locating them throughout a laboratory requires the aisles to be wider than would otherwise be necessary. Because the additional space in the other parts of the aisle is not needed, a significant amount of floor space will be wasted.

Handwashing, Water Supply, and Plumbing

The CML should have sufficient sinks to accommodate staining, waste disposal, and handwashing. To prevent laboratory-acquired infections (3, 16), handwashing sinks should be designed so that they can be operated with knee or foot controls. One sink should be located near the laboratory entrance to facilitate handwashing by staff and visitors as they leave the laboratory. Drainpipes should be able to handle the types and volumes of liquid waste generated within the laboratory.

Plumbing is expensive to install at any time but especially so once laboratory construction is completed. In addition, the plumbing and water supply cannot be moved easily in

modern buildings, as one must drill through a concrete floor and then work in the ceiling space of the floor below. This space typically is filled with heating, ventilating, and air-conditioning (HVAC) systems, lighting, IT and telecommunications cables, and electrical power lines, making it difficult and expensive to work there. Such a project is also disruptive to the occupants of the floor below. Therefore, the water supply and plumbing needs should be assessed carefully during the design phase of the project.

Countertops

Countertops at workbenches should be 24 in. deep, with work areas no more than 4 to 5 ft wide. A working space of these dimensions is the most efficient because the entire space is within arm's length for most workers. There should be additional space to each side for storage and equipment. Some countertops will need to be deeper to accommodate countertop-model equipment. Heavy pieces of equipment should be on freestanding tables designed to accommodate the necessary weight. Centrifuges should also be on freestanding tables to minimize the transfer of vibrational forces to adjacent countertops. Sensitive analytical balances should be on freestanding tables. Most modular casework systems include tables that are of the same length and width as the individual countertop pieces and which can be integrated into the overall laboratory layout.

The height of workbenches can be that of a desk (29 to 30 in.) or a counter (36 in.). While there are advantages to both heights, use of one or the other is largely a matter of personal preference. Modular furniture can be adjusted to either height, whereas built-in casework obviously is fixed at one height.

Countertops should be made of materials that can be cleaned and disinfected easily, are durable, and can be replaced or repaired as needed. Most countertops in CMLs do not need to be acid resistant. Countertops that are stain resistant are desirable. Countertops adjacent to sinks should be constructed of water-resistant materials so that repeated exposure to water does not damage them. Lighter colors tend to show stains more but have the benefit of making the laboratory brighter. Practical issues aside, colors generally are selected on the basis of interior design needs and personal preference.

Electrical Power Supply

Electrical outlets should be liberal in number and in excess of the current need. These are easily installed during construction, but upgrading the electrical power supply can be expensive and difficult once construction is completed. One important task during the design phase of the project is to perform a comprehensive audit of the electrical needs of the laboratory, particularly as related to 110- versus 220-V power supplies. The need for emergency power supplies should also be assessed, as this requires a separate electrical power supply. Only critical pieces of equipment should be on the emergency power supply. Critical equipment should be wired into a central alarm system so that the appropriate persons can be notified of any power failures.

HVAC

The HVAC system in a clinical laboratory must be designed so that the laboratory meets the necessary biosafety level while maintaining a constant ambient temperature within a narrow range. Thus, the design of an HVAC system is a challenging task for architects and mechanical engineers. Moreover, once installed, an HVAC system cannot be easily modified: it is one of the most expensive parts of construction, it resides in a relatively inaccessible space, and changing the HVAC in one area of a building may have effects in other areas of the building.

Installing an HVAC system is one of the more expensive parts of laboratory construction. Because revising an existing HVAC system can be expensive or impractical, it is imperative that the design and installation be done correctly. Balancing the airflow in a CML is challenging: (i) CMLs must have lower air pressure than in adjacent areas; (ii) air temperatures in a CML must be maintained within a narrow range; (iii) exhaust air from a CML cannot recirculate into the building; and (iv) the HVAC system must accommodate special needs for odor control. Although it is desirable to use special plenums that draw off odors from workbenches (which is of particular concern in the specimen processing area, parasitology section, anaerobic bacteriology section, and autoclave room), these can exhaust large amounts of air from the CML and make balancing the airflow difficult. For all these reasons, adjustments to the HVAC system may be necessary after the laboratory has been occupied.

IT and Telecommunications

General Considerations

The modern clinical laboratory is highly dependent upon IT and telecommunications systems. Modern telecommunications systems are complex and need to support telefax units, sophisticated telephone systems, videoconferencing, and other types of telecommunications. In the same way, modern IT systems need to meet both current and anticipated needs such as the introduction of new versions of operating systems, databases, and other applications. The IT infrastructure should accommodate the larger institution's (e.g., hospital's) health care information system, the laboratory information system, the facility intranet, and the Internet. Ideally, the IT infrastructure should be designed for high-speed access, have redundant data storage and processing capacity, and have sufficient types and numbers of workstations to accommodate changing IT needs. Because the most efficient laboratories are paperless, it is important that the IT infrastructure support this type of environment.

For many laboratory staff members, and certainly for clerical and administrative staff, most of the day is spent using a computer. The computer workstation has become the focus of most offices and many laboratories. A robust IT system supports a variety of applications that are of immediate benefit to the laboratory staff. Any modern laboratory should have the infrastructure needed to support a modern IT system. In particular, the cable plant should be generic in design and have a fiber-optic backbone with a fiber-optic cable to each outlet in the laboratory. This cable architecture accommodates current IT needs but will also facilitate future transition to voice and video capability. There should be redundancy in the network infrastructure. IT and telecommunications systems should be designed so that information retrieval is limited to those who are authorized to access patient records. The design and installation of the IT and telecommunications systems in a laboratory should be done in close collaboration with the information services within the institution. Once systems have been installed, it is expensive or impractical to make changes to the IT and telecommunications infrastructure.

Wireless Networks

The increased use of devices such as wireless-capable laptop computers as workstations, personal digital assistants for data storage and retrieval, pen tablets, and "smart" cellular telephone systems makes it necessary for health care facilities to have wireless networks. The primary advantage of wireless systems is that users can receive and transmit data signals from any location rather than from only those locations that are cabled for network access. Wireless systems can also be used for dispatch and communication for employees who, by the nature of their work, need to be contacted at sites removed from traditional workstations. This type of system is often a Voice over Internet Protocol (VoIP) system, which operates much like a cell phone but works only over the wireless network in a facility. Another wireless application is the use of radio frequency identification, which can be used to tag and track items by using a simple web-based interface.

Offices and Administrative Support

Office space should be located close to but not within the laboratory. Offices should be sufficient to support the managerial, administrative, research, and teaching functions of the laboratory. Just as it makes little sense for a clinical laboratory to be located off-site, it makes equally little sense for the office space that ostensibly supports a laboratory to be in a remote location. Successful clinical and faculty recruitment and retention often hinge on adequate office space. Compared with other parts of a health care facility, office space is inexpensive to build, maintain, and renovate. It is in the long-term interests of the institution to make the modest investment needed for this part of the laboratory.

The process of designing offices should follow the same principles as those that guide the design of a clinical laboratory: offices should be private, quiet, efficient, and pleasant places to work or to visit. Although some institutions have opted for an open office plan where low modular barriers separate offices, open offices do not provide the privacy necessary for counseling employees or for discussing confidential matters, nor are they quiet. Offices should be equipped with the office equipment, IT and telecommunications infrastructure, and other features that are necessary to make them efficient. Many offices that are associated with clinical laboratories are too small to be pleasant places to work or to visit. Although offices should be sufficiently large, offices that are too large waste space, which never is in excess. As a general rule, individual offices should be no smaller than 100 ft^2. Traditional furniture is less efficient than modular furniture; office size should be adjusted according to the type of furniture that is used. Laboratory directors and supervisors should have offices that are large enough to accommodate several persons during meetings. Offices of up to 200 ft^2 are not unreasonable for directors.

Work Environment

Ergonomic considerations should receive emphasis in laboratory design. Casework, drawers, shelves, keyboard trays, lighting, and space should all be designed according to ergonomic standards. Both ceiling and task lighting should be abundant and well placed. Signs, bulletin boards, and other means of communication should be placed where laboratory staff and visitors can easily see them. A modest investment in the ergonomic and aesthetic properties in the laboratory will go a long way toward making it a pleasant and efficient workplace.

Safety and Security

As stated in the introduction, above all other considerations, a laboratory should be a safe place. For general safety considerations, this can be achieved by ensuring that the laboratory meets all building codes and architectural standards related to safety. For safety considerations related to the practice of clinical microbiology, this can be achieved by designing the laboratory to meet biosafety level 2 criteria and, where necessary, biosafety level 3 criteria.

Clinical laboratories must meet the safety and security requirements of accrediting and regulatory bodies. Eyewash stations, safety showers, sprinkler systems, fire extinguishers and blankets, fire alarms, spill control kits, and emergency power and lighting should be included as specified by building codes. Water supplies should have either backflow preventers or vacuum breaker devices to prevent the inadvertent contamination of potable water supplies.

The laboratory should be designed so that it can be secured during off-hours, or when staffing is minimal. Institution-specific security concerns will guide the need for more comprehensive security assets such as security cameras, restricted access, or electronic monitoring of access.

Cleaning and Waste Handling

A clinical laboratory should be designed so that it can be cleaned easily. All surfaces should be made of materials that are easily cleaned and disinfected. Carpet should never be used as a floor material in a clinical laboratory. To facilitate cleaning, floors should be kept free of clutter; there is no excuse for using floors in a clinical laboratory for storage space.

The laboratory design should accommodate the handling of the large amounts of biohazardous waste that are generated each day. There should be adequate space for waste containers within the laboratory, for biohazardous waste as well as standard waste. Large bins for both types of waste should be located outside the laboratory but nearby. Large pieces of floor-model equipment should be permanently housed on wheels so that they can be moved easily for cleaning. A housekeeping closet should be located close to the laboratory to facilitate daily cleaning.

Some laboratories maintain an on-site autoclave for medium preparation or decontamination of wastes. Some smaller autoclaves are self-contained, but larger autoclaves require steam lines that must be taken into account early in the design process.

THE DESIGN AND CONSTRUCTION PROCESS

Predesign Phase

Beginning the Process

Architecture, engineering, and construction are complex disciplines. Just as one cannot expect a clinical microbiologist to be familiar with the terminology, processes, and regulations of those disciplines, one should not expect an architect, engineer, or contractor to be familiar with the terminology, processes, and regulations that guide the day-to-day operations of a clinical laboratory. Thus, perhaps the most important skill needed to initiate and complete a design or renovation project is communication. Successful design, construction, and renovation projects are characterized by a commitment to education and communication. This is of particular importance when any of the parties who

are involved in the project have little or no prior experience in designing or renovating a laboratory. It is not unusual to meet architects, engineers, or contractors who have no experience with clinical laboratories, just as it is not unusual to meet laboratorians who have never been involved with a laboratory construction or renovation project. It is also not unusual to meet architects, engineers, or contractors who have experience with research or industrial laboratories but not clinical laboratories. Experience with the former does not necessarily translate into expertise in the latter. To facilitate communication and education, it is important to have a clear understanding of the experience and expertise of all the parties who will be involved with the project.

Laboratory Representative

The first step in designing a laboratory is for the laboratory administration to appoint a person who will be the spokesperson throughout the design and construction process. Such an appointment should not be made or taken lightly; this is a significant commitment of time and energy that will extend over one or more years. The laboratory administration must give this person the time needed to meet the commitment, as well as the responsibility and authority to make many decisions, often on short notice. Because so many persons are involved in construction and renovation projects, because projects take so long to complete, and because the staff must live with the outcome for many years, the laboratory representative must have a clear understanding of budget constraints, space allocations, laboratory operations, and hospital and clinic operations. There must be clear lines of communication and authority. The laboratory representative should be selected carefully on the basis of communication skills, experience in laboratory administration, and decision-making ability. This person need not be the laboratory director, although the director generally is in a better position to negotiate for necessary resources than is a senior technologist.

Budget and Space Allocations

The next step in designing a laboratory is to assess, realistically and accurately, the current and future needs of the laboratory, as well as the resources required to meet those needs. Both new and renovated laboratories should be designed to accommodate future expansion of test volume and type. This includes planning for office space, specimen receiving and processing, benches, informatics, communications, and the introduction of automation and future test technologies.

The next step is to obtain realistic design and construction budgets. Hospital laboratory construction is expensive. Nonetheless, fiscal constraints should not interfere with designing and building a safe and efficient laboratory. Along the same lines, realistic allocations of space must be done prior to the design phase. It is expensive and wasteful to design a laboratory and then to be faced with redesigning all or part of it to accommodate changes in the budget or space allocations. An adequate investment to do the project right in the first place is the most economical approach to providing a functional laboratory.

Part of developing a realistic and accurate budget is to decide whether to build a new laboratory or to renovate an older one. This obviously involves decisions about the health care facility as a whole. Estimating the costs of new construction (whether for a new building or expansion of an existing one) is generally straightforward. In contrast, estimating the costs of renovations is challenging. First, original construction drawings may not be available or may no longer be accurate due to changes made after the original construction was completed. Thus, the architect and engineer may have limited knowledge of how the laboratory was constructed or modified. Second, laboratories built according to past architectural standards and building codes may not meet current standards and codes. Third, older facilities are likely to contain asbestos in insulating material and/or floor tiles, as well as lead-based paint. Abating either material is a complex and expensive process. Fourth, older buildings were often built with fixed ceilings and walls, complicating changes in lighting, the HVAC system, IT and telecommunications cabling, plumbing, and the electrical power supply. Fifth, some older buildings do not have the load capacity to support heavy pieces of equipment. Last, construction in older buildings often reveals unexpected issues that must be addressed, adding to the cost and complexity of the project. It is for these and other reasons that it may cost more to renovate an existing building than it would to build a new one.

Design Phase

Several general principles should guide the design phase (10). First, the greater the investment in planning, the more likely a project will be completed on time and under budget. Second, users will be happy with the results of a project only if they believe that they have been able to make significant contributions to it. Third, there need to be clear lines of accountability and communication. Fourth, user expectations should be expressed clearly and unequivocally at the outset; no architect or engineer should be expected to make major changes midway in a project. Last, logic and common sense should guide decisions throughout the process (5).

The first task for the architect, designer, and engineer (the design team) is to understand who the laboratory representative will be, who will have authority to make decisions, and the limits of the budget and space allocations. The next task is for them to learn the needs of the laboratory. These tasks should be undertaken in this order; it is important for the design team to know the constraints of the project before the design phase begins. Once the design team has completed these tasks, the knowledge gained can be used to develop realistic and workable design plans. As the design phase continues, it is for the most part largely one in which the design team works with the laboratory staff to accommodate the needs of the laboratory within the constraints of the project. In many cases, there will be insufficient space or funds to accommodate the needs of the laboratory; in cases such as this, either the laboratory administration must acquire the necessary space or funds or the project will need to be scaled back.

Once preliminary design plans have been drafted and agreed upon, the laboratory staff must address the myriad of details necessary to design a functional laboratory. Every conceivable detail should be thought of and addressed. Nothing should be taken for granted. It is far less expensive and easier to remove features from a design plan than it is to add them at a later point, particularly during the construction phase. The latter process, known as change orders, is one of the most common reasons for construction projects to go over budget. An even thornier problem is the feature that should have been included but cannot be added at any cost once construction has begun.

After final construction documents have been drafted and approved, bids will be requested from general contractors.

Any necessary specifications should be included in the request-for-bids document. Once a general contractor has been selected, that contractor will recruit subcontractors to provide services that the general contractor does not provide. The last step prior to construction is for the institution and general contractor to obtain all necessary building permits and other legal documents needed for the project.

Construction Phase

For new laboratory construction, the construction phase generally proceeds for some time before the laboratory representative needs to be involved. The point at which the laboratory representative needs to work closely with the contractor is when the contractor begins to install walls, electrical power, IT and telecommunications cables, plumbing, and casework. From this point on, the laboratory representative will be called upon to make many unexpected decisions, often on short notice, and to clarify ambiguities in construction documents. It is expensive to make changes at this point in the process, but necessary changes should be made at this time rather than years later, when costs are even higher and the disruption in the laboratory makes the changes impractical.

Renovation projects vary in the amount and types of construction that are needed. Many projects require minimal demolition and few changes to the HVAC, plumbing, electrical power supply, and telecommunications and IT systems. In projects such as these, many of the changes are in casework only, or are more cosmetic in nature, and can be accomplished while the laboratory continues to operate. For more extensive renovations, the required demolition makes it necessary to gut the laboratory, in which case the project more closely resembles that of constructing a new laboratory.

Postconstruction Phase

The postconstruction phase is one of the most important, yet often neglected, phases in the process. Almost all construction projects have a warranty, usually for a short period, and the postconstruction phase provides the opportunity to use the warranty to correct things that were not completed or were done incorrectly. The laboratory staff should monitor carefully everything associated with the project, record their findings, and communicate them to the general contractor at the earliest possible time. The longer one waits, the more difficult it becomes for the contractor to return to the site to correct problems. Once the warranty has expired, then it becomes expensive to fix something that could have been done earlier at no cost.

SUMMARY

The construction of a new clinical laboratory, or the renovation of an existing one, is an excellent opportunity to improve the operations and efficiency of a clinical laboratory. It also offers the laboratory staff an opportunity to assess existing laboratory processes and to modify them. A successful construction or renovation project is characterized by the investment of large amounts of time in planning and designing the new facility, good communication between all of the parties involved in the project, a logical and common-sense approach to the project, and realistic expectations. Done well, a new or renovated laboratory facility will accommodate the needs of the laboratory staff for many years.

RESOURCES

Some general resources are listed in the references (1, 2, 5, 9, 10). The reader who needs additional information should consult The American Institute of Architects (http://www.aia.org/). The Institute can provide additional information, including a list of architects in a given area who have experience in designing laboratories and other health care facilities.

Laboratory Consultation, Communication, and Information Systems

JOSEPH M. CAMPOS

4

The flow of information to and from clinical laboratories was revolutionized more than 30 years ago by the introduction of the first computerized laboratory information system (LIS) (2, 13). The initial rationale for a computerized LIS was purely financial; namely, the LIS enabled more efficient billing for laboratory services. Shortly thereafter, improved reporting of textual and numerical test results was enabled by the evolving feature set. Clinical microbiology laboratories began reaping important benefits when it became possible to issue culture and complex antimicrobial susceptibility reports via the LIS.

LISs continue to thrive in the clinical microbiology laboratory today. These laboratories furnish vital information to health care providers, especially those who manage patients with infectious diseases. Laboratory test results essential for the diagnosis and treatment of infections can be reported in a clear and logically presented manner via the LIS. Additional information that promotes optimum patient management, such as guidance for specimen collection, interpretation of test results, and suggestions for additional testing, can also be added (16). Clinical microbiologists today are brokers of critical information that strongly benefits patient care (20). The goal of this chapter is to review the state of information management in clinical microbiology laboratories today, emphasizing the central role of the LIS.

HEALTH INSURANCE PORTABILITY AND ACCOUNTABILITY ACT OF 1996

A significant event that greatly affects the management of health care information in the United States was the passage of the Health Insurance Portability and Accountability Act of 1996 (HIPAA). HIPAA has had an influence so enormous that it is appropriate to begin this chapter with a description of its impact. One of its primary purposes is to maintain the security and privacy of information found in patient medical records. The standards also address the mechanisms by which information can be coded and exchanged electronically. This exchange includes the distribution of laboratory test data to clinicians, insurers, and patients.

HIPAA governs the manner in which patient-specific health information can be generated, disseminated, and stored in the United States (26). A related regulation intended to assist in the implementation of HIPAA was also promulgated and is entitled *Standards for Privacy of Individually Identifiable Health Information* (the Privacy Rule) (21). It was crafted by the Department of Health and Human Services and became effective on 14 April 2001. Most health care institutions and health care plans were obligated to comply with the Privacy Rule by 14 April 2003. Small health care plans were able to delay compliance until 14 April 2004. Although the provisions of HIPAA and the Privacy Rule do not apply to health care organizations outside of the United States, they establish standards for handling patient information that are relevant to and worthy of consideration by governments in all countries.

The Privacy Rule characterizes the safeguards that health care providers must take to protect the privacy of health information. It establishes standards that protect the medical records and other personal health information of patients. It provides patients more control over their own health data and defines limits on the use and distribution of health records by other entities. It declares that patients are entitled to examine and obtain copies of their own health records and to request that mistaken information be corrected. Patients are also at liberty to find out what disclosures of their health information have been made and to whom. The Privacy Rule holds violators of the standards accountable for their actions by the imposition of civil and criminal penalties. It does, however, permit disclosure of patient-specific health information to public health authorities in order to protect the general public health.

Patient-specific data produced by clinical microbiology laboratories in the United States fall under the jurisdiction of HIPAA. It does not matter whether the information is verbal, written, or electronic. The information may be distributed during the preanalytical, analytical, or postanalytical phase of testing and may be advisory, instructional, results oriented, or interpretive. Clinical microbiologists are expected to deliver this information to health care providers in a timely and comprehensible fashion without violating the tenets of HIPAA.

BUILDING THE MICROBIOLOGY COMPONENTS OF LISs

The LISs in use today offer many tools that support the communication of information between clinical microbiology laboratories and health care providers. In order to capitalize on these tools, the individuals responsible for building the

microbiology component of the LIS must thoroughly understand microbiology testing. Ideally, these individuals should be clinical microbiologists with a strong interest in and commitment to building their module of the LIS. If this arrangement is not possible, the builders of the microbiology module should request and receive close guidance from clinical microbiologists during system configuration and validation testing.

In an increasing number of health care facilities, laboratory tests are no longer ordered directly in the LIS by laboratory personnel but instead are requested by clinicians using a computerized order entry system with an electronic interface with the LIS. Under this circumstance, clinical microbiologists must have major input during the selection and formatting of information that will be seen by those ordering microbiology tests in any of these accessory systems. This may require clinical microbiologists to insist that they participate in the order entry information system building and/or validation process. Too often, laboratory personnel are overlooked when teams are assembled for this purpose.

The ordering of microbiology tests and the viewing of microbiology test results are different from those in other laboratory disciplines. Specimens for microbiology testing are collected from a variety of body sites, and there must be a provision in the ordering information system to inform the laboratory from whence specimens were collected. Because the quality of microbiology specimens often deteriorates with time, the time of specimen collection should be documented during the ordering process. Microbiology test results are usually nonnumerical and consist of complex composites of text and tables of antimicrobial susceptibility data. In some instances, initial microbiology test results prompt the automatic ordering of "reflex" tests (e.g., the ordering of antimicrobial susceptibility tests when culture results are positive).

Test Codes

As they are built into the LIS, all laboratory tests are assigned codes (mnemonics) and code translations. It is advantageous if a rigorously applied convention is used during the code assignment process. Logically devised coding conventions promote the remembrance of codes by LIS users. Most systems permit codes of up to six characters in length and allow codes to contain both alphabetical and numerical characters. Although many laboratories depend on alphabetical codes abstracted from actual test names (e.g., URICUL for urine culture and BLOCUL for blood culture), some laboratories use predominantly numerical coding schemes to match codes in other institutional information systems and to eliminate code conflicts among tests with similar names.

A laboratory test may have more than one name in general use (e.g., syphilis serology and the rapid plasma reagin [RPR] test). It is advisable that cross-references to commonly used synonyms for a test be identified during test building so that user-initiated searches for different names for a test will link to the same test code. Otherwise, LIS users will lose patience when they are unable to find a test that they wish to order and they will order it inappropriately as a miscellaneous test.

Entering Results While Ordering Tests

Some LISs allow or even require that results for one or more components of a test or battery be entered during the ordering process. This is often true for microbiology cultures, in which the specimen description is one of the test or battery components. When specimen descriptions are predictable for tests (e.g., a pharyngeal swab for a pharyngeal culture), it is helpful if the LIS can automatically answer the specimen description with a default specimen code. This streamlines the ordering process and eliminates ordering errors. Of course, default specimen description codes should be overridable when appropriate.

TABLE 1 Sample LIS test and battery names and their pending texts[a]

Name	Pending text
Aerobic blood culture	Results in <5 days
CSF culture and Gram stain	Results in <72 h
Fungal culture	Results in <21 days
GC culture	Results in <72 h
Bordetella pertussis culture	Results in <7 days
Urine culture	Results in <24 h
CMV culture	Results in <48 h (M–F)
Res Vir antigen panel	Results in <24 h
Group A *Streptococcus* detection	Results in <2 h
RPR	Results in <24 h

[a] Abbreviations: GC, *Neisseria gonorrhoeae;* CMV, cytomegalovirus; Res Vir, respiratory virus; M–F, Monday through Friday.

Pending Text

Some LISs can be configured to display informative text automatically while test results are pending (Table 1). Examples of "pending text" that might be used with microbiology tests include the expected turnaround time for test results, a telephone number to call if there are questions regarding the test, or a notice that a reflex test will be ordered if the result is positive. The pending text ceases to display once test results have been entered into the LIS.

Text Code Dictionaries

Perhaps the largest effort during the building of the microbiology section of an LIS is in preparing the text code dictionaries. Several dictionaries must be built, including those for microbiology text codes, microbiology method codes, growth medium codes, workload codes, antimicrobial susceptibility codes, specimen description codes, and microorganism name codes.

During the creation of the microbiology dictionaries, an important decision must be made regarding the assignment of microorganism name codes. The use of a consistently applied scheme that is understood by microbiology laboratory personnel simplifies the entry of culture results, since the correct codes for most microorganisms can be determined "on the fly." One coding convention in common use is to take the first letter of the microorganism's genus name and the first several letters of the species name (Table 2). A limitation of this system occurs when codes for different microorganisms turn out to be identical (e.g., ECOLI for both *Escherichia coli* and *Entamoeba coli*). Another system used by some laboratories is to take the first three letters of the genus name and the first three letters of the species name (assuming that the LIS permits six-letter codes). In this case, the mnemonic for *E. coli* the bacterium would be ESCCOL and that for *E. coli* the protozoan would be ENT COL. However, problems still occur in assigning codes for microorganisms like *Oligella ureolytica* and *Oligella urethralis* (OLIURE in both instances). Any coding system utilized will encounter its own set of problems, and thus a secondary

TABLE 2 Sample microorganism name codes and their translations

Microorganism code	Translation
AACTI	*Actinobacillus (Haemophilus) actinomycetemcomitans*
ABAUM	*Acinetobacter baumannii*
ABIOSP	*Abiotrophia (Granulicatella)* sp. (nutritionally variant *Streptococcus*)
ABOVI	*Actinomyces bovis*
ABSISP	*Absidia* sp.
ACANSP	*Acanthamoeba* sp.
ACAVI	*Aeromonas caviae*
ACHRSP	*Achromobacter* sp.
ACIDSP	*Acidiminococcus* sp.
ACINSP	*Acinetobacter* sp.

system should be used when codes specified by the primary convention are ambiguous (e.g., use ECOLI for the bacterium and ENCOLI for the protozoan).

Some LISs permit the creation of group codes for microorganisms that enable users to refer to a group of related microorganisms simultaneously. Generally, group members share a property in common. Examples of group codes might be ANA for anaerobes, GNB for gram-negative bacilli, MOLD for filamentous fungi, and VIRUS for viruses. Rational assignment of microorganisms to groups should be done by individuals with an understanding of both the microbiology laboratory and the planned uses for microorganism group codes in the LIS.

Antimicrobial Susceptibility Batteries

The creation of antimicrobial susceptibility batteries is an essential part of building the microbiology section of an LIS. This undertaking is preceded by defining antimicrobial agent tests that yield numerical results or text codes indicating whether isolates are susceptible, intermediately susceptible, or resistant. Groups of these tests are then assembled to correspond to batteries of antimicrobial agents reflective of the reporting wishes of the laboratory. Separate batteries are usually defined for different categories of microorganisms, like gram-negative bacilli, gram-positive cocci, anaerobes, gram-negative urinary tract isolates, streptococci, and enterococci, among others. In some cases, a separate battery should be created for a single microorganism species (e.g., *Streptococcus pneumoniae*) if that is consistent with accepted local practices (e.g., standards promulgated by the Clinical and Laboratory Standards Institute [CLSI] in the United States) (10). When an isolate belongs to more than one isolate category (e.g., a urine culture isolate of *Escherichia coli* belongs to both the gram-negative bacilli and gram-negative urinary tract isolate categories), then the category that describes the isolate more specifically should take precedence (gram-negative urinary tract isolate battery in this example).

The group of antimicrobial agents assigned to each battery should be based on input from clinicians (particularly infectious diseases physicians), from the microbiology laboratory, and from the recommendations published by the CLSI (10). Many LISs permit the recording and storage of results for a large group of antimicrobial agents but selective reporting of only a limited group of results (e.g., those for agents present in the hospital formulary). As a cost containment initiative, some LISs enable the cascading of results so that a result for an expensive or potentially toxic agent is displayed only if the result for a less expensive or less toxic alternative is resistant (e.g., a ceftriaxone result for *Escherichia coli* is reported only if the cefazolin result is resistant). The decisions of which results to report under different situations should be based on a consensus of the groups mentioned above.

Before antimicrobial susceptibility results can be reported, specific text codes (antimicrobial susceptibility codes) must be defined for the standard designations of susceptible, intermediately susceptible, and resistant (e.g., S for susceptible, I for intermediately susceptible, and R for resistant). Some LISs offer the option of defining additional antimicrobial susceptibility codes that can be used creatively for crafting more functional antimicrobial susceptibility reports. For example, codes can be placed in antimicrobial susceptibility reports to remind technologists to take specific actions. A code like NOINTP can be used to indicate that testing of a particular antimicrobial agent versus a specific microorganism has not been standardized by the CLSI. A code like ESBL can be in place for expressing results for ceftazidime versus *Escherichia coli, Klebsiella pneumoniae, Klebsiella oxytoca,* and *Proteus mirabilis* when the MIC is >1 μg/ml. This code would remind technologists to check isolates for extended-spectrum beta-lactamase production before final reports are issued.

Sophisticated antimicrobial susceptibility reports that include cost information and recommended dosages for antimicrobial agents can be created by some LISs. Reports containing relative or actual cost information reduce pharmacy expenditures by encouraging clinicians to select less expensive antimicrobial agents that still show excellent in vitro activity. Reports with dosage recommendations are particularly helpful in hospitals where medical student, intern, and resident training is taking place.

Billing for Laboratory Tests

The driving force that led to the development of the first LIS was a desire to capture laboratory test billing more efficiently than could be accomplished manually. Because billing transactions could be initiated automatically upon test ordering or upon specimen receipt, it was no longer necessary to complete paper charge tickets that were manually transcribed into ledgers or stand-alone electronic billing systems (23).

Microbiology billing can be more complicated than that in other laboratory sections due to the automatic ordering of follow-up tests (e.g., a laboratory-initiated order for an antimicrobial susceptibility test when a clinically significant microorganism is detected by culture). Such reflex orders may follow initial culture orders by several days, raising the possibility in the United States of difficult-to-reimburse late charges if the billing transactions are handled improperly. Fortunately, most LISs are sophisticated enough to handle billing for laboratory-initiated orders in a manner satisfactory to payers for laboratory services.

Current procedural terminology (CPT) codes were first devised by the American Medical Association in 1966. Among the 8,736 codes in the current 2006 listing is a small group applicable to microbiology testing. Fee-for-service reimbursement for laboratory testing is dependent upon inclusion of the appropriate CPT code(s) in bills for laboratory services rendered. The construction of test and battery billing maintenance in LISs includes indicating the applicable CPT codes so that these critical bits of information can be forwarded electronically to the hospital billing information

system. Although significant improvement in the description of microbiology CPT codes has occurred in recent years, enough ambiguity yet remains that individuals with microbiology expertise should be involved in entering CPT codes into the LIS.

Most vendors have fashioned their LIS microbiology modules so that billing for the most frequent reflex test, antimicrobial susceptibility testing, occurs automatically without manual intervention. The billing transaction includes the appropriate CPT code for sending to the hospital billing information system. It is also feasible with some LISs to use the same automatic billing feature to charge for other reflex tests, such as Western blotting for human immunodeficiency virus type 1 (HIV-1) antibody-positive specimens and confirmatory fluorescent treponemal antibody testing for RPR-positive specimens. In these situations, the reflex test can be built in a manner similar to an antimicrobial agent battery. Each band on a Western blot strip, for example, could be defined as an antimicrobial agent test, and unique susceptibility result codes could be defined to indicate the presence or absence of each antibody band. Apart from the automatic billing feature, this approach offers the benefit of querying results from these other reflex tests using LIS microbiology report functionality.

Microbiology laboratories are allowed to bill additionally for specific activities performed during specimen processing or identification of isolates (Table 3). Examples include the grinding of tissue prior to culture inoculation and the performance of three or more biochemical tests to identify a culture isolate. Since these activities apply only to certain specimens or cultures, they need to be billed on an ad hoc basis. This is accomplished via technologist entry of charges into the LIS as the charges are incurred. Alternatively, charges can be entered as a group when final culture results are issued.

LIS Work Sheets

Individual work sheets (or work lists) are used to group similar laboratory tests within the LIS, providing a convenient way to divide the laboratory workload among technologists. Individual work sheets can be printed by technologists at the beginning of a work shift to obtain lists of specimens or cultures that require their attention that day. Work sheets also can be printed at the end of a work shift to double-check that specimens or cultures were not overlooked. The statuses of tests assigned to individual work sheets can be monitored by calling up standard LIS reports. Examples of these reports are those that provide lists of pending test results and overdue test results.

Microbiology tests are usually assigned to work sheets that correspond to laboratory workbenches, such as the blood culture bench, the respiratory culture bench, and the urine culture bench. For this reason, individuals who understand how the microbiology laboratory is organized should have a voice in assigning tests to work sheets.

Some LISs permit the definition of group work sheets, which are groups of individual work sheets that have characteristics in common (Table 4). Group work sheets are of utility to microbiologists with supervisory responsibilities that span more than one workbench. If the microbiology laboratory staff includes separate section supervisors responsible for bacterial testing, fungal testing, and virologic testing, group work sheets can be defined that enable each section supervisor to monitor the statuses of tests in his or her domain. Similarly, an all-encompassing group work sheet can be defined that includes all of the microbiology individual work sheets. By calling up this work sheet, the laboratory supervisor or director can monitor all tests being worked on in the laboratory.

Work sheet maintenance may include the option of defining the number of days following specimen receipt at which results from tests assigned to individual work sheets are considered overdue. For the overdue log to be functional, the results of tests assigned to individual work sheets must become overdue after the same period of time. It would be impractical to place routine blood cultures (incubated for 5 days) and fungal blood cultures (incubated for 21 days) on the same work sheet if the overdue log is going to be used.

LIS Rules

LIS rules enable laboratories to eliminate errors, automate certain tasks, and minimize manual data entry (3, 30). Rules can apply preanalytically to guide the ordering of tests based on the patient's age, the patient's diagnosis, or previous results in the patient's laboratory file. They also can be used to identify unnecessary test orders to eliminate wastage of reagents and technologist time. Rules can be used during the analytical phase of testing to flag questionable antimicrobial susceptibility results or to remind technologists to report critical test results by telephone. Rules can be triggered

TABLE 3 Examples of manually billed microbiology tests[a]

Bill code	Name	CPT code(s)
M8011H	Bacterial ID (aerobic) × 1	87077
M8012H	Bacterial ID (aerobic) × 2	87077 × 2
M8013H	Bacterial ID (aerobic) × 3	87077 × 3
M8016H	Bacterial ID (anaerobic) × 1	87076
M8031H	Yeast ID × 1	87106
M8035H	Mold ID × 1	87107
M8041H	Viral ID × 1	87253
M8056H	ID by gas-liquid chromatography	87143
M8025H	ID by nucleic acid probe	87149
M8058H	ID by pulsed-field gel electrophoresis	87152
M8051H	Serogrouping by agglutination × 1	87147
M8061H	Concn for AFB smear or culture	87015
M8071H	Mycobacterial ID	87118
M8076H	Macroscopic ID (helminth)	87169
M8077H	Macroscopic ID (arthropod)	87168
M8081H	Tissue homogenization	87176

[a] Abbreviations: ID, identification; AFB, acid-fast bacillus.

TABLE 4 Sample group work sheet codes and names

Work sheet code	Work sheet name
BLOOD	Blood cultures
CSF	CSF cultures
MISCEL	Miscellaneous cultures
RESPIR	Respiratory cultures
URINE	Urine cultures
ANA	Anaerobic cultures
MYCOB	Mycobacterial cultures
MYCOL	Mycology cultures
SEROL	Serologic tests
PARA	Parasitology exams
MICRO	Microbiology group
VIROL	Virology group
MICVIR	Microbiology-virology group

postanalytically to provide clinicians with predefined interpretive comments that clarify the clinical significance of test results and recommend additional testing to consider. The creation of LIS rules suitable for microbiology testing requires individuals who understand both the laboratory and the capability of the rules engine.

LIS rules usually are defined as "if-then" statements. An "if" statement specifies the condition that triggers a rule. A "then" statement describes the actions to be taken when an "if" condition is met. An example of a commonly employed microbiology rule is as follows: if a *Staphylococcus aureus* isolate is resistant to oxacillin ("if" statement), then the susceptibility results for all beta-lactam antimicrobial agents should be reported as resistant ("then" statement). Sophisticated rules engines can process more complex "if-then" statements that include multiple conditions linked by operators such as "and," "or," "greater than," "less than," and "equal to."

Rules should be organized into one or more hierarchies. One hierarchy should define the points at which rules should be executed. This is important because when two or more rules apply in temporal proximity to one another, the corresponding actions should be taken in a logical sequence. For example, separate rules that call for ordering a "clean catch" urine culture for patients older than 18 years and then conditionally reporting a fluoroquinolone susceptibility result if the culture result is positive need to be evaluated in the correct order. The execution point for the rule concerning patient age is at the ordering stage and that for the rule regarding susceptibility testing is at the results stage. The logical order for executing these rules is (i) order rule and (ii) results rule, with the results rule being applied only if the order rule has already been executed. This sequence prevents the results rule from causing a fluoroquinolone susceptibility result to be reported for a patient of less than 18 years of age.

A second hierarchy should determine the action sequence when two or more applicable rules have the same execution point. Examples here are (i) a rule that prevents the ordering of duplicate rotavirus antigen tests for the same patient within 24 h and (ii) a rule that adds a rotavirus antigen test to a culture order for stool specimens collected by the emergency department from patients of less than 12 months of age between 1 January and 30 April. Many rules engines in this situation would execute the rules in the order they were created. Logically, the laboratory's intent is for the rule that prevents the ordering of a second rotavirus assay to take precedence over the rule that automatically orders a rotavirus test.

INFORMATION SHARING DURING THE PREANALYTICAL PHASE OF TESTING

During the preanalytical phase of testing, clinicians wish to select tests that are likely to provide diagnostically useful or therapeutically important information. Clinical microbiologists can be extremely helpful during this phase by supplying information that assists in appropriate test selection.

Laboratory Test Catalog

An important way in which clinical microbiologists benefit patient care is by assisting clinicians in selecting tests to order in a rational manner. This assistance can be offered by fielding telephone queries. However, a more effective method that is available at all times is to develop a catalog of tests that is comprehensive, information rich, and easily accessed.

The laboratory test catalog should be a dynamic document. When new diagnostic tests become available, whether they are performed in-house or not, the list of tests available to clinicians should be updated. Strong consideration should be given to supplying more than just the names of tests. Specimen requirements (including minimum quantity, collection container, and transport conditions), expected turnaround times for test results, and charges for tests are among the relevant bits of information that should be included (Table 5).

Many commercial laboratories publish catalogs on paper that are distributed to ordering sites throughout their customer base. Some laboratories prepare catalogs in a loose-leaf format that enables easy updating as new tests are added

TABLE 5 Sample catalog information about CSF culture and Gram stain[a]

Category	Information
1. Name of test	CSF culture and Gram stain
2. Synonyms or alternate names	CSF C/S; Culture, CSF
3. Specimen type(s)	CSF, ventricular fluid, or subdural fluid
4. Minimum specimen volume	1 ml
5. Specimen container	Sterile, leak-proof container
6. Transport instructions	Bring to laboratory immediately
7. Information needed	None
8. Special requirements	Send tube no. 2 of 4
9. Test schedule, approx TAT	Daily, 72 h
10. Laboratory section	Microbiology
11. Prior approval or notice	Not needed
12. Requisition	Microbiology
13. Storage instructions	Refrigeration (4°C)
14. Reflexive order conditions	Antimicrobial susceptibility test if pathogen recovered
15. CPT code(s)	87070, 87205
16. Comments	Gram stain automatically performed
17. Price	$x.xx

[a] Abbreviations: C/S, culture and sensitivity; TAT, turnaround time.

and old tests are eliminated. Interactive electronic catalogs offer even more advantages. Electronic catalog contents can be quickly searched by using key words or phrases to locate desired information. They can be modified easily and as often as necessary. They can include links to electronic journal articles, textbooks, and resources found on the Internet that contain more information about the tests.

Laboratory Requisitions

Historically, laboratory requisitions have been sheets of paper containing a list of tests from which clinicians can select their orders. The requisitions are delivered to the laboratory accompanied by appropriately labeled specimens, and laboratory personnel then enter the orders into the LIS (if one is in use). With advances in information system technology, an increasing number of hospitals are now utilizing electronic order entry systems in which caregivers place their own orders and the orders are sent electronically to the LIS. Simultaneously, specimen labels are generated at the ordering location and are placed on specimen containers in the presence of the patient to minimize the likelihood of mislabeled specimens. When the labeled specimens arrive in the laboratory, their receipt is recorded in the LIS. Bar-coding technology enables specimen receipt recording and the subsequent tracking of specimens in the laboratory to be accomplished quickly and accurately by wanding the specimen labels with a bar code scanner.

The use of paper requisitions is decreasing. Their biggest drawback is that these requisitions are inflexible when it comes to the addition or removal of tests from the list of choices. However, when they are necessary they can still be used effectively with a little foresight. They should be printed in small batches that last only a few months. When new batches are ordered, the requisition contents should be reviewed and modified where necessary. There should be a location on the requisition where missing test names can be handwritten, and the date the requisition was printed should be evident to enable efficient removal of outdated requisitions from ordering locations.

Electronic requisitions found in computerized order entry systems are much more flexible than paper requisitions. These requisitions can be accessed through the LIS, the hospital information system, an order entry module with an interface with the LIS, or an Internet-based order entry system. The list of tests can be modified quickly whenever there is a change, and there is no worry of exhausting the supply of requisitions. As with paper requisitions, there must be a capacity for ordering tests that are missing from the electronic list. That is generally accomplished through the use of a "miscellaneous" test category in which test specifics (e.g., test name and specimen description) are entered during the ordering process. When a significant number of requests for the same miscellaneous test are received by the laboratory, a practice should be in place for incorporating the test onto the electronic requisition.

The use of the Internet for ordering laboratory tests has been escalating in frequency because it is possible to order from computer workstations located anywhere in the world (27). All that is needed on the ordering computer are Internet browsing software and authorized access to the password-protected ordering system. A concern over this manner of order communication is the possibility of unauthorized electronic eavesdroppers' acquiring sensitive patient information. Sophisticated means of encrypting the information stream exist to protect patient confidentiality and achieve HIPAA compliance.

INFORMATION MANAGEMENT DURING THE ANALYTICAL PHASE OF TESTING

Although information flows predominantly from clinicians to the laboratory in the preanalytical phase of testing and vice versa during the postanalytical phase of testing, the analytical phase of testing finds the laboratory seeking information from other internal and external sources. The clinical microbiology laboratory, in particular, depends heavily on access to repositories of information during the analytical phase of testing. That is because much of the work is visual or decision table oriented. The information received from these sources is then acted upon by individuals in the laboratory.

Procedure Manuals

Laboratory regulatory agencies require all laboratories to maintain up-to-date procedure manuals that are accessible to workers at all times that testing is in progress. Most laboratories rely on traditional procedure manuals comprising pages of information stored in loose-leaf binders. The loose-leaf format lends itself well to the preparation of photocopies for simultaneous use at multiple workbenches and the replacement of outdated procedures with newer versions. A more modern approach is the conversion of paper procedure manuals into a series of online documents that are stored in a word-processing format (e.g., x.doc), portable document format (e.g., x.pdf), or Internet browser format (e.g., x.htm) (25). Such documents are easily modified and can be printed on paper, if desired. Documentation of annual review can be accomplished efficiently and unequivocally via electronic signature. Color photographs to illustrate procedural steps can be embedded in the documents. Perhaps the greatest advantage is that the entire procedure manual can be searched rapidly by using key words or phrases to quickly locate a particular procedure or group of procedures. The CLSI publishes a frequently revised guideline for the preparation of paper or electronic laboratory procedure manuals (approved guideline GP2-A5) that most laboratories follow (6).

Image Libraries

Photographs are indispensable to the accurate identification of many microorganisms, particularly those in the fungal and parasitic groups. Photographs of gross colonies and microscopic morphologies of a variety of microorganisms can be maintained in image repositories that are useful in differentiating similar microorganisms from one another. Every clinical microbiology laboratory should have a collection of photographs to which technologists can refer during their work. The repository may consist of photographs in a textbook, images in a text atlas, or 35-mm slides maintained in the laboratory.

One of the spin-offs of current information system technology has been a growing reliance in the laboratory on digital images instead of images recorded on film (24, 29). High-resolution images can be stored on inexpensive magnetic and optical media and can easily be manipulated and enhanced with computer software. Many laboratories have taken advantage of the dramatic reductions seen recently in the cost of image-capturing hardware (e.g., scanners and cameras) and are building their own image libraries. Images can be placed on servers located anywhere in the world and be viewed and/or downloaded nearly instantaneously over the Internet (4).

Tables of Microbiological Data

Laboratory identification of many microorganisms is based on a comparison of their physiologic and biochemical test properties with those described in reference databases. This comparison can be accomplished manually with a side-by-side assessment or via flowchart analysis. Many microbiology laboratories still identify microorganisms through analysis of information found in tables and flowcharts in textbooks, journal articles, and government documents. This approach is laborious and time-consuming but has the advantage of including human judgment in the decision-making process.

The use of tables to identify microorganisms relies upon determining the best fit between the properties of an unknown microorganism and those of a group of microorganisms belonging to the same species. The tables usually indicate the percentages of species members that exhibit positive results for particular tests. Although this approach is effective when test results for an unknown microorganism closely match those for an established species, it may yield inaccurate identifications when test results are dissimilar to those for known species.

The same information found in the identification tables described above can be converted into computerized databases and then quickly and accurately compared with the properties of an unknown microorganism. This method has been used for many years in a proprietary fashion by the manufacturers of some commercially available systems for microbial identification. The sophisticated analysis includes weighting of key properties and pattern recognition to derive best-fit identifications. The likelihood of an identification and the degree of a microorganism's dissimilarity from similar microorganisms can also be calculated.

It is also possible for individual clinical microbiologists to convert their own identification tables and those present in the public domain into queriable databases. This can be accomplished by using off-the-shelf database software programs to prepare such databases manually. The same software can then be used to define queries that identify the microorganisms included in the database whose biochemical test results best match those for an unknown microorganism.

Flowchart Algorithms

Flowchart algorithms are another approach to microorganism identification that has been used for many years. This approach differs from the use of tables in that identification test results with the greatest discriminating power are placed at the top of the decision tree and are assigned greater weight than results further down the flowchart. Although the early decisions in the flowchart algorithm are often based on unambiguous test results, the decisions made further down in the flowchart may be based on more ambiguous test results or on test results that have lower discriminating abilities.

Laboratory Work Cards

More than that in any other area of laboratory medicine, accurate microbiology testing depends on a reliable flow of information between technologists assigned to different work shifts or work days. That is because microbiology testing of many specimens (especially cultures) cannot be completed in a single work shift and more than one technologist may be involved in the testing. Accordingly, laboratories must have a mechanism in place for sharing information among technologists that concisely communicates the status of testing. Some form of microbiology work card is the solution for many laboratories. Some microbiology laboratories, even those with an LIS, still employ paper work cards that are maintained at each workstation. Technologists record the work performed daily on individual work cards. Information is documented in the form of handwritten standardized codes, short phrases, or check boxes that are understandable by coworkers. Work cards for completed tests undergo supervisory review and are stored for at least 2 years per regulatory requirement.

Almost all LISs can be configured to record microbiology culture workup information on electronic templates that are accessed by individuals working on the same cultures at later times (Table 6). Information is entered onto the electronic work card in the form of text codes or short strings of free text. Entries on the work card are generally organized by isolate or by culture medium and then by chronological order within each of these categories. The benefits of paperless entry include guaranteed legibility, easy supervisory review of work, and automatic indexing of workup data to simplify data queries later. The electronic work card also can be configured to standardize culture workups and accrue workload data for productivity analyses.

Instrument Interfaces

The proliferation of semiautomated and automated instruments for laboratory testing has greatly increased the volume of data transfer between instruments and LISs. Information transfer can be accomplished through manual transcription or automatic communication of data via electronic interfaces.

Transfer of information to and from instruments that do not have an electronic interface with an LIS is accomplished by manual entry. The number of keystrokes required for this activity can be limited on the LIS side through the use of text codes or keyboard mapping to insert commonly used words, phrases, or even blocks of text. Because of the human component of information entry, transcription errors are an ever-present threat and the fidelity of data entry should be constantly monitored by supervisory review.

Far easier and much more reliable than manual transcription is the automatic transfer of information between instruments and LISs (8, 9). This transfer can be accomplished through the use of scripted or electronic interfaces. A scripted interface is in essence a very fast electronic typist. It transcribes information from an instrument to the LIS in the same manner that a technologist would—but much faster and more accurately. The electronic interface is more complicated in that it converts a stream of data from one system into a format understandable by the other system. Batch

TABLE 6 Sample work card entries for *S. pneumoniae* blood culture isolate

Work card prompt	Response
GRST (Gram stain)	GPCPSM (gram-positive cocci in pairs)
CAT (catalase)	NEG (negative)
PHON (telephone report)	DONE (completed)
OPT (optochin)	POS (positive)
BESC (bile esculin)	NEG (negative)
NACL (6.5% NaCl tolerance)	NEG (negative)
BDIL (broth dilution MIC)	DONE (completed)
PURPLT (purity plate)	AOK (pure culture)
SAVE (save isolate on slant)	DONE (completed)

interfaces send data on demand, and dynamic interfaces send data as soon as they become available. Unidirectional interfaces transfer information in a single direction, either from the LIS to an instrument (download) or from an instrument to the LIS (upload). Bidirectional interfaces are more costly and complicated to set up since data must be able to flow in either direction.

The decision as to which type of interface is more suitable for a microbiology instrument depends on the timeliness with which the data are needed, the traffic capacity (bandwidth) of the interface, and the cost-benefit ratio of having data flow in one or both directions. Interfaces that download specimen demographic information from an LIS to an instrument are almost always desirable because they eliminate the need for transcribing required information from one system to another. Interfaces that upload data from an instrument to an LIS are valuable when the data sets are large and contain information that will be reported directly to clinicians (e.g., microbial identification and antimicrobial susceptibility data). When the instrument data are only preliminary in nature and require follow-up work at the laboratory workbench (e.g., positive blood culture results from an automated blood culture instrument), justifying the expense of a bidirectional interface is more difficult.

Inventory Management

Inventory management modules are available for some LISs and are intended to help organize and monitor the utilization of laboratory supplies (7). Some modules also assist with equipment maintenance activities. These systems generate reports regarding ordering patterns for laboratory supplies and can print equipment maintenance logs. They also provide helpful data for cost analysis studies based on supply utilization. If a record of the usage of supplies can be entered into one of these modules, the module can provide a real-time indication of inventory. Some inventory modules also track expiration dates of supplies by lot number. They alert laboratory personnel when additional supplies should be ordered and may even produce paper or electronic order requisitions for submission to the purchasing department. When new supplies are received, inventory levels can be updated in the module. If supplies are not received when expected, the module can remind laboratory personnel to contact the vendor to determine the reason.

Quality Control

The quality control modules found in many LISs aid clinical microbiology laboratory managers by streamlining the entry and review of quality control data. They provide data entry screens and reports that are customized to the requirements of the laboratory. They offer reminders to the laboratory when scheduled quality control data have not been entered. They also send warnings to the laboratory when quality control results are out of range and require the entry of the remedial action taken. When out-of-range quality control results are entered, the individual entering the results is alerted immediately. The LIS then waits for either replacement of the out-of-range results or acknowledgment that the out-of-range results are correct as entered. Acknowledgment that out-of-range quality control results are correct qualifies the results for an exception report that should be reviewed daily by supervisory personnel.

Most LISs are able to plot numerical quality control data on a LIS-defined Levey-Jennings control chart, evaluate the data, and notify users when results are "out of control." A Levey-Jennings control chart is a graphical display of quality control data that indicates the expected mean, the ± 2 standard deviation boundary around the mean, and the ± 3 standard deviation boundary around the mean. The assumption is that if the test method is stable and being performed correctly, current quality control results should exhibit a statistical distribution similar to that of past quality control results. Results outside the ± 2 standard deviation boundary should be encountered no more than 5% of the time, and results beyond the ± 3 standard deviation boundary should be seen no more than 1% of the time. When quality control results fall within the specified boundaries, the test is "in control," the results are acceptable, and patient results can be reported. When quality control results are outside the specified boundaries, the test is out of control, the results are unacceptable, and patient results cannot be reported. The CLSI criteria for evaluating antimicrobial susceptibility quality control data are based on principles similar to those used by Levey-Jennings charts.

Many LISs are also able to evaluate numerical quality control results according to rules developed by Westgard many years ago (31). The data examined may be limited to a single control or may include the results from several controls. An example of a Westgard rule violation that applies to a single control is as follows: a single quality control result falls outside the acceptable range, defined as ± 2 standard deviations from the mean. An example of a rule infraction that involves results from several controls is as follows: four consecutive quality control results are more than 1 standard deviation away from the mean in the same direction. The quality control module in most LISs can be set to apply any of the Westgard rules that have been defined within the system. The rules that will be applied usually can be individualized according to the quality control tests being performed.

Quality Assurance

Generic quality assurance rules can be applied automatically to test results to enhance the recognition of potential problems. The rules listed below frequently are "hard coded" in the LIS software used by laboratories. Additional site-specific quality assurance rules can be defined with the aid of the rules engine described earlier in this chapter.

1. Normal-value checking. Most laboratory regulatory agencies mandate that test results be accompanied by the expected values for the test ("normal range"). Expected values for these tests may be expressed as a numerical threshold or a range for quantitative tests (e.g., expected antistreptolysin O titer, <200 IU/ml), or expected results may be expressed as a text code for qualitative tests (e.g., expected HIV-1 antibody result, "negative"). Inclusion of the expected value or result aids clinicians in interpreting the clinical significance of test results. Most LISs provide a mechanism for defining age-specific, gender-specific, and even species-specific expected values for test results. The expected values are incorporated automatically by the LISs into the test report. Results that are outside the normal value range qualify for a daily quality assurance report. In the microbiology laboratory, normal-value checking generally is limited to nonculture testing.

2. Comparison of current results with past results. Virtually all LISs have the capability of comparing current test results for a patient to those from the same test last performed on the same patient within a defined period of time. Sequential results that exhibit a user-defined significant difference trigger a "delta check" flag. It is the laboratory's responsibility to investigate flagged results to confirm that

the sequential specimens were collected from the same patient or that testing irregularities did not occur during the generation of either result. Once confirmation is achieved, the flagged results can be released for viewing by clinicians. Results that elicit a delta check flag qualify for a daily quality assurance report. In the microbiology laboratory, delta checking is limited typically to nonculture testing.

3. Critical-value checking. An unfortunate type of medical error originating in the clinical laboratory is the failure to notify clinicians of critical test results in a timely fashion as mandated by hospital policy. Almost as important as reporting the critical result itself is documenting that prompt clinician notification has occurred. Critical test results usually are defined as results that require immediate medical interventions of a life-saving nature. Examples from the microbiology laboratory include positive cerebrospinal fluid (CSF) Gram stain results and positive blood culture results. Through the use of LIS-defined automatic flagging of critical test results or the use of a rules engine to analyze laboratory data to identify critical results, the LIS can be an important safeguard against these types of medical errors (14, 15, 17). Results that are deemed critical qualify for a daily quality assurance report.

4. Comparison of smear and culture results. Some LISs are able to perform some quality assurance checks that are unique to the clinical microbiology laboratory. One that is often available is comparison of Gram stain and culture results. When Gram stain findings suggest that microorganisms of a particular morphology are present, the LIS will alert users if the culture results do not include a microorganism with that morphology. Deviations between Gram stain and culture results qualify for a daily quality assurance report.

5. Detection of "bug-drug" antimicrobial susceptibility result inconsistencies. Some LISs allow users to define expected antimicrobial susceptibility results for specific antimicrobial agents versus particular microorganisms. When results differ from the expected, a message displays requesting the technologist to review the result and either change it or file it manually. Acceptance of an unexpected result qualifies the result for a daily quality assurance report.

INFORMATION SHARING DURING THE POSTANALYTICAL PHASE OF TESTING

Communication of information to clinicians from the microbiology laboratory is especially vital during the postanalytical phase of testing, for it is this information that is the basis for patient management decisions. The mode of communication may be verbal, written, or electronic, and the information often consists of more than just test results.

Test Results Reporting

The most frequent information passed on to clinicians during the postanalytical phase of testing consists of the test results themselves. When it comes to microbiology testing, some results are released in their entirety all at once and others are issued sequentially as data become available. Examples of the former situation include results from antigen detection tests, nucleic acid probe tests, and certain microscopic assays. Instances of the latter sort include negative antigen detection results that require confirmation by a more sensitive method and culture results accompanied by a Gram stain report and/or antimicrobial susceptibility data. LISs can report initial microbiology results in preliminary reports and then release final reports once all testing is completed.

Some LISs calculate the transport time for microbiology specimens, which is then displayed in the final report. The specimen transport time is the elapsed time between collection and receipt of specimens by the laboratory, although in some external order entry systems the specimen collection time may actually be the test ordering time. Clinical microbiologists should understand the meaning of transport time as calculated by their LISs before relying on these data during investigation of specimen transport problems.

Another important time point in the processing of microbiology specimens for culture is the plating (setup) time—especially when the laboratory inoculating culture media are remote from the specimen collection site. Some LISs now display the plating time in culture reports to identify specimens that may have experienced processing delays. The plating time is also used by these LISs in calculating the elapsed time for "no growth update" reports (e.g., a preliminary blood culture report might read, "No growth after 18 hours of incubation").

Microscopic examination and culture results are usually displayed in separate sections of the LIS report. Stained-smear results typically are found near the top of the report, since they are available first and acted upon more immediately than culture results. Culture findings frequently evolve with time as one or more isolates are detected and then identified in a stepwise process. For example, a culture that is positive for *Haemophilus influenzae* may be reported initially to contain "pleomorphic gram-negative coccobacilli consistent with *Haemophilus* sp.," then to contain "presumptive *Haemophilus* sp.," and finally to contain "*Haemophilus influenzae* not typeable" as more information is learned about the isolate.

Improved taxonomic techniques during the past 30 years have led to the reclassification of many microorganisms into different or newly created genera and species. While microorganism name changes are a nuisance for laboratory personnel as they are forced to adjust to new nomenclature, they can create serious confusion among clinicians trying to interpret the significance of culture results. The LIS can be an effective tool in keeping clinicians up to date with microorganism name changes. By way of illustration, it is no more difficult for an LIS to issue a culture report as "3+ growth of *Rhizobium (Agrobacterium) radiobacter*" than as "3+ growth of *Rhizobium radiobacter.*" The former report is helpful to clinicians more familiar with the older taxonomic designation.

Interpretive Reports

One of the more innovative ways that clinical microbiology laboratories can benefit patients is through provision of interpretive reports that accompany test results. This is especially true for tests that yield complex results, like HIV-1 genotyping. Virtually all LISs enable clinical microbiologists to supplement test results with comments that were created and stored previously or with free text comments crafted in real time while test results are being reported. Libraries of prewritten comments can be maintained in the LIS and incorporated into reports individually or strung together as a group of comments when the situation warrants.

Supplementation of Microbiology Test Data with Digital Images

While still an uncommon practice, the potential for enhancement of microbiology reports with digital images is very real. Inclusion of digital photographs of Gram stains, acid-fast stains, ova and parasite preparations, or any other microscopic finding is technologically feasible today. Similarly,

photographs of subjectively read test results such as those for group A streptococcal antigen, *Cryptococcus neoformans* antigen, RPR, and many others could also be stored in the LIS for quality assurance purposes. Data from objectively read tests, such as optical density readings from enzyme immunoassays, are commonly stored in the LIS already. It would seem that a more compelling argument could be made for recording visual evidence of subjectively read test results. The precedent for storing digital images has already been set by several commercially available pathology and diagnostic imaging information systems. Many offer optional image storage repositories maintained on separate servers. Pathology and radiology reports can include hypertext links that lead users to photographs stored on the image server. In this way, clinicians have the opportunity to view for themselves the images that led to the pathologist's or radiologist's findings. The same could be true for clinical microbiology results.

Antimicrobial Susceptibility Reports

Antimicrobial susceptibility results, in many circumstances, are more valuable to clinicians postanalytically than are culture results. Hence, these data must be displayed in a fashion that promotes unequivocal understanding of the results so that correct therapeutic decisions can be made. Most LISs enable laboratories to display antimicrobial susceptibility data in a variety of formats, including linear, columnar, and tabular displays. Most enable easy addition or deletion of antimicrobial agents in predefined batteries and also allow the addition of practical information to reports, such as CLSI-recommended comments pertaining to antimicrobial susceptibility test results. In some instances, the report can be customized to show antimicrobial agent dosage information, route of administration, achievable levels of antimicrobial agents in the blood and urine, and the cost of antimicrobial agent therapy.

Virtually all LISs enable the entry of qualitative (S, I, and R) or quantitative (MIC or inhibitory zone diameter) susceptibility data. If quantitative data are entered, the LIS can refer to its own tables of user-entered interpretive criteria (obtained from the CLSI or other official agencies) to convert the data into clinician-friendly qualitative results. The interpretive criteria must be updated frequently by laboratory personnel as important changes are made on an annual basis.

The authors of the CLSI *Performance Standards for Antimicrobial Susceptibility Testing* have recommended carefully worded statements that can be added to susceptibility reports to aid clinicians in the correct interpretation of susceptibility results (10). Such comments can be added via manual insertion of free text, manual insertion of blocks of stored text, or automatic insertion of blocks of stored text after recognition of an appropriate situation by the LIS rules engine.

Nonculture Test Results Reporting

The development of rapid, CLIA-waived, point-of-care assays for diagnosis of infectious diseases has led to an increase in the numbers of nonculture microbiology tests being performed. Most of these tests do not fit into the traditional microbiology battery of microscopic examination, culture findings, and antimicrobial susceptibility results. They are more similar to tests performed in other sections of the clinical laboratory and thus need to be defined in the LIS in a manner different from that for cultures. If such tests are not defined as microbiology tests, it is essential that the report include a description of the specimen, information that is not always part of the test reports from other sections of the clinical laboratory.

Delivery of Test Results to Clinicians

There are many mechanisms by which microbiology test results can be delivered to clinicians. The requirements that all mechanisms have in common are that the results must reach clinicians

1. In a timely manner. Results must be available to clinicians within a time frame that enables appropriate interventions to be made.
2. In a legible and understandable format. Results must be easily read and presented in unambiguous language so that suitable action can be taken.
3. In a form that is free of typographical or transcriptional errors. Systems must be in place that reduce the release of misleading or erroneous laboratory data.

The most frequent means for distributing laboratory test results is still the paper report. Many LISs are set up to print paper reports daily that are then distributed by couriers to clinicians and added to the patient's medical record. Some LISs print the patient's entire up-to-date laboratory file each day with the expectation that reports from previous days will be discarded. Other LISs print only the patient's "new laboratory activity" so that daily reports are added to previously printed reports already in place in the clinician's office or the patient's medical record.

Interim reports show the status of current laboratory activity for each patient selected. Reports can be limited to new activity since the last interim or cumulative report was printed, or they may be printed for all activity that took place over a specified date range. The test results in interim reports are usually displayed in reverse chronological order, with no further sorting available. Some LISs permit interim reports to be called up for groups of patients according to the ordering physician or the patients' location.

Cumulative reports contain results of patient tests grouped by the type of test or the specimen collection site. Examples of cumulative report headers include "Bacterial Cultures," "Fungal Cultures," and "Nucleic Acid Probes" when sorting is by test categorization and "Blood Cultures," "Urine Cultures," and "Genital Nucleic Acid Probes" when sorting is by specimen collection site. It should be the responsibility of the clinical microbiology laboratory leadership, with input from clinicians, to decide the style of cumulative report that is more suitable for a particular hospital. Within each group of tests under a cumulative report header, test results usually are sorted in reverse chronological order. Most LISs can call up cumulative reports by patient, ordering physician, or patient location. Most hospitals depend on postdischarge cumulative reports to serve as the official record of laboratory test results.

Generation of Ad Hoc (User-Defined) Reports

There are occasions in which none of the hard-coded LIS reports available to the laboratory contain the information needed for a specific purpose. Yet, every LIS stores a wealth of useful data elements within tables that may not be accessible via running preset reports (1). Most LISs offer optional modules that enable users to perform user-defined queries of the LIS database. The queries may be made with proprietary LIS-specific tools, or if the LIS data are stored in an open database connectivity (ODBC)-compliant relational database, queries may be made with ODBC-compliant off-the-shelf software (e.g., Microsoft Access or Business Objects

Crystal Reports). Such queries generally are intended to assemble data for a retrospective review of a particular data set. For example, if one wished to obtain a list of all patients during the previous 5 years who had positive blood cultures with simultaneous white blood cell counts of greater than 18,000 per mm^3, an ad hoc query would be the easiest manner to collect the data.

Once the ad hoc query is defined and run, the output report is stored in the LIS or on the user's workstation, usually as a delimited text file, spreadsheet file, or database file. From here the report can be printed on paper or, if resident on the LIS, can be downloaded to a personal computer via a serial port connection to the LIS or via a "file transfer protocol" across the hospital computer network. The ad hoc report file in a personal computer can be opened using standard spreadsheet or database software. Spreadsheet tools (e.g., sorting, filtering, and pivot tables from Microsoft Excel) can be used to analyze the data (22). Database tools (e.g., Microsoft Access and Business Objects Crystal Reports) can be used to perform further queries or configure attractive displays of the data.

Paperless Reports

The trend toward operating clinical laboratories as paperless entities is gathering momentum. Under this paradigm, LIS reports are not printed on paper but instead are printed to files stored on magnetic or optical disk media. Such reports are stored in easily accessible formats, are readily distributed to authorized individuals, and are quickly retrievable for review at any time. If it is necessary to obtain a paper report, the report file can be sent electronically to a printer.

Although an increasing number of hospitals are encouraging clinicians to view laboratory results via a clinician portal rather than in the LIS, all LISs provide on-demand viewing of laboratory test results online. LIS inquiry functions enable the review of test results for specimens collected on a particular date or range of dates or for a single test or group of tests performed in a particular section of the laboratory. Some LISs enable viewing of serial quantitative data in graphical format so that numerical trends are more easily spotted.

For those hospitals that expect clinicians to order laboratory tests and view laboratory results in a clinician order entry-results-viewing portal, an interface must be built between the clinician portal and the LIS. The advantage to this approach is that clinicians can be trained to perform a wide variety of functions (e.g., ordering and viewing laboratory results, ordering and viewing diagnostic imaging results, ordering pharmaceuticals, and viewing patient vital signs and progress notes) on a single information system. This strategy fits in nicely with the tendency in U.S. hospitals toward greater provider interaction with information systems. The major disadvantage is that the format for displaying laboratory test results may not be as feature rich and well organized in a clinician portal as it would be in an LIS.

Electronic Delivery of Reports

When the LIS is a node on the hospital local-area or wide-area computer network, it becomes feasible to transmit report files electronically to workstation nodes and printers on the network. Some LISs possess report scheduling capability by which preset or ad hoc reports can be run at designated daily, weekly, monthly, quarterly, or annual intervals, printed automatically to files, and then sent to workstations or groups of workstations within the network. In fact, a growing number of laboratories no longer print patient discharge cumulative reports on paper. Alternatively, they print the reports to a file and send the file via the hospital local-area network to the health information management department (medical records) for inclusion in the patient's electronic medical record.

Another emerging trend among laboratories is granting access to laboratory test results via the Internet (11). Authorized individuals are able to log in to an Internet information server where an up-to-the-minute copy of the laboratory test result database resides. Users then can view results over a secure, encrypted channel from anywhere in the world.

Another recent technological development is the ability to transmit laboratory test results via a wireless connection to hand-held devices such as alphanumeric pagers, digital telephones, and personal data assistants. Although still in its infancy, this methodology has the potential to replace the telephoning of critical laboratory reports to clinicians, if a means for acknowledging receipt of the report can be implemented. One can also envisage daily downloading of interim reports for a clinician's patient list to a hand-held device. It remains to be seen whether the complex laboratory data found in microbiology reports can be transmitted and viewed effectively on these hand-held devices.

Verbal Delivery of Reports

Verbal delivery of laboratory results, in almost every instance, is an adjunct to conveying results by other means. Verbal reporting very often is the method of choice for initial reporting of critical values. In the microbiology arena these may be preliminary results, such as the Gram stain morphologies of microorganisms growing in blood cultures, or they may be final results such as positive results for a test to detect cryptococcal antigen in CSF. When noncritical laboratory results are delivered verbally, it is often in situations in which clinicians telephone the laboratory because they do not have access to the standard means of results distribution. This method of reporting microbiology results must be carried out with caution since it is very easy for complicated results to be confused or misunderstood. Reading back of verbally communicated critical reports has become the norm in the United States. The other common context for verbal discussion of test results is during the course of a consultation over results released previously in another manner.

Consultations Concerning Laboratory Reports

Passive consultations from the laboratory perspective are those in which clinicians contact the laboratory for advice in interpreting test results. Such consultations concerning microbiology results should be handled by the laboratory director or the supervisor, one of whom should be reachable for this purpose at all times. Active consultations are those in which laboratory directors or supervisors seek out clinicians to discuss the clinical significance of test results and suggest additional tests that should be considered. Although active consultations require commitment and effort on the part of the laboratory staff, the return on the investment is easily appreciated in terms of improved patient care.

An underutilized method of communication between the microbiology laboratory and clinicians is the addition of information signed by the laboratory director to patient medical records. This information can be of great assistance to clinicians in the understanding of test results and can provide valuable suggestions for follow-up testing. The advantages of this route of information sharing are that the clinical

microbiologist's observations can be read at the convenience of clinicians and that the information is located in the same place in the medical record as key information from other clinical services.

Most hospitals and regulatory agencies require that the medical staff bylaws specify the individuals who are authorized to place information in patient medical records. It is the responsibility of the microbiology laboratory director and his or her colleagues in laboratory medicine to ensure that they have the necessary authorization if this is a desired practice.

Preparation of Periodic Antibiogram Reports

A much-appreciated service provided by many clinical microbiology laboratories is the distribution of cumulative institutional antimicrobial susceptibility data reports to clinicians (28). These reports generally are prepared on an annual basis but may be offered more frequently if warranted. In an attempt to standardize the contents of antibiogram reports, the CLSI has issued document M39-A2, entitled *Analysis and Presentation of Cumulative Antimicrobial Susceptibility Test Data* (5). This document recommends methods for recording and analyzing antimicrobial susceptibility data for epidemiologically significant microorganisms. To avoid biasing the data, the standard recommends including only the first isolate of a particular species from a patient per analysis period and including only isolates derived from cultures performed for diagnostic purposes. To improve the statistical validity of the data, the standard urges limiting the report to organisms tested 30 or more times during the analysis period.

At the time of this writing, most LIS vendors are still determining how they will help laboratories comply with the recommendations in the CLSI M39-A2 document. In the meantime, clinical microbiologists should consider downloading their antimicrobial susceptibility data to a personal computer and then preparing their cumulative antimicrobial susceptibility reports with the aid of spreadsheet or database software that enables compliance with the CLSI document (Table 7).

TABLE 7 Sample pivot table from Microsoft Excel showing antimicrobial susceptibility data for *S. pneumoniae* tested during calendar year 2005

Culture battery	(All)
Collection month	(All)
Collection year	2005
Order location	(All)
Order physician	(All)
Specimen description	(All)
Gender	(All)

Drug	Result (%)		
	S	I	R
Ceftriaxone (CSF)[a]	68	10	22
Ceftriaxone (other)[a]	81	17	2
Chloramphenicol	100		0
Clindamycin	88	2	10
Erythromycin	59	2	39
Levofloxacin	100	0	0
Penicillin	45	25	30
Trimethoprim-sulfamethoxazole	55	4	41
Vancomycin	100		0

[a] CSF, isolate recovered from cerebrospinal fluid; other, isolate recovered from specimen other than cerebrospinal fluid.

Submission of Laboratory Results to External Repositories

Jurisdictional regulations (e.g., those issued by local, county, state, or national agencies) mandate that hospitals and/or laboratories report positive test results for diagnosis of certain infectious diseases to public health authorities. Traditionally, this reporting has been accomplished via written notification that is either mailed or faxed to the responsible authority. Some LISs are beginning to include software tools that make it easier for clinical microbiology laboratories to comply with reporting regulations (19). Automatic faxing of reports to designated telephone numbers is now a feature of selected LISs. This capability is being extended by some LISs to enable submission of HIPAA-compliant encrypted reports via e-mail and the Internet.

Another emerging phenomenon in some hospitals is a joint venture between clinical microbiology laboratories and infection control departments to export data in a secure fashion to a commercial external data warehouse where the data are analyzed on a fee-for-service basis to detect epidemiologically significant trends. Reported experience has indicated that such a program does enable identification of problem areas in the hospital where infection control intervention might be useful (12).

SUMMARY

LISs have enabled tremendous progress to be made in the dissemination of information from the clinical microbiology laboratory to providers of health care (18). Laboratory test data are delivered more efficiently and accurately than ever before. Other information that is imperative to the ordering of correct tests, the collection of appropriate specimens, and the interpretation of test results can be communicated effectively. The role of these systems in the daily practice of clinical microbiology will only continue to increase in importance. It behooves all clinical microbiologists to become more knowledgeable about and comfortable with information systems, for they are perhaps the most powerful tool available to us in our new role as information brokers.

General Principles of Specimen Collection and Handling

J. MICHAEL MILLER, KAREN KRISHER, AND HARVEY T. HOLMES

5

In terms of the effectiveness of the laboratory, nothing is more important than the appropriate selection, collection, and handling of a specimen for microbiologic diagnosis. When specimen collection and management are not priorities, the laboratory can contribute little to patient care. Consequently, all members of the medical staff involved in this process must understand the critical nature of ensuring specimen quality. It is the responsibility of the laboratory to provide complete and accurate specimen management information in a form that can be easily incorporated into the procedure manual of those health care workers (i.e., nurses and other allied nursing personnel) who have primary responsibility for the collection of specimens. The information provided should address safety, selection, collection, transportation, acceptability, and labeling. This chapter provides an approach for developing a policy for proper collection and handling of specimens destined for analysis in the clinical microbiology laboratory for adult and pediatric patients. Special emphasis is given to and more details are provided for pediatric specimens in this chapter because of the unique character of this patient population and the special procedures often required for obtaining appropriate specimens. Details of specimen management can be found in the relevant chapters for each major group of microorganisms covered in this Manual (bacteriology, chapter 20; virology, chapter 80; mycology, chapter 116; parasitology, chapter 133).

Appropriate specimen management, or the lack of it, affects patient care in several very important ways (19). It is the key to accurate laboratory diagnosis that directly affects patient care and patient outcome; it influences therapeutic decisions; it affects hospital infection control and prevention, patient length of stay, and overall hospital costs; it plays a major role in laboratory costs; and it clearly influences laboratory efficiency. For these reasons, every laboratory should develop a rational, sound, and relevant specimen management policy and enforce it as strictly as possible.

SAFETY

Biosafety at the laboratory bench is of primary concern to laboratorians. Health care workers may be unaware of the potential etiologic agent(s) residing in the specimen being transported to the laboratory. Policies designed to protect laboratory and other personnel from accidental exposure to these agents must be in place. Most microbiology laboratory texts, including chapter 8 of this Manual, have sections on laboratory procedures that should contain safety information related to specimen management. Specific reference material on biosafety should be available in every microbiology laboratory. The reference materials available in the laboratory could include *Biosafety in Microbiological and Biomedical Laboratories,* 4th ed. (69) and *Biosafety in the Laboratory: Prudent Practices for the Handling and Disposal of Infectious Materials* (52).

In general, laboratorians should comply with the following policies for safety in specimen management:

1. Wear gloves, gowns, and, where appropriate, masks and/or goggles when collecting specimens (17).
2. Use leak-proof specimen containers and transport the containers within a sealable, leak-proof plastic bag with a separate compartment for paperwork (18).
3. Never transport syringes with needles to the laboratory. Instead, transfer the contents to a sterile tube or remove the needle with a protective device, recap the syringe, and place it in a sealable, leak-proof plastic bag (60).
4. Do not transport leaking specimen containers to the laboratory or process them. Notify the physician or the responsible nurse of the leaking container and explain the potential compromised nature of the results if processing is continued; ask for a repeat specimen. If a new specimen is submitted, autoclave and discard the leaking one (50). If another specimen cannot be obtained, e.g., needle aspirates, body fluids, or bone marrow, work with the existing specimen container within a biological safety cabinet.

SELECTION AND COLLECTION OF THE SPECIMEN

Before a specimen is collected for analysis, the specimen or the collection site must be selected and must represent a location of active disease. Even careful collection methods will produce a specimen of little clinical value if it is not obtained from a site where the infection is active. Some of the common sites of infection where ready sources of contamination reside include the bladder, where urethral organisms and those from the perineum may easily contaminate the urine specimen; blood, which is not infrequently contaminated by commensal flora from the venipuncture site; the endometrium, which may contain commensal vaginal

flora; fistulas, which may contain organisms from the gastrointestinal tract; the middle ear, a specimen from which will be contaminated with flora of the external auditory canal if a swab is used to collect the specimen; the nasal sinus, which may contain nasopharyngeal flora; and sites of subcutaneous infections and superficial wounds, which are commonly contaminated by skin and mucous membrane flora.

General specimen selection and collection guidelines should include the following:

1. Avoid commensal contamination from indigenous flora, whenever possible, to ensure a sample representative of the infectious process (9, 50, 60). Specimens from many sites of infection may contain an etiologic agent that would be considered part of the normal flora in a healthy host. This "background noise" of normal flora (i.e., from skin, membranes, and the respiratory tract) could interfere with the interpretation of culture results as well as overgrow and obscure the true agent of disease.
2. Select the correct anatomic site from which to obtain the specimen and collect the specimen by the proper technique and with the proper supplies, as described in the tables of this and subsequent chapters of this Manual.
3. Optimize the capture of anaerobes from specimens by using the proper precautions, procedures, and supplies; biopsy or needle aspirates are the specimens of choice, while anaerobic swabs are the least desirable (35, 50). Never refrigerate specimens for anaerobic culture but, rather, maintain them at room temperature (32).
4. Collect adequate volumes; insufficient material may yield false-negative results.
5. Place the specimen in a container designed to promote the survival of suspected agents and to eliminate leakage and potential safety hazards.
6. Label each specimen container with the patient's name and identification number, source, specific site, date, time of collection, and initials of the collector (21).

The collection of specimens with swabs may or may not be the method of choice for the collection of a particular specimen for microbiologic analysis (37, 50). It is critical that specimen collectors know the appropriate device and method for the collection of samples. Swab tips for specimen collection are usually made of cotton, Dacron (a polyester), or calcium alginate. Most come with a plastic shaft, although swabs with wooden shafts are available. The swabs with wooden shafts are generally not recommended for routine specimen collection because they may contain toxic products and could inactivate herpes simplex virus and interfere with some *Ureaplasma* identification methods. Cotton-tipped swabs are less popular today because they may contain fatty acids that could interfere with the survival of some bacteria and *Chlamydia* spp. However, most nonfastidious bacteria are not affected if cotton-tipped swabs are used. Cotton-tipped swabs are also suitable for the collection of specimens from the vagina, cervix, or urethra for the detection of *Mycoplasma*. Dacron- and rayon-tipped swabs have a wide range of uses including the collection of specimens for the detection of viruses and can facilitate the survival of *Streptococcus pyogenes*. Calcium alginate-tipped swabs can be toxic for lipid-enveloped viruses and some cell cultures as well as for some strains of *Neisseria gonorrhoeae* and *Ureaplasma urealyticum*. These are useful for the collection of specimens for *Chlamydia* spp. (37). Newer tips of polyurethane foam are finding wide acceptance.

Swabs with flexible wire shafts and small tips are recommended for use for the collection of nasopharyngeal specimens, including sampling for *Bordetella pertussis*, and male urethral specimens for diagnosis of gonorrhoea. Specimens on plastic-shafted swabs that are labeled by the specimen collector as "nasopharyngeal" are not likely to be true representatives of nasopharyngeal flora and may actually contain representatives of the nasal or throat flora (50).

TRANSPORTATION

1. All specimens must be promptly transported to the laboratory, preferably within 2 h (35). If processing is delayed, specimens collected for the detection of bacterial agents may be stored under specified conditions (see chapter 20).
2. In general, do not store specimens for bacterial culture for more than 24 h. Viruses, however, usually remain stable for 2 to 3 days at 4°C (37, 38).
3. Optimal transport of clinical specimens, including specimens for anaerobic culture, depends primarily on the volume of material obtained. Submit small amounts within 15 to 30 min of collection; biopsy tissue may be maintained for up to 20 to 24 h, if stored at 25°C in an anaerobic transport system (35).
4. Otherwise, surgical or biopsy specimens are usually stored at 4°C for up to 1 week or per laboratory policy.
5. Environmentally sensitive organisms include *Shigella* spp. (which should be processed immediately), *Neisseria gonorrhoeae, N. meningitidis,* and *Haemophilus influenzae* (which is sensitive to cold temperatures). Never refrigerate spinal fluid, genital, eye, or internal ear specimens (50). Storage conditions for some specimens and agents are summarized in Table 1.
6. Transportation of clinical specimens and transportation of infectious substances from one health care facility or laboratory to another, regardless of the distance, requires strict attention to specimen packaging and labeling instructions (17, 18, 37). Materials for transport must be labeled properly and packaged and protected during transport. The courier vehicles must also be marked and designated as carrying biologic agents. Any clinical specimen, including swabs, scrapings, body fluids, or tissues, that is known or reasonably expected to contain a pathogen is classified as an *infectious substance*.

For specific packaging and shipping instructions, one can refer to a number of sources; the most comprehensive instructions are described by the Department of Transportation in 49 *Code of Federal Regulations* (http://hazmat.dot.gov/ or http://www.iata.org). Several areas of packaging and shipping are of extreme importance, and one must ensure that everyone involved in packaging and shipping (including courier activities) is current on the specific regulations, including the legal responsibilities of the laboratory as a "shipper"; the proper use of certified packaging (only packaging that has been certified by the United Nations for infectious substances can be used); the proper use of necessary package labeling and markings; and the proper completion of the required documentation. Frequent referral to the appropriate websites is recommended in order to ensure that compliance with the latest recommendations is accomplished.

Bacterial and Fungal Specimen Transport

Containers for specimen transport and directions on how to use them are often available from the laboratory. The potential etiologic agent suspected in the patient dictates the specific collection method and transport system that will support the viability of the agent. Specimens for fungal cultures should not be collected with a swab because of the

TABLE 1 Storage conditions for various transport systems and suspected etiologic agents[a]

Preservative or medium type	Specimens held at 4°C	Specimens held at 25°C
No preservative	Autopsy tissue, bronchial wash, intravenous catheter, CSF (viral agent), lung biopsy, pericardial fluid, sputum, urine (all)	CSF (bacterial agents), synovial fluid
Anaerobic transport media		Abdominal fluid, amniotic fluid, anaerobic cultures, aspirates, bile, cul-de-sac material, deep lesion material, IUD for *Actinomyces* sp., lung aspirate, placenta (delivery by cesarean section), sinus aspirate, tissue (surgery), transtracheal aspirate, urine (suprapubic aspirate)
Direct inoculation of media		Corneal scraping, blood cultures, RL or BG plates for *Bordetella* spp., JEMBEC plates for *Neisseria gonorrhoeae,* vitreous humor
Aerobic transport media[b]	Burn wound biopsy, *Campylobacter* spp., ear (external), *Shigella* spp., *Vibrio* spp., *Yersinia* spp.	Bone marrow, *Bordetella* spp., cervix, conjunctiva, *Corynebacterium* spp., ear (internal), genital cultures, nasopharynx, *Neisseria* spp., *Salmonella* spp., upper respiratory tract specimens

[a] Abbreviations: BG, Bordet-Gengou; IUD, intrauterine device; JEMBEC, John E. Martin biological environmental chamber; RL, Regan-Lowe medium.
[b] Stuart's medium, charcoal-impregnated swabs originally formulated for *N. gonorrhoeae* transport; Amies medium, modified Stuart's medium that incorporates charcoal in medium instead of in the swab; Cary & Blair medium, similar to Stuart's medium but modified for fecal specimens, with the pH increased from 7.4 to 8.4.

potential interference of the swab fibers with direct microscopic examination of the specimen. Swabs are acceptable for use for the collection of specimens for the detection of suspected yeast infections, however. Most specimen containers must be sterile since the presence of contaminating flora from nonsterile containers may lead to errors in culture interpretation. Containers for feces need not be sterile but should be clean containers with tight-fitting lids. If there is a question as to whether a specimen container should be sterile for a specific specimen, assume that it should be sterile.

Other useful products and devices include sterile, screw-capped containers for collecting urine or sputum specimens. The containers should be prepared and packaged for patient use, with directions, including illustrations, that can be understood by patients. Biopsy and tissue specimens may also be placed into these sterile cups, although "biopsy" samples may tend to be smaller than "tissue" samples. To keep these tissues moist, one may add a small amount of nonbacteriostatic saline to the cup rather than wrap the tiny tissue specimen in gauze. Sterile petri dishes or special envelopes can be used to transport hair, skin, or nail scrapings to the mycology laboratory. Commercial transport devices for *N. gonorrhoeae* such as the JEMBEC (John E. Martin biological environmental chamber) system with CO_2 tablets may provide better results than CO_2-containing bottles, especially for transport by courier. The bottles may not have consistent amounts of CO_2, and improper manipulation during inoculation causes a loss of the atmosphere.

As with bacterial specimens, fungal specimens for culture should be placed into sterile containers and transported to the laboratory promptly. For skin and nail scrapings, cleansing of the site with 70% alcohol is required prior to specimen collection. Nail scrapings for submission to the laboratory must be collected from the deeper, infected portion of the nail, and the initial superficial scrapings should be discarded because they will likely be contaminated. A UV lamp (Wood's lamp) is helpful when selecting infected hair since some dermatophytes will fluoresce. Details can be found in chapter 116. Most other specimens, including blood, other sterile body fluids, and urine, respiratory, fecal, and tissue specimens, are collected and submitted as described elsewhere for bacterial or mycobacterial specimens.

Virus, Rickettsia, Chlamydia, and Mycoplasma Transport

The methods and media used for the transport of bacteria are inappropriate for the transport of viruses and chlamydiae. Viral transport media (VTM) prevent drying, maintain viral viability during transport, and prevent the overgrowth of contaminating bacteria. Many of the formulations contain either Eagle's minimum essential medium or Hanks' balanced salt solution, along with fetal bovine serum or bovine serum albumin (BSA). VTM may be prepared in-house or purchased commercially. There is little evidence in the literature that one VTM is better than another. However, in virtually all cases where a specimen is submitted for viral analysis, the specimen should be selected and collected in a manner appropriate for the target organ (37).

Liquid-based transport systems contain a protein (BSA, gelatin, or fetal bovine serum) and a combination of antimicrobial agents in a buffered solution. Tissue for viral analysis may also be placed into this type of medium. A phosphate-buffered sucrose-containing transport system (2SP) may be used for virus and chlamydia transport. The antimicrobial agents present in the 2SP are not inhibitory to *Chlamydia* spp.

A transport system containing human newborn foreskin fibroblasts is commercially available and useful for recovery and early detection of cytomegalovirus and herpes simplex virus. This cell system has a limited shelf life and is useful only for viruses that grow in fibroblasts.

If specimens should arrive in the laboratory having been inappropriately placed into Stuart's or Amies bacterial transport systems, the swabs may be transferred into one of the systems of liquid VTM.

Recovery of rickettsia seems to be enhanced if glutamate is present in a sodium-free, buffered salt solution. A sucrose-phosphate-glutamate transport medium containing BSA is often used to transport rickettsiae, mycoplasmas, and chlamydiae (37). Manufacturers of nucleic acid probes, amplification systems, or enzyme immunoassay (EIA) antigen detection systems often recommend or supply specific transport media and swabs for the collection and transport of specimens to be tested in their systems.

SPECIMEN ACCEPTABILITY OR REJECTION CRITERIA

At times, specimens arriving in the laboratory may have been improperly selected, collected, or transported. This is essentially the equivalent of a specimen being out of control. This out-of-control process must receive the same attention as does an out-of-control identification method or susceptibility test; there must be a corrective action. Processing and reporting results for these specimens to the physicians may provide misleading information that can lead to misdiagnosis and inappropriate therapy. Consequently, the laboratory must adhere to a strict policy of specimen acceptance and rejection.

Listed below are several examples of situations in which specific laboratory policies must be formulated and enforced to ensure specimen quality:

1. No label. Do not process, but immediately contact the submitting physician or nurse. For specimens obtained by noninvasive means (urines, sputums, or throat specimens), have a new specimen submitted. For specimens obtained by invasive procedures (needle aspirates, body fluids, or tissues), process the specimen only after directly consulting with the physician who obtained the specimen and/or the patient's physician. Note the problem on the report, complete with an incident report and documentation of the corrective action taken.
2. Prolonged transport. Do not process, but alert the submitter and request a repeat specimen for specimens obtained by noninvasive means. Note the problem on the patient's report: "Received after prolonged delay." For specimens obtained by invasive procedures (needle aspirates, body fluids, or tissues), directly contact the patient's physician and process as in situation no. 1 above.
3. Improper or leaking container. Do not process. Immediately call the submitter and request a repeat specimen, where appropriate. Note the problem on the patient's report and the corrective action taken. For specimens obtained by invasive procedures (needle aspirates, body fluids, or tissues), directly contact the patient's physician and process as in situation no. 1 above.
4. Specimen unsuitable for request (e.g., request for anaerobic culture for a specimen transported aerobically). Do not process. Contact the submitter, clarify the test request, and indicate the discrepancy. Request a proper specimen for the test requested.
5. Duplicate specimens on the same day for the same test request (except blood and tissue). Do not process. Place the specimen in the proper preservative at the correct storage temperature. Call the submitter and indicate the duplication. Note the problem on the report.

There may be instances in which a given specimen must be processed even though its quality is compromised, e.g., a difficult or unusual case, and then only after a consult between the patient's physician and the laboratory director. Table 2 lists specimens that provide little, if any, clinical information; processing of these specimens should be discouraged.

TABLE 2 Specimens to be discouraged due to questionable microbial information

Specimen type	Alternative or comment
Burn, wounds (swabs)	Submit tissue or aspirate
Colostomy, discharge	Do not process
Decubiti (swabs)	Submit tissue or aspirate
Foley catheter tip	Do not process
Gangrenous lesion (swab)	Submit tissue or aspirate
Gastric aspirates of newborns	Do not process
Lochia	Do not process
Periodontal lesion (swab)	Submit tissue or aspirate
Perirectal abscess (swab)	Submit tissue or aspirate
Varicose ulcer (swab)	Submit tissue or aspirate
Vomitus	Do not process

Sterile body fluids may be submitted from patients with serious or life-threatening illness and must be handled quickly and appropriately. The decision of whether to centrifuge the fluid and culture the specimen on agar media or in blood culture bottles must be incorporated into the laboratory protocol. Table 3 lists some management suggestions for handling sterile body fluids (8).

While the above discussion has focused more on general policy issues surrounding specimen management, the details of specimen management for adults are covered in subsequent and appropriate sections of this Manual. Infants and children represent an important patient population that is often overlooked in specimen management discussions, and there are many instances in which specimens from this patient group require special methods for selection, collection, and transport. The section that follows provides perspective and guidance on these issues.

SPECIMEN MANAGEMENT ISSUES FOR PEDIATRIC PATIENTS

Collection of specimens from pediatric populations may be influenced by factors not encountered when dealing with adults. The types of disease as well as the anatomic areas primarily affected by the infectious agent may differ. Recognition of the critical differences inherent in the collection of specimens for microbiological assays from infants and children aids in optimizing the detection of pathogens from this patient population. Table 4 summarizes the salient features of specimen management in this special population.

The volumes of specimen available for testing vary according to the age and size of the child. Limited volumes are especially pertinent to the collection of blood, urine, cerebrospinal fluid (CSF), other sterile fluids, and tissue samples submitted for culture. Multiple phlebotomies performed for a variety of diagnostic tests can affect the volume of blood collected for culture due to the concern of critical volume depletion in infants and smaller children. The diagnosis of certain types of bacterial meningitis may be hindered by the smaller volumes of CSF available, coupled with the problems inherent in performing lumbar puncture in this age group. The average total volume of CSF in children and

TABLE 3 Specimen management of sterile body fluids other than blood and CSF[a]

Fluid	Collection container	Concentration	Stain	Comment
Amniotic	Anaerobic tube	No	Gram stain	
Culdocentesis	Anaerobic tube	No	Gram stain	
Dialysis effluent	Isolator tube, urine cup, or Bx2	Centrifuge or filter	Gram stain or AO (low detection rate)	<100 leukocytes/ml is normal; use one-third of filter for one of three media
Pericardial	B and/or anaerobic tube	Cytospin from tube	Gram stain from cytospin	Few leukocytes in normal fluid
Peritoneal (ascites)	Bx2 (10 ml) + anaerobic tube	Cytospin from tube	Gram stain from cytospin	<300 leukocytes/ml is normal
Pleural (effusion, transudate, thoracentesis, empyema)	Anaerobic tube	Cytospin from tube	Gram stain from cytospin	>5 ml needed for fungi; none to a few leukocytes is normal; many leukocytes are found with empyema
Synovial	B + anaerobic tube	Cytospin from tube	Gram stain from cytospin	A few leukocytes is normal

[a]The information in this table is from reference 8 and reprinted with permission of Elsevier. Abbreviations: B, blood culture bottle; Bx2, aerobic and anaerobic blood bottles; AO, acridine orange stain. Cultures and stains can be done from any cytospin sediment.

infants is approximately 40 to 90 ml, while the volume range for adults is 90 to 150 ml. Lastly, infants and children not only excrete smaller volumes of urine but are also often unable to void on command. In some cases, <1.0 ml of urine may be available for testing.

The greatest challenge, therefore, for laboratories processing specimens from pediatric patients is making the most of the limited amounts of specimens received for culture. Although the procedures for the collection of many specimen types mirror the protocols used for adult patients, some important differences exist.

Blood Samples for Cultures

Use of proper skin disinfection techniques is even more important in children prior to collection of blood for culture since only one bottle collected during a 24-h period may be available for culture, making the categorization of contaminant versus pathogen difficult to assess. Due to the low incidence of anaerobic bacteremia, routine inoculation of an anaerobic blood culture bottle is not warranted. Although the collection of blood from infants and children by venipuncture is achievable by skilled phlebotomists, venous access in pediatric inpatients is often through peripheral or central venous catheters, which eliminates the need for attempts to gain peripheral venous access. Such lines are used primarily for administration of fluids and therapeutic drugs and are infused with heparin to inhibit clotting when not in use. When the catheter is used to obtain blood cultures, the line must be adequately disinfected and flushed of all inhibitory substances before the specimen is obtained. Since volume depletion in the patient is a concern, the amount of fluid to be discarded, as well as the amount of blood available for testing, is limited. The procedure utilized most often, the discard method, is based on the amount of fluid flushed from the line on the weight and size of the child (39). Minimal discard volumes for infants, for example, are in the range of 0.3 to 1.0 ml (59). In response to the decreased volumes of blood that can be obtained from pediatric patients for culture, blood culture bottles that contain approximately 20 ml of broth and that accommodate an inoculation volume of up to 4 ml are available. The smaller volume of broth allows for a close approximation of the recommended blood-to-broth ratio necessary to diminish the effect of growth inhibitors.

Cerebrospinal Fluid

The primary reason for collection of CSF is for the diagnosis of acute bacterial or viral meningitis or CSF shunt infections. Lumbar puncture is sometimes difficult in an infant or child. A specimen obtained by lumbar puncture that yields only blood is indicative of a failure to access the subarachnoid space (23). If the CSF initially contains a small amount of blood but clears as additional fluid is collected, a repeat lumbar puncture is not required. If only a small amount of fluid is retrieved from the patient due to age and size, CSF containing clotted blood is sometimes sent for culture pending a repeat lumbar puncture. The clot is homogenized prior to plating, and an acridine orange fluorescent stain of a direct smear of a cytospin preparation is recommended to facilitate rapid detection of potential pathogens. Gross blood in the specimen may obscure the visualization of organisms when stained by Gram's method.

Ventricular shunts are used for drainage in patients who overproduce CSF. Ventricular shunt malfunctions in both children and adults are associated with infection and/or disconnection or obstruction of the catheter (26, 54). The majority of shunt infections are acquired at the time of shunt placement and are associated with organisms usually considered skin flora, such as *Staphylococcus epidermidis* or *Propionibacterium acnes* (12, 67).

Specimens for Detection of Otitis and Sinusitis

Acute otitis media is also a common pediatric disease (11, 53). Uncomplicated otitis media does not require confirmation by culture; however, a persistent infection may require retrieval of fluid from the middle ear via tympanocentesis for identification of the specific pathogen causing the infection. A swab specimen of the external auditory canal is unsuitable for diagnosis of acute otitis media or otitis media with effusion. Potential contamination of purulent drainage with resident flora may interfere with accurate analysis of the culture.

Uncomplicated sinusitis is often treated empirically on the basis of the patient's clinical presentation (71). Specimens for culture may be obtained from patients with chronic sinusitis refractory to therapy. Bilateral cultures are recommended (71). Secretions from the region of the maxillary ostium are sampled with a swab under direct vision; however, unless the specimen is obtained very carefully, interpretation of culture

TABLE 4 Requirements for pediatric specimen collection

Specimen type and source	Collection	Comments
Blood for culture		
Peripheral	As for adults. Withdraw a volume of ≥0.5 ml and inoculate into the blood culture bottle.	Collection of larger volumes will aid in retrieval of low concentrations of circulating organisms. Inoculation of one aerobic bottle is usually sufficient.
Peripheral catheter (see comment)	Disinfect the venipuncture site. Insert the catheter and attach a T-connector with syringe to the catheter and withdraw the blood for culture.	A blood culture may be obtained when a peripheral catheter is inserted.
Indwelling central venous catheter	After disinfection, disconnect the extension tubing or cap from the catheter hub. Disinfect the hub. Withdraw a minimum volume of blood and discard. Attach a second sterile syringe and withdraw an additional ≥0.5 ml for culture.	Accidental aspiration of heparin may inhibit the growth of bloodborne pathogens; therefore, flush the catheter with heparin or saline.
Implantable device (for therapy administration)	Disinfect the skin site. Insert a Huber needle through the skin into the apparatus; follow the procedure for collection of blood from a central venous catheter described above.	These devices may rarely be used for vascular access for the retrieval of blood for culture.
CSF		
Lumbar puncture	As for adults.	Difficulties are often encountered in patient positioning and restraint; in addition, there are limitations to the volume of fluid retrievable.
Ventricular shunts	As for adults.	Correct labeling of shunt fluid is important because organisms considered "contaminants" from lumbar punctures may be significant pathogens in ventricular shunt infections.
Dermatologic specimens		
Bacterial and viral cultures		
Pustule or vesicular lesions	Disinfect surface and allow to dry. Unroof the pustule. Aspirate fluid for culture and then insert swab and rotate vigorously to collect fluid and cells from the advancing margin.	Specimens that contain no inflammatory cells are from the superficial areas of the lesion and new specimens must be collected. Viral pathogens are best retrieved from the base of a lesion.
Petechiae, purpura, ecthyma gangrenosa	With a scalpel blade, vigorously scrape the outer margin of the lesion.	A Gram stain of petechiae material may give an indication of meningococcal infection.
Fungi	For a dry lesion, scrape the lesion with a scalpel, glass slide, or toothbrush. For moist lesions, use a Dacron swab. For hair, use scissors and forceps. For nails, scrape with a scalpel. Place scraping directly onto fungal medium or place in a sterile container and send for culture.	A small toothbrush is useful for collection of scrapings.
Specimens for detection of scabies	Disinfect the area and allow to dry. Apply a single drop of mineral oil to the papule and abrade the infested area with a sterile scalpel. Transfer skin scrapings to a sterile container or microscope slide with coverslip for transport to the lab.	Place the microscope slide with coverslip in a secure holder so that the coverslip is not dislodged during transit.
Feces		
Bacterial and viral cultures	As for adults. A rectal swab showing feces is suitable for bacterial or viral culture.	Devices that fit into the toilet bowl or techniques such as lining a diaper with plastic wrap facilitate retrieval of feces for testing.
C. difficile toxin	As for adults.	Toxin-producing strains of *C. difficile* may be normal in some infants <2 years of age. Interpret a positive toxin result for individuals in this age group with caution.

(Continued on next page)

TABLE 4 *(Continued)*

Specimen type and source	Collection	Comments
Ovum and parasite examination	As for adults. Submit feces-coated rectal swabs only for antigen detection EIAs, not routine ovum and parasite examinations.	See bacterial and viral cultures. The volume of preservatives present in commercial ovum and parasite collection and transport tubes should be adjusted to retain the recommended stool-to-fixative ratio of 3:1.
Pinworms	Use a commercial paddle sampling device or place the adhesive side of a cellophane tape strip onto a microscope slide. Peel back the tape to expose the adhesive side of the tape. While holding the slide against an applicator, press the tape firmly against the perianal skin. Replace the tape back over the slide and press the adhesive side onto the slide.	The applicator stick provides a safe backing for the glass slide while gentle pressure is applied to the skin for collection of the specimen with the adhesive. Do not use "invisible" or "magic" tape.
Gastric aspirates (may not provide clinically relevant data)	A premeasured length of lubricated catheter is passed gently into the mouth or nasopharynx and is continued through the esophagus into the stomach. The contents are aspirated and place in a sterile container for immediate transport to the lab. If no gastric secretions are obtained, a lavage of sterile distilled water is collected for specimen processing.	Three consecutive early-morning, fasting specimens are preferred for mycobacterial culture, but infants may not be able to provide such a sample. Collect the aspirate as long after the last feeding as possible. Environmental mycobacterial species may appear in aspirated formula. Neutralization of the specimen must occur upon arrival in the lab.
Genital specimens	Use a small-tipped Dacron swab with a flexible smooth wire. The specimen of choice for a prepubertal female is a vaginal swab or washing. Collect a urethral swab from prepubertal males.	STDs in prepubertal girls involve the vagina as opposed to the cervix. Specimens from adolescents are the same as those collected from adults.
Ear specimens		
Otitis (otitis media)	Cleanse the external auditory canal with an antiseptic. Using an otoscope, insert a 1-ml tuberculin syringe with a 3.5-in 22-gauge spinal needle bent at a 30° angle through the tympanic membrane and aspirate the fluid in the chamber into a sterile vial or syringe.	Needle aspiration of fluid (tympanocentesis) is the recommended method for obtaining a specimen. A purulent discharge from a ruptured membrane can be collected for culture by using a sterile swab.
Respiratory specimens		
Bronchoalveolar lavage specimens	As for adults.	Specimens from unsheathed catheters may contain contaminating oropharyngeal flora. In infants and younger children, <10 ml is often retrieved. If >10 ml is collected, centrifuge the sample prior to plating.
Protected brush specimens	As for adults.	
Nasal specimens	Insert a sterile swab at least 1 cm into the opening of the anterior nares.	Used primarily for surveillance of methicillin-resistant *Staphylococcus aureus* or to assess upper respiratory tract colonization in children with immunologic defects.

(Continued on next page)

TABLE 4 Requirements for pediatric specimen collection *(Continued)*

Specimen type and source	Collection	Comments
Nasal washes	Aspirate approximately 4 ml of sterile saline into a 1-oz tapered rubber bulb. Tip the patient's head back approximately 70 degrees and insert the bulb into the nostril until it is occluded. Squeeze the bulb to dispense the saline, hold for a few seconds and then release to collect the secretions. Dispense the specimen into a sterile container and transport to the lab as soon as possible.	A nasal wash or nasal aspirate (see below) is often cited as the preferred specimen type for collection of respiratory secretions for culture for either viruses or *Bordetella pertussis* and direct smear examination and in pediatric patients. Transport specimens for viral cultures on ice.
Nasopharyngeal aspirate	Attach a sterile suction catheter to a (mucus) trap and introduce the end of the catheter into the nasopharynx until resistance is encountered. Withdraw the catheter 1–2 cm and apply suction to aspirate the sample. Dispense the specimen into a sterile container and immediately transport it to the lab.	See nasal wash. Transport specimens for viral cultures on ice.
Nasopharyngeal swab specimens	Insert the swab into the nasopharyngeal cavity to the point of resistance and then gently rotate it. Place the swab into an appropriate transport medium and send to the lab immediately.	Young children and infants require use of a swab with a small-tip circumference such as a calcium alginate or small-tip Dacron swab. Transport specimens for viral cultures on ice.
Throat swab specimens	Tilt the child's head back and ask the child to open the mouth as wide as possible. Carefully insert the sterile swab(s) into the oral cavity and sample the surfaces of the back of the throat and tonsils.	In children, the major pathogen of bacterial pharyngitis is group A streptococci (GAS). If a rapid screen of a throat swab specimen for GAS is performed, collect two swabs to do a culture to confirm negative screening findings or to rule out a possible false positive caused by a member of the *Streptococcus anginosus* group. Avoid touching other areas of the oral cavity to prevent specimen contamination with oropharyngeal flora.
Tracheal aspirate	After oxygenation of the patient, attach a sterile suction catheter to a (mucus) trap and introduce the end of the catheter into the trachea until resistance is encountered. Withdraw the catheter 1–2 cm and apply suction to aspirate the sample.	Although grading systems for assessment of the quality of pediatric tracheal aspirates have been proposed, careful evaluation is required prior to their implementation.
Transtracheal aspirate	As for adults.	
Sputum specimens	As for adults.	Since children are often unable to produce sputum, tracheal aspirates are more often collected in pediatric populations.
Specimens for detection of viruses	Specimens of choice are similar to others in this table (45).	Rectal swabs are acceptable for detection of rotavirus antigen.
Specimens for detection of *Chlamydia*	Conjunctival and/or nasopharyngeal swabs are appropriate for neonatal screening.	See genital specimens above. Vaginal (females) or urethral (males) swabs are required for chlamydia culture for the determination of sexual abuse.

results may be hindered by the presence of contaminating flora. Needle aspiration of the sinus is recommended for definitive diagnosis of the etiologic agent of infection (49).

Respiratory Specimens

For the diagnosis of group A streptococcal pharyngitis (10, 14), collection of two pharyngeal swabs is optimal for performance of both a rapid antigen detection assay and culture (one swab for each assay). A single swab shared for both methods may reduce the sensitivity of the antigen detection assay due to a reduction in the concentration of organisms available after culture inoculation (10). Although the reported sensitivities of some rapid assays may suggest that a confirmatory culture may be eliminated in the event that the screen is negative,

careful consideration must be given to the possible implications of an undetected infection in some children (10). The collection of nasopharyngeal swab specimens, washes, or aspirates for culture and/or detection of antigens of respiratory viruses and *Bordetella pertussis* is satisfactory (4, 47, 48). Again, collection of more than one swab increases the chance of isolate detection. Transport of swabs in a suitable holding medium is necessary to ensure organism viability if delays are anticipated between the time of collection and specimen receipt by the laboratory. Due to the small diameter of the nasal passages in some infants and children, coupled with inflammation of the nasal mucosa during the infection, specimen collection with a swab is sometimes more difficult and thus provides an inadequate sample.

A sputum specimen for diagnosis of pneumonia is difficult to obtain from children. More commonly, a tracheal or endotracheal tube aspirate is sent for microbiological culture. The utility of endotracheal tube aspirates as predictors of pediatric lower respiratory tract infection is influenced by the role that accumulated secretions within the tube play in the promotion of bacterial colonization (30, 62, 75). A bronchoalveolar lavage or the use of a protected brush will provide a superior specimen for intubated children with clinical evidence of pneumonia (44, 46, 74). Although pediatric bronchoscopes are available, the tubing diameter is sometimes too large for certain pediatric patients. In these situations, a small-diameter catheter is useful for performance of the lavage (2, 43). If an unprotected catheter is used, however, commensal oral flora will reduce the chances for recognition of the true etiologic agent. Aspiration of gastric secretions is performed for infants and children with presumed pneumonia caused by *Mycobacterium tuberculosis* (1, 61). After the patient has fasted overnight, the swallowed respiratory secretions are aspirated from the stomach by using gastric intubation and sent for diagnostic testing (1, 64). Problems with this method include the inability of infants on a feeding schedule to maintain a fasting state prior to specimen collection. Lastly, many pediatric centers provide care for children with cystic fibrosis. Specimens from these patients are periodically sent to the laboratory for surveillance of lower respiratory tract colonization by various potentially pathogenic microorganisms. Recommended specimens for culture of these types of organisms include sputum, tracheal aspirates, or throat swabs (6, 29, 56).

Genital Specimens

Genital specimens are usually collected from pediatric patients for (i) investigation of possible sexual abuse or rape or (ii) diagnosis of premenarchal vulvovaginitis and/or urethritis. Since these specimens are often irretrievable, every effort must be made to process pediatric urogenital specimens for culture. Although the cervix is the specimen source for diagnosis of gonorrhea and chlamydia in adolescent and adult females, detection of these sexually transmitted diseases (STDs) in prepubertal females requires sampling of the vaginal vault (5). A urethral swab sample is collected from prepubescent males. Culture is required for confirmation of both types of infections (5). Antigen detection assays are not acceptable due to the high reported rates of false positivity (33, 72). Likewise, the performance of molecular methods has not been adequately assessed for detection of STDs in children and is not considered admissible in the event of legal proceedings (34).

Urine Specimens

Collection of uncontaminated urine specimens from pediatric patients is a challenge. The acquisition of a clean-catch specimen from older children is hindered by the same problems experienced with adult patients. A urine specimen collected by catheterization is used for all pediatric age groups and, if performed properly, can yield a specimen free of urethral contaminants (4). Although suprapubic aspiration is considered the optimum method for urine collection from infants, the technique is frequently unsuccessful in dehydrated patients (4). Specimens must be transported to the lab within 30 min of collection or stored under refrigeration for no longer than 24 h (50). Urine transport systems containing preservatives are available for adult patients, who characteristically excrete larger volumes of urine. For optimum performance, the urine and preservative must be in the ratio recommended by the manufacturer. At present, no transport system is available to accommodate the lower-volume pediatric urine specimens.

Fecal Specimens

The best clinical predictors of a positive stool culture in children are a combination of persistent diarrhea of >24 h in duration, fever, and either blood in the stool or abdominal pain with nausea and vomiting (20, 45, 57, 61, 66). Many cases of endemic diarrhea occur in children <5 years of age and are caused by pathogens that are endemic to an area, such as rotavirus, shigellae, *Giardia lamblia,* and cryptosporidia (20). Since most diarrheal disease is community acquired, a single stool culture obtained during the first 72 h after admission to the hospital can be used for diagnosis for almost 98% of children with bacterial gastroenteritis (15, 16, 55). Depending on the age of the child, nosocomially acquired diarrheal disease is most often attributed to rotavirus or *Clostridium difficile* (13, 28). Interpretation of positive *Clostridium difficile* toxin assay results for children <2 years of age may be difficult due to intestinal colonization of this group with toxin-producing strains (22, 42, 68). A freshly obtained stool sample is preferable for all fecal assays. A rectal swab is less optimal but is acceptable for recovery of bacterial enteric pathogens, surveillance for multidrug-resistant organisms, and performance of certain antigen detection assays. A rectal swab is not recommended for some detection assays for *Clostridium difficile* toxin. If a delay in transport is anticipated, fecal specimens for either bacterial culture or parasite detection should be placed in an appropriate transport medium or preservative, respectively. In order to maintain the 3:1 recommended ratio of stool to preservative for parasite transport vials, the volume of preservative in the vial may require adjustment prior to inoculation of a small pediatric sample.

Pinworm *(Enterobius vermicularis)* infection is a common ailment of children. After establishment of infection in the colon, the female adult pinworm periodically migrates to the perianal area and deposits her eggs on the skin. Commercial sampling paddles are available for sampling, but cellophane or cellulose tape applied to the perianal skin in the morning, before the patient washes or defecates, enables collection of the eggs for identification.

Specimens from Neonates

The neonatal nursery and intensive care unit pose unique challenges for the microbiology laboratory. The problems inherent in decreased sample amounts available from these tiny patients may be compounded by the unpredictable response to infection displayed by neonates (31, 51). For example, isolates retrieved from the mucous membranes, skin, ear canal, nasopharynx, gastric aspirate, or rectum usually do not match the results of blood, CSF, or tissue cultures (31, 51). Differentiation of colonization versus true infection, therefore,

may be very difficult. Microorganisms are acquired either through transmission in utero, during delivery, or from nosocomial spread via hospital personnel, various medical devices, or environmental sources (36, 63). Infections reported to occur in neonates include sepsis, meningitis, otitis media, diarrhea, osteomyelitis or septic arthritis, conjunctivitis or orbital cellulitis, pneumonia, and various skin infections (7, 24, 27, 31, 51, 70, 73). Congenital infection is most often caused by agents such as *Toxoplasma gondii* or viruses such as herpes simplex virus, cytomegalovirus, varicella-zoster virus, parvovirus, enterovirus, rubella, or hepatitis B virus (25, 31, 41, 51, 65). Collection methods and appropriate specimen types for neonates are similar to those recommended for older infants and children with the exception of blood for culture. Depending on the age of the newborn, recommended sampling sites include the peripheral vein, umbilical artery, and capillary blood (31). Although a minimum of 0.5 to 1.0 ml is most often cited as the recommended amount of specimen to be collected, larger volumes are recommended for optimal recovery of organisms (40, 58).

Viral Specimens

Since smaller specimen volumes are often received from pediatric patients, newer molecular methods may aid in the detection of pediatric systemic or central nervous system viral infections. The antigenemia assay for detection of cytomegalovirus in blood may be impeded by both the smaller specimen volumes and the smaller polymorphonuclear leukocyte concentrations in neutropenic children undergoing transplantation or therapy for oncological problems. Details regarding diagnosis of viral infections can be found in chapter 80 of this Manual.

Dermatologic Specimens

Rashes are a common manifestation of many childhood illnesses. The same techniques are used to sample skin lesions from children and adults. A small, disposable toothbrush is valuable for obtaining scrapings of certain types of dermatophytic fungal lesions and produces fewer traumas than using a scalpel (3). Retrieval of skin samples for detection of scabies often yields no visible organism; however, the distribution of lesions differs between infants and young children and their older counterparts (3).

Procedures for the Storage of Microorganisms

CATHY A. PETTI, KAREN C. CARROLL, AND LARRY G. REIMER

6

Long- and short-term preservation of microorganisms for future study has a long tradition in microbiology. Culture collections of microorganisms are valuable resources for scientific research in microbial diversity and evolution, patient care management, epidemiological investigations, and educational purposes. Preserved individual strains of microorganisms serve as permanent records of microorganisms' unique phenotypic profiles and provide the material for further genotypic characterizations. Such reference collections can encompass rare infectious agents unique to an individual or catalog the history of disease caused by common pathogens such as those responsible for community outbreaks.

There are multiple methods for microbial preservation. Effective storage is defined by the ability to maintain an organism in a viable state free of contamination and without changes in its genotypic or phenotypic characteristics. Secondly, the organism must be easily restored to its condition prior to preservation. Microbial preservation methods have been evaluated extensively over the past 50 years, and often, optimal methods for preservation depend on a microorganism's taxonomic classification. Review articles, monographs, and books have been published that provide detailed information about the storage of various types of microorganisms (1, 10, 14, 15, 27). For clinical microbiology laboratories, simple and broadly applied methods are necessary to maintain organisms for short- and long-term recovery. This chapter presents methods that can be used for the storage of bacteria, protozoa, fungi, and viruses.

OVERVIEW OF PRESERVATION METHODS

Short-Term Preservation Methods

Direct Transfer to Subculture

The simplest method for maintaining the short-term viability of microorganisms, most often used for bacteria, is periodic subculture to fresh medium. Although simple, if microorganisms are saved for more than 1 week, this method is potentially labor-intensive, requires extensive laboratory space, and may compromise a microorganism's phenotypic profile. Each transfer to a new subculture increases the likelihood of mutation with undesirable changes in a microorganism's characteristics.

The interval between transfers varies among organisms. Additionally, the rate of mutation is quite variable. Some organisms appear stable indefinitely with repeated transfer, and others may change phenotypic traits after as few as two or three passages. The actual rate of mutation, however, has not been studied using sequencing technology. Issues that must be addressed with direct transfer include the medium to be used, the storage conditions, and the frequency of transfer.

Maintenance Medium

The medium should support the survival of the microorganism but minimize its metabolic processes and slow its rate of growth. Extreme environments should be avoided because microorganisms have the unique ability to adapt through mutation events in order to survive in suboptimal surroundings. A medium with too high a nutrient content will induce rapid replication that requires more frequent transfers. The optimal medium for maintaining microorganisms has not been clearly defined and most likely varies from one genus to another. Media that have been used include distilled water, tryptic soy broth, and nutrient broths (e.g., from Becton Dickinson and Co. and Oxoid Ltd.), all of which may be used with or without cryopreservatives.

Storage Conditions

Many laboratories store organisms, most often bacteria, for short periods on routine agar media at the workbench. Cultures kept in this fashion are subject to drying. A better method is to transfer organisms into screw-top test tubes and to store them in an organized location away from light and significant temperature changes. To prevent drying, caps can include rubber liners, or film can be wrapped over the top of the tube before or after the cap is screwed on. Storage at lower temperatures (5 to 8°C) slows metabolic processes and maintains viability for longer periods.

Frequency of Transfer

There is no set protocol for the frequency of transfer since storage conditions, media used, and types of microorganisms vary among laboratories. Individual laboratories should conduct studies for each category of microorganism to determine acceptable intervals between transfers under their conditions used for storage. Such studies would involve performing subcultures at scheduled times until the laboratory identifies an acceptable interval between transfers at which

a microorganism can reliably and reproducibly be recovered. (When transfers are performed, 5 to 10 representative colonies should be used to avoid the possibility of introducing an altered genotypic or phenotypic characteristic.)

Quality Control Procedures

Although it is not necessary with each transfer, the status of the specimen should be assessed periodically. Ongoing viability, stability of phenotype, microorganism identity, and the rate of contamination of specimens should be determined and noted in a log.

Immersion in Oil

An alternative to capping tubes is to add a layer of mineral oil to the top of the specimen. Many bacteria and fungi can be stored for periods of up to 2 to 3 years by this method, and transfers are not needed as frequently. Microorganisms are still metabolically active in this environment, and mutations can still occur. Contamination of the specimen can occur if the mineral oil is not adequately sterilized.

Mineral oil should be medicinal-grade oil with specific gravity of 0.865 to 0.890 (e.g., from Roxane Laboratories or Becton Dickinson and Co.). For sterilization, it should be heated to 170°C for 1 to 2 h in an oven (10). Autoclaving is not considered acceptable.

To prepare the specimen, an inoculum of 5 to 10 colonies of the microorganism should be placed on an agar slant or in tubed broth media. Once growth is identified, a layer of mineral oil at least 1 to 2 cm deep is added, and the agar must not be exposed to air. As with the simple transfer method, tests for viability should be performed to determine the optimal transfer schedule that will ensure microorganism recovery. Transfers will be less frequent than those of microorganisms stored without oil; however, oil is more difficult to add to vials and to clean up in the event of spills.

Freezing at −20°C

Refrigeration or freezing in ordinary freezers at −20°C may be used to preserve microorganisms for periods longer than those that can be accomplished by repeated transfers. Viability may be maintained for as long as 1 to 2 years for specific microorganisms, but overall, damage caused by ice crystal formation (15) and electrolyte fluctuations (10) results in poor long-term survival. The medium used for storage appears to be important, since preservation times vary from a few months to 2 years depending upon which medium is used (12, 15, 17). Modern self-defrosting freezers with freeze-thaw cycles must be avoided because cyclic temperature fluctuation will destroy the microorganism.

Drying

Although most microorganisms do not survive drying, molds and some spore-forming bacteria may be dried and stored for prolonged periods. Soil can be used as a storage medium if it is autoclaved and air dried. Soil should be autoclaved for several hours on two successive days. It is then transferred into sterile glass tubes. A 1-ml suspension of the microorganism is inoculated into the tube, and the tube is left open to air dry before being closed with a sterile stopper. The sample is stored in a refrigerator (10). Although potentially effective, soil is not a standardized, defined, and consistent product for use over long periods. Instead, commercial silica gel can be used in small cotton-plugged tubes after being heated in an oven to 175°C for 1.5 to 2 h (15), with moderately successful recovery of fungi. Alternatively, a suspension of 10^8 microorganisms can be inoculated onto sterile filter paper strips or disks. The paper is dried in air or under a vacuum and is placed in sterile vials. These vials can be stored in the refrigerator for up to 4 years, and then single strips or disks can be removed as needed (10). This method is commonly used for quality control organisms.

Storage in Distilled Water

Most organisms do poorly in distilled water, but some survive for prolonged periods. Many fungi and *Pseudomonas* sp. survive for several years in distilled water at room temperature (15, 21). McGinnis et al. found that with the exception of fungi that do not easily sporulate, 93% of yeasts, mold, and aerobic actinomycetes can be easily and inexpensively preserved this way (20).

Long-Term Preservation Methods

Whereas the methods described above may be used to store microorganisms for periods of up to a few years, ultralow-temperature freezing and freeze-drying (lyophilization) are recommended for long-term storage. Although the initial investment in ultralow-temperature freezers and lyophilization may be costly, these methods are less labor-intensive over time, require less laboratory space (e.g., a cryovial versus broth or agar media), and reduce the chances of mutation events. Of course, mutations may still occur, and this phenonomen was recently observed in *Staphylococcus aureus* strains that lost the *mec*A gene during long-term preservation at −80°C (30). Similar to those with other preservation methods, survival rates after freeze-drying vary with species. Evaluating microorganisms over a 10-year period, Miyamoto-Shinohara et al. found that survival rates after freeze-drying for *Brevibacterium* sp. and *Corynebacterium* sp. approached 80% whereas those for *Streptococcus mutans* decreased to 20% after 10 years (21).

Ultralow-Temperature Freezing

Microorganisms can be maintained at temperatures of −70°C or lower for prolonged periods. Systems for achieving these temperatures include ultralow-temperature electric freezers and liquid nitrogen storage units. With either system, unwanted heating can occur due to the loss of electrical power or liquid nitrogen. Close observation of the system and an adequate alarm mechanism are essential since any increase in temperature will reduce viability. In the event that the temperature does rise, restoring power and returning to the target storage temperature as quickly as possible are essential. The presence of a cryopreservative such as glycerol may reduce the risk to microorganisms upon short exposure to higher temperatures (22). If thawing does occur, there are no guidelines for rapid restoration of the storage condition. Refreezing of the sealed vials as described below may be considered.

Storage Vials

Storage vials must be able to withstand very low temperatures and maintain a seal for their contents. Plastic (polypropylene) or glass (borosilicate) tubes may be used. Plastic vials with screw tops and silicone washers are much easier to use than glass vials that must be sealed with a flame and then scored and broken open. Several commercial suppliers stock acceptable vials (e.g., Fisher Scientific Products, VWR Scientific, Wheaton Science Products, and Becton Dickinson and Co.). Vials come in a variety of sizes. Half-dram vials are available from several suppliers and can be conveniently packaged in a 12-by-12 grid so that 144 vials are stored in one box or layer.

Cryoprotective Agents

To protect microorganisms from damage during the freezing process, during storage, and during thawing, cryoprotective agents are often added to the culture suspension. Whereas most bacteria, fungi, and viruses survive better with such additives, studies have shown that cryoprotective agents will significantly damage others. The reader is referred to detailed references for specifics (Table 1) (1, 15). Rapid freezing without additives may still be acceptable for the long-term survival of protozoa, although freeze-drying may be preferred.

There are two types of cryoprotective agents: those that enter the cell and protect the intracellular environment and others that protect the external milieu of the organism. Glycerol and dimethyl sulfoxide (DMSO) are most often used for the former; sucrose, lactose, glucose, mannitol, sorbitol, dextran, polyvinylpyrrolidone, polyglycol, and skim milk are used for the latter. Combinations of agents as well as detergents (e.g., Tween 80 and Triton WR 1339), other carbohydrates (e.g., honey), and calcium lactobionate have also been used. The most universal cryoprotectant is DMSO; however, the optimal cryoprotectant often varies with the microorganism. For example, glycerol appears to be best suited for the preservation of bacteria. A current and comprehensive review of protectant additives used in the cryopreservation of microorganisms is provided by Hubalek (16).

TABLE 1 Common procedures for preservation of microorganisms

Organism group	Storage method	Cryopreservative	Storage temp (°C)	Storage duration (yr)
Gram-positive bacteria	Transfer	None	Room temp	0.2–0.3
	Immersion in mineral oil	None	4	0.6–2
	Freezing	Sucrose, glycerol	−20	1–3
	Ultralow-temp freezing	Skim milk, sucrose, glycerol	−70 to −196	1–30
	Lyophilization	Skim milk, sucrose	4	30
Streptococci	Freezing	Skim milk	−20	0.2
	Ultralow-temp freezing	Skim milk	−70 to −196	0.2–1
	Lyophilization	Skim milk	4	0.5–30
Mycobacteria	Freezing	Skim milk	−20	3–5
	Ultralow-temp freezing	Skim milk	−70 to −196	3–5
	Lyophilization	Skim milk	4	16–30
Gram-negative bacteria	Transfer	None	Room temp	0.1–0.3
	Immersion in mineral oil	None	4	1–2
	Freezing	Sucrose, lactose	−20	1–2
	Ultralow-temp freezing	Sucrose, lactose, glycerol	−70 to −196	2–30
	Lyophilization	Skim milk, sucrose, lactose	4	30
Spore-forming bacteria	Transfer	None	Room temp	0.2–1
	Immersion in mineral oil	None	4	1
	Drying	None	Room temp	1–2
	Freezing	Glucose	−20	1–2
	Ultralow-temp freezing	Skim milk, glycerol	−70 to −196	2–30
	Lyophilization	Skim milk, lactose	4	30
Filamentous fungi	Transfer	None	4 to 25	2–10
	Immersion in mineral oil	None	Room temp	1–40
	Storage in distilled water	None	Room temp	1–10
	Drying	Soil, silica gel	Room temp	1–4
	Ultralow-temp freezing	Glycerol, DMSO	−70 to −196	2–30
	Lyophilization (sporeformers)	Glycerol, sucrose, DMSO, skim milk	4	2–30
Yeasts	Storage in distilled water	None	Room temp	1–2
	Drying	Nutrient medium	Room temp	1–2
Protozoa	Freezing	Blood, nutrient broth with DMSO or sucrose	−20 to –40	
	Ultralow-temp freezing	Blood, nutrient medium with DMSO or glycerol	−70 to −196	
Viruses	Transfer	Nutrient medium	4	0.5
	Ultralow-temp freezing	SPGA	−70 to −196	1–30
	Lyophilization	SPGA	4	6–10

Glycerol is added at a concentration of 10% (vol/vol), and DMSO is added at 5% (vol/vol). Prior to use, glycerol is sterilized by autoclaving. Once prepared, it can be stocked at room temperature for months. DMSO must be filter sterilized and can be stored in open containers for only 1 month prior to use.

Of the external products, skim milk is the most often used. Dehydrated skim milk is purchased from medical product suppliers (e.g., Becton Dickinson and Co. and Oxoid). It is autoclaved and used in a final concentration of 20% (wt/vol) in distilled water (1). This is double the concentration suggested by the manufacturers if the intent is to make a reconstituted equivalent of regular milk.

Preparation of Microorganisms for Freezing

Microorganisms are inoculated into a medium that adequately supports maximal growth. Cultures are allowed to mature to the late growth or stationary phase before being harvested. Broth specimens are centrifuged to create a pellet of microorganisms. The pellet is withdrawn and resuspended in 2 to 5 ml of broth with the appropriate concentration of cryoprotectant additive. For agar specimens, broth containing the cryoprotectant is placed on the surface of the agar. The surface is scraped with a pipette or sterile loop to suspend microorganisms, and then the broth mixture is pipetted directly into freezer vials. Alternatively, the agar surface can be scraped with a sterile loop. The microorganisms can then be transferred directly into the vial of cryoprotectant and emulsified into a final dense suspension. The volume of the aliquots to be frozen is typically 0.2 to 0.5 ml.

Freezing Method

The American Type Culture Collection (ATCC) recommends slow, controlled-rate freezing at a rate of 1°C per min until the vials cool to a temperature of at least −30°C, followed by more rapid cooling until the final storage temperature is achieved (1). Controlled-rate freezers are required for the initial phase of cooling. Studies in the 1970s showed that uncontrolled-rate freezing may be acceptable for most organisms and is much less expensive or labor-intensive (15). When organisms are stored in liquid nitrogen, however, it is still recommended that vials be placed initially in a −60°C freezer for 1 h and then transferred into the liquid nitrogen. When organisms are stored permanently at −60 to −70°C, the vials can be placed directly into the freezer.

Small glass beads or plastic beads (e.g., from Fisher Scientific Products or Wheaton Science Products) can also be added to storage vials before freezing. The culture suspension will coat the beads, and then individual beads can be removed from storage for reconstitution without thawing the entire sample (8).

Thawing

Damage to microorganisms occurs as they are warmed from the frozen state. Critical temperatures appear to be between −40 and −5°C. Studies suggest that rapid warming through these temperatures improves recovery rates. Stored culture vials should be warmed rapidly in a 35°C water bath until all ice has disappeared (1, 15). Once a vial is thawed, it should be opened and the organism should be transferred to an appropriate growth medium immediately. Great care must be exercised during the thawing phase since rapid temperature changes and resulting air pressure changes inside vials can cause the vials to explode. Protective clothing and eyewear must be worn during this process.

Freeze-Drying (Lyophilization)

Freeze-drying is considered to be the most effective way to provide long-term storage of most bacteria. Better preservation occurs with freeze-drying than with other methods because freeze-drying reduces the risk of intracellular ice crystallization that compromises viability. Removal of water from the specimen effectively prevents this damage. On the other hand, the process of drying causes extensive damage to molds, protozoa, and most viruses. Hence, these microorganisms cannot be stored by this method. Among bacteria, the relative viability with lyophilization is greatest with gram-positive bacteria (sporeformers in particular) and decreases with gram-negative bacteria (15), but overall, the viability of bacteria can be maintained for as long as 30 years. In addition, large numbers of vials of dried microorganisms can be stored with limited space, and organisms can be easily transported long distances at room temperature.

The process combines freezing and dehydration. Organisms are initially frozen and then dried by lowering the atmospheric pressure with a vacuum apparatus. Freeze-drying has been extensively reviewed in the past (14), and the required equipment includes a vacuum pump connected in line to a condenser and to the specimens. Specimens can be connected individually to the condenser (manifold method) or can be placed in a chamber where they are dehydrated in one larger air space (chamber or batch method). Alexander et al. and Heckly have both published detailed descriptions of equipment options (1, 14).

Storage Vials

Glass vials are used for all freeze-dried specimens. When freeze-drying is performed in a chamber, double glass vials are used. In the chamber method, an outer soft-glass vial is added for protection and preservation of the dehydrated specimen. Silica gel granules are placed in the bottom of the outer vial before the inner vial is inserted and cushioned with cotton. For the manifold method, a single glass vial is used. For both methods, the vial containing the actual specimen is lightly plugged with absorbent cotton. The storage vial in the manifold method or the outer vial in the chamber method must be sealed to maintain the vacuum and the dry atmospheric condition. All vials are sterilized prior to use by heating in a hot-air oven.

Cryoprotective Agents

Research concerning cryoprotective agents has been extensively reviewed (14). In general, the two most commonly used agents are skim milk and sucrose. Skim milk is used most often for chamber lyophilization, and sucrose is used most often for manifold lyophilization. Skim milk is prepared by making a 20% (vol/vol) solution of skim milk in distilled water. The solution is divided into 5-ml aliquots and autoclaved at 116°C with care taken to prevent overheating and caramelizaton of the solution. The preparation is then used in smaller volumes as described above for freezing. Sucrose is prepared in an initial mixture of 24% (vol/vol) sucrose in water and added in equal volumes to the microorganism suspension in growth medium to make a final concentration of 12% (vol/vol).

Preparation of Microorganisms for Freezing

As with simple freezing, maximum recovery of organisms is achieved by using microorganisms in the late growth or stationary phase from the growth of an inoculum in an appropriate growth medium. High concentrations of microorganisms are considered to be important. The ATCC recommends a

concentration of at least 10^8 CFU/ml (1), and Heckly suggests a concentration of 10^{10} CFU/ml or higher (15).

Freeze-Drying Methods

In the chamber method, inner vials with the microorganism suspension are placed in a single layer inside a stainless steel container. This container is placed in a low-temperature freezer at −60°C for 1 h. The container is then transferred to a chamber containing dry ice and ethyl Cellosolve (Becton Dickinson and Co.) and covered with a sealable vacuum top, which is connected in sequence to a condenser reservoir also filled with dry ice and ethyl Cellosolve and to a vacuum pump. The vacuum is maintained at a minimum of 30 μm Hg for 18 h. At the same time, the outer vials are prepared by being heated in an oven overnight, filled with silica gel granules and cotton, and placed in a dry cabinet with <10% relative humidity. The freeze-dried inner vials are inserted into the outer vials, and the outer vials are heat sealed. Multiple different strains or species should probably not be processed in the same batch. Cross contamination rates vary from 0.8 to 3.3% when two different microorganisms are placed on opposite sides of the same container and are as high as 8.3 to 13.3% when microorganisms are intermingled (3).

In the manifold method, a rack of individual vials is used rather than a single container. The rack is placed in a dry ice-ethyl Cellosolve bath. After the freezing process, the vials are connected by individual rubber tubes in sequence to the condenser container filled with dry ice and ethyl Cellosolve and to the vacuum pump. As in the method described above, the vacuum is maintained at 30 μm Hg for 18 h and then the individual vials are sealed.

Storage

Individual vials need to be appropriately labeled and sorted. Storage at room temperature does not maintain viability and is not recommended. Storage at 4°C in an ordinary refrigerator is acceptable, but survival may be improved at temperatures of −30 to −60°C (1, 14).

Reconstitution

Care must be taken when opening vials for reconstitution because of the vacuum inside the vial. Safety glasses should always be worn, and vials should be covered with gauze to prevent injury if the vial explodes when air rushes in. Reconstitution should also be conducted in a closed hood to avoid dispersal of microorganisms. The surface of the vial should be wiped with 70% alcohol, and then the top of the glass vial can be scored and broken off or punctured with a hot needle. A small amount (0.1 to 0.4 ml) of growth medium is injected into the vial with a needle and syringe or a Pasteur pipette, the contents are stirred until the specimen is dissolved, and then the entire contents are transferred with the same syringe or a pipette to appropriate broth or agar media. A purity check must be done on each specimen because of the possibility of either cross contamination or mutation during the preservation process.

Procedures for Specific Organisms

Procedures for specific organisms are described below and summarized in Table 1.

Bacteria

All of the material presented in this chapter applies primarily to the preservation of bacteria. Simple transfer, storage under mineral oil, drying, or freezing at −20°C can maintain bacteria for short periods; freezing in ultralow-temperature electric freezers at −70°C or in liquid nitrogen at −196°C or freeze-drying can provide long-term preservation. A summary of the studies of bacterial preservation has been published (15). In general, serial transfer will preserve bacteria for up to a few months, storage under mineral oil or with drying will last 1 to 2 years, freezing at −20°C will preserve bacteria for 1 to 3 years, freezing at −70°C will preserve bacteria for 1 to 10 years, and freezing in liquid nitrogen and freeze-drying will preserve bacteria for up to 30 years (10). For fastidious bacteria such as *Streptococcus pneumoniae*, *Neisseria* spp., and *Haemophilus* spp., the optimal methods are lyophilization and freezing at −70°C by using Trypticase soy broth with glycerol as a preservation medium (23, 26, 31). Stock cultures of quality control microorganisms can be maintained in a cryopreservative suspension for up to 1 year at −20°C or indefinitely at −70°C.

Protozoa

Information concerning the preservation of protozoa is limited, in keeping with the infrequent need for such a process in clinical microbiology laboratories. Variable methods for individual genera are described. In general, freezing appears to be preferred to freeze-drying. All of the following procedures are as described by the ATCC (1).

Acanthamoeba sp., *Leishmania* sp., *Naegleria* sp., *Trichomonas* sp., and *Trypansoma* sp. can be handled as described above for ultralow-temperature freezing with 5% (vol/vol) DMSO as the cryoprotecting agent. These organisms should be stored in liquid nitrogen.

Acanthamoeba sp. and *Naegleria* sp. can also be dried at room temperature onto filter paper. Aliquots of a microorganism suspension (0.3 ml) are pipetted onto the paper in a shell vial and dried in air for 14 days at room temperature and then in a vacuum desiccator for an additional week. The vials are sealed and stored in liquid nitrogen.

Entamoeba sp. is stored frozen at −40°C. Specimens should be suspended in a mixture of growth medium containing 12% (vol/vol) DMSO and 6% (vol/vol) sucrose.

Leishmania sp. may also be prepared by inoculation of the organism into an animal host. At the peak of infection, the spleen is harvested and homogenized in half the final volume of ATCC medium 811 salt solution. Freezing is completed with 10% glycerol as the cryoprotectant.

Plasmodium sp. can be stored from infected blood samples. At the height of parasitemia, blood is obtained and anticoagulated with the following preparation: 1.33 g of sodium citrate, 0.47 g of citric acid, 3.00 g of dextrose, 200 mg of heparin (sodium), and 100 ml of distilled water. The final concentration of anticoagulant added to blood is 10%. To this anticoagulated blood, 30% glycerol in 0.0667 M phosphate buffer is added to a final concentration of 10% (vol/vol) glycerol. Freezing should occur in liquid nitrogen.

Trypanosoma sp. must be harvested from an animal host. At the peak of parasitemia, blood is withdrawn into heparinized tubes and diluted 1:1 in Tyrode's solution (8.0 g of NaCl per liter, 0.02 g of KCl per liter, 0.2 g of $CaCl_2$ per liter, 0.1 g of $MgCl_2$ per liter, 0.05 g of NaH_2PO_4 per liter, 1.0 g of $NaHCO_3$ per liter, and 1.0 g of glucose per liter) with 1 to 5% phenol red added. Then 5% DMSO is added as the cryoprotectant, and the specimen is stored in liquid nitrogen.

Yeasts and Filamentous Fungi

All of the techniques described above have been applied to the storage of yeasts and fungi (5, 10, 15, 27). The individual

method employed depends upon the species to be preserved and whether or not it sporulates.

Subculturing. Subculturing is the simplest method of maintaining living fungi and involves serial transfer to fresh solid or liquid media. Storage is accomplished usually at room or refrigerator temperature. Fungi may be maintained by subculturing for a number of years. Care must be taken to avoid aerosolization and contamination of the laboratory or other specimens.

Storage under oil. Whereas species of *Aspergillus* and *Penicillium* have remained viable under oil for 40 years (27), many species have shown deterioration after 1 to 2 years and must be transferred periodically. Taddei et al. also reported the successful storage and recovery of actinomycetes stored under paraffin oil for 10 to 30 years (28).

Water storage. Many fungi can be stored successfully for prolonged periods in distilled water (21, 24). A simple method is to pipette 6 to 7 ml of sterile distilled water onto 2-week-old culture slants in screw-cap tubes. The spores and fragments of hyphae are dislodged by scraping with the pipette, and the suspension is transferred to a sterile 1-g vial, which is tightly capped and stored at 25°C. Fungi are revived by subculturing 0.2 to 0.3 ml of the suspension to appropriate media (4).

An alternative method is to cut agar blocks from the growing edge of a fungal colony and place them in sterile distilled water in bottles with screw-cap lids (13). The cultures are stored at 20 to 25°C. The fungi are retrieved by removing a block and placing it mycelium side down on growth medium appropriate for that species (27). Contamination (22.8%) is a significant problem with this method (13).

Drying. Drying as described above has been used for fungi. Only 6 of 16 genera of fungi stored in this fashion survived for 4 years (2). The greatest success is reported for sporulating fungi stored in silica gel or in soil (27).

Freezing. Fungi have been successfully preserved by storage in liquid nitrogen by using glycerol or DMSO as cryopreservatives. Broth cultures containing nonpathogenic fungi are disrupted in a Waring blender and suspended in equal parts of DMSO or glycerol to achieve final concentrations of 5 or 10%, respectively. Pathogens should not be disrupted in a mechanical blender because of the potential biohazard associated with aerosolization. *Histoplasma, Paracoccidioides,* and *Blastomyces* species should be frozen in the yeast phase, and *Coccidioides* species should be frozen in the early mycelial phase to minimize exposure of laboratory personnel. Otherwise, procedures for freezing are as described above.

Freeze-drying. Most spore-forming fungi can be preserved by freeze-drying. Cultures to be stored by freeze-drying should be grown on agar or broth media to the point of maximum sporulation (1) and processed as described above. Survival in storage for many years has been demonstrated (6, 25), but this is true only for sporulating organisms. Young vegetative hyphae of fungi do not survive freeze-drying (27).

Viruses

Viruses tend to be more stable than other microorganisms because of their small size and simple structure and the absence of free water. Many viruses can be stored for months at refrigerator temperatures or for years by ultralow-temperature freezing or freeze-drying. Storage at −20°C is not recommended (15, 18). Larger viruses tend to be less stable than smaller ones (11).

Ultralow-temperature freezing is effective in a number of situations. In addition to cryoprotectants described above, sucrose-phosphate-glutamate containing 1% bovine albumin (SPGA) (15, 18) and hypertonic sucrose are particularly effective, the latter for storing labile viruses such as respiratory syncytial virus (19). If ultralow-temperature freezing is employed, the rate of freezing should be as high as possible, using small-volume suspensions (0.1 to 0.5 ml). In addition to freezing of pure isolates, stool specimens known to contain viral enteric pathogens have been maintained at −70 to −85°C for 6 to 10 years with reasonable recovery and no change in the morphological characteristics of astroviruses, small round structured viruses, enteric adenoviruses, rotaviruses, and caliciviruses (32).

Gallo et al. evaluated five types of media for the storage of human immunodeficiency virus-infected peripheral blood lymphocytes and concluded that freezing peripheral blood lymphocytes in RPMI 1640 containing 10% fetal bovine serum and 10% DMSO and storing them at −60°C is acceptable for human immunodeficiency virus isolation (9).

Freeze-drying is probably the optimum method for preserving viruses for extended periods. A detailed review of acceptable procedures has been published (11). Virus suspensions freeze-dried in medium supported with SPGA appear to survive better (15, 29). Lyophilization of polioviruses and other enteroviruses works best when electrolytes are removed by dialysis or ultrafiltration (15).

Select Agents

In response to the Public Health Security and Bioterrorism Preparedness and Response Act of 2002, federal regulations require laboratories that store select agents to register and comply with the standards established by the act (7). A current and complete list of microorganisms considered to be select agents can be found at www.cdc.gov/od/sap. Regardless of the method for long-term preservation, laboratories must register with the Department of Health and Human Services and Centers for Disease Control and Prevention Select Agent Program. In order to minimize risk to public health and safety, select agents must be stored in a highly secured area with restricted access and appropriate safeguards. Only registered individuals who have completed training for handling select agents can access and retrieve these microorganisms from storage. An accurate and current inventory of select agents held in long-term storage must be maintained.

Decontamination, Disinfection, and Sterilization

ANDREAS F. WIDMER AND RENO FREI

7

Decontamination, disinfection, and sterilization are basic components of any infection control program. Patients expect that any reusable instrument or device used for diagnosis or treatment has undergone a process to eliminate any risks for cross-infection. However, the infection control literature documents many reprocessing failures, including numerous reports of transmission of nosocomial pathogens from contaminated endoscopes (30, 102, 224, 231, 234). Before 1990, it was very difficult to prove a causal relationship between a contaminated device and a subsequent nosocomial infection. Today, state-of-the-art clinical epidemiology supported by molecular typing tools such as pulsed-field gel electrophoresis, PCR, and genome sequencing can enable the hospital epidemiologist to prove a causal relationship between the use of a contaminated device and a consequent infection. Molecular epidemiology has, thus, provided scientific tools that can identify the limitations of the available disinfection and sterilization methods and can provide the impetus to improve reprocessing technologies.

Despite those advances, little research has been done that will lead to major breakthroughs in disinfection and sterilization in the near future. Thus, we believe the key issues instead will be to standardize and optimize our applications of current knowledge. Clearly, more research is needed in this field, but resources for such work have been limited. In fact, most disinfectants were introduced to the market more than 20 years ago and little is known about their modes of action and the mechanisms of resistance. Excellent reviews on this topic are published by Block (34), by McDonnell and Russell (169), and by Russell et al. (200). In addition, few basic procedures in decontamination, disinfection, and sterilization have been tested in randomized clinical trials. In this chapter, we have tried to cite the highest level of evidence available. However, given the dearth of studies, we have often had to cite results of observational studies, animal models, in vitro tests, and expert opinion because higher levels of evidence are not available.

Despite the lack of resources, reprocessing techniques, disinfectants, and general infection control practices have garnered more attention recently than in the past. This is due in part to the increasing frequency of multiresistant bacterial pathogens at a time when pharmaceutical companies have shifted from developing antimicrobial agents to designing drugs for chronic diseases (261). Moreover, new pathogens, such as the viruses causing severe acute respiratory syndrome (SARS) and avian influenza (122) and the prions causing Creutzfeldt-Jakob disease (CJD), and variant CJD (vCJD), are emerging for which there are few if any treatments. Consequently, the medical community needs better knowledge on disinfection and sterilization to prevent the spread of these pathogens.

PRINCIPLES OF TERMINOLOGY, DEFINITIONS, AND CLASSIFICATION OF MEDICAL DEVICES

Background

There is no uniform terminology for disinfection and sterilization, and many problems arise as a result. Many terms are ill defined even within the United States and Europe. In addition, the testing procedures for disinfectants are not as far advanced and well defined as those for testing the MIC for an organism based on the recommendations of the Clinical and Laboratory Standards Institute (formerly NCCLS). However, there currently are efforts to standardize and harmonize the terminology on an international level. For example, International Organization for Standardization (ISO) norms for sterilization were published in 2004. Manufacturers now must provide specific data on how to reprocess their medical devices. In the past, such information was frequently missing in the users' manuals.

Classification of Devices for Reprocessing

Background

The principal goal of disinfection and sterilization is to reduce the numbers of microorganisms on a device to a level that is insufficient to transmit infectious organisms, with a considerable safety margin. The most conservative approach would be to reprocess all items and devices with overkill sterilization. Obviously, not all items must undergo the most vigorous process to eliminate any microorganisms. For example, items such as blood pressure cuffs that are used at nonsterile body sites do not need to be sterilized between patients. In contrast, only sterilization will eliminate any risk of infection from devices used in normally sterile body sites. In some cases, the best choice may be to use disposable items instead of reusable devices, because reprocessing may be more expensive or may not provide the desired level of

safety. The latter may apply to items in contact with the neural tissue of a patient suffering from any form of CJD or with tonsils and other lymphatic tissues of persons with bovine spongiform encephalopathy (BSE) or vCJD (26, 67, 260). Therefore, devices must be classified to allow staff to define the appropriate method for disinfection and/or sterilization for each item. A classification system should balance the potential risks for transmission of infection (e.g., the infectious dose) and the resources available to achieve the necessary or desired level of antimicrobial killing.

The most commonly used classification was proposed by Earle H. Spaulding in 1968 (232). He proposed three categories that are based on a device's potential for transmitting infectious agents: critical, semicritical, and noncritical (Table 1). The Centers for Disease Control and Prevention (CDC) cites this classification in its *Guidelines for Handwashing and Hospital Environment Control* (http://www.cdc.gov/mmwr/preview/mmwrhtml/rr5116a1.htm), and the U.S. Food and Drug Administration (FDA) cites it in its document *Content and Format of Premarket Notification [510(k)] Submissions for Liquid Chemical Sterilants and High-Level Disinfectants* (see http://www.fda.gov/cdrh/index.html). Most infection control professionals worldwide use this classification as well. However, this simple classification does not work perfectly for all devices. Even the definition of sterilization as the absence of any viable microorganisms must be revised to address the prions responsible for CJD and vCJD (187).

Critical Items

Items that enter normally sterile parts of the human body, such as surgical instruments, implants, and invasive monitoring devices (Table 1), are classified as "critical items." Because items classified as critical carry the highest risk for the patient, sterilization is the preferred method for reprocessing of these items. Autoclaving is the method of choice if the device is not heat labile. Alternative sterilization processes that use ethylene oxide or plasma require prolonged times, and the FDA has not approved them for use with instruments that have small, dead-end lumens, which are difficult to sterilize. Liquid sterilization with a glutaraldehyde-based formulation or peracetic acid is acceptable if sterilization by one of the methods mentioned above is not feasible and the formulation and/or automated device has been cleared by the FDA.

Semicritical Items

Semicritical objects come into contact with mucous membranes or nonintact skin and should be free of microorganisms except spores. Intact mucous membranes generally resist bacterial spores but are susceptible to other microorganisms such as vegetative bacteria (e.g., *Mycobacterium tuberculosis*) and viruses (e.g., human immunodeficiency virus [HIV] and cytomegalovirus). Examples of semicritical equipment include anesthesia equipment, respiratory equipment, and endoscopes. These items should be processed with a high-level disinfectant such as glutaraldehyde, stabilized hydrogen peroxide, peracetic acid, or a chlorine compound. Chlorine compounds corrode items and, therefore, are rarely used to disinfect medical devices.

Noncritical Items

Noncritical items, such as bedside tables, crutches, stethoscopes, furniture, and floors, come into contact with intact skin only. Intact skin is a very effective barrier against microorganisms, and therefore, these items and devices do not need to be sterilized. Such items pose a very low risk for direct transmission of pathogens and can usually be cleaned at the bedside or wherever they have been used with a low-level disinfectant. For example, health care workers can disinfect their stethoscopes by wiping the surfaces with alcohol. However, noncritical devices can contribute to the transmission of pathogens by the indirect route. For instance, up to 60% of cultures of the environments near patients colonized or infected with vancomycin-resistant enterococci are positive for this organism (56). Health care workers can contaminate their hands when they touch these surfaces. If they do not practice hand hygiene, they can spread these pathogens

TABLE 1 Spaulding classification of devices

Clinical device	Definition	Example	Infectious risk	Reprocessing procedure	
				FDA classification	EPA classification
Critical device	Medical device that is intended to enter a normally sterile environment, sterile tissue, or the vasculature	Surgical instruments	High	Sterilization by steam, plasma, or ethylene oxide; liquid sterilization acceptable if no other methods feasible	Sterilant or disinfectant
Semicritical device	Medical device that is intended to come in contact with mucous membranes or minor skin breaches	Flexible endoscope	High, intermediate	Sterilization desirable; high-level disinfection acceptable	Sterilant or disinfectant
Noncritical device	Medical device that comes in contact with intact skin	Blood pressure cuff, electrocardiogram electrodes	Low	Intermediate or low level	Hospital disinfectant with label claim for tuberculocidal activity
Medical equipment	Device or component of a device that does not typically come in direct contact with the patient	Examination table	Low	Low-level disinfection, use of sanitizer	Hospital disinfectant without label claim for tuberculocidal activity but with claim for virucidal activity against HIV

TABLE 2 Principles of medical device classification

Classification	FDA regulation	Premarket requirements by the FDA	Proposed classification by the Global Harmonization Task Force[a]	Examples
Class I	Least regulated, requires fewest regulations	None	A	Band-Aid, tongue depressor
Class II	Must meet federal performance standards	Premarket notification [510(k)]	B	Surgical gowns, drapes, scrub sponges
			C	Orthopedic implants
Class III	Implanted and life-supporting or life-sustaining devices are required to have FDA approval for safety and effectiveness	Premarket approval	D	Artificial hearts

[a] Details available at http://www.ghtf.org/sg1/inventorysg1/pd_sg1_n015r22.pdf.

to devices or directly to other patients. Therefore, noncritical items must be decontaminated if they are likely to be contaminated with pathogenic organisms.

The FDA also has developed a classification based on safety considerations and the regulations manufacturers must meet before marketing a device. Medical products are listed as class I to III products (Table 2). Simple products such as a tongue depressor are classified as class I medical products, which must meet very simple requirements before they can be marketed legally. Class II products, such as autoclaves, require premarket notification [510(k)] demonstrating that the device to be marketed is at least as safe and effective as a legally marketed device. Class III devices are those that support or sustain human life and are of substantial importance in preventing impairment of human health (e.g., a pacemaker). Due to the level of risk associated with class III devices, the FDA requires companies to file a premarket approval (PMA) application to obtain marketing clearance (section 515 of the Federal Food, Drug and Cosmetic Act). The PMA application must contain sufficient valid scientific evidence documenting that the device is safe and effective for its intended use (56).

DECONTAMINATION AND CLEANING

In Europe, decontamination basically means cleaning an item to remove organic material, protein, and fat. In the United States, the term describes a cleaning step and any additional step required to eliminate any risk of infection to health care workers while they handle a device without protective attire. The FDA defines the cleaning process as including all steps necessary to remove, inactivate, or contain contamination, beginning immediately after an item has been used for clinical purposes; continuing with the steps to decontaminate, clean, and package a device up to the first step of the sterilization process; and ending with quality control tests.

Regardless of regulations, cleaning is always the initial step of the decontamination process on both continents. In this chapter, we will use the term decontamination to describe the removal of debris, blood, and proteins and most microorganisms. This process usually, but not necessarily, renders the device "safe to handle" by health care workers who are not wearing protective attire. Basic definitions are outlined in Table 3.

The first step in reprocessing used medical devices is for health care workers to prevent debris from drying on the items. Research on prion diseases demonstrates that removal of debris is seriously impaired if the debris is allowed to dry on a medical device (87). Therefore, the reprocessing cycle should start as soon as possible and items should be kept wet if delays in reprocessing are anticipated (115, 179). Cleaning can be done physically or chemically; it can also be done by hand, by sonication, or by use of washers. In the United States, cleaning is frequently performed manually with water and a detergent. In Europe, many countries rely primarily on washers-disinfectors that rinse items with cold water and then with warm water plus a detergent. The cycle is completed with hot water at >90°C. Items such as bedpans and urinals can be cleaned and disinfected by putting the items into a machine, pushing a button, and removing them after a 2- to 5-min procedure.

All sterilization techniques other than steaming have been shown to fail in 1 to 40% of sterilization cycles if residual proteins and/or salts are not removed by a proper cleaning process (11). Even steam sterilization at 134°C for 18 min, recommended by the World Health Organization (WHO) to inactivate prions, can fail to prevent cross-transmission if the device does not undergo a cleaning process (87, 115, 179).

For floors, surfaces, and noncritical items, cleaning with a detergent is sufficient in most situations and a disinfection process contributes little if any additional effect (76). In addition, residual proteins and debris that escape the cleaning process may interfere with disinfectants and even cause them to lose activity (76). In the United States, routine disinfection of environmental surfaces in patient care areas is recommended as an additional safety precaution in case the environment is contaminated with unrecognized body fluids; in Europe, this practice is restricted to intensive care units and emergency rooms (227).

DISINFECTION

Disinfection is the second critical step in reprocessing of medical devices. To be effective, disinfection must be preceded by thorough cleaning and it must be done properly. Staff must check the disinfectant's concentration regularly if it is diluted at the place of use, even if it is diluted with an electronically monitored dilution device. Failures of the valve or other critical parts of the device can result in an insufficient final concentration, which usually cannot be detected by checking either the appearance or the odor of

TABLE 3 Definitions and terms

Term	Standard[a]	Technical-microbiological log CFU reduction	Comment
Sterilization	(Closely monitored) validated process used to render a product free of all forms of viable microorganisms, including all bacterial endospores	$\geq 10^6$ log CFU reduction of the most resistant spores for the sterilization process studied, achieved at the half-time of the regular cycle (ISO 14937)	Prions require an adapted definition because of their high resistance to any form of sterilization
Disinfection	Elimination of most if not all pathogenic microorganisms, excluding spores	No clear-cut defined reduction level; a minimum estimate is $\geq 10^3$ log CFU reduction of microorganisms, excluding spores; log unit reductions of 4 to 5 commonly achieved for devices; these are estimates, because there is no international standardization	Some high-level disinfectants achieve microbial reduction, including level of reduction of spores similar to sterilization, if long incubation times and/or temperatures of >25°C are applied; this is called liquid sterilization by sterilants
Decontamination	Reduction of pathogenic microorganisms to a level at which items are "safe to handle" without protective attire	Elimination of debris and proteins by cleaning and/or a disinfection or sterilization process; in Europe, the process is restricted to cleaning only, which achieves a minimum reduction of ≥1 log CFU; most cleaning processes achieve ≥ log CFU reductions of 3 to 5; these are estimates, because there is no international standardization	Manual and/or mechanical cleaning with water and detergents or enzymes is a prerequisite before disinfection or sterilization; in Europe, this term is used for cleaning of items; in the United States, it defines the process that makes an item "safe to handle"; it may include a cleaning process but also a disinfection or even a sterilization process; the U.S. term "decontamination" refers to the health care workers' safety; in Europe, the term is used for the item only
Antisepsis	Patient related: disinfection of living tissue or skin Health care worker related: reduction or removal of transient microbiological flora	Preoperative skin preparation with an alcohol-based iodine compound Hand washing: (scrub) reduction of ≥1 log CFU Hand disinfection (rub-in): reduction of ≥2.5 log CFU	Antiseptic agents are handled as drugs by the FDA

[a] Examples for standards are as follows: ethylene oxide sterilization (industrial facility use, ISO 11135; health care facility use, ANSI/AAMI ST 41) and moist-heat sterilization (industrial facility use, ISO 11134; health care facility use, ANSI/AAMI ST 46).

the disinfectant. Many manufacturers provide test strips to check for the appropriate concentration. Of note, numerous outbreaks have occurred when staff members have not followed appropriate protocols. For example, *Klebsiella oxytoca* caused an outbreak after an infection control committee allowed staff members to decrease the concentration of a glutaraldehyde-based surface disinfectant because they did not like the odor. The outbreak stopped after staff members resumed use of the disinfectant to the recommended concentration (190). An outbreak of 58 cases of *Mycobacterium xenopi* infection occurred when instruments used for discovertebral operations were rinsed with tap water after they were disinfected (22).

Principles and Antimicrobial Activities of Compounds

The antimicrobial spectrum of disinfectants varies. Low-level disinfectants destroy lipid-enveloped viruses such as HIV and most vegetative bacteria (Fig. 1) (35), but many disinfectants, including alcohol, are ineffective against nonlipid or small viruses such as poliovirus. For example, isopropyl alcohol has little activity against poliovirus, but >90% ethanol is very active (247). Intermediate-level disinfectants are effective against nonlipid or small viruses, such as poliovirus, and high-level disinfectants are effective against mycobacteria (Table 4).

The antimicrobial spectra of disinfectants are tested differently from those of antimicrobial agents. Microbiology laboratories that test disinfectants must know the special methods needed to accurately assess the activities of disinfectants. In fact, MICs are of little help because the goal of disinfection is to kill rather than inhibit the growth of microorganisms. In contrast to sterilization curves, killing curves for disinfectants are not linear and the rate of log killing decreases as the inoculum concentrations decrease (i.e., as the number of CFU per milliliter decreases). Therefore, a 3-log-unit killing is more easily achieved with disinfectants if the inoculum is large, e.g., 10^8 CFU, than if

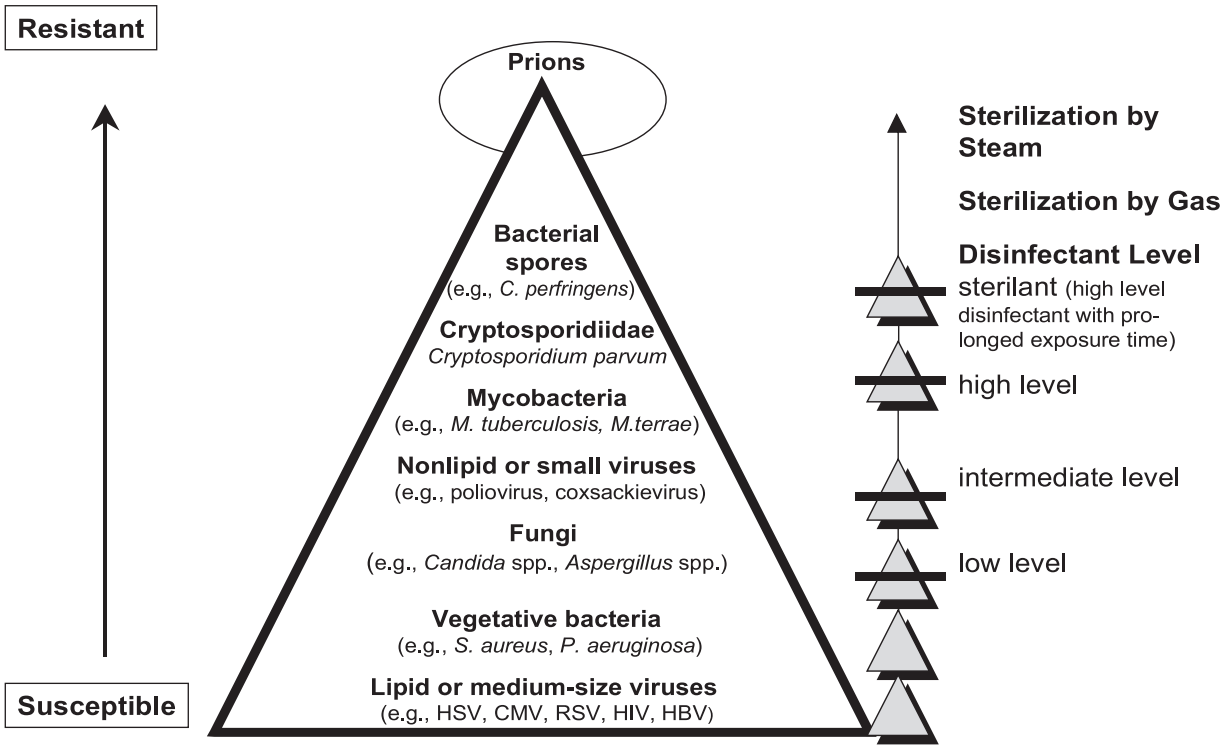

FIGURE 1 Microorganisms' resistance to disinfectants. HSV, herpes simplex virus; CMV, cytomegalovirus; RSV, respiratory syncytial virus; HBV, hepatitis B virus.

the inoculum is 10^4 CFU. Most disinfectants must be inactivated before they are incubated in media or plated because bacteria do not grow in the presence of very low concentrations of a disinfectant (inhibitory effect). However, if the compound is inactivated, bacterial growth can be demonstrated. Like antimicrobial agents, some disinfectants display a postexposure effect on bacterial growth. The postexposure effect has been quantified for a variety of disinfectants. Alcohols in general have little, if any, postexposure effect, but chlorhexidine, octenidine, and chloramine delay regrowth after exposure for several hours (35).

The FDA requires that the microbicidal efficacy of liquid chemical sterilants and high-level disinfectants be assessed in three different types of tests before these products can be legally marketed in the United States.

1. Potency testing incorporates the Environmental Protection Agency (EPA)'s test requirements for registration of germicides, such as the Association of Official Analytical Chemists' (AOAC) sporocidal test, tuberculocidal test, and use dilution tests for *Staphylococcus aureus* ATCC 6538, *Salmonella enterica* serovar Cholerasuis ATCC 10708, and *Pseudomonas aeruginosa;* EPA virucidal tests for viruses including poliovirus type 2 and herpes simplex virus; and FDA-recommended tests, such as total killing and end-point analysis and comparison of survivor and predicted curves. (Note that in Europe, disinfectants should have been tested by the methods defined by established or proposed European Norms [EN] such as EN 1040 [bactericidal activity] and EN 1275 [fungicidal activity]).

2. Simulated-use testing involves testing the disinfectant under artificially created worst-case scenarios to determine how long instruments need to be in contact with the disinfectant if cleaning failed and the instruments are still contaminated with substantial organic matter and microbes. The instruments are contaminated with an organic load and appropriate test microorganisms (the organism depends on the level of disinfection being claimed); the conditions of the artificially contaminated devices represent worst-case postcleaning conditions before exposure to the germicide.

3. "In-use" testing involves cleaning medical devices used for clinical purposes according to a facility's operating procedures.

As noted above, the FDA includes a tuberculocidal test in its test procedures. This test does not account for the effect of cleaning before devices are disinfected. Devices are treated with 2% horse serum (proteinaceous load) and with 10^5 to 10^6 CFU of *Mycobacterium terrae* or equivalent nontuberculous mycobacteria. Under these conditions, a device would need to be immersed in a disinfectant (e.g., 2.4% alkaline glutaraldehyde) for >45 min at >25°C for complete tuberculocidal killing. However, Rutala and Weber demonstrated that proper cleaning eradicates at least 4 log units of microorganisms (209), and Hanson et al. showed that cleaning bronchoscopes before disinfection removes all detectable contaminants, with an up to 8-log-unit reduction in the viral load (114). Therefore, Rutala and Weber recommend that the FDA accept a standardized cleaning protocol followed by a 20-min immersion at 20°C with an FDA-approved disinfectant as adequate to kill mycobacteria (209). The EPA maintains an updated list of registered low-level and intermediate-level disinfectants (http://www.epa.gov/oppad001/chemregindex.htm) and the FDA maintains a list of approved high-level disinfectants and sterilants (http://www.fda.gov/cdrh/ode/germlab.html) on their websites.

TABLE 4 Overview of common disinfectants[a]

Germicide(s)	Use dilution	Level of disinfection	Active against:						Important characteristics									Applications in hospitals
			Bacteria	Lipophilic viruses	Fungi	Small or hydrophilic viruses	*Mycobacterium tuberculosis*	Bacterial spores	Shelf life of >1 wk	Corrosive/ deleterious effect	Residue	Inactivated by organic matter	Skin irritant	Eye irritant	Respiratory irritant	Toxic	Environmental concerns	
Glutaraldehyde	2–3.2%	High/CS	+	+	+	+	+	+	+	−	+	−	+	+	+	+	−	Endoscopes
Hydrogen peroxide	3–25%	High/CS	+	+	+	+	+	±	+	±	−	±	+	+	−	+	−	Contact lenses
Chlorine	100–1,000 ppm free chlorine	High	+	+	+	+	+	±	+	+	+	+	+	+	+	+	±	Selected semicritical devices
Isopropyl alcohol	60–95%	Intermediate	+	+	+	±	+	−	+	±	−	±	±	+	−	+	−	Small-area surfaces
Glucoprotamine	1.5–4%	Intermediate	+	+	+	+	+	−	+	−	−	−	+	+	−	−	−	Diagnostic instruments
Phenolic compounds	0.4–5% aqueous	Intermediate	+	+	+	±	+	−	+	−	+	−	+	+	−	+	+	Surgical instruments
Iodophors	30–50 ppm free iodine	Intermediate	+	+	+	+	±	−	+	±	+	+	±	+	−	+	−	Medical equipment
Quaternary ammonium compounds	0.4–1.6% aqueous	Low	±	+	±	−	−	−	+	−	+	+	+	+	−	+	−	Disinfection in food preparation areas and floors

[a] Data from references 34, 89, 201, and 247 and from the *Laboratory Biosafety Manual*, World Health Organization, Geneva, Switzerland, 1983 (268a). Abbreviations: CS, chemical sterilant; +, yes; −, no; ±, variable results. Efficacy of the disinfectants is based on an exposure time of less than 30 min at room temperature. Spores require prolonged exposure times (up to 10 h) unless used with a washer-disinfector at higher temperatures.

Definitions and Terms (Adapted from FDA and EPA Definitions)

Since the FDA regulates the most critical part of disinfection and sterilization, FDA definitions are used throughout the chapter unless stated otherwise. The most important definitions are given in Table 5.

Guidelines for Choosing a Disinfectant

Rutala published guidelines for the selection and use of disinfectants and recommendations on the preferred method for disinfection and sterilization of patient care items (62, 201, 202). The CDC recently issued guidelines for environmental infection control in health care facilities including recommendations for cleaning and disinfection (227).

When choosing a disinfectant, staff members should review its effectiveness against the expected spectra of pathogens (Tables 4 and 5) to ensure that it is adequate for the intended purpose. In addition, the staff must ensure that the disinfectant is compatible with the devices it is intended to disinfect and that devices that are immersed longer than recommended will not be damaged. The latter factor is important because staff members may forget to remove instruments (e.g., during weekends or night shifts). Prolonged exposure to a disinfectant may damage the instrument. Staff members should also consider the toxicity, odor, compatibility with other compounds, and residual activity of disinfectants (Table 6). It is prudent to contact colleagues already using a disinfectant before introducing it in a health care facility. The experience of health care professionals at different institutions can be helpful, allowing the staff to learn about problems such as interactions with detergents, unexpected coloring and odors, and employees' responses to the change. We have found that employees often complain bitterly after a disinfectant has been changed. Moreover, a new disinfectant used on environmental surfaces may interact with those used in the past and temporarily release unpleasant odors. Written infection control standards describing how to care for environmental surfaces can help staff members avoid combining incompatibile equipment and disinfectants. Once staff members have identified a product that meets a facility's needs, only strong evidence from good studies should lead a facility to replace it with a new product (e.g., one that has improved activity or works faster).

Disinfection by Heat Versus Immersion in Germicides

Disinfection by heat has become much more common than in the past and has replaced disinfection with germicides for many applications in European health care facilities, including our institution, the University Hospital Basel, Basel, Switzerland (225). The advantages of these devices are obvious: (i) the processes are automated and are monitored and documented in a manner similar to that for sterilization, (ii) microogranisms have not developed resistance to the processes, and (iii) the cost per load is probably less than that for germicides. In addition, studies by Gurevich et al. (111) indicate that pasteurization with a germicide is more effective than pasteurization without a germicide. However, washers include a cleaning process with an average reduction of 4 log units, coupled with heat disinfection (5-log-unit killing; washer-disinfectors such as the AMSCO Reliance 430 achieve an inactivation factor of >5 log units [111, 139]), resulting in a total reduction of 8 to 9 log units. This surpasses any international requirements for high-level disinfection.

Thermal disinfection has several disadvantages. First, the cost to purchase and install the equipment is much higher than that for systems using a germicide. Second, considerable power is needed to heat the water. Third, some nonspore-forming microorganisms such as enterococci resist temperatures of up to 71°C for 10 min. Thus, recommendations such as those in the United Kingdom (the Department of Health requires 65°C for 10 min, 71°C for 3 min, or 80°C for 1 min) may not be adequate for these organisms (43).

Medical washer-disinfectors that are intended to clean, low- and intermediate-level disinfectants, and dry surgical instruments, anesthesia equipment, hollowware, and other medical devices are exempt from the premarket notification procedures described by FDA in subpart E of part 807 of the chapter subject to §880.9. The ISO provided standards for these processes in preapproval ISO norm 15883 (prEN ISO 15883), which defines the standards for disinfection of washer-disinfectors by heat with and without the addition of disinfectants (http://www.iso.org). The ISO has not defined a temperature at which these devices must work but rather allows manufacturers to choose a temperature in a given range at which their devices should operate.

In the United States, hot-water pasteurization is generally performed at 77°C for 30 min (36), but few scientific data

TABLE 5 FDA and EPA definitions of important terms

Term	Definition
Germicide	Agent that destroys microorganisms; the prefixes of terms with the suffix "-cide" (e.g., virucide, fungicide, bactericide, sporicide, and tuberculocide) indicate which microorganisms the germicide kills
Sterilant (chemical)	Chemical germicide that achieves sterilization
High-level disinfectant	Germicide that when used according to the labeling kills all microbial pathogens except large numbers of bacterial endospores
Intermediate-level disinfectant	Germicide that when used according to the labeling kills all microbial pathogens except bacterial endospores
Low-level disinfectant	Germicide that when used according to the labeling kills most vegetative bacteria and lipid-enveloped and medium-size viruses; such disinfectants are regulated by the EPA
Minimum effective concentration	Minimum effective concentration of a liquid chemical germicide that achieves the microbicidal activity claimed by the manufacturer
Cleaning (or precleaning)	Removal of foreign material (e.g., organic or inorganic contaminants) from medical devices as part of a decontamination process

TABLE 6 Overview of common antiseptic compounds[a]

Compound(s)	Antiseptic effect on[b]:					Rapidity of action	Residual activity[b]	Typical concn(s) (%)	Affected by organic matter	Safety for humans
	Gram-positive bacteria	Gram-negative bacteria	Viruses	Fungi	*Mycobacterium tuberculosis*					
Alcohols	+++	+++	++[c]	+++	+++	15–30 s	None	70–95	?[e]	Drying, flammable
Chlorhexidine	+++	++	++	+	++	Min	+++	4, 2, 0.5 in alcohol	Minimally	Leads to ototoxicity and keratitis
Iodophors	+++	++	++	++	++	Min	+	10, 7.5, 2, 0.5	Yes	Causes skin irritation
Octenidine[d]	+++	+++	++	++	++	Min	+++	0.1	Minimally	Limited data on safety
PCMX	++	+	+	+	+	Min	++	0.5–3.75	Minimally	Appears to be safe

support the use of a particular temperature. prEN ISO 15883 introduces the A_0 concept, which is based on the fact that a defined temperature will generate a predictable lethality effect against microorganisms. Corresponding exposure temperatures and time periods that achieve high-level disinfection can be calculated by assuming the presence of particularly heat-resistant microorganisms in numbers in excess of those likely to be encountered on the medical devices to be processed. prEN ISO 15883 introduces the term A_0 for moist-heat disinfection (thermal disinfection). The A_0 value of a moist-heat disinfection process denotes the lethality effects expressed in terms of the equivalent time in seconds at a temperature of 80°C delivered by the process to the medical device with reference to microorganisms possessing a z value of 10. Given a predefined A_0, equivalent killing of microorganisms is achieved if the following formula is followed: $A_0 = \sum 10^{(80-T)/Z}\Delta t$, where T is temperature in Celsius and t is time in seconds. An A_0 value of 600, which can be achieved at 80°C over 10 min, 90°C over 1 min, or 70°C over 100 min, is the minimum requirement for noncritical medical devices (273, 274). An A_0 value of at least 3,000, which can be achieved by exposure to hot water (e.g., at 90°C; the medical device must tolerate this temperature for >5 min), must be employed for medical devices contaminated with heat-resistant viruses such as rotavirus and hepatitis B virus. An A_0 value of at least 3,000 is also appropriate for high-level disinfection of all semicritical devices. The test procedure based on the A_0 concept has been highly reproducible and found to be suitable to test washer-disinfectors (273, 274).

Overview of Commonly Used Disinfectants for Devices

Glutaraldehyde

Among aldehydes that exhibit biocidal activity, including glyoxal, *ortho*-phthalaldehyde (OPA), succinaldehyde, and benzaldehydes, glutaraldehyde and formaldehyde are the most extensively studied aldehydes. In-depth reviews may be found elsewhere (21, 198, 201). Glutaraldehyde is the predominant commercially available aldehyde. Because it has potent and broad-spectrum microbiocidal activity and is compatible with many materials (including metal, rubber, and plastic), glutaraldehyde is often regarded as the high-level disinfectant and chemical sterilant of choice in many health care facilities. Glutaraldehyde-based formulations are most commonly used for high-level disinfection of medical equipment such as endoscopes, transducers, dialysis systems, and anesthesia and respiratory therapy equipment (201).

The mechanism of action is complex and is related to the alkylation of sulfhydryl, hydroxyl, carboxy, and amino groups in the cell wall, cell membrane, nucleic acids, enzymes, and other proteins of microorganisms. The biocidal activities of glutaraldehyde solutions are dependent on a variety of variables, such as pH, temperature, concentration at the time of use, the presence of inorganic ions, and the age of the solution (21). Aqueous solutions of glutaraldehyde are usually acidic and are not sporicidal in this form. Therefore, they need to be activated by adding an alkalinizing agent. These activated solutions, however, rapidly lose their activity because glutaraldehyde molecules polymerize at an alkaline pH. Therefore, the shelf life of such solutions is limited to 14 days unless the manufacturer recommends otherwise. To overcome this problem, some manufacturers have developed novel formulations with longer shelf lives (e.g., activated dialdehyde solutions containing 2.4 to 3.5% glutaraldehyde with a maximum reuse life of 28 days).

The activities of disinfectants increase as the temperature rises. Among eight disinfectants tested, glutaraldehyde was found to be the chemical most strongly affected by temperature (99). Some stable acid glutaraldehydes may be used at temperatures of 35 to 55°C at concentrations below 2%. Glutaraldehyde retains its activity in the presence of organic matter.

A standard 2% aqueous solution of glutaraldehyde buffered to pH 7.5 to 8.5 is bactericidal, tuberculocidal, sporicidal, fungicidal, and virucidal. It rapidly kills both gram-negative and gram-positive vegetative bacteria. Longer exposure times are required to inactivate spores and mycobacteria. Spores of *Bacillus* and *Clostridium* spp. are generally destroyed by 2% glutaraldehyde in 3 h, whereas spores of *Clostridium difficile* are eliminated more rapidly (206). In contrast, *Cryptosporidium parvum* oocysts remain viable and infectious after 10 h in a 2.5% glutaraldehyde solution (268). Several investigators have questioned glutaraldehyde's ability to inactivate mycobacteria. For example, Rubbo et al. (197) demonstrated that glutaraldehyde inactivates *Mycobacterium tuberculosis* more slowly than alcohols, formaldehyde, iodine, and phenol. Ascenzi (21) showed in the quantitative suspension test that 2% glutaraldehyde kills only 2 to 3 log units of *Mycobacterium tuberculosis* in 20 min at 20°C. Similarly, Collins (66) reported that glutaraldehyde cannot completely inactivate a standardized suspension of *Mycobacterium tuberculosis* within 10 min. Nontuberculous mycobacteria such as *Mycobacterium avium*, *Mycobacterium intracellulare*, and *Mycobacterium gordonae* are more resistant to inactivation than *Mycobacterium tuberculosis* (65). These and other data suggest that 20 min (at 20°C) is the minimum exposure time needed to reliably inactivate tuberculous and nontuberculous mycobacteria by using 2% glutaraldehyde, provided that the contaminated item has been thoroughly cleaned before disinfection (131, 201). Glutaraldehyde-resistant mycobacteria have been isolated from endoscope washers-disinfectors (107, 251) (see "Endoscopes" below).

The virucidal activity of glutaraldehyde extends to the nonenveloped (hydrophilic) viruses, which are generally more resistant to disinfectants than are the enveloped (lipophilic) viruses. Numerous viruses were documented to be inactivated, including HIV, hepatitis A virus, hepatitis B virus, poliovirus type 1, coxsackievirus type B, yellow fever virus, and rotavirus (21, 141).

Disadvantages of glutaraldehyde include the fact that it coagulates blood and can fix proteins and tissue to surfaces (167, 201). In addition, glutaraldehyde has a pungent and irritating odor and its vapor at the level of 0.2 ppm irritates the eyes, throat, and nose. Health care workers exposed to glutaraldehyde can develop allergic contact dermatitis, asthma, rhinitis, and epistaxis. Measures that may minimize employee exposure include covering immersion baths with tight-fitting lids, improving ventilation, and using ducted exhaust hoods or ductless fume hoods with vapor absorbents, personal protective equipment, and appropriate automated machines for endoscope disinfection (12, 201). Due to dilution, glutaraldehyde concentrations commonly decline during use in manual and automatic baths used for endoscopes (167). Test strips should be used to ensure that the glutaraldehyde concentration has not fallen below 1 to 1.5%. Equipment disinfected with glutaraldehyde and rinsed inadequately has caused serious clinical complications including proctocolitis (colonoscopes; 79, 262); and keratopathy (ophthalmic instruments; 48). Because the infectivity of prions can be stabilized when instruments are treated with formaldehyde before they are autoclaved (48), aldehydes are no longer recommended for disinfecting endoscopes in some European countries (e.g., France; see "Bovine Spongiform Encephalopathy and Variant Creutzfeldt-Jakob Disease" below).

ortho-Phthalaldehyde

The 0.55% OPA solution has been approved as a high-level disinfectant by the FDA and by agencies in other countries. However, different countries or areas have set different exposure times for a 0.55% solution of OPA at 20°C to achieve high-level disinfection: 12 min in the United States, 10 min in Canada, and 5 min in Europe, Asia, and Latin America.

Compared with glutaraldehyde, OPA has several advantages: (i) it does not require activation, (ii) it is compatible with many materials (i.e., similar to glutaraldehyde), (iii) it is more stable during storage and can be reused as well at a pH range as wide as 3 to 9, (iv) it has low vapor properties, (v) its odor is barely perceptible, and (vi) it is more rapidly mycobactericidal than glutaraldehyde in vitro and has good activity against glutaraldehyde-resistant strains at longer exposure times (93). However, 0.5% OPA is slowly sporicidal and does not inactivate all spores within 270 min of exposure (255). In addition, OPA stains proteins, skin, clothing, and instruments. OPA vapors may irritate the respiratory tract and eyes. At present, the effects of long-term exposure and safe exposure levels are not well defined. Therefore, OPA must be handled with appropriate safety precautions (i.e., by using gloves, fluid-resistant gowns, and eye protection) and it must be stored in containers with tight-fitting lids.

If additional studies corroborate OPA's advantages, this compound may replace glutaraldehyde for many uses, especially endoscope disinfection. The new agent appears to be particularly useful in washer-disinfectors, where glutaraldehyde-resistant mycobacteria have emerged (251, 255).

Formaldehyde

Formaldehyde and its condensates are reviewed in depth elsewhere (192). Formaldehyde in aqueous solutions or as a gas has been used as a disinfectant and sterilant for many decades. Its use in the health care setting, however, has sharply decreased for several reasons. The irritating vapors and pungent odor produced by formaldehyde are apparent at very low levels (<1 ppm). In addition, allergy to formaldehyde is fairly common. Moreover, the Occupational Safety and Health Administration in the United States and the Health and Safety Executive of the United Kingdom indicated that formaldehyde vapors may be carcinogenic. Thus, the Occupational Safety and Health Administration limits the 8-h time-weighted average exposure in the workplace to a concentration of 0.75 ppm. Elevated levels of occupational exposures have been found among workers in dialysis units and gross anatomy laboratories (8). Consequently, formaldehyde and formaldehyde-releasing agents are used infrequently in health care institutions, despite this agent's broad-spectrum microbicidal activity. In fact, formaldehyde has been largely replaced by peracetic acid as an agent for disinfecting hemodialysis equipment and water dialysate tubing systems. Paraformaldehyde vaporized by heat is used to decontaminate biological safety cabinets.

Chlorine and Chlorine-Releasing Compounds

Due to its hazardous nature, chlorine gas is rarely used as a disinfectant. Among the large number of chlorine compounds commercially available, hypochlorites are the most

widely used disinfectants. Hypochlorite has been used for more than a century and remains an important disinfectant. Rutala and Weber published an extensive review of uses for inorganic hypochlorite in health care facilities (210), and Karol reviewed the potential hazards and significant benefits of chlorine use (139).

Aqueous solutions of sodium hypochlorite are usually called household bleach. Bleach commonly contains 5.25% sodium hypochlorite, or 52,500 ppm of available chlorine; a 1:10 dilution of bleach provides about 300 to 600 mg of free chlorine per liter. Alternative chlorine-releasing compounds frequently used in health care facilities include chloramine-T, sodium dichloroisocyanurate tablets, and chlorine dioxide. Demand-release chlorine dioxide is an extremely reactive compound and must be prepared at the point of use. It is used primarily to chlorinate potable water, swimming pools, and wastewater. In Europe, commercial chlorine dioxide preparations are available to disinfect instruments.

In aqueous solutions, all chlorine compounds release hypochlorous acid, the most likely active compound. The mechanism of microbicidal action of hypochlorous acid has not been fully elucidated, but it inhibits key enzymatic reactions within cells and denaturates proteins. Lowering the pH or raising the temperature or concentration increases its antimicrobial efficacy. Chlorine compounds have broad antimicrobial spectra including, at higher concentrations, bacterial spores and *Mycobacterium tuberculosis*. Therefore, hypochlorite can be used as a high-level disinfectant for semicritical items.

Concentrations of 100 ppm of available chlorine inactivate vegetative bacteria and viruses in 10 min. Suspension tests document that both enveloped and nonenveloped viruses, including HIV, hepatitis A and B viruses, herpes simplex virus types 1 and 2, poliovirus, coxsackievirus, and rotavirus, are inactivated (210). In one study, a concentration of 100 ppm of chlorine eliminated 99.9% of *Bacillus subtilis* endospores in 5 min (267). However, endospore-forming bacteria, mycobacteria, fungi, and protozoa usually are less susceptible to chlorine than other microorganisms, and high concentrations of chlorine (1,000 ppm) are required to completely destroy them. Despite this limitation, sodium hypochlorite solutions (500 and 1,600 ppm) have been reported to decrease *Clostridium difficile* environmental contamination and to terminate an outbreak of infections caused by this organism (134). *Cryptosporidium* oocysts are particularly resistant to chlorine. These oocysts remain infective for several days in swimming pool water containing recommended chlorine concentrations; because of their small size, they may not be removed efficiently by conventional pool filters. Outbreaks of *Cryptosporidium* infections have been associated with drinking water and swimming pools (16). Of note, chloramine-T and sodium dichloroisocyanurate seem to have lower sporicidal activities than does sodium hypochlorite.

Hypochlorite is fast acting, nonstaining, nonflammable, and inexpensive. However, its use is limited because it is corrosive, inactivated by organic matter, and relatively instable. Sodium hypochlorite can injure tissues; however, such injury occurs rarely in health care facilities (210). Inhalation of chlorine gas may irritate the respiratory tract, resulting in a cough, dyspnea, and pulmonary edema or chemical pneumonitis. The potential carcinogens trihalomethanes have been detected in chlorine-treated water, and high levels of trihalomethanes can be detected when hospitals hyperchlorinate their water systems (118).

Chlorine compounds have other important disadvantages. Blood or other organic matter substantially inactivates hypochlorites and other chlorine compounds. Consequently, items used for patient care and environmental surfaces must be cleaned before hypochlorite is used. In addition, the presence of a biofilm (e.g., in the pipes of a water distribution system) also reduces the efficacy of chlorines significantly. Moreover, the free available chlorine levels in solutions can decay to 40 to 50% of the original concentration after the container has been opened for one month. Therefore, concentrations higher than those established in laboratory experiments should be used in practice. Loss of free chlorine can be minimized if the solutions are dilute and alkaline, kept and used at room temperature, and stored in closed opaque containers.

Depending on the concentrations employed, sodium hypochlorite is used in hospitals as a high-level disinfectant for selected semicritical devices (e.g., dental equipment and mannequins used for cardiopulmonary resuscitation training), as an intermediate-level disinfectant (e.g., hemodialysis equipment), and as a low-level disinfectant for environmental surfaces and hydrotherapy tanks. For example, the CDC recommends that health care workers use a 1:100 dilution (5,000 ppm) of hypochlorite to decontaminate spills of blood and certain other body fluids (53). Because chlorine can be inactivated by blood and other organic material, a full-strength solution or a 1:10 dilution will be safer unless the surface is cleaned before it is disinfected (62, 88, 258). Household bleach also can be used to disinfect table tops and incubators, to clean spills in laboratories, or to disinfect syringes used by drug addicts if sterile disposable syringes are not available (54).

At low concentrations, chlorines (usually about 0.5 ppm of free chlorine) are used to chlorinate the drinking water. Hyperchlorination of institutional water systems has controlled epidemics caused by *Legionella pneumophila* (118) but also corrodes the water distribution system (118). Stabilized solutions of chlorine dioxide appear to be less toxic and more efficacious than chlorine for controlling growth of legionellae (113). A growing number of municipal water treatment plants in the United States are using monochloramine as a residual disinfectant. Chloramination of drinking water has several advantages over the use of free chlorine, including decreasing the risk of Legionnaires' disease at the municipal level or in individual hospitals (144). However, outbreaks of *Cryptosporidium* infections have occurred in cities that use chloramines in their drinking water.

Hydrogen Peroxide

Hydrogen peroxide, a strong oxidizer, is used for high-level disinfection and sterilization. It produces destructive hydroxyl free radicals that attack membrane lipids, DNA, and other essential cell components. Although the catalase produced by anaerobic and some aerobic bacteria may protect cells from hydrogen peroxide, this defense is overwhelmed by the concentrations used for disinfection (154). Generally, a 3% hydrogen peroxide solution is rapidly bactericidal, but it kills organisms with high cellular catalase activity (e.g., *Staphylococcus aureus* and *Serratia marcescens*) less rapidly. Surprisingly, 3% hydrogen peroxide was ineffective against vancomycin-resistant enterococci (164, 223).

Spores are more resistant than vegetative bacteria to hydrogen peroxide. For example, a 3% solution of hydrogen peroxide destroyed 10^6 spores in six of seven exposure trials that were 150 min long; a 10% solution always was successful in 60 min (257). Higher concentrations of hydrogen peroxide (17.7 and 35.4%) killed *Bacillus subtilis* spores in 9.4 and 2.3 min, respectively (152). In a recent investigation,

10% hydrogen peroxide was the most active of the seven chemical disinfectants tested against *Bacillus subtilis* spores (218). However, other investigators found that the sporicidal activity of hydrogen peroxide was lower than those of peracetic acid and chlorine (10). Hydrogen peroxide's sporocidal activity can be enhanced by increasing the concentration or the temperature or by using it in conjunction with ultrasonic energy, ultraviolet radiation, and some chemical agents such as peracetic acid (162, 170, 247).

A 0.3% solution of hydrogen peroxide inactivates HIV in 10 min (162), and a 3% concentration inactivates rhinovirus in 6 to 8 min at 37°C (170). However, a 6% solution did not inactivate poliovirus at 1 min (247).

Hydrogen peroxide does not coagulate blood and does not fix tissues to surfaces. In fact, it may enhance removal of organic material from equipment. Hydrogen peroxide has a low toxicity for humans. It decomposes into oxygen and water, and therefore, it is environmentally safe. It is neither carcinogenic nor mutagenic. Concentrated solutions may irritate the eyes, skin, and mucous membranes. Hydrogen peroxide can be destroyed easily by heat or enzymes (catalase and peroxidases). Stabilized solutions can be used for high-level disinfection of semicritical items. However, one must consider the corrosive effects of hydrogen peroxide on copper, zinc, and brass in using this disinfectant (201). The FDA has approved commercial products containing either 7.5% hydrogen peroxide alone or combinations with peracetic acid as liquid sterilants and high-level disinfectants for processing of reusable medical and dental devices (http://www.fda.gov). Concentrations of 3 to 6% are used to disinfect ventilators, soft contact lenses (3% for 2 to 4 h) (125), and tonometer biprisms (153, 154, 201). Vaporized hydrogen peroxide is also used for plasma sterilization (see below).

Despite its limited toxicity, hydrogen peroxide can damage human tissues. Patients exposed to endoscopes contaminated by residual hydrogen peroxide have developed pseudomembrane-like enterocolitis (pseudolipomatosis) (216). In addition, patients who were exposed to tonometer tips disinfected with hydrogen peroxide and rinsed improperly suffered corneal damage (153). Use of hydrogen peroxide to clean wounds and to develop dental regimens remains controversial (154).

Peracetic Acid

Peracetic acid (or peroxyacetic acid) is a more potent germicidal agent than hydrogen peroxide and was the most active agent in several in vitro studies (9, 219). Concentrations of $<1\%$ are sporicidal even at low temperatures. The mechanism of action of peracetic acid has not been fully elucidated, but it is likely to be similar to that of hydrogen peroxide and other oxidizing agents. Peracetic acid remains effective in the presence of organic matter. At low concentrations it is considerably less stable than hydrogen peroxide; preparations with appropriate stabilities have been developed and are commercially available. Peracetic acid corrodes steel, galvanized iron, copper, brass, and bronze, and it attacks natural and synthetic rubbers. In addition, concentrated solutions can seriously damage eyes and skin. Furthermore, some investigators have raised concerns about the potential toxicity of the combination of peracetic and acetic acids (117). Feldman et al. reported that mortality rates in freestanding dialysis facilities that reprocess dialyzers with peracetic and acetic acid are higher than those in facilities that discard dialysis filters or used formaldehyde for reprocessing (86). To date, investigators have not determined whether the higher death rate is caused by the disinfectants or is associated with other practices at the facilities or with patient risk factors.

Nevertheless, because peracetic acid has powerful germicidal activity and does not produce toxic residues, peracetic acid is very attractive for use in health care settings, most frequently in combination with hydrogen peroxide to disinfect hemodialyzers. The FDA lists several commercial products containing a combination of peracetic acid and hydrogen peroxide as high-level disinfectants and chemical sterilants. The use of peracetic acid for chemical sterilization of instruments and endoscopes (STERIS System 1) is discussed below.

Alcohols

For centuries, the alcohols have been appreciated for their antimicrobial properties. Alcohol is defined by the FDA as having one of the following active ingredients: ethyl alcohol, 60 to 95% by volume in an aqueous solution, or isopropyl alcohol, 50 to 91.3% by volume in an aqueous solution. Ethyl alcohol (ethanol) and isopropyl alcohol (isopropanol) are the alcoholic solutions most often used as surface disinfectants and antiseptic agents in health care institutions because they possess many qualities that make them suitable both for disinfection of equipment and for antisepsis of skin. They are fast acting, minimally toxic to the skin, nonstaining, and nonallergenic. Alcohols evaporate readily, which is advantageous for most disinfection and antisepsis procedures. The uptake of alcohol by intact skin and the lungs when alcohol is used topically is negligible. Alcohols have better wetting properties than water due to their lower surface tensions, which along with their cleansing and degreasing actions make alcohols effective skin antiseptics. Alcoholic formulations used to prepare the skin before invasive procedures should be filtered to ensure that they are free of spores, or 0.5% hydrogen peroxide should be added (193). Alcohols are also excellent products for intermediate-level and low-level disinfection of small, clean surfaces, equipment, and the environment (e.g., rubber stoppers of medication vials, stethoscopes, and medication preparation areas).

Alcohols have some disadvantages. If alcoholic antiseptics are used repeatedly, they may dry and irritate the skin. Therefore, preparations for hand disinfection should contain emollients (see "Hygienic Hand Disinfection" below). Moreover, alcohols may damage rubber, certain plastic items, and the shellac mountings of lensed instruments after prolonged and repeated use (201). Moreover, alcohols are flammable (one should consider the flash point) and, thus, must not be used on large surfaces, particularly in closed, poorly ventilated areas. Alcohols cannot penetrate protein-rich materials. Therefore, a spray or a wipe with alcohol may not disinfect a surface contaminated with blood or other body fluids that has not been cleaned first.

The exact mechanism by which alcohols destroy microorganisms is not fully understood. The most plausible explanation for the antimicrobial action is that they coagulate (denaturate) proteins (e.g., enzymatic proteins), impairing specific cellular functions (150). Ethyl and isopropyl alcohols at appropriate concentrations have broad spectra of antimicrobial activities that include vegetative bacteria, fungi, and viruses. In fact, their antimicrobial efficacies are enhanced in the presence of water, with optimal alcohol concentrations being 60 to 90% by volume.

Alcohols (i.e., 70 to 80% ethyl alcohol) rapidly (i.e., 10 to 90 s) kill vegetative bacteria, such as *Staphylococcus aureus*, *Streptococcus pyogenes*, *Enterobacteriaceae*, and *Pseudomonas aeruginosa,* in suspension tests (193). Isopropyl alcohol is

slightly more bactericidal than ethyl alcohol (150) and is highly effective against vancomycin-resistant enterococci (223). It also has excellent activity against fungi, such as *Candida* spp., *Cryptococcus neoformans*, *Blastomyces dermatitidis*, *Coccidioides immitis*, *Histoplasma capsulatum*, *Aspergillus niger*, and dermatophytes and mycobacteria, including *Mycobacterium tuberculosis*. However, alcohols generally do not destroy bacterial spores. In fact, fatal infections due to *Clostridium* spp. occurred when alcohol was used to sterilize surgical instruments.

Both ethyl and isopropyl alcohols inactivate most viruses with a lipid envelope (e.g., influenza virus, herpes simplex virus, and adenovirus). However, several investigators found that isopropyl alcohol has lower virucidal activity against naked, nonenveloped viruses (201). In the experiments by Klein and DeForest, 2-propanol, even at 95%, could not inactivate the nonenveloped poliovirus type 1 and coxsackievirus type B in 10 min (141). In contrast, 70% ethanol inactivated these enteroviruses (141). Neither 70% ethanol nor 45% 2-propanol killed hepatitis A virus when their activities were assessed on stainless steel disks contaminated with fecally suspended virus. Among 20 disinfectants tested, only 3 reduced the titer of hepatitis A virus by greater than 99.9% in 1 min (2% glutaraldehyde, sodium hypochlorite with >5,000 ppm of free chlorine, and a quaternary ammonium formulation containing 23% HCl) (166). Bond et al. (35) and Kobayashi et al. (143) demonstrated that 2-propanol (70% for 10 min) or ethanol (80% for 2 min) made human plasma contaminated with hepatitis B virus at high titer noninfectious for susceptible chimpanzees (143). Both 15% ethyl alcohol and 35% isopropyl alcohol (162) readily inactivate HIV, and 70% ethanol rapidly inactivates high titers of HIV in suspension, independent of the protein load. However, the rate of inactivation decreased when virus was dried onto a glass surface and high levels of protein were present (249). In a suspension test, 40% propanol reduced the rotavirus titer by at least 4 logs in 1 min (147) and both 70% propanol and 70% ethanol reduced the release of rotavirus from contaminated fingertips by 2.7 log units. In comparison, the mean reductions obtained with liquid soap and an aqueous solution of chlorhexidine gluconate were 0.9 and 0.7 log units, respectively (17).

Phenolics

Since Lister's pioneering use of phenol (carbolic acid) as an antiseptic, a large number of phenol derivatives (or phenolics) have been developed and marketed. Phenol derivatives originate when one of the hydrogen atoms on an aromatic ring is replaced by a functional group (e.g., an alkyl-, benzyl-, phenyl-, amyl-, or chlorogroup). The three phenolics most commonly used as constituents of disinfectants are *o*-phenylphenol, *o*-benzyl-*p*-chlorophenol, and *p-tert*-amylphenol. The addition of detergents to the basic formulation results in products that clean, dissolve proteins, and disinfect in one step. Phenolics at higher concentrations act as gross protoplasmic poisons, penetrating and disrupting the bacterial cell wall and precipitating the cell proteins (180). Lower concentrations of these compounds inactivate cellular enzyme systems and cause essential metabolites to leak from the cell.

Phenol compounds at concentrations of 2 to 5% are generally considered bactericidal, tuberculocidal, fungicidal, and virucidal against lipophilic viruses (180). However, the manufacturers' efficacy claims have generally not been verified by independent laboratories or the EPA (201). A collaborative study by Rutala and Cole documented that randomly selected EPA-registered phenolic detergents or quaternary ammonium compounds do not consistently meet the manufacturers' bactericidal label claims (203). Phenolics tested by the AOAC use dilution method at the recommended use dilution failed to kill *Pseudomonas aeruginosa* in 33 to 78% of laboratories. However, extreme variability of test results has been observed among laboratories testing identical products (203).

Phenolics at in-use dilutions are not lethal to bacterial spores. Terleckyi and Axler found that a 2% phenolic kills a wide spectrum of clinically important fungi except *Aspergillus fumigatus* (242). Although 5% phenol inactivated both lipophilic and hydrophilic viruses, Klein and DeForest found that 12% *o*-phenylphenol was effective only against lipophilic viruses (141). Similarly, other investigators demonstrated little or no virucidal effect of a phenolic against coxsackievirus type B4, echovirus type 11, or poliovirus type 1 (178). Martin et al. showed that a 0.5% commercial phenolic formulation (2.8% *o*-phenylphenol and 2.7% *o*-benzyl-*p*-chlorophenol) inactivated HIV (162) but that another commercial product containing phenolics at a final concentration of 1% did not completely inactivate cell-associated HIV suspended in blood (81). A phenol-based preparation (14.7% phenol diluted 1:256 in tap water) and a bleach dilution (800 ppm of available chlorine) reduced rotavirus numbers similarly and interrupted transfer of virus from disks to fingerpads (222).

Phenolic compounds are relatively tolerant of anionic and organic matter. They are absorbed by rubber and plastics and leave a residual film, which may irritate skin and tissues. *p-tert*-butylphenol and *p-tert*-amylphenol have been reported to depigment skin. Although differences between the various compounds exist, phenolics are degraded in wastewater at a lower rate than other germicides, which limits their use in Europe.

Phenolic germicidal detergent solutions may be used for intermediate-level and low-level disinfection of surgical instruments and noncritical patient care items. These compounds are also appropriate for decontaminating the hospital environment, including laboratory surfaces. They should not be used to disinfect bassinets and incubators because they can cause hyperbilirubinemia in infants (201).

Quaternary Ammonium Compounds

A wide variety of quaternary ammonium compounds (quats) with antimicrobial activities have been introduced in the past decade. Some of the compounds used in health care settings are benzalkonium chloride, alkyldimethylbenzyl ammonium chloride, and didecyldimethyl ammonium chloride. Quats are cationic surface-active detergents, which appear to kill microorganisms by disrupting cell membranes, inactivating enzymes, and denaturating cell proteins (171). However, they have limited antimicrobial spectra. Products sold as hospital disinfectants are not sporicidal and are generally not tuberculocidal or virucidal against hydrophilic viruses. Scientific investigations using the AOAC use dilution method have not reproduced the bactericidal and tuberculocidal claims made by the manufacturers (204). Consequently, health care workers should be suspicious of the claims on labels and of results from in-house evaluations that have not been verified by an independent laboratory. The germicidal activity may have been overestimated because the compounds tested were incompletely inactivated. In this case, the bacteriostatic (inhibitory) activity rather than the bactericidal activity is measured (171). The antimicrobial spectra of quats may be improved by combining them with amines and biguanides or by using them at higher temperatures in washing machines.

Several outbreaks of infections have been associated with quat solutions contaminated in use by gram-negative bacteria such as *Pseudomonas* spp. or *Serratia marcescens* or by *Mycobacterium abscessus* (90, 177, 244). The contaminated solutions were used as antiseptics on skin and tissue and as disinfectants on patient care supplies and equipment (e.g., cardiac catheters and cystoscopes). In fact, microbiology laboratories use the quat cetrimide in selective media to isolate *Pseudomonas aeruginosa*.

Quats have other disadvantages. Genes conferring resistance to quats have been detected in 6 to 42% of *Staphylococcus aureus* isolates collected in Japan and Europe (165). Organic matter, anionic detergents (soaps), and materials such as cotton and gauze pads can reduce the microbicidal activities of quats. Despite these limitations, quats are nonstaining, odorless, noncorrosive, and relatively nontoxic. They are excellent cleaning agents, but sticky residue may build up on surfaces. On the basis of their limited antimicrobial spectra, they should be used in hospitals only for environmental sanitation of noncritical surfaces such as floors, furniture, and walls (201).

Other Germicides of Interest

Glucoprotamine, the conversion product of L-glutamic acid and cocopropylene-1,3-diamine, possesses a broad antimicrobial spectrum that includes vegetative bacteria, mycobacteria, fungi, and enveloped viruses (77, 173). A clinical study examining used specula from a gynecologic clinic demonstrated that the product killed >6 log units of vegetative bacteria excluding spores (263). The manufacturer's data sheets indicate good compatibility of the compound with humans, the environment, and various materials. A commercial product, available in Europe, can be used to disinfect instruments and endoscopes.

Peroxygen compounds have proven efficacy against bacteria, bacterial spores, fungi, and a broad spectrum of viruses. A 1% concentration of a new commercial formulation containing peroxygen achieved a 10^5-fold increase in killing of *Bacillus subtilis* in 2 to 3 h in the absence of blood, but killing was poor in the presence of blood (64). Moreover, several investigators have found that peroxygen has poor mycobactericidal activity (45, 107). In addition to other applications, these compounds may be suitable for disinfecting laboratory equipment and workbenches.

Superoxidized water is prepared at the point of use by the electrolysis of NaCl solution, which generates hypochlorous acid and a mixture of radicals with strong oxidizing properties (175). Freshly generated solutions rapidly destroy bacteria including spores and mycobacteria, fungi, and viruses in the absence of organic loading (229). A commercial adaption of this process (i.e., Sterilox) has been marketed in Europe since 1999 and recently was approved by the FDA (see "Endoscopes" below) (175). Because Sterilox solutions are unstable, they should be used only once for high-level disinfection. Some investigators have claimed that superoxidized water is compatible with instruments and that it does not damage the environment, irritate the respiratory tract and skin, or corrode metal. However, others have reported that superoxidized water damages flexible endoscopes. Further studies are needed to explore the use of this new disinfectant in clinical settings.

Metals such as copper and silver ions inactivate a wide variety of microorganisms (217). Although further work is required to explore their use in health care, they currently are used to disinfect water and to prevent infections associated with medical devices (e.g., intravascular catheters impregnated with silver sulfadiazine). For example, copper-silver ionization systems are successfully used to minimize legionella colonization in water systems (237).

Surfacine is a new, silver-based surface germicide that may be applied to inanimate or animate surfaces. Surfacine immediately eliminates microorganisms from surfaces and also has long-term residual activity (44, 212). This novel antimicrobial coating might be suitable for a wide range of applications including preventing microbial contamination of medical devices, if further studies confirm the promising preliminary data.

Specific Issues

Cleaning and Disinfecting Surfaces and Floors

In general, the environment is not a primary reservoir for nosocomial pathogens. However, in some cases, such as respiratory syncytial virus (112) and the SARS coronavirus (97), environmental contamination may be important. The CDC's recent guidelines for environmental infection control in health care facilities recommend using an EPA-registered hospital detergent-disinfectant designed for general housekeeping purposes in patient care areas, especially in intensive care units, operating rooms, and emergency rooms, where blood, body fluids, or multidrug-resistant organisms may have contaminated surfaces (227). A one-step process is adequate in most areas, but a rinse step is necessary in nurseries and neonatal intensive care units, especially if a phenolic agent is used (270). Products with quats allow staff members to clean and disinfect in one step, but residual quats may leave surfaces sticky and smeared. Other products may require a two-step approach, a cleaning step and a disinfection step, doubling the human resources needed to do the work. "High-touch" surfaces (e.g., doorknobs, bedrails, and light switches) should be disinfected more frequently than "low-touch" surfaces. A simple detergent is adequate for cleaning surfaces for other patient-care areas and in nonpatient-care areas. Cleaning with a detergent is much more important than adding a disinfectant to the solution. In fact, several studies found that adding a disinfectant does not prolong the reduction in bacterial loads on surfaces (76). Routine disinfection of environmental surfaces is necessary in all areas housing patients in contact isolation (e.g., patients infected with methicillin-resistant *Staphylococcus aureus* [MRSA]). A recent study indicates that twice-daily disinfection is necessary to control an outbreak with vancomycin-intermediate *Staphylococcus aureus* (73).

Emergence of Resistance to Biocides

Microorganisms rarely become resistant to disinfectants. However, frequent use of sublethal concentrations of disinfectants can select for resistant strains (19, 37, 253). Mechanisms of resistance include acquisition of resistance plasmids, changes in the cell membrane (e.g., chlorhexidine in *Pseudomonas stutzeri*), capsule formation (*Klebsiella* spp.), and activation of the *norA* efflux pump *(Staphylococcus aureus*). A large proportion of household soaps now contain antibacterial agents (up to 45% in one study), which may increase the probability that resistant bacteria will emerge (183). Multiple outbreaks have been associated with soaps containing antibacterial agents such as chlorhexidine, hexetidine solution, and chlorxylenol (19, 37, 253). However, the concentrations of biocides used in the health care setting are much higher than the minimum biocidal concentrations in vitro. Therefore, resistance has not become a major problem in the clinical setting to date. Readers desiring more information

about disinfectants and antiseptics (34, 89) and resistance to these agents should read several excellent articles (34, 89, 157, 228).

Inactivation of Emerging Pathogens and Antibiotic-Resistant Bacteria

New and emerging pathogens such as vCJD prions, noroviruses, SARS coronavirus, avian influenza virus, hypervirulent *Clostridium difficile*, Panton-Valentine leukocidin-producing *Staphylococcus aureus*, and gram-negative rods producing extended-spectrum β-lactamases or metallo-β-lactamases threaten the public health. Only limited data exist regarding the susceptibility of emerging pathogens to commonly used disinfectants or sterilants. Surrogate microbes have been studied for some pathogens. Examples include feline calicivirus for noroviruses, vaccinia virus for variola virus, and *Bacillus atrophaeus* (formerly *Bacillus subtilis*) for *Bacillus anthracis* (259). Other infectious agents that cannot be evaluated by standard testing procedures (e.g., hepatitis C virus) have been tested by alternative methods, such as PCR. With the exception of prions, there is no evidence that emerging pathogens are less susceptible to approved standard disinfection and sterilization procedures than are comparable classical pathogens. (Inactivation of prions, including those associated with vCJD, is discussed below.) In particular, there are no data demonstrating that disinfectants used at recommended contact conditions and concentrations are less effective against antimicrobial-resistant bacteria than against antimicrobial-susceptible bacteria (213). Standard disinfection and sterilization procedures for patient care equipment as recommended in guidelines and in this chapter are adequate to disinfect or sterilize instruments or devices contaminated with blood and other body fluids (213).

Other than one peroxygen compound, hospital disinfectants registered by the EPA do not have specific claims for activity against noroviruses. Because noroviruses are nonenveloped, most quats do not have significant activity against them. Phenolic-based preparations have been found to be active in vitro against a surrogate virus from this group. However, concentrations two- to fourfold higher than those recommended by the manufacturers for routine use may be required. In the event of a norovirus outbreak, the CDC recommends using a hypochlorite solution (minimum chlorine concentration of 1,000 ppm) to decontaminate hard, nonporous, environmental surfaces (http://www.cdc.gov/ncidod/hip/gastro/norovirus.htm).

SARS coronavirus and avian influenza virus are inactivated by sodium hypochlorite and a commercially available peroxygen compound (148); phenolic compounds and quats are less effective. A sporicidal germicide is required to efficiently eliminate *Clostridium difficile* spores. In a recent study, glutaraldehyde (2%), peracetyl ions (1.6%; equivalent to 0.26% peracetic acid), and acidified nitrite demonstrated biocidal activity against *Clostridium difficile* spores (269). Hypochlorite-based disinfectants have been used, with some success, to disinfect environmental surfaces in areas with ongoing transmission of *Clostridium difficile*. Recent nosocomial outbreaks of *Clostridium difficile* infections caused by virulent strains suggest that hospitals may need to focus more on environmental cleaning and disinfection (168).

Decontamination in the Event of Biological Terrorism

If a biological agent is released, environmental decontamination measures may be necessary to decrease the risk of spreading the disease. A decontamination agent should be effective against possible pathogens and readily available at a reasonable cost. Therefore, sodium hypochlorite (household bleach) is usually recommended, especially if bacterial spores are involved. This agent is well suited for various decontamination procedures in the laboratory and health care settings. In addition, it may be used to decontaminate protective equipment and clothing worn by first responders and decontamination workers.

Smallpox virus does not survive long in the environment but may remain viable for extended periods under favorable conditions. CDC guidelines recommend incinerating items that are not needed or cannot be decontaminated, sterilizing items in an autoclave or an ethylene oxide sterilizer, decontaminating spaces and rooms with vaporized paraformaldehyde (or use of an Amphyl fogger), and soaking equipment or wiping down surfaces with a 5% aqueous solution of a phenolic germicidal detergent (http://www.bt.cdc.gov/DocumentsApp/Smallpox/RPG/GuideF/Guide-F.pdf). Because contaminated clothing can spread the virus to personnel, bed linens and clothes must be autoclaved or laundered in hot water supplemented with bleach (119). Disinfectants that are used for standard hospital infection control, such as sodium hypochlorite and quaternary ammonium compounds, decontaminate surfaces effectively (119). Only vaccinated personnel should perform the decontamination procedures.

Bacillus anthracis spores are extremely stable and can remain viable for decades in the environment (129). The CDC recommends that laboratory staff use a 1:10-diluted hypochlorite solution when addressing spills and items and surfaces contaminated with *Bacillus anthracis* (http://www.bt.cdc.gov/Agent/Anthrax/LevelAProtocol/Anthracis20010417.pdf). Decontamination of a building or of large areas contaminated with anthrax spores is extremely difficult. Spotts Whitney et al. have summarized the literature on the inactivation of *Bacillus anthracis* spores (233). *Clostridium botulinum* and its spores are killed by a 1:10 dilution of sodium hypochlorite. Heat (>85°C for 5 min) or 0.1 M sodium hydroxide (contact time, 20 min) inactivates the toxin (20). Persons with direct exposure to powder or liquid aerosols containing *Franciscella tularensis* should wash their body and clothing with soapy water (74). In the circumstances of a laboratory spill or intentional release, environmental surfaces can be decontaminated with a 1:10-diluted hypochlorite solution. After 10 min, a 70% alcohol solution can be used to further clean the area and reduce the corrosive action of the bleach (74). *Yersinia pestis* does not survive long outside the host. The WHO estimated that a plague aerosol would be effective and infectious for 1 h. Thus, areas exposed to aerosols of *Yersinia pestis* do not need to be decontaminated (128).

Equipment or environmental surfaces contaminated with the agents causing Ebola hemorrhagic fever, Marburg hemorrhagic fever *(Filoviridae)*, Lassa fever, and related infections (those with *Arenaviridae* and *Bunyaviridae*) should be disinfected by using a suitable registered hospital disinfectant or a 1:100 dilution of a hypochlorite solution. Surfaces grossly soiled with vomitus or stool should be disinfected with a 1:10 dilution of a hypochlorite solution. If possible, serum samples used for laboratory tests should be pretreated with heat inactivation at 56°C and polyethylene glycol *p-tert*-octylphenyl ether (Triton X-100). Treatment with 10 μl of 10% Triton X-100 per 1 ml of serum for 1 h reduces the titers of hemorrhagic fever viruses in serum samples. If treatment with Triton X-100 is not feasible, heat inactivation alone may reduce infectivity somewhat (52).

Medical, public health, and laboratory responses to the release of organisms and toxins that pose a risk to national security (i.e., variola major virus [smallpox virus], *Bacillus anthracis*, *Clostridium botulinum* toxin, *Francisella tularensis*, *Yersinia pestis*, and certain filoviruses and arenaviruses) are discussed in chapter 9 of this Manual and in numerous publications (20, 74, 119, 128, 129). The CDC published guidelines for the management of patients with suspected viral hemorrhagic fever (52) and recently posted updated guidelines at http://www.cdc.gov/ncidod/hip/BLOOD/VHFinterimGuidance05_19_05.pdf.

Endoscopes

Reprocessing of endoscopes is probably the most challenging reprocessing task in health care. Multiple outbreaks have been associated with insufficient reprocessing techniques or defects in endoscopes (Table 7). However, ample data indicate that a sufficient level of safety can be achieved even with manual disinfection of endoscopes if the guidelines are followed strictly (163). Flexible endoscopes have intricate, sophisticated small parts that are difficult to clean, which must be cleaned before they can be disinfected because organic material such as blood, feces, and respiratory secretions interfere with disinfection (68). A large study of several centers in the United States found that 23.9% of specimens from the internal channels of 71 gastrointestinal reprocessed endoscopes grew $\geq 10^6$ CFU of bacteria and that 78% of the facilities did not sterilize all biopsy forceps (135). Other studies have documented that up to 40% of the institutions do not follow published guidelines for endoscope disinfection (12, 84, 104) and that reuse of disposable endoscopic accessories is common in the United States. These items frequently are not sterilized, and reprocessing protocols are not standardized. Therefore, reused disposable items might be a source of cross-transmission (61, 68).

Currently, most high-level disinfectants approved by the FDA for reprocessing of endoscopes contain >2% aldehyde with or without peracetic acid (http://www.fda.gov/cdrh/ode/germlab.html). However, aldehydes should be used only after completion of the cleaning cycle because they may stain prions to the instruments. Endoscopes, which are semicritical items, must be immersed in ≥2% glutaraldehyde for ≥20 min to achieve the necessary level of disinfection. These parameters are sufficient to kill ≥3 log units of mycobacteria, the most resistant vegetative bacteria. However, glutaraldehyde-resistant mycobacteria have been identified (107). Several authors have raised concerns that *Clostridium difficile* may not be fully inactivated by standard reprocessing procedures, but transmission of *Clostridium difficile* by contaminated endoscopes has not been reported to date. Moreover, cryptosporidia withstand several hours of exposure to glutaraldehyde (268) but do not survive on dry surfaces (191).

The glutaraldehyde concentration in commercial cleaner-disinfectors can decrease by more than 50% after 2 weeks, which may promote the emergence of resistant bacteria (251). Higher concentrations of glutaraldehyde (3.2% instead of 2%) appear to be safe for endoscopes and achieve the required ≥3-log-unit killing with a higher margin of safety than that achieved with the standard concentration (7). OPA and peracetic acid plus hydrogen peroxide can be used to disinfect endoscopes. Because the latter might corrode some endoscopes, reprocessing staff should ensure that the manufacturer of the endoscope approves this disinfectant for reprocessing.

Automated washer-disinfectors specifically for endoscopes were developed, in part, to reduce the work needed to reprocess endoscopes and to decrease the risk of human

TABLE 7 Outbreaks and pseudo-outbreaks associated with contaminated endoscopes or instruments for minimally invasive procedures

Microorganism(s)	No. of cases	No. of deaths	Yr of publication	Problem identified	Type of outbreak	Reference(s)
Klebsiella pneumoniae, Proteus vulgaris, Morganella morganii	11	0	2005	Loose port of the bronchoscope's biopsy channel	Mixed	57
Pseudomonas aeruginosa	16	0	2005	Defective biopsy forceps	Mixed	68
Pseudomonas aeruginosa	3	0	2004	Probable defective endoscope	Infections	91
Pseudomonas aeruginosa	39	3	2003	Loose biopsy port cap in the bronchoscope	Infections	234
Pseudomonas aeruginosa	18	0	2001	Improper connection to liquid sterilization device	Mixed	230
Mycobacterium xenopi	58	0	2001	Inappropriate disinfection of microsurgical instruments, tap water rinse after disinfection	Infections	22
Pseudomonas aeruginosa	11	2	2000	Failure of washer-disinfector, purchased without expert advice, poor maintenance	Infections	211, 224
Pseudomonas aeruginosa, mycobacteria	29	0	1999	Problems related to the use of STERIS System 1 processor	Mixed	15
Hepatitis C virus	2	0	1997	Cleaning, immersion	Infections	46
Mycobacterium tuberculosis	2	0	1997	Cleaning, immersion	Infections	174
Mycobacterium tuberculosis (multidrug resistant)	5	1	1997	Cleaning, immersion	Infections	3
Pseudomonas aeruginosa	23	0	1996	Failure of washer-disinfector	Pseudo-outbreak	32
Nontuberculous mycobacteria	4	0	1992	Failure of washer-disinfector	Pseudo-outbreak	108
Multiple microorganisms	377	7	1993	Cleaning, immersion, use of tap water, poorly designed washer-disinfector	Infections	231 (review)

errors during manual reprocessing. These machines rinse the endoscopes, clean them in several steps, and run a full-cycle disinfection process. The time endoscopes are exposed to disinfectants is set by the machine and cannot be shortened, as it can be by busy staff members who are manually reprocessing endoscopes.

However, endoscope washers can become contaminated with pathogenic bacteria. For example, one study found gram-negative bacteria and/or mycobacteria in 27% of cultures of specimens obtained before the final alcohol rinse and in 10% of cultures of specimens obtained thereafter. In the same study, 37 and 27% of the manually disinfected endoscopes remained contaminated at the same time points (92). In 1992, Olympus recalled its 835 model endoscope washers because the design allowed the internal tanks and tubing to become colonized by waterborne organisms such as *Pseudomonas* spp. (recall no. Z-039/040-2 by the FDA). In 1999, the CDC reported three outbreaks related to the STERIS System 1 (15). This device is supposed to sterilize the endoscopes, but they must first be cleaned manually (42). Table 7 summarizes outbreaks related to endoscopes, including those related to contaminated washer-disinfectors.

Newer washer-disinfectors should continuously monitor the pressure in all channels to detect debris blocking the channels, provide adapters for all types of endoscopes, use an appropriate disinfection process with an FDA-approved disinfectant, use filtered water or sterile water for rinsing, and have a built-in automatic disinfection process. These washer-disinfectors can help staff members trace problems by monitoring and documenting the disinfecting process in a manner similar to that used by autoclaves.

To avoid problems, knowledgeable staff should review currently marketed machines before purchasing a washer-disinfector to ensure that the one they choose is appropriate for their needs (23). To facilitate this process, the FDA recommends that the manufacturer provide a list of all brands and models of endoscopes that are compatible with the washer-disinfector and highlight limitations associated with processing of certain brands and models of endoscopes and accessories. Preferably, the manufacturer should identify endoscopes and accessories that cannot be reliably reprocessed in the device (negative list). In addition, health care workers should be trained to use the equipment and monitored subsequently to ensure that they follow the protocol exactly. Although not mandatory, it is prudent to regularly culture the rinse water of washer-disinfectors for pathogens such as *Pseudomonas* spp. and *Mycobacterium* spp. to identify problems before clinical cases occur. However, outbreaks may occur despite negative routine culture results (191, 268).

If washer-disinfectors recycle water, residual glutaraldehyde may remain on the endoscopes. Manual reprocessing is more prone to leave residual glutaraldehyde on endoscopes than are automated washer-disinfectors (83). Thus, endoscopes that are manually disinfected should be thoroughly rinsed to remove any residual disinfectant, specifically glutaraldehyde. Patients exposed to residual glutaraldehyde can develop colitis (79, 262).

Reprocessed endoscopes should be stored vertically (to facilitate drying) in a cabinet (to protect them from dust and secondary contamination). Reprocessed endoscopes that are stored for days or weeks probably should be reprocessed again before use or, alternatively, the channels should be rinsed with 70% alcohol that is filtered to remove spores if this agent is compatible with the instrument. However, the necessity of these precautions has not been established.

Guidelines for infection prevention and control in flexible endoscopes have been updated (12) and should be consulted before choosing of a method and/or disinfectant for reprocessing. The following checklist adapted from the FDA recommendations may help staff members reprocessing endoscopes avoid errors (http://www.fda.gov/cdrh/safety/endoreprocess.html).

1. All staff members must comply with the manufacturer's instructions for cleaning endoscopes.
2. Determine whether your endoscope is suitable for reprocessing in an automatic washer-disinfector, which is the preferred method.
3. Compare the reprocessing instructions provided by the endoscope and washer-disinfector manufacturers and resolve any conflicting recommendations.
4. Follow the instructions provided by the manufacturers of the endoscopes and the chemical germicides.
5. Consider drying endoscopes with alcohol.
6. Monitor adherence to the protocols for reprocessing of endoscopes.
7. Provide comprehensive, intensive training for all staff members who reprocess endoscopes; keep records of persons attending training.
8. Label endoscopes sent for repairs as "contaminated equipment for repair."
9. Implement a comprehensive quality control program.

An updated list of sterilants and high-level disinfectants approved by the FDA in a 510(k) with general claims for processing of reusable medical and dental devices can be found on the FDA website (http://www.fda.gov/cdrh/ode/germlab.html). Rutala and Weber have reviewed these substances (211, 212). Of note, more than 20% of all damage to endoscopes is associated with disinfecting agents. Therefore, staff members who reprocess these items must ensure that the instruments and the disinfectant are compatible (61). A new norm (prEN ISO 15883-4) will soon be adapted for washer-disinfectors designed for thermolabile endoscopes.

Dental Equipment

Critical and semicritical dental instruments should be sterilized; if they will not be used immediately, they should be packaged before they are sterilized. All high-speed dental handheld pieces should be sterilized routinely between patients. Handheld pieces that cannot be heat sterilized should be retrofitted to attain heat tolerance; if this is not feasible, they should not be used. The adequacy of sterilization cycles should be verified by periodically (e.g., at least weekly) including a biological indicator with the load. This recommendation is rarely followed in Europe (109). In fact, 33% of British dental practices do not have a policy on general disinfection and sterilization procedures and only 3% own a vacuum autoclave (24).

Environmental contamination can be a problem in dental offices. For example, *Legionella* spp. can contaminate the air-water syringes and high-speed outlets in dental units. Moreover, Piazza et al. found that about 6% of samples from workbenches, air turbine handheld pieces, holders, suction units, forceps, and dental mirrors were positive by PCR for hepatitis C virus (184). Therefore, infection control issues, particularly in regard to hepatitis C and B viruses, may be more important in dentistry than has been appreciated previously.

The CDC and the American Dental Association (ADA) have published guidelines for infection control in dental settings (1, 55). The ADA recommends that metal and porcelain equipment be immersed in glutaraldehyde or exposed to

this disinfectant, that removable dentures and acrylic or porcelain be disinfected with iodophors or chlorine compounds, and that wax rims or bite plates be disinfected with a spray containing iodophors. Additional information can be found on the website of the ADA (http://www.ada.org/prof/resources/positions/doc_policies.pdf).

Disinfectants for Living Tissue

Compounds that disinfect living tissue are frequently called antiseptic agents. They must meet many more requirements than compounds used to disinfect inanimate surfaces, e.g., floors. In addition, some of the agents are considered drugs and, thus, are regulated by the FDA. The antimicrobial spectra of commercially available agents are summarized in Table 6. The choice of an agent should not be based only on the desired effect but, like that of antimicrobial agents, on side effects. Antiseptics rarely cause serious side effects, and most agents on the market have excellent safety profiles. Nevertheless, health care workers must remember that these agents can cause side effects such as anaphylactic shock in patients who have contact with chlorhexidine (82, 182).

Hygienic Hand Washing and Hand Disinfection

Hand hygiene is the single most important infection control measure (40). However, it remains difficult to motivate health care workers to perform this simple procedure faithfully (78). The CDC has published detailed guidelines on hand hygiene (40), and in 2006, the WHO launched a global effort to improve hand hygiene in health care facilities (http://www.who.int/patientsafety/events/05/HH_en.pdf). In-depth reviews have been published by several authors (137, 245, 264).

Microorganisms on the hands can be classified into three groups (186): (i) transient flora, which are contaminants taken up from the environment; (ii) resident flora, which are permanent microorganisms on the skin (264); and (iii) infectious flora. Resident bacteria, most of which are on the uppermost level of the stratum corneum, have low pathogenicity and infection rates, and persons with normal immune systems who do not have implants or foreign bodies rarely acquire infections with these organisms. The density of resident bacteria on the skin ranges between 10^2 and 10^3 CFU/cm^2, and these resident bacteria limit colonization with more pathogenic microorganisms (i.e., they contribute to colonization resistance). During their daily work, health care workers can contaminate their hands with pathogens. If they do not practice good hand hygiene, they can transmit these organisms to susceptible patients. Several studies indicated that pathogens such as *Staphylococcus aureus* (127), *Klebsiella pneumoniae* (2), *Acinetobacter* spp., *Enterobacter* spp., and *Candida* spp. can be found on the hands of >20% of health care workers. Moreover, numerous epidemics have been traced to health care workers' contaminated hands (41, 215, 221, 266, 272).

The goal of hand hygiene outside the operating room is to eliminate the transient flora without altering the resident flora. Hand washing for 15 and 30 s kills 0.6 to 1.1 and 1.8 to 2.8 log units, respectively (196). However, health care workers are very busy and frequently wash their hands for less than 10 s, which is insufficient to kill the transient flora (245, 264). One major advantage of the alcohol-based hand rubs is that performing hand hygiene with these products takes about 25% of the time required for hand washing (245, 264). Moreover, compliance with hand-washing procedures does not exceed 40% even under controlled study conditions (40). However, recent studies have shown that compliance with the use of the alcohol-based hand rubs exceeds that with hand washing (185). Furthermore, other studies have demonstrated that rubbing one's hands with an alcohol-based hand rub kills bacteria and most viruses more effectively than hand washing with a medicated soap (27, 194). Of note, investigators have not determined whether the level of killing is associated with the efficacy of preventing nosocomial infections.

Alcohol-based hand rubs have several other practical advantages for hand hygiene over washing with soap and water. Dispensers for the alcohol-based products are less expensive than sinks and can be installed at locations that are more convenient for health care workers. Furthermore, unlike sinks (172), the dispensers have not been associated with outbreaks.

Given the numerous advantages of these products, the CDC's current hand hygiene guidelines recommend that health care facilities consider introducing alcohol-based hand rubs as the primary mode of hand hygiene (40). Most health care institutions in northern Europe now use an alcohol-based hand rub for many indications for which hand washing was previously the standard of care. At the University Hospital Basel, the use of an alcohol-based hand rub has replaced hand washing in >85% of opportunities for hand hygiene, provided that the hands are not visibly soiled (A. Trampuz, N. Lederray, and A. F. Widmer, *Program Abstr. 41st Intersci. Conf. Antimicrob. Agents Chemother.*, abstr. K1335, 2001). Also at the University Hospital Basel, dispensers for alcohol-based hand rub are available between all beds and at each nurse's desk; two dispensers are available at each bed in intensive care units. Among 4,500 health care workers, we have not identified a single case of documented allergy to the alcohol-based hand rub, resulting in an incidence density of <1:45,000 person-years. Dermatitis may occur, most frequently related to insufficient use of emollients and ointments.

In the United States, health care facilities should consult with the fire marshal before installing dispensers because many states have laws that prohibit placing multiple containers in emergency exits and halls. However, there are no published reports of fires caused by these products in Europe and such events are also very rare in the United States (39).

Surgical Hand Washing (Scrub) or Surgical Hand Disinfection (Rub-In)

In contrast to hand hygiene outside of the operating room, the surgical hand scrub aims to eliminate both transient and resident flora so that if the surgeon's gloves are punctured or torn, the bacteria from his or her hands do not contaminate the surgical site. Tiny holes are observed in ≥30% of surgeons' gloves after operations, even when high-quality gloves are used. Cruse and Foord found that the incidence of surgical site infection is three times higher if the surgeon's gloves are punctured than if they are intact after the procedure (5.7 and 1.7%, respectively) (71). An experimental study demonstrated that the level of bacterial leakage through pin holes ranges between 10^3 and 10^4 CFU (94). Moreover, a persistent antimicrobial effect is required after washing or disinfection to limit bacterial regrowth underneath the gloves (96). Thus, antiseptic preparations intended for use as surgical hand preparations are evaluated for their abilities to reduce the number of bacteria released from hands (i) immediately after scrubbing (immediate activity), (ii) after surgical gloves have been worn for 6 h (persistent activity), and (iii) after numerous applications over 5 days (cumulative activity). Immediate and persistent activities are considered the most important. Guidelines in

the United States recommend that agents used for surgical hand preparation should significantly reduce the number of microorganisms on intact skin, contain a nonirritating antimicrobial preparation, have broad-spectrum activity, and be fast acting and persistent. Agents such as chlorhexidine that have a prolonged postexposure effect are preferred because of this theoretical advantage, but there are no data from controlled clinical trials proving that the incidence of surgical site infections is lower when chlorhexidine is used.

Alcohol-based surgical rubs have several advantages over traditional surgical scrubs. Alcoholic preparations are more effective than any medicated soap for the surgical scrub, and they do not alter the skin as much as chlorhexidine washes do. Moreover, the water supply in an operating room may harbor *Pseudomonas* spp. that may contaminate the hands of surgical personnel after they perform their surgical scrub (31). Brushes, which are used during a surgical scrub, may do more harm than good, and they should be used only to clean the fingernails, not to clean the skin. Given the advantages of the alcohol-based preparations, the presurgical scrub has been replaced in many European countries by the alcohol-based surgical rubs (245), and the WHO's guidelines recommend the surgical hand rubs (WHO guidelines are available at http://www.who.int). Alcoholic gels are frequently promoted but are significantly less effective than liquids and should not be used in the operating room (146). A very rapid protocol (1.5 min) for the surgical hand rub has been recently proposed and was rapidly accepted by surgeons at the University Hospital Basel (138).

Of note, both routine hand hygiene and surgical hand preparations must balance removing unwanted bacteria from health care workers' hands and maintaining the integrity of the health care workers' skin because damaged skin is more likely than normal skin to become colonized with pathogenic organisms. Therefore, either hand hygiene products should contain emollients or health care facilities should provide moisturizing hand lotions, which do not damage latex, for their staff so their skin does not become dry, cracked, and irritated.

Presurgical Skin Disinfection

The aim of skin disinfection is to remove and kill rapidly the skin flora at the site of a planned surgical incision. However, currently available antiseptics do not eliminate all microorganisms at the incision site. In fact, coagulase-negative staphylococci can be isolated frequently even after three applications of agents such as iodine-alcohol to the skin (98).

The FDA defines a skin disinfectant as a "fast acting, broad-spectrum and persistent antiseptic-containing preparation that significantly reduces the number of microorganisms on intact skin" (14). Spore-free alcohols are well suited for this purpose, but they lack persistent activity; iodine is frequently added for this purpose (100). Povidone-iodine continuously releases free iodine that results in a prolonged antmicrobial effect. However, for a short-term procedure, alcoholic preparations can be sufficient for skin preparation.

Before a patient's skin is prepared for a surgical procedure, the skin should be free of gross contamination (i.e., dirt, soil, or any other debris) (160). Although preoperative showering has not been shown to reduce the incidence of surgical site infections, this practice may decrease bacterial counts and ensure that the skin is clean (195). The antiseptics used to prepare the skin should be applied by using sterile supplies and gloves or a no-touch technique, moving from the incision area to the periphery (160). The person preparing the skin should use pressure because friction increases the antibacterial effect of the antiseptic. For example, alcohol applied without friction reduces bacterial counts by 1.0 to 1.2 log CFU compared with 1.9 to 3.0 log CFU when friction is used. In comparison, alcoholic sprays have little antimicrobial effect and produce potentially explosive vapors (156).

Common Antiseptic Compounds

Alcoholic Compounds

The reader is referred to "Alcohols" above. As outlined above, alcohol is the most important skin disinfectant. Alcohols used for skin disinfection before invasive procedures should generally be free of spores to avoid any contamination. Although the risk of infection is minimal, the low additional cost for a spore-free product is justified. One study indicated that isopropyl alcohol from a commercial hand rub may be absorbed through the dermis, violating religious beliefs of some health care workers (246). However, the WHO resolved this issue in the guidelines that they will publish in 2006.

Chlorhexidine

Chlorhexidine gluconate, a cationic bisbiguanide, has been widely recognized as an effective and safe antiseptic for nearly 40 years (75, 189). Chlorhexidine formulations are extensively used for surgical and hygienic hand disinfection (see the discussion above). Other applications include preoperative showers (or whole-body disinfection), antisepsis in obstetrics and gynecology, management of burns, wound antisepsis, and prevention and treatment of oral disease (e.g., plaque control, pre-and postoperative mouthwash, and oral hygiene) (75, 189). When chlorhexidine is used orally, its bitter taste must be masked and it can stain the teeth. Intravenous catheters coated with chlorhexidine and silver sulfadiazine are used to prevent catheter-associated bloodstream infections (159).

Chlorhexidine is most commonly formulated as a 4% aqueous solution in a detergent base. However, alcoholic preparations have been demonstrated in numerous studies to have better antimicrobial activity than detergent-based formulations (151). Bactericidal concentrations destroy the bacterial cell membrane, causing cellular constituents to leak out of the cell and cell contents to coagulate (75). Chlorhexidine gluconate's bactericidal activity against vegetative gram-positive and gram-negative bacteria is intermediately rapid. In addition, chlorhexidine provides persistent antimicrobial action that prevents the regrowth of microorganisms for up to 6 h. This effect is desirable when a sustained reduction in microbial flora reduces infection risk (e.g., during surgical procedures). Chlorhexidine has little activity against bacterial and fungal spores except at high temperatures. Mycobacteria are inhibited but are not killed by aqueous solutions. Yeasts and dermatophytes are usually susceptible, although the fungicidal action varies with the species (74). Chlorhexidine is effective against lipophilic viruses (e.g., HIV, influenza virus, and herpes simplex virus types 1 and 2), but viruses such as poliovirus, coxsackievirus, and rotavirus are not inactivated (75). Unlike that of povidone-iodine, blood and other organic material do not affect the antimicrobial activity of chlorhexidine significantly (155). However, inorganic anions and organic anions such as soaps are incompatible with chlorhexidine and its activity is reduced at extreme acidic or alkaline pHs and in the presence of anion- and non-ion-based moisturizers and detergents.

Microorganisms can contaminate chlorhexidine solutions (181), and resistant isolates have been identified. For

example, Stickler found chlorhexidine-resistant *Proteus mirabilis* after chlorhexidine was used extensively over a long period to prepare patients for bladder catheterization (235). Chlorhexidine resistance among vegetative bacteria was thought to be limited to certain gram-negative bacilli (such as *Pseudomonas aeruginosa*, *Burkholderia* [*Pseudomonas*] *cepacia*, *Proteus mirabilis*, and *Serratia marcescens*) (236). However, genes conferring resistance to various organic cations, including chlorhexidine, have been identified in *Staphylococcus aureus* clinical isolates (165, 176).

Chlorhexidine has several other limitations. When absorbed onto cotton and other fabrics, it usually resists removal by washing. If a hypochlorite (bleach) is used during the washing procedure, a brown stain may develop (75). Long-term experience with the use of chlorhexidine has demonstrated that the incidence of hypersensitivity and skin irritation is low. However, severe allergic reactions including anaphylaxis have been reported previously (82, 271). Although cytotoxicity has been observed with exposed fibroblasts, no deleterious effects on wound healing have been demonstrated in vivo. There is no evidence that chlorhexidine gluconate is toxic if it is absorbed through the skin, but ototoxicity can occur when chlorhexidine is instilled into the middle ear during operative procedures. High concentrations of chlorhexidine and preparations containing other compounds (e.g., alcohols and surfactants) may damage eyes (239).

Iodophors

Iodophors essentially have replaced aqueous iodine and tincture as antiseptics. Iodophors are chemical complexes of iodine bound to a carrier such as polyvinylpyrrolidone (povidone) or ethoxylated nonionic detergents (poloxamers). These complexes gradually release small amounts of free microbicidal iodine. The most commonly used iodophor is povidone-iodine. Its preparations generally contain 1 to 10% povidone-iodine, which is equivalent to 0.1 to 1.0% available iodine. The active component appears to be free molecular iodine (I_2). A paradoxical effect of dilution on the activity of povidone-iodine has been observed. As the dilution increases, bactericidal activity increases up to a maximum and then falls (105). Commercial povidone-iodine solutions at dilutions of 1:2 to 1:100 kill *Staphylococcus aureus* and *Mycobacterium chelonae* more rapidly than do stock solutions (28). *Staphylococcus aureus* can survive a 2-min exposure to full-strength povidone-iodine solution but cannot survive a 15-s exposure to a 1:100 dilution of the iodophor (28). Thus, iodophors must be used at the dilution stated by the manufacturer.

The exact mechanism by which iodine destroys microorganisms is not known. Iodine may react with microorganisms' amino acids and fatty acids, destroying cell structures and enzymes (105). Depending on the concentration of free iodine and other factors, iodophors exhibit a broad range of microbicidal activity. Commercial preparations are bactericidal, mycobactericidal, fungicidal, and virucidal but not sporicidal at the dilutions recommended for use. Prolonged contact times are required to inactivate certain fungi and bacterial spores (201). Despite their bactericidal activities, povidone-iodine and poloxamer-iodine solutions can become contaminated with *Burkholderia (Pseudomonas) cepacia* or *Pseudomonas aeruginosa*, and contaminated solutions have caused outbreaks of pseudobacteremia and peritonitis (29, 69). In fact, *Burkholderia cepacia* survives for up to 68 weeks in a povidone-iodine antiseptic solution (13). The most likely explanation for the prolonged survival of these microorganisms in iodophor solutions is that organic or inorganic material and biofilm may mechanically protect the microorganisms.

Iodophors are widely used for antisepsis of skin, mucous membranes, and wound sites. A 2.5% ophthalmic solution of povidone-iodine is more effective and less toxic than silver nitrate or erythromycin ointment for prophylaxis against neonatal conjunctivitis (ophthalmia neonatorum) (130). In some countries, povidone-iodine alcoholic solutions are used extensively for skin antisepsis before invasive procedures (18). Iodophors containing higher concentrations of free iodine may be used to disinfect medical equipment. Solutions designed for use on the skin should not be used to disinfect hard surfaces because the concentrations of the antiseptic solutions are usually too low for this purpose (201).

The risk of side effects, such as staining, tissue irritation, and resorption, is lower for iodophors than for aqueous iodine. Iodophores do not corrode metal surfaces (105). However, a body surface treated with an iodine or iodophor solution may absorb free iodine. Consequently, increased serum iodine levels (and serum iodide levels) have been found in patients, especially when large areas were treated for a long period (105). For this reason, hyperthyroidism and other disorders of thyroid functions are contraindications for the use of iodine-containing preparations. Likewise, iodophors should not be applied to pregnant and nursing women or to newborns and infants (50). Because severe local and systemic allergic reactions have been observed, iodophors and iodine should not be used for patients with allergies to these preparations (256).

Iodophores have little if any residual effect. However, for a limited time they may have residual bactericidal activity on the skin surface, because free iodine diffuses into deep regions and also back to the skin surface (105). The antimicrobial efficacy of iodophors is reduced in the presence of organic material such as blood.

Triclosan and PCMX

Triclosan (Irgasan DP-300 or Irgacare MP) has been used for more than 30 years in a wide array of skin care products, including hand washes, surgical scrubs, and consumer products. A review of its effectiveness and safety in health care settings has been published previously (132). A concentration of 1% has good activity against gram-positive bacteria, including antibiotic-resistant strains, but less activity against gram-negative organisms, mycobacteria, and fungi. Limited data suggest that triclosan has a relatively broad antiviral spectrum, with high-level activity against enveloped viruses, such as HIV type 1, influenza A virus, and herpes simplex virus type 1. However, the nonenveloped viruses prove more difficult to inactivate. Clinical strains of *Staphylococcus aureus* with low-level resistance to triclosan have been identified, and the clinical significance of this remains unknown (238). Triclosan is added to many soaps, lotions, deodorants, toothpastes, mouthrinses, commonly used household fabrics, plastics, and medical devices. Moreover, the mechanisms of triclosan resistance may be similar to those involved in antimicrobial resistance (6) and some of these mechanisms may account for the observed cross-resistance of laboratory isolates to antimicrobial agents (63). Consequently, concerns have been raised that widespread use of triclosan formulations in non-health care settings and products may select for biocide resistance and even cross-resistance to antibiotics. However, environmental surveys have not demonstrated an association between triclosan usage and antibiotic resistance (199).

Triclosan solutions produce a sustained residual effect against resident and transient microbial flora that is minimally affected by organic matter. Numerous studies have not identified toxic, allergenic, mutagenic, or carcinogenic potential. Triclosan formulations may help control outbreaks of MRSA infections when the formulations are used for hand hygiene and for bathing of patients (132). However, some MRSA isolates have reduced triclosan susceptibility. Triclosan formulations are less effective than 2 to 4% chlorhexidine gluconate when used for surgical scrub solutions; properly formulated triclosan solutions may be used for hygienic hand washing.

PCMX (chloroxylenol) is an antimicrobial used in handwashing products. It is available at concentrations of 0.5 to 3.75%. Its properties are similar to those of triclosan. Nonionic surfactants may neutralize PCMX.

Octenidine

Octenidine dihydrochloride is a novel bispyridine compound, which is an effective and safe antiseptic agent. The 0.1% commercial formulation compares favorably with other antiseptics with respect to antimicrobial activity and toxicologic properties. In vitro and in vivo, it rapidly kills both gram-positive and gram-negative bacteria as well as fungi (101, 226). Octenidine is virucidal against HIV, hepatitis B virus, and herpes simplex virus. Similar to chlorhexidine, it has a marked residual effect. No toxicologic problems have been found when the 0.1% formulation was applied according to the manufacturer's recommendations. The colorless solution is a useful antiseptic for mucous membranes of the female and male genitals and the oral cavity (25), but its bad taste limits its use orally. In a recent observational study, the 0.1% formulation was highly effective and well tolerated for the care of central venous catheter insertion sites (243). The results of this study have also been supported by a randomized controlled clinical trial (M. Dettenkofer and A. F. Widmer, *Abstr. Eur. Congr. Clin. Microbiol. Infect. Dis.*, 2006, Nice, France, abstr. O147). Octenidine is not registered for use in the United States.

STERILIZATION

Principles, Definitions, and Terms

As outlined in Table 3, sterilization is not a relative term but defines the complete absence of any viable microorganisms, including spores. However, this absence cannot be proved by current microbiologic techniques (133). Therefore, sterilization can be defined as a closely monitored, validated process used to render a product free of all forms of viable microorganisms, including all bacterial endospores. To test the ability of sterilization systems to meet the latter definition, manufacturers developed a worst-case scenario that allows the process (log killing) to be quantified and estimates the probability of process failure. Large safety margins were included in this test, which is based on the assumption that items are heavily contaminated with spores, soil, and proteins. Note that although these conditions are used for the testing, in clinical practice items that are heavily soiled should not be sterilized and such a scenario would represent a critical failure of the reprocessing cycle. Any device undergoing sterilization first must undergo an appropriate cleaning process.

A manufacturer must demonstrate that a sterilizer is effective against a wide range of clinically important microorganisms before it can be approved by the FDA. In addition, proof of efficacy must be performed with organisms (usually bacterial spores) that have been shown to be the most resistant to the new technology. A validated and reliable biological indicator must be developed, and studies must establish that sterility will be consistently achieved when critical process parameters operate within a defined range. This assures the operator that as long as there is no operational error or equipment failure, sterility is achieved.

Several guidelines are essential documents for staff members who need to understand reprocessing and sterilization of medical devices. The ISO 14937 document provides general criteria for characterizing a sterilizing agent and for the development, validation, and routine control of a sterilization process for medical devices. ISO 11134 (moist heat) and ISO 11135 (ethylene oxide) documents describe the standards for use of these methods of sterilization in the industrial setting in the United States. The American National Standard Institute/Association for the Advancement of Medical Instrumentation published adaptations of these standards for health care facilities: standard 46 (moist heat) and standard 41 (ethylene oxide) (Table 3). In Europe, EN 550, EN 554, and EN 285 define the standards for steam and ethylene oxide sterilization. ISO 14161 provides guidance that staff can use when selecting and using biological indicators and when interpreting the results of these tests. ISO 17664 specifies which information medical device manufacturers must provide so that the medical device can be processed safely and will continue to function properly. Readers are referred to other references for additional information about sterilization (34, 106, 133).

Monitoring

Any sterilization process must be monitored by mechanical, physical, chemical, and facultatively biological methods. Before routine use, the performance of the machine should be validated with the most difficult load used at the institution to ensure that the process is safe. In addition, a printout of the physical parameters (e.g., temperature and pressure) during sterilization should be kept for documentation purposes. In 1963, Bowie and Dick determined that if residual air remained in a sterilizer after the vacuum phase and there was only one package in the chamber, the air would concentrate in that package (38). They developed the Bowie-Dick test to determine whether steam penetration and air removal occurred successfully. This test does not provide information about the sterilization process.

Chemical indicators placed on items in a sterilizer change color if they are exposed to adequate temperatures and exposure times. They are inexpensive, easy to use, and provide a visual indication that the item has been exposed to the sterilization process. Good clinical indicators are able to identify a sterilizer failure. However, some are too sensitive, giving false-positive results (205, 208), which may cause unnecessary recalls of adequately sterilized items. Less sensitive chemical indicators do not detect small deviations in the process.

Biological indicators are the best monitors of the sterilization process. If the spores in commercially available standard biological indicators do not grow during an appropriate incubation period, the results indicate that the process was able to kill $\geq 10^6$ CFU. For flash sterilization, the Attest Rapid Readout biological indicator detects the presence of a spore-associated enzyme, α-D-glucosidase, and permits the staff to assess the efficacy of sterilization within 60 min (252). Staff members should investigate positive biological indicators because they can provide the only indication that something is wrong with the sterilization process (51).

An important question is whether a load can be distributed before the final results of the biological indicator are available (i.e., parametric release). The Joint Commission on Accreditation of Healthcare Organizations standard allows the use of appropriate chemical indicators without routine use of a biological indicator. A common approach is to use the sterilized items if the physical and chemical parameters of adequate sterilization were met without waiting for the culture results from the biological indicators.

In Europe, routine use of biological indicators is not required if the sterilizer has undergone testing by a validation procedure used for industrial steam sterilization (EN 285, EN 550, EN 554, or EN 556). Most sterilizers in European hospitals probably do not meet these very strict requirements (250), and consequently, biological indicators are used regularly to ensure that they are working properly. These industrial standards for validation of steam sterilization will be implemented in health care organizations, but this change is controversial because of the associated expenses. The future is likely to involve parametric release with regular validation and/or commissions of the equipment. Legal issues will probably determine the outcome of this discussion, and lawyers are likely to accept nothing but a zero risk. However, the goal of a zero risk for contamination in central sterilization services will probably contribute to excessive health care costs. Therefore, standards for sterilization should exclude a risk for contamination after the reprocessing cycle but should avoid steps that are performed only for legal reasons.

Packaging, Loading, and Storage

Items that are clean and dry should be inspected and then wrapped and packaged (or put in containers) before sterilization. Wrappers should allow steam or gas to penetrate into the package but should protect the items from recontamination after sterilization. Items wrapped only in muslin can become contaminated when they are handled after steam sterilization (265). Items should be labeled with information such as expiration date, type of sterilization, and identification code so that items can be traced.

Steam Sterilization

The most reliable method of sterilization is one that uses saturated steam under pressure. It is inexpensive, nontoxic, and very reliable.

Steam penetrates fabrics, and its inherent safety margin is much higher than that of any other sterilization technique. Therefore, it should be used whenever possible. Obviously, other techniques must be used for heat-sensitive items. Steam irreversibly coagulates and denaturates microbial enzymes and proteins. Three parameters are critical to ensuring that steam sterilization is effective: the amount of time the items are exposed to steam, the temperature of the process, and the level of moisture. Unlike time and temperature, the moisture condition in the autoclave cannot be directly determined. The D value determines the time required to kill 10^6 CFU of the spores most resistant to the sterilization process under study. Devices or instruments must reach the desired temperature, which is not necessarily identical to the temperature displayed on the autoclave's gauge. A drop of only 1.7°C (3°F) increases the time required to sterilize an item by 48%. Without moisture, a temperature of 160°C is required for dry-heat sterilization. Dry air does not provide steam for condensation, and the heat transfer to objects is slower than it is when moisture is present. Pressurized steam quickly transfers energy to the sterilizer load and causes more rapid denaturation and coagulation of microbial proteins. In addition, pressurizing the steam allows one to achieve dry 100% saturated steam. Thus, there is no mist that may cause the packaging and/or the items to become wet.

Residual air in the autoclave interferes with the sterilization process. The amount of air within the sterilizer can be estimated by comparing the chamber pressure with the saturated steam pressure calculated from the average chamber temperature. A measured pressure greater than the calculated saturated pressure indicates the presence of residual air in the chamber. Such monitoring devices are common in the United Kingdom.

Several types of autoclaves are available: gravity displacement steam sterilization, prevacuum steam sterilization, and steam flash-pressure pulsing steam sterilization autoclaves. The sterilization process is less consistent in gravity displacement steam sterilizers than in the other sterilizers (70). For example, gravity displacement autoclaves are more likely than the other systems to leave residual air in the chamber before the steam is introduced. Prevacuum sterilizers resolved part of this problem and cut the cycle time in half. However, the effectiveness of sterilization still can be compromised by small leaks (1 to 10 mm Hg/min) in the sterilizer (133). The most current technology is the steam flash-pressure pulsing steam sterilization technique, in which air leaks do not decrease the effectiveness of the process. This method nearly eliminates the problem of air in the chamber and reduces the thermal lag upon heating of the load to the desired exposure temperature (70).

The process of sterilization has several cycles: conditioning, exposure, and drying. Common cycles for steam sterilization in prevacuum or flash-pressure pulsing steam sterilizers are 121°C for 15 min (121°C for 30 min in a gravity displacement sterilizer) and 132°C for 4 min (see the FDA addendum to the sterilizer guidance, issued 19 September 1995 [http://www.cenorm.org]). EN 554 requires steam sterilizers to provide this temperature throughout the entire chamber within a narrow margin (0 to +3°C).

Flash sterilization is an emergency process used, for example, after a surgical instrument, which is needed immediately, is dropped during a procedure (158). Unwrapped devices are placed in a sterilizer (usually in the operating suite and sometimes without a biological indicator) and exposed to pressurized steam for 3 min. The autoclaves employed are gravity displacement sterilizers that have the problems mentioned previously. If health care workers are in a hurry, they may not clean the item properly, which will prevent proper sterilization. In addition, because the items are not wrapped, they can be contaminated easily when they are transported to the operating room. Even properly wrapped sterile items can become contaminated if they are transported several times (265). Moreover, some patients have been injured by items that were flash sterilized (214). Therefore, flash sterilization is controversial, and several investigators have suggested that it should be used only in emergency situations when no other device is available. Flash sterilization should not replace standard sterilization protocols (85) and should not be used to save time in sterilizing items by the standard methods or to avoid purchasing extra instrument sets (160). Because documentation takes time, staff members often do not document appropriately when they use flash sterilization. Consequently, if something goes wrong, tracing the sterilized items may be impossible.

Ethylene Oxide Gas

Temperature- and/or pressure-sensitive items have been sterilized traditionally with ethylene oxide in a standard gas.

Ethylene oxide inactivates all microorganisms, including spores, probably by an alkylation process. *Bacillus subtilis* bacterial spores are among the most resistant, and therefore, these are used as a biological monitor for this process. A new rapid-readout ethylene oxide biological indicator will indicate an ethylene oxide sterilization process failure by producing fluorescence, which is detected in an autoreader within 4 h of incubation at 37°C, and a color change related to a change in the pH of the growth media within 96 h of continued incubation (212).

The process of sterilizing items with ethylene oxide begins by adding nitrogen gas to remove air or by evacuating the chamber. Items are then exposed to ethylene oxide at 55°C (130°F). Six variable but interdependent parameters—gas concentration, vacuum, pressure, temperature, relative humidity, and time of exposure—must be controlled when ethylene oxide is used. The gas concentration cannot be measured on line, limiting the extent of monitoring. Therefore, the concentration should be validated as outlined by ISO 11135.

Ethylene oxide sterilization has several disadvantages; it is useful only as a surface sterilizer because it does not reach blocked-off surfaces. In addition, ethylene oxide is flammable, explosive, and carcinogenic to laboratory animals and it requires special safety precautions. Moreover, items sterilized by ethylene oxide must be aerated for approximately 12 h to remove any traces of the gas. Thus, the entire process takes >16 h, but modern ethylene oxide sterilizers can run at shorter cycles. Furthermore, toxic residues can be trapped in the wrapper or the items. Polyvinyl chloride and polyurethane absorb ethylene oxide readily and require long periods to dissipate the oxide. The wrapper should be a barrier against recontamination after sterilization, but it also can prevent ethylene oxide from reaching the item. Therefore, only materials with documented ethylene oxide penetration and dissipation properties should be used as wrappers.

The future of ethylene oxide in sterilization is limited, mainly due to its toxicity. However, no currently available technology, including plasma sterilization (see below), can replace sterilization with ethylene oxide entirely. In addition, sterilization with ethylene oxide does not fail as frequently as sterilization with plasma when residual proteins and/or salts are present on the items (11).

Plasma Sterilization

Low-temperature plasma is produced in a closed chamber with a deep vacuum, an electromagnetic field, and a chemical precursor (hydrogen peroxide or a mixture of hydrogen peroxide and peracetic acid). The resulting free radicals, the chemical precursors, and the UV radiation are thought to rapidly destroy vegetative microorganisms, including spores.

Sterrad

The Sterrad 100 sterilizer, the first plasma sterilizer for use in health care facilities, has been on the market in Europe since 1990 and in the United States since 1993. In August 1997, the Sterrad 100 system was approved to sterilize certain surgical instruments with long lumens, such as those used in urologic, laparoscopic, and arthroscopic procedures, including instruments with single stainless steel lumens of ≥3 and <400 mm in length. The Sterrad 100S has since replaced the Sterrad 100. The Sterrad 100S adds one sterilization cycle and, thereby, fulfills the requirement to kill 10^6 CFU of spores at the half point of the cycle. A smaller device, the Sterrad 50, has been independently tested for efficacy (207). Other sizes, e.g., the large Sterrad 200, approved by the FDA in 2003, can sterilize small lumens (single stainless steel lumens with an inside diameter of 1 mm or larger and Teflon or polyethylene lumens with an inside diameter of 6 mm or larger). The new Sterrad NX system, approved by the FDA in April 2005, is the fastest low-temperature hydrogen peroxide gas plasma sterilizer yet. This system employs a new vaporization system that removes most of the water from the hydrogen peroxide, improving diffusion of peroxide into lumens. Consequently, a broad range of instruments, including single-channel flexible endoscopes, can be processed within 38 min. In 2001, the FDA cleared biological indicators suitable for plasma sterilization.

Regardless of the model, the basic steps are the same. Medical instruments are placed in the sterilization chamber, a strong vacuum is created in the chamber, and a solution of 59% hydrogen peroxide and water is automatically injected from a cassette into the sterilization chamber. The solution vaporizes and diffuses throughout the chamber, surrounding the items to be sterilized. Radiofrequency energy is applied to create an electric field, which in turn generates the low-temperature plasma, inducing free radicals. The combination of the diffusion pretreatment and plasma phases sterilizes the item while eliminating harmful residuals. At the end of the cycle, the radiofrequency energy is turned off, the vacuum is released, and the chamber is filled with filtered air, returning it to normal atmospheric pressure.

Plasma sterilizers have several disadvantages. First, materials that absorb too much hydrogen peroxide (e.g., cellulosics and some nylons such as those from connectors, cables, and insulators), materials that catalytically decompose hydrogen peroxide (e.g., copper and nickel alloys from electrical wire, solder, and surgical instruments), and materials that react with hydrogen peroxide such as organic dyes (colored anodized aluminum) and organic sulfides of solid lubricants in endoscopic devices cannot be sterilized in a Sterrad. Second, the cassettes required to run the device and the special nonmuslin wrappers are relatively expensive.

Low-Temperature Sterilization by Ozone

The 125L ozone sterilizer uses medical-grade oxygen, water, and electricity to generate ozone within the sterilizer to provide an efficient sterilant without producing toxic chemicals or using high temperatures. (It runs at 25 to 35°C.) Ozone forms when oxygen is submitted to an intense electrical field that separates oxygen molecules into atomic oxygen (O), which in turn combines with other oxygen molecules (O_2) to form triatomic oxygen (O_3), or ozone, providing a sterility assurance level of 10^6 in approximately 4 h. At the end of the cycle, the oxygen and water vapor safely vent directly into the room. The sterilization chamber has a capacity of 125 liters. Processed medical instruments require no aeration at the end of the sterilization cycle. Medical devices are packaged in a TS03 sterilization pouch or in anodized aluminum sterilization containers. The TS03 OZO-TES'P' self-contained biological and chemical indicators should be used to evaluate the machine's performance. An ozone sterilizer can be installed as a free-standing unit or recessed behind a wall. These devices are used primarily in Canada. They are approved by the FDA, but few health care facilities in the United States use them.

Liquid Sterilization

The FDA approved the STERIS System 1 in 1988, but this system is not considered a sterilizer in Europe (72). The machine is designed to sterilize immersible devices, including flexible endoscopes, with 35% liquid peracetic acid (an

FDA-approved sterilant that is sporicidal [123, 126], supplemented with buffering, anticorrosion, wetting, and surface-active agents). Peracetic acid is automatically diluted with sterile filtered water, and the items are exposed for 12 min. The entire sterilization process takes approximately 30 min at ca. 50°C. Items can be used immediately after the process is completed and do not need to be aerated.

Clinical studies of the STERIS System 1 have been performed with bronchoscopes, hysteroscopes, colonoscopes, and rigid endoscopes (42, 254). Independent efficacy tests demonstrated some failures (42). Exposure time and temperature are monitored electronically, and conductivity is used as a surrogate marker for peracetic acid concentration. However, the machine can complete its cycle normally and print a report stating that the concentration of peracetic acid was in the normal range when it was run intentionally without peracetic acid (161). Commercially available spores can be used for monitoring sterilization (145), but false-positive test strips can occur, related to improper use of the clip that attaches the test strips (110). Other disadvantages of this system include the high cost of purchasing and using the equipment, which is considerably greater than the cost of purchasing and using systems for high-level disinfection with glutaraldehyde (95). In addition, the device does not clean the items. Thus, the cleaning step adds to the overall time of reprocessing the items. The STERIS System 1, like all other nonsteam sterilizers, cannot meet the requirements for sterilization if residual debris and/or proteins are present on the items.

Hot Air Sterilization

Hot air sterilization is not a state-of-the-art technology, but it is still used in many countries. However, the distribution of dry heat to the instruments requires long exposure times. Temperatures of >185°C resinify paraffin, destroying instruments' lubrication, and higher temperatures are corrosive, resulting in loss of hardness. Therefore, hot air sterilization has largely been replaced by better, safer, and faster technologies.

REUSE OF SINGLE-USE DEVICES

Current FDA policy states that the responsibility for the safety and performance of reprocessed single-use devices lies with the reprocessor, not the original manufacturer. The FDA considers the hospital to be the manufacturer of a single-use device if the device has been resterilized. Therefore, the reprocessor must ensure that the reprocessed items are sterile and are not contaminated with toxic substances such as endotoxins or residual ethylene oxide and that the product's integrity, composition, and function are essentially identical to those of a new product. Most hospitals cannot afford to generate appropriate data on the quality and performance of reprocessed single-use items. In addition, if a manufacturer changes the product, the reprocessor needs to redo the analyses before the device can legally be marketed after reprocessing (management-of-change guidelines). The FDA published a final guidance (see the website for details: http://www.fda.gov/cdrh/ohip/guidance/1333.html and http://www.fda.gov/cdrh/ohip/guidance/1408.html).

Some institutions resterilize items that have not been used on patients but that, for instance, were dropped and/or had the packages damaged. Even this approach can be problematic. For example, the FDA published an alert documenting that the quality of an implant that was originally sterilized with ethylene oxide and then resterilized with steam was impaired by the reprocessing method (see http://www.fda.gov/cdrh/steamst.html for details). In addition, the quality, product integrity, and performance of many reprocessed plastic or rubber products are unknown. Moreover, the FDA does not allow health care facilities that send equipment and supplies to a reprocessing company to transfer full responsibility to that company (see the full text at http://www.fda.gov/medwatch/safety/1997/device.htm). Furthermore, if a hospital reprocesses a single-use device, the hospital is responsible for ensuring that the device complies with all applicable FDA labeling requirements, even if the device is exempt from the premarket requirements. If the hospital does not ensure that the device complies with FDA labeling requirements, the device is misbranded and the hospital may be considered in violation of section 301(k) of the Food, Drug and Cosmetic Act. As of 14 August 2001 and 14 February 2002, the FDA enforces premarket filing requirements for reprocessed class II devices (i.e., moderate-risk devices such as a cardiac mapping catheter used to map electrical activity of the heart; http://www.fda.gov/cdrh/comp/guidance/1168.pdf) and marketing clearance requirements. Many issues are not yet resolved. The FDA has set a prioritization scheme (http://www.fda.gov/cdrh/reuse/1156.pdf).

In many countries throughout the world, health care facilities reprocess single-use items (sometimes illegally) because resources are limited and this activity may be the only way to provide patients with access to state-of-the-art health care. In fact, a commercial reprocessor in Germany legally reprocessed >4 million single-use items without any serious reported side effects, saving between 30 to 50% of the cost of new items. Thus, we believe that new reprocessing technologies using washer-disinfectors coupled with highly effective low-temperature sterilizers can kill all microorganisms, even in narrow lumens such as cardiac catheters. We also believe that with the expertise of infection control personnel, health care facilities can provide the desired level of microbiological and toxicological safety. However, they probably cannot ensure that the design and function of the devices are still adequate. Thus, in the United States and countries with similar regulations on quality assurance programs, reuse of single-use devices may not be cost-effective. In addition, organizations that sell used single-use devices to patients and/or insurance companies as new devices will encounter legal and ethical issues. Because devices change and new devices are introduced, it is difficult for health care facilities and reprocessing companies to do the studies needed to document that reprocessing is safe, thus making it difficult to reprocess single-use devices on a large scale. However, financial restriction may change the current belief that patients will not accept reprocessed single-use devices. The reader should consult the FDA website and experts in the field before considering reprocessing of single-use devices.

BOVINE SPONGIFORM ENCEPHALOPATHY AND VARIANT CREUTZFELDT-JAKOB DISEASE

CJD has been identified on all continents and is thought to occur worldwide. The incidence of CJD is estimated to be about 1 case per 10^6 persons per year. Most cases of CJD are sporadic; <10% of CJD cases may be related to a genetic autosomal dominant predisposition, and some nosocomial cases are related to the use of contaminated tissue or contaminated human growth hormone. It is generally accepted that eating BSE agent-contaminated meat is the cause of vCJD (121, 188). The vCJD has brought about a major medical and economic crisis in Europe (49, 140, 188).

By 1 January 2006, 154 cases were reported from the United Kingdom. Cases that fulfill the new WHO case definition (21 May 2001) also have been reported from France (14 cases), Canada (1 case), Spain (1 case), Ireland (1 case), and Italy (1 case). The peak of the epidemic was in the year 2000 (28 cases in the United Kingdom), falling to 5 cases in the United Kingdom in December 2005. In the United States, one patient who was a former resident of the United Kingdom has been diagnosed with vCJD and the first case of BSE in cattle was identified in 2003. However, more cases may occur because 37 tons of "meals of meat or offal" that were "unfit for human consumption" was sent from the United Kingdom to the United States in 1997, well after the government banned imports of such risky meat (59). As of 2006, no curative therapy is available for CJD or vCJD; however, several approaches have been investigated with limited success (103).

The agent causing vCJD is not a classic microorganism but an altered prion protein (5, 33, 187, 220). Its origin remains obscure, but the BSE agent from cattle is most probably responsible for the vCJD in humans. In the 1980s a step in tallow extraction from rendered carcasses was eliminated, allowing some tissue infected with scrapie to survive the process and allowing the infectious agent to be recycled as cattle-adapted scrapie or BSE. The animal food was no longer sterilized at 134°C for 20 to 30 min but, rather, was pasteurized before being fed to animals whose carcasses, with encased spinal cords and paraspinal ganglia, were later processed legally into hot dogs, sausages, and precooked meat patties (47). Investigators postulate that a high incidence of scrapie in sheep and a large proportion of sheep in the mix of carcasses that was rendered for livestock feed may explain why the incidence of BSE in British cattle was more than 10 times higher than that in cattle in any other European country. In the United Kingdom, the number of people exposed to potentially infective doses through food may be extremely high.

vCJD has a different clinical presentation and occurs at a much younger age than CJD (60). The mean age at death from vCJD is 28 years; only 6 of 90 patients died at the age of 50 years or older (248). Two hypotheses that may explain why the age group of 50 and under is most affected are that the incubation period is shorter in the young than in the elderly and that the young are more susceptible to infection. In addition, all patients genotyped so far are homozygous for methionine on codon 129 of the prion protein gene. It is postulated that heterozygous individuals may have much longer incubation times before vCJD becomes evident. Therefore, asymptomatic carriers may pose a risk for transmission if they undergo routine surgery and instruments are not reprocessed by a prion-safe program.

Patients suffering from vCJD harbor large numbers of prions in their tonsils and spleens before they have signs, symptoms, and pathological findings from the disease. In contrast, patients with sporadic CJD suffer from spongiform encephalopathy long before the prion spreads into muscles and lymphoid tissue (120). Consequently, France has developed very strict precautions. For example, the United Kingdom required that all tonsillectomies be performed with disposable instruments. In 2002, this practice was discontinued because serious complications arose when disposable instruments were used.

The fact that the vCJD prion agent is found in lymphoid tissue and tonsils indicates that prions are not restricted to neural tissue (103). Studies of sheep naturally infected with scrapie demonstrate that the infectious agent first appears in lymphatic tissue of the tonsils and gastrointestinal tract, suggesting that the oral route may be the principal mode of transmission. In addition, numerous studies underline the importance of B cells in transmission of the BSE agent (142). Lymphatic organs typically show early accumulation of prions and B cells, and follicular dendritic cells are required for efficient neuroinvasion. The actual entry into the central nervous system probably occurs via peripheral nerves, and the prion accumulates in neural tissue once inflammation of the lymphoid tissue is in progress (116).

Experimental evidence from animal models indicates that blood can contain prion infectivity, which suggests a potential risk for transmissible spongiform encephalopathy transmission via proteins isolated from human plasma (124). Three cases of probable transmission by blood transfusion raise more concern about the safety of the blood supply (4). In the United States, beginning in August 1999, persons who resided in or traveled to the United Kingdom for a total of 6 months from 1980 through 1996 have been deferred from blood donation, as have persons who received bovine insulin derived from cattle in the United Kingdom. Recently, both the American Red Cross and the FDA announced new, expanded deferrals for travel and residence in the United Kingdom and other European countries (58) and they are conducting a look back to consider recipients who received potentially contaminated blood. The United Kingdom no longer collects plasma from its inhabitants and, as a further precautionary measure, has instituted leukocyte reduction (removal of white blood cells) for blood transfusions.

Previously, problems with reprocessing of instruments used on patients with CJD were limited to invasive instruments that came into contact with neural tissue, predominantly instruments used in neurosurgery. However, as noted above, vCJD is highly lymphotropic, so that any instruments used on lymphoid tissues may be contaminated with prions (142). As outlined above, appropriate reprocessing of surgical items includes cleaning, disinfection, and sterilization. Aldehydes enhance the resistance of prions and abolish the inactivating effect of autoclaving (48). Therefore, aldehydes are no longer recommended for disinfecting surgical instruments in Europe before they have undergone a thorough cleaning process. In France, aldehydes are no longer used for endoscope reprocessing, despite evidence that peracetic acid may stain prions as well (136). Small resistant subpopulations of infective prions may survive autoclaving at 132 to 138°C. These resistant subpopulations are not inactivated by reautoclaving, and they have biological characteristics that differentiate them from the main population (240). The worst-case scenario is that the agent for vCJD might become self-replicating when it contaminates surgical instruments. Therefore, prions challenge reprocessing techniques like never before.

The minimum requirements for decontamination procedures and precautions for materials potentially contaminated with either the agent that causes CJD or the agent that causes vCJD remain unknown. However, it is clear that dry heat (160°C for 24 h), formaldehyde sterilization, and standard steam sterilization do not sterilize prion-contaminated items (80). The scientific uncertainties and lack of data do not allow agencies like national health departments, the WHO, or the CDC to formulate guidelines that are completely evidence based, and this explains why various countries have taken different approaches to addressing issues of reprocessing of instruments. In January 2001, the British government spent the equivalent of $300 million to improve reprocessing techniques in Central Sterilization Services and required the use of disposable instruments for tonsillectomies. The French Public Health Office published their recommendations on 14 March 2001. They require all

surgical instruments with potential exposure to lymphatic tissue, the central nervous system, or the eyes to be soaked in sodium hypochlorite for 1 h or NaOH for 1 h and sterilized at 134°C for 18 min. If instruments do not tolerate this aggressive approach, they must be cleaned twice, treated with various chemicals such as peracetic acid, iodophores, 3% sodium dodecyl sulfate, or 6 M urea, and autoclaved at 121°C for 30 min. Since 2002, Switzerland requires all surgical instruments to be sterilized at 134°C for 18 min. The background of the Swiss recommendation is that the usual rendering process for carcasses, which was discontinued, resulted in only a 1-log-unit reduction of the infectious particles (241). Therefore, a reduction in the number of infectious particles may suffice to stop transmission. The CDC recommends that instruments exposed to potentially prion-contaminated items to be autoclaved for 1 to 1.5 h at 132 to 134°C, immersed in 1 N sodium hydroxide for 1 h at room temperature, or immersed in 0.5% hypochlorite sodium (at least 2% free chlorine) for 2 h at room temperature. (See the CDC website for further information: http://www.cdc.gov/ncidod/dvrd/vcjd/index.htm.) However, these recommendations are not based on what is known about the agent of vCJD.

High-risk patients are patients with suspected CJD and their family members, patients treated with pituitary extracts, and patients who received cornea transplants. In addition, items should be considered contaminated with prions if a brain biopsy for the diagnosis of CJD is requested. Instruments used in such procedures should be discarded or placed under quarantine until the histopathological diagnosis is known. The incidence of vCJD in the United Kingdom is decreasing rapidly, indicating that current reprocessing techniques suffice. However, knowledge about this topic is increasing rapidly over time and our current understanding may be shown to be false in the future (26). In May 2005, British officials published an excellent assessment of the risk for contaminating surgical instruments with prions (http://www.dh.gov.uk/assetRoot/04/11/35/42/04113542.pdf). The key observation in this report is that on average 0.2 mg of protein remains on surgical instruments despite "standard cleaning and disinfection," which is sufficient to cause an experimental case of CJD. Therefore, more research and new methods of cleaning and disinfection are needed for surgical instruments. The reader is referred to the websites of the CDC, the FDA, and the WHO to obtain the most recent updates on this topic.

Prevention and Control of Laboratory-Acquired Infections*

MICHAEL A. NOBLE

8

Laboratory biosafety describes the active, assertive, evidence-based process that laboratorians use to prevent microbial contamination, infection, or toxic reaction as they actively manipulate live microorganisms or their products, thereby protecting themselves, other laboratory workers, the public, and the environment (43). The goals of a laboratory safety program are to prevent laboratory-acquired infections in workers and to prevent accidental releases of live agents that may endanger humans, animals, and plants. Laboratory safety programs involve all aspects of the laboratory cycle, starting before the specimens or microorganisms arrive in the facility, including the processes used to handle specimens or organisms in the laboratory (e.g., the proper use of reagents, materials, and equipment and the safe storage and transport of specimens and organisms), and culminating when specimens or cultures are terminally sterilized or pathogenic microorganisms are destroyed. Laboratories must train their personnel to use safe practices and must develop methods for monitoring work practices.

EPIDEMIOLOGY

Infections are usually characterized as laboratory acquired in retrospect, and these assessments are often based on the assumption that the only likely exposure occurred while the person was in a laboratory or on the finding that a source of exposure outside the laboratory cannot be identified. Consequently, trivial laboratory events may be considered possible exposures (30, 37). However, one must appreciate that the total laboratory testing cycle begins well before the sample actually reaches the laboratory (the preanalytic phase of laboratory testing) and that personnel can be exposed while they collect and transport samples. In the past, infections acquired while personnel collected samples were considered to be laboratory acquired if the samples were collected solely for a laboratory investigation. Currently, infections acquired by phlebotomists through needle stick injuries are routinely considered to be laboratory-acquired infections (24), but infections acquired by phlebotomists when they inhale droplet nuclei (e.g., those from chicken pox) as they collect samples in patients' rooms are not included in this category (23).

Microbiology laboratories run by pioneers including Pasteur and Koch were active by 1840 to 1860. The first known laboratory-acquired infection, Mediterranean fever, was reported in 1899 (11). Sulkin and Pike conducted the first systematic study of laboratory-acquired infections when they surveyed 5,000 American laboratories in 1951 (22). Sulkin extended this study in 1961 and 1965, and Pike extended it further in 1976. In total, Sulkin and Pike cited 3,921 laboratory infections between 1930 and 1974, with a mortality of 164 (4.1%). These infections were reported from research facilities (2,307; 58.8%), diagnostic facilities (677; 17.3%), industries producing biological products (134; 3.4%), and teaching facilities (106; 2.7%); 697 (17.8%) did not have a source specified.

The results of four surveys performed in the United Kingdom between 1971 and 1991 indicated that within clinical facilities, the most infections were identified among workers in the microbiology laboratory, followed by those in the autopsy service (23). Over the 20-year period, the number of infections reported each year dropped more than 80%, from 104 to only 17. It would be tempting to conclude that this decline indicates that laboratories are becoming safer; however, there are no active monitoring or surveillance programs that capture the true number of accidents and infections. Thus, even comprehensive listings of laboratory-acquired infections are incomplete (52).

LABORATORY SAFETY AND PERSONAL ATTRIBUTES

Phillips conducted a matched-case control study of 33 laboratory workers who experienced laboratory-associated injuries over a 2-year period and found no differences in ages, lengths of employment, years of formal education, use of glasses, use of prescription medications, off-the-job accidents, or driving records for person with injuries and those without injuries (45). However, persons in the group who had accidents were significantly more likely to have had a laboratory accident or a laboratory infection before the 2-year study period and were significantly more likely to have a low opinion of laboratory safety programs. When the conditions surrounding the accidents were examined, 36% of accidents were found to occur when the employee was working too quickly, either just before lunch or at the end of the day. In 30% of accidents, the employee acknowledged breeching safety regulations. In summary, in this study attitudes and work habits were important

*This chapter contains information presented in chapter 9 by Andreas Voss and Eric Nulens in the eighth edition of this Manual.

contributing factors to laboratory accidents. Similar results linking attitudes and behaviors with poor safety practices continue to be found.

Over time, laboratorians have learned that even conventionally accepted practices can result in serious infection. Mouth pipetting, marking blood spots, transporting samples to the laboratory in corked or sheathed sharps, recapping needles, and eating or smoking in the laboratory were at one time common practices in properly run medical laboratories. All of these practices are now known to be risky and are prohibited. Other common practices, such as examining bacterial culture plates with an eyeglass or sniffing plates to help identify organisms, are now controversial (9). Thus, to maintain and improve laboratory safety, staff members must review and critique current practices diligently and be open to changing their procedures as appropriate.

RISK-BASED CLASSIFICATION OF MICROORGANISMS

The international community has developed a common risk classification scheme for microorganisms that can help laboratories determine the best laboratory practices and environmental requirements . Group 1 biological agents are unlikely to cause human disease. Group 2 biological agents can cause human disease and may be a hazard to workers but are unlikely to spread to the community; effective prophylaxis or treatment is usually available. Group 3 biological agents cause severe human disease and are a serious hazard to workers; they may spread to the community, but effective prophylaxis or treatment is usually available. Group 4 biological agents cause severe human disease and are a serious hazard to workers; they may present a high risk of spreading to the community, and effective prophylaxis or treatment is usually not available. A partial list of microorganisms by category is provided in Table 1.

Different countries usually classify organisms consistently. However, there are some organisms that are classified differently by different countries. These differences can affect a laboratory's certification, and laboratories that send agents domestically or internationally must know the local and international requirements.

Conventionally, laboratory behavior and practices have been matched to the level of risk associated with expected hazards. (See Table 2 for practices considered to be appropriate for handling of samples with group 2 agents.) Recently, microbiologists have begun to rely less on a rigid classification of organisms when designing laboratory practices and rather to mix different levels of containment and safety practices to match the risk posed by each organism. Thus, in working with a particular organism, the best laboratory practice may be to use biosafety level 2 containment with a higher level of safety practices. Moreover, laboratorians should not treat all situations as equal. Rather, they must consider biosafety to be a

TABLE 1 Risk-based classification of microorganisms[a]

Group	Bacterium(a)	Virus	Fungus(i)	Parasites
1	No clinical organisms			
2	*Bacillus* species (not *Bacillus anthracis*)	Adenovirus	*Cryptococcus* species	All clinically important parasites
	Clostridium species	Calicivirus	*Candida* species	
	Corynebacterium diphtheriae	Coronavirus (not Co-V)	All dermatophytes	
	Escherichia coli	Herpesvirus	*Aspergillus* species	
	Enterobacteriaceae	Influenza virus		
	Mycobacteria other than *Mycobacterium tuberculosis*			
	Staphylococcus species			
	Streptococcus species			
3	*Bacillus anthracis*	Lymphocytic choriomeningitis Hantaan virus	*Coccidioides immitis*	
	Brucella species	St. Louis encephalitis virus	*Blastomyces dermatitidis*	
	Coxiella burnetii	Japanese encephalitis virus	*Histoplasma capsulatum*	
	Francisella tularensis	Western equine encephalitis virus	*Paracoccidioides braziliensis*	
	Mycobacterium tuberculosis	West Nile encephalitis virus		
	Mycobacterium avium	SARS coronavirus		
		Prions		
4		Lassa virus		
		Marburg virus		
		Ebola virus		
		Herpes simiae virus		

[a] Based on reference 29a. This table is presented as a guide only. It should not be considered to be either complete or consistent with all jurisdictions. Specific national requirements may differ from the information presented in this table.

TABLE 2 Standard microbiology practices for all laboratories (biosafety level 2 and higher)[a]

1. A documented safety manual must be available for all staff.
2. Personnel must receive training on the potential hazards associated with the work involved and the necessary precautions to prevent exposure to infectious agents.
3. Eating, drinking, smoking, storing either food or personal belongings, and applying cosmetics are not permitted.
4. Mouth pipetting is prohibited.
5. Long hair is to be tied back or restrained.
6. Access to laboratory and support areas is limited to authorized personnel.
7. Doors to working areas in laboratories must not be left open.
8. Open wounds and cuts should be covered with waterproof dressings.
9. Laboratories are to be kept clean and tidy.
10. Protective laboratory clothing, properly fastened, and footwear with closed toes and heels must be worn by all personnel, visitors, trainees, and others working in the laboratory.
11. Eye and face protection must be used where there is a known or potential risk of exposure to splashes or flying objects.
12. Gloves must be worn for all procedures that may involve direct skin contact with biohazardous material. Gloves are to be removed when a laboratory task is completed and before leaving the laboratory.
13. Protective laboratory clothing must not be worn in nonlaboratory areas.
14. If known or suspected exposure occurs, contaminated clothing must be decontaminated before laundering.
15. The use of needles, syringes, and other sharp objects should be limited strictly. Needles should not be bent, sheared, recapped, or removed from the syringe; they should be promptly placed in a puncture-resistant sharps container for disposal.
16. Hands must be washed with an appropriate antiseptic soap or rubbed with an alcohol-based hand gel after gloves have been removed, before leaving the laboratory, and at any time after handling materials known or suspected to be contaminated.
17. Work surfaces must be cleaned and decontaminated with a suitable disinfectant at the end of the day and after any spill of potentially biohazardous material.
18. Contaminated materials and equipment that are removed from the laboratory for servicing or disposal must be appropriately decontaminated.
19. Autoclaves used for decontamination should be regularly monitored with biological indicators.
20. All contaminated materials must be decontaminated before disposal or reuse.
21. Leak-proof containers are to be used to transport infectious materials.
22. Spills, accidents, breaches of containment, or exposures to infectious materials must be reported immediately to the laboratory supervisor.
23. An effective rodent and insect control program must be maintained.

[a] Adapted from references 29a and 56a.

dynamic rather than a static interaction. Factors that influence risk include the specific biohazardous agents, the sample volumes, the concentrations of the agents in the samples, the most likely routes of exposure, the workload, host factors (e.g., immunosuppression or pregnancy), the complexity of the task, and the knowledge and experience of the worker.

ASSESSING RISK AND HAZARDS

To plan strategies for improving safety, the staff first must recognize risk factors, potential weak points in processes, and possible solutions. Regular laboratory audits can also help the staff recognize specific problems, and sometimes these problems can be solved by implementing or reactivating established guidelines. A failure modes and effects analysis can help the staff assess current approaches and plan improvements.

BIOSAFETY AND CLINICAL LABORATORY DESIGN

Persons designing laboratories, including the containment equipment and facilities, must know the classifications of microorganisms flowing into a laboratory. For research laboratories, where the microorganism load is known, the process of matching risk and containment is straightforward. However, in clinical laboratories, the contents of samples are usually unknown and specimens may contain microorganisms across the spectrum of classification. That being said, most isolates recovered from clinical samples are classified as biosafety level 1 or 2; thus, most clinical laboratories must be able to provide containment level 2 (Table 3). Laboratories that process viral cultures or investigate mycobacterial cultures should be designed to accommodate level 3. Laboratories that may handle exotic pathogens in risk group 4 must have high-containment level 4 facilities.

In the wake of the 2001 terrorist attacks in New York and the anthrax mail scares that happened shortly afterwards, microbiologists have become aware that laboratory biosafety measures are a component of bioterrorism defense (18, 35, 49, 53). Specific funding has been allocated for the construction of new national and regional biocontainment laboratories. Laboratories with increased levels of containment and security are useful not only for addressing possible bioterrorism and biosecurity issues but also for handling specimens from epidemics of emerging infections, such as severe acute respiratory syndrome (SARS) and pandemic influenza. These laboratories must control access to their facilities, systematize procedures for specimen receiving and disposal, develop incident reporting and emergency response plans, provide security for stored agents, and if appropriate, track specimens accurately and develop trace-back systems (40, 48, 49). Caution needs to be taken to ensure that the needs for confidentiality and information containment do not interfere with the open communications necessary for laboratory safety and public health (37).

TABLE 3 Laboratory design requirements for biosafety level 2 laboratories[a]

1. A space separated from public areas by lockable doors
2. Laboratory doors with appropriate signage
3. Door openings of sufficient size to allow safe passage of equipment
4. Work surfaces that are nonabsorptive and scratch, stain, chemical, and heat resistant
5. A means of treating waste before disposal must be readily available.
6. Windows designed to prevent ingress of flying insects
7. Separate spaces for street and laboratory clothing
8. Ready access to hand-washing sinks
9. Emergency showers and eye-washing stations
10. Biosafety cabinets and other primary containment equipment (recommended)
11. Hand-washing sinks that can be operated without hands (recommended)
12. An air supply of 100% outside air with no recirculation (recommended)

[a] Adapted from references 29a and 56a.

SAFETY EQUIPMENT AND THE CLINICAL LABORATORY

Splashguards

Splashguards, the minimum level of safety equipment, should be made of cleanable, clear glass or plastic and should be large enough to protect workers from gross splashes. Memos and procedure descriptions should not be taped onto splashguards because they prevent workers from seeing what they are doing. Splashguards can be effective barriers provided that they are appropriately placed with respect to both workflow and the workers' heights. Staff members can use splashguards as an appropriate alternative to biosafety cabinets when opening vacuum blood tubes.

Biosafety Cabinets

Biosafety cabinets can protect the laboratory worker and the laboratory environment from splashes and aerosols and also protect samples from becoming contaminated (55, 56). Class 1 cabinets have an open front and are under negative pressure with respect to the laboratory; these cabinets exhaust their air through a HEPA filter, and the exhausted air usually is returned to the work area. Class 2 cabinets increase the level of safety by including a HEPA-filtered downward-flow air curtain, which increases the degree of separation between the air in the room and the air in the cabinet. Class 2 cabinets may exhaust air back to room air (Class 2A) or through an exhaust system to the air outside the building (Class 2B). Class 2B cabinets can be further subclassified based on additional features. Class 3 cabinets are completely enclosed and provide gas-tight containment. They are accessible only through glove ports. Class 3 cabinets provide the most suitable containment for working with exotic pathogens. Because class 1 and class 2A units exhaust air into the laboratory, they should not be used to handle volatile chemicals and reagents. Because biological safety cabinets often have open heating elements or flames and may not have anticorrosive ductwork, they should not be used as alternatives to chemical fume hoods.

All safety cabinets must be tested and certified by a qualified person on a regular basis to ensure that they maintain their required face velocity and negative pressure. That being said, even properly maintained and certified cabinets can malfunction and put staff members at risk if equipment and materials are improperly placed inside the cabinet. If the cabinet is overcrowded or equipment is stacked against the front or back grill, airflow will be disrupted and contaminated air may backwash out the front of the unit.

Chemical Fume Protection

A fume hood is a mechanically ventilated, partially enclosed workspace where harmful volatile chemicals and reagents can be handled safely. The primary function of a fume hood is to contain and remove gases and vapors. Most fume hoods use ducts and a fan to capture heat and airborne chemical contaminants, transport them out of the work area, and discharge them into the atmosphere outside the building. Chemical fume hoods differ from biosafety cabinets in that they are usually ducted, must be constructed of noncombustible materials, and must be explosion proof. Nonducted, or recirculating, fume hoods cannot be used in the laboratory to contain volatile chemicals (17). Laboratories that work with specific highly corrosive reagents or chemicals such as perchloric acid or with radioisotopes need fume hoods designed to accommodate these agents.

Fume hoods must be placed in rooms with sufficient airflow that is properly balanced so that the air entering the fume hood is replaced and backwash into the room is prevented (17). Chemical fume hoods should be tested regularly for face velocity and for containment with the ASHRAE 110 tracer gas test. Face velocity alone is not a valid indication of containment (17).

Centrifuges

The safety centrifuge was first described in 1975 (28). However, accidental contamination of laboratories and personnel continues to occur because staff members do not use centrifuges properly (19, 27). Rotors can become contaminated if plastic centrifuge tubes crack or distort while being spun (27). If the O-ring seals on containers and rotors do not create a good seal, organisms can be aerosolized (29). Thus, centrifuges must be maintained properly (2) and must be used properly. Laboratories should maintain a log for each centrifuge that includes the rotor serial number, the speed in revolutions per minute, the spin duration, the time of use, and the operator's name for each use (2). Basic safety procedures for centrifuges include having workers (i) keep a centrifuge's lid closed while the centrifuge is operating, (ii) stay with a centrifuge until the full operating speed is attained and the machine is running without vibrating, (iii) stop immediately and check the load balances if the centrifuge vibrates, (iv) check swing-out buckets for clearance and support, (v) use a noncorrosive product to clean and disinfect rotors and cups after each use, (vi) report all spills and breakage to the laboratory safety officer, and (vii) clean spills as soon as aerosols have settled.

Sharps Protection

Scalpels, needles, broken glass, and other sharps commonly cause injuries and laboratory-2 acquired infections (7). To the extent possible, staff members either should not use sharps by hand or should use safety barriers (25). Because sharps may be contaminated with infectious or cytotoxic agents or both, they should be discarded in sharps containers.

Sharps containers minimize injuries and transmission of potentially harmful agents if they are readily accessible and appropriately used. Sharps containers used in medical laboratories should be designed specifically for sharps such as needles, syringes with needles, blades, clinical glass, and other items capable of causing cuts or punctures (25). Sharps containers should be leak proof and puncture resistant and should not degrade in autoclaves, either require no assembly or be easy to assemble, have a designated fill line, be appropriately labeled, and be available in a variety of sizes. Within this framework, manufacturers can implement a variety of designs. Sharps containers should resist toppling over and should be durable enough to withstand being dropped onto a hard surface (6). Containers that are not resistant to penetration or compression put staff members at risk. Tin cans or other containers should not be used in lieu of containers designed specifically for sharps.

Sharps containers must be labeled prominently with the universal biohazard symbol. In addition, sharps containers for sharps contaminated with cytotoxics must display the cytotoxic hazard symbol. The international color code is yellow for biohazardous medical sharps and red for cytotoxic medical waste including contaminated sharps.

Staff members should never force sharps into a container, and they should not fill containers to more than three-quarters of their maximum capacity to avoid accidents from overfilling. Once filled, sharps containers should be securely and irreversibly closed for containment. The containers should be sterilized in an autoclave and then disposed of in accordance with local requirements. Containers with sharps contaminated with cytotoxic or prion proteins must be incinerated.

Most sharps containers are designed for single use only. However, some commercial units that can be reused are now available. These containers must be transported to a central disposal unit where they can be opened safely, emptied, decontaminated, and redistributed.

REQUIREMENTS OF THE INTERNATIONAL ORGANIZATION FOR STANDARDIZATION

The International Organization for Standardization Technical Committee 212 has developed documents that medical laboratories should use to improve their performance, including ISO 15189:2003, *Medical Laboratories—Particular Requirements for Quality and Competence* (32c), and ISO 15190:2003, *Medical Laboratories—Requirements for Safety* (32d). In those countries where laboratories are certified or accredited according to International Organization for Standardization requirements, these documents are considered essential standards.

ISO 15190:2003 states that the laboratory's management is responsible for the safety of all employees and visitors to the laboratory and that ultimate responsibility rests with the laboratory director. The laboratory must identify an appropriately trained and experienced laboratory safety officer to assist the laboratory director and managers with safety issues. The laboratory safety officer must have the authority to stop activities that are deemed unsafe. The laboratory safety officer is responsible for designing and maintaining the laboratory safety program and for monitoring its effectiveness. The International Organization for Standardization requires that a laboratory safety program include a laboratory safety manual, safety audits (see Table 4 for audits required by ISO 15190:2003), inspections, risk assessments, and safety records. For further details, ISO 15190:2003 is available through the International Organization for Standardization website (www.iso.ch) or the Clinical and Laboratory Standards Institute (www.clsi.org).

TABLE 4 Laboratory safety audits required by ISO 15190:2003 (32d)

Health and safety policy
Written procedures that include safe work practices
Safety-oriented education and training of staff
Safety-oriented supervision
Use and maintenance of hazardous materials and substances
Health surveillance
First-aid equipment and services
Accident and illness investigations
Health and safety committee review
Records and statistics on accidents and near misses
Review of safety program
Regular site safety inspections

SAFETY PREPAREDNESS AND THE MATERIAL SAFETY DATA SHEET

Every laboratory should have a readily accessible written plan that staff members can use in case of emergencies or accidents. Laboratories can use published guidelines (25) as they prepare their own plan. In addition, up-to-date Material Safety Data Sheets (MSDS) for all chemicals and microorganisms; equipment and materials for containment of spills, including personal protective equipment, absorbent, and disinfectant (bleach or accelerated hydrogen peroxide); and personnel trained in first aid should be readily available, and their locations should be known by all staff members. Moreover, staff members should know the location of emergency equipment, including showers and eye-washing stations; should know routes for evacuation in case of a fire or a spill; and should practice evacuating regularly. Showers and eye-washing stations should be tested regularly to ensure that they will function when needed. A regular internal safety audit program should assess whether staff members are prepared to deal with accidents.

MSDS for chemicals should be obtained from the supplier, or may be available from a variety of commercial and free Internet sites. A list of MSDS for microorganisms is available through the Public Health Agency of Canada website (http://www.phac-aspc.gc.ca/msds-ftss/).

It is beyond the scope of this chapter to address the specifics of the medical management following accidents that involve infectious agents. That being said, laboratories should follow several steps if exposures occur. Staff members should (i) report every accident or injury, including those that are seemingly trivial (30), to the appropriate safety officer or supervisor; (ii) clean scratches and puncture wounds immediately; (iii) seek medical attention quickly, especially if it is recommended by first-aid attenders or occupational health advisors (5); and (iv) give the microorganism's MSDS to the clinician evaluating the injury if the likely or probable

agent is known. In addition, staff members should investigate each incident to learn the details of the accident and to identify its root causes and recommend preventive measures. Subsequently, staff members should audit compliance with the recommendations to ensure that they have been incorporated into practice in a timely manner.

HAND HYGIENE AND THE USE OF PERSONAL PROTECTIVE EQUIPMENT

Hand Hygiene

Hand washing and hand antisepsis are the most useful techniques for preventing transmission of microorganisms and for protecting staff from laboratory-acquired infections (14). Hands can become contaminated when staff members collect samples, handle sample containers, handle contaminated equipment, or touch sample storage units.

Nonmedicated detergent-based soap products and water do not disrupt normal skin flora but can reduce the number of transient hand flora, including both bacteria and viruses (14, 54). The efficacy of hand washing with such products is directly related to the duration of the procedure. Plain soaps can dry and irritate skin. Plain soaps may be appropriate in public washrooms but are not appropriate in the clinical laboratory. A variety of antimicrobial products are available, including products containing chlorhexidine, triclosan, iodophors, and others. Staff members should consider issues such as the types of organisms processed by the laboratory and also characteristics of each product (e.g., the fragrance, consistency, and propensity to irritate and dry skin) when selecting products for use in the laboratory.

Waterless, alcohol-based hand hygiene products can be rapid and convenient alternatives to hand washing with water and antimicrobial soap products, especially when a sink with running water is not immediately accessible (38, 54). The efficacy of alcohol-based products may be reduced when staff members' hands are soiled or are contaminated with spore-forming organisms or nonenveloped viruses (54). Staff members should wash their hands with an antimicrobial soap and with water when their hands are visibly soiled or are contaminated with proteinaceous materials or with materials that have a high microbial load.

Gloves

Gloves can be an important barrier within the laboratory, provided that they are used appropriately (25). Clearly, gloves prevent damage when hands are exposed to heat, cold, and toxic materials. For example, staff members should use insulated gloves when they take materials out of −70°C freezers, when they work with liquid nitrogen, and when they remove materials from autoclaves. General purpose utility gloves (kitchen or rubber gloves) provide ample protection for cleaning of biological spills and for decontamination. Utility gloves can be cleaned and reused. They should be examined regularly for cracks, tears, and peeling, and damaged utility gloves should be discarded. Staff members handling chemical solvents, toxic chemicals, and dyes should not use utility gloves but rather should use chemical-resistant gloves that should be available in all laboratories that handle chemical solvents. Disposable gloves of latex, vinyl, or nitrile can effectively reduce exposure risk, especially for handling blood, body fluids, and excrement. These gloves are particularly important because staff members may be unaware of the abrasions on their hands (36). In specific settings, staff members may need gloves that are elbow or shoulder length.

Disposable gloves do not prevent needle stick injuries, but double gloving can reduce the volume of blood or body fluids carried by a needle. Cotton undergloves may provide more protection from sharps injuries than a second vinyl or latex glove. In the morgue, staff members may need to wear chain mail gloves. Gloves provide an important protective barrier; however, they may also be a source of harm. Vinyl, latex, or cotton undergloves can reduce contact irritation that some staff members note when using rubber gloves. If staff members wear gloves for long periods, moisture can damage the skin on their hands (16, 20, 47). Surveys of dentists who wear gloves for 6 h daily indicate that many, especially young women with preexisting eczema, develop glove intolerance including glove-related mucous membrane irritation such as conjunctivitis, rhinitis, and asthma (57).

Gloves are easily torn. In-use durability studies indicate that vinyl gloves may tear as often as 40% of the times they are used, depending upon the presence of powder and the length of the user's fingernails (36). Latex gloves are more durable but may cause atopic reactions.

Staff members must remove their gloves at the end of a task or when the task is interrupted to prevent environmental contamination and transmission of pathogenic organisms. Indeed, persons wearing contaminated gloves can contaminate the equipment (42) and can also transmit organisms that cause serious infections (46). Moreover, gloves reduce microbial contamination of the hands but do not prevent it entirely. Therefore, staff members must still use hand hygiene when they remove gloves. Phlebotomists often wear gloves while collecting specimens, but this may not be essential if the risk of exposure to blood and body fluids is sufficiently low or if gloves of an appropriate size or material are not readily available. Regardless of whether phlebotomists do or do not wear gloves while collecting specimens, they should always remove their gloves between patients and wash their hands or use an alcohol-based hand gel.

IMMUNIZATION

Mental alertness and good laboratory practices are the most important aspects of laboratory safety, but immunizations are also an important source of protection. Immunizations may not prevent infections, but usually they protect persons against serious illness. All laboratory staff, including pregnant women, should have a complete primary immunization with tetanus and diphtheria toxoids and should receive a booster every 10 years (4). Laboratory workers who have direct contact with patients and those with chronic pulmonary or cardiovascular disease or other chronic illnesses including diabetes mellitus and renal dysfunction or who are immunocompromised should receive the influenza immunization annually. All staff members with possible occupational exposure to human blood and body fluids should receive the hepatitis B vaccine.

Cases of meningococcal illness possibly linked to laboratory exposure have been identified (3, 13, 21). Thus, microbiologists who are routinely exposed to meningococci, especially if these organisms may be aerosolized, should consider receiving meningococcal immunization. Laboratorians working with specific pathogens and in specific situations should consider additional immunizations such as a human diploid cell rabies vaccine, typhoid vaccine, and vaccinia vaccine (39, 41). In the past, *Mycobacterium bovis* BCG vaccination was considered of value for health care workers; however, it is no longer recommended as a primary strategy for controlling tuberculosis because the protective efficacy of the vaccine in health

care workers is uncertain (8). Prior immunization with BCG may cause difficulty in the interpretation of tuberculin skin test responses following true infection with *Mycobacterium tuberculosis* (15).

LABORATORY-ACQUIRED HIV INFECTION, HEPATITIS B, AND HEPATITIS C

Laboratory workers are at risk for exposure to hepatitis C virus (HCV), hepatitis B virus (HBV), and human immunodeficiency virus (HIV). However, safeguards introduced into medical laboratories have decreased the risk. For example, after the hepatitis B vaccine was introduced in 1982, the incidence of hepatitis B infection was decreased by more than 95% (25).

According to the Division of Health Care Quality Promotion of the Centers for Disease Control and Prevention (http://www.cdc.gov/ncidod/hip/BLOOD/hivpersonnel.htm), between 1978 and December 2001, only 16 clinical laboratory workers acquired HIV infection occupationally; 17 other persons may have acquired their infections in laboratories. We have no information on the prevalence of hepatitis C in health care workers. However, the National Center for Infectious Diseases estimates that about 2 health care workers out of 100 (1.8%) will become infected with HCV (range, 0 to 10%) after injuries with needles or sharps contaminated with HCV-positive blood (http://www.cdc.gov/ncidod/diseases/hepatitis/c/faq.htm#1h).

Given the publicity about bloodborne pathogens, laboratory directors may assume that their employees understand the epidemiology of these organisms and will take steps to protect themselves. However, recent surveys of health care workers demonstrate that existing and new staff members need to be educated frequently (51).

LABORATORY-ACQUIRED PARASITIC INFECTIONS

In her extensive review, Herwaldt has described 200 cases of laboratory-acquired parasitic infections occurring between 1929 and 1999 (30). Although the distribution of infection-associated pathogens changed from decade to decade, the number of cases identified in each decade (19 to 28) remained relatively constant. Sharps (needle and glass) injuries were common factors, often occurring when workers manipulated research animals or produced blood smears for malaria.

PRIONS

Samples from patients with Creutzfeldt-Jakob disease (CJD) may be submitted to the laboratory for investigation. To date there are no known cases of laboratory-acquired CJD and there is no evidence that laboratorians are at increased risk of developing CJD. That being said, staff members who handle samples should wear gloves and should discard samples as medical waste. No special precautions are required for disposal of body fluids (50).

Prions are extremely difficult to inactivate. Therefore, equipment that has been exposed to tissues, especially those of neurological origin, from patients with CJD should either be disposed of if they do not tolerate heat or autoclaved at 134°C for 18 min (prevacuum sterilizer) or at 121 to 132°C for 1 h (gravity displacement sterilizer). Autoclaving in water may be more effective than autoclaving in its absence (26). Equipment may also be soaked in 1N NaOH for 1 h (26, 34). Work surfaces that may have been contaminated by the tissue should be cleaned with a 1:10 dilution of sodium hypochlorite. Other chemical treatments that have been described as milder alternatives include a combination of proteinase K and sodium dodecyl sulfate (34), proteinase K followed by an alkaline cleaner, and proteinase K followed by treatment in vaporized hydrogen peroxide (26).

Variant CJD is unique among human prion disease because the prion protein accumulates in follicular dentritic cells of lymphoid tissue (31, 33). In the United kingdom, studies of lymphoid tissue have identified the presence of prion protein (PrP) in appendices and tonsils (32). This has led to concern of possible contamination of blood, transplant tissues, and surgical instruments. The presence of long-term asymptomatic carriage and the absence of readily available diagnostic tests and a definitive significance of the findings make it difficult to implement new specific policies and procedures for processing routine samples and cleaning surgical and pathology equipment.

SARS CORONAVIRUS

The outbreak of SARS caused by a coronavirus raised international concern among the infection control and laboratory communities about the hazards of aerosol spread of communicable viruses. Information collected during the epidemic demonstrated that staff members in microbiology laboratories and those who receive and accession respiratory samples, especially via vacuum tube delivery systems, may have been at risk (44). However, the virus could be readily contained (10). In fact, laboratory workers had one of the lowest rates of illness or serological conversion and only one death was suspected to result from a laboratory accident, which occurred in a level 4 facility (44).

To ensure that laboratory workers are safe while working with the SARS coronavirus, guidelines developed in Singapore recommend that staff members in laboratories equipped and designed at biosafety level 2 use practices more consistent with biosafety level 3, such as opening specimen containers and handling the samples only in biosafety cabinets (10). In addition, samples should be centrifuged only in sealed safety buckets that are opened within a cabinet. Finally, N95 respirators should be considered for additional protection.

LABORATORY-ACQUIRED INFECTIONS AND EXTERNAL QUALITY ASSESSMENT

Infections acquired in clinical laboratories are not always associated with clinical samples. Documented clusters of bacterial infections have been associated with samples sent to laboratories for proficiency testing (12), and quality control organisms have contaminated other samples in laboratories (1). Regardless of the source of the specimens, staff members in clinical microbiology laboratories must use appropriate biosafety practices when handling any and all viable microorganisms.

SAFETY AND POINT OF CARE

Medical laboratories are responsible for all laboratory tests, even those performed outside of the laboratory itself. Increasingly, medical laboratories are responsible for point-of-care testing for monitoring of blood glucose, coagulation, and oxygenation. Despite the improved equipment and hygiene protocols, patients continue to acquire hepatitis B and C from

contaminated point-of-care devices. To prevent transmission of bloodborne pathogens when staff members use these devices, they must adhere strictly to infection control protocols for use and cleaning of this equipment. The International Organization for Standardization final draft international standard ISO/FDIS 22870, *Point-of-Care Testing (POCT) Requirements for Quality and Competence* (32b), provides guidance on quality management for point-of-care testing.

TRANSPORTATION OF SAMPLES

Laboratories are responsible to prevent, to the extent possible, people from being exposed to infectious agents that are present in laboratory samples, including samples being transported to and from the laboratory. The laboratory should ensure that leak-proof containers are available for transporting specimens within a clinic or hospital and that the containers are transported in a secure outer package such as a sealable plastic bag, preferably emblazoned with the international biohazard label. Samples that are transported outside of the facility should be packaged in a secure, firm outer container. The sample container itself should be surrounded with materials that protect it and that also could absorb a spill if the container was damaged. Specimens transported outside the facility, especially by road, rail, water, or air, must be packaged and shipped according to local and federal regulations. Most jurisdictions prohibit transporting samples of infectious agents through the postal service.

Air transport of microorganisms is governed by federal regulations that must comply with the requirements of the International Civil Aviation Organization (ICAO) as adopted by the International Air Transport Association. The ICAO specifies the requirements for packaging and labeling, including the proper shipping name and appropriate UN number, for samples known to contain infectious agents based on the sources of the samples and the likely pathogens contained. Every laboratory that transports samples is required to have at least one person who is certified in knowing the requirements for packaging and transport, including how to complete the shipping documents.

For additional information, staff members can refer to the ICAO's *Technical Instructions for the Safe Transport of Dangerous Goods by Air* (32a) or to federal requirements (http://hazmat.dot.gov/regs/rules.htm).

ELECTRONIC INFORMATION SOURCES AND RESOURCES

Laboratory safety is a primary focus of interest for many organizations. Some of the agencies have the authority to regulate laboratory practices in their specific nation or area of jurisdiction. Nonregulatory sites, including international organizations, can provide instructive materials that aid laboratory staff in improving their safety programs. Table 5 contains a list of sites that provide important current safety information.

Laboratory Detection of Potential Agents of Bioterrorism*

ROSEMARY HUMES AND JAMES W. SNYDER

9

Since the events of 11 September 2001 and the anthrax release in October 2001, bioterrorism preparedness and response have remained a high priority for the nation. Clinical microbiology laboratories serve as sentinels with the major responsibility to raise suspicion of a possible bioterrorism-associated agent based on the information gleaned from the recovery of a suspicious microbial agent. Consequently, clinical microbiologists must be familiar, through education and training, with the targeted agents of bioterrorism and the application of standardized diagnostic procedures designed to rule out or refer such agents for confirmatory testing. Clinical and public health laboratories must enhance their partnerships and communication to ensure that potential bioterrorism events are detected early. This chapter provides an overview of the most important issues. Other American Society for Microbiology (ASM) publications on this subject include references 15 and 21, the second edition of the *Clinical Microbiology Procedures Handbook* (18), and the ASM website (http://www.asm.org). The Centers for Disease Control and Prevention (CDC) also provides extensive information on bioterrorism preparedness and the agents of concern on its website (http://www.bt.cdc.gov).

HISTORY

There is evidence of germ warfare dating back to the ancient Greeks and Romans, long before individuals understood the germ theory of disease or deliberately tried to produce biological weapons of mass destruction. The U.S. Army and Air Force had an offensive biological weapons research program at Fort Detrick, Md., from 1942 to 1969. The Biological and Toxic Weapon Convention in 1972 resulted in an agreement that development of biological weapons should be stopped worldwide (9, 28). Most Western governments ceased their offensive programs; however, the former Soviet Union activated a clandestine program that was called Biopreparat. Following his defection from the Soviet Union in 1992, Ken Alibeck, Deputy Director of Biopreparat, revealed important details about the program's development of a variety of bioterrorist agents (1, 11).

Immediately following the Gulf War of 1991, the United Nations' inspectors in Iraq found evidence that Saddam Hussein had been building a bioweapons program, and they destroyed all biologic material that was found. Concerned that Iraq had reestablished a program to create weapons of mass destruction, the U.S. government developed extensive smallpox response plans and vaccinated health care workers, first responders, and soldiers in 2003, before the second Gulf War (2). However, UN inspectors did not find any evidence of an active bioweapons program when the regime fell.

Prior to 2001, the most well-known example of bioterrorism in the United States occurred in 1984, when followers of Bhagwan Shree Rajneesh sprayed an aerosolized form of *Salmonella enterica* serovar Typhimurium on salad bars at two local restaurants in Dalles, Oreg., to prevent local citizens from voting in an upcoming election. The resulting outbreak affected 750 people (35).

The threat posed by bioterrorism and the panic caused by such events were demonstrated in the fall of 2001, when 23 cases of anthrax (12 cases of inhalational anthrax and 7 confirmed and 4 suspected cases of cutaneous anthrax) occurred among persons in the District of Columbia, Florida, New Jersey, New York, and Connecticut after an unidentified perpetrator mailed *Bacillus anthracis* spores in letters (5–7, 19, 20, 23, 24, 36). Law enforcement personnel, public health officials, and community health care providers, including clinical laboratories, were inundated by citizens who found powdery substances, letters, packages, and other materials which they were certain contained anthrax spores. More than 125,000 samples were tested, many in areas where there was no evidence of anthrax contamination (27). This outbreak and its aftermath demonstrated that federal, state, community, and institutional bioterrorism readiness plans needed to be updated. Clinical microbiologists have an essential role in these plans; they will likely be the first to detect the etiologic agent(s) and must promptly report their results to the proper authorities. Consequently, clinical microbiologists should have a general understanding of biological terrorism, including the technical and administrative principles that will help them recognize and manage such an event.

GENERAL FEATURES OF BIOTERRORISM

Definitions

Biological terrorism (bioterrorism) is defined as "the intentional use of microorganisms or toxins derived from living organisms to produce death or disease in humans, animals,

* This chapter contains information presented in chapter 10 by James W. Snyder and Alice S. Weissfeld in the eighth edition of this Manual.

or plants." From the public and private health perspective, bioterrorism can be defined as the deliberate release of pathogens or toxins into a civilian population with the intent to cause illness or death (17, 19, 21). Humans, agricultural animals, and plants could be targets of bioterrorism (17, 39).

Biological warfare refers to using biological agents (i.e., microbial pathogens and/or toxins) indiscriminately against masses of people including either military personnel or civilians. The terms biocrime or biothreat are used when a bioterrorist, which may be an individual or a state- or nonstate-sponsored group, targets a specific group or individual. A biocrime is a criminal act in which biological agents are used as weapons, and a biothreat is characterized as a suspected but unconfirmed release of a biological agent(s) (15). The bioterrorism-associated cases of anthrax that occurred in the United States in October and November 2001 are examples of a biocrime.

Bioterrorism events are categorized as either overt or covert. A covert event or attack will not be recognized immediately because of the delay between exposure and onset of illness (i.e., the incubation period). For example, the case of inhalational anthrax in the journalist from Florida in 2001 represented a *covert* event because the etiology was unknown until gram-positive bacilli were seen in the patient's cerebral spinal fluid, but the subsequent anthrax cases were *overt* events because the contaminated letters contained a note announcing the threat. As exemplified in the Florida case, emergency medicine physicians and other primary health care providers, including clinical microbiologists, will most likely identify the first cases in a covert event (8).

Characteristics Suggesting Biological Attacks

Covert attacks pose the greatest challenge to early detection; thus, microbiologists should be aware of the epidemiological and microbiological clues that suggest that an act of bioterrorism or a biocrime has occurred (21; U.S. Army Medical Research Institute of Infectious Diseases (USAMRIID): Biological Warfare and Terrorism Medical Issues and Response Satellite Broadcast, 26 to 28 September 2000). Some key indicators are as follows:

- A single case of a disease is caused by an uncommon agent (e.g., *Burkholderia mallei*, *Burkholderia pseudomallei,* or hemorrhagic fever virus)
- Large numbers of people have unexplained diseases or die unexpectedly
- A disease does not occur naturally in a given geographic area
- The illness is unusual (or atypical) for a given population or age group, or presents in an unusual fashion
- The incidence of a disease (e.g., tularemia or plague) increases substantially above its stable endemic rate
- Unusual deaths or illness among animals precedes or accompanies illness or death in humans
- Isolates from distinct sources at different times or locations have a similar genetic type
- The agent is transmitted in an atypical manner through aerosols, food, or water, suggesting deliberate sabotage

CATEGORIZATION OF BIOLOGICAL AGENTS

Biological agents are classified as pathogens or toxins. The CDC and its affiliated partners developed a targeted (critical) agent list (Table 1) based on (i) the agent's ability to cause mass casualties, be widely disseminated, and be transmitted from person to person and (ii) the public's likely perceptions of a potential intentional release of particular agents. Although few individuals or terrorist groups possess the scientific and

TABLE 1 Critical biological agent categories for public health preparedness

Biological agent(s)	Disease
Category A[a]	
Bacillus anthracis	Anthrax
Clostridium botulinum (botulinum toxins)	Botulism
Francisella tularensis	Tularemia
Yersinia pestis	Plague
Variola major	Smallpox
Filoviruses and Arenaviruses (e.g., Ebola virus, Lassa virus)	Viral hemorrhagic fevers
Category B[b]	
Coxiella burnetii	Q fever
Brucella spp.	Brucellosis
Burkholderia mallei	Glanders
Burkholderia pseudomallei	Melioidosis
Alphaviruses (VEE, EEE, WEE)[c]	Viral encephalitis
Rickettsia prowazekii	Epidemic typhus
Toxins (e.g., ricin, staphylococcal enterotoxin B, *Clostridium perfringens* epsilon toxin)	Toxic syndromes
Chlamydia psittaci	Psittacosis
Food safety threats (e.g., *Salmonella* spp., *Escherichia coli* O157:H7, *Shigella* spp.)	Gastroenteritis, hemolytic uremic syndrome
Water safety threats (e.g., *Vibrio cholerae*, *Cryptosporidium parvum*)	Gastroenteritis
Category C	
Emerging pathogens and potential risks for the future	
Emerging threat agents (e.g., Nipah virus, hantavirus)	

[a] Agents that pose the greatest threat due to their infectiousness relative, ease of transmission, or high mortality.
[b] Agents having a moderate ease of transmission and morbidity with a low rate of mortality.
[c] VEE, Venezuelan equine virus; EEE, eastern equine encephalomyelitis virus; WEE, western equine encephalomyelitis virus.

technical resources needed to weaponize and successfully disperse an agent via aerosol (the most likely mode of dispersal), the targeted agents possess unique advantages that make them suitable for bioterrorism or biocrimes.

The CDC has defined biothreat levels (A to C) to categorize the critical agents on the basis of their threat to national security, their ability to cause morbidity and mortality, and their potential for genetic engineering. Category A organisms are considered to pose the greatest threat to national security because they (i) can be easily disseminated or transmitted from person to person; (ii) cause high mortality; (iii) may afflict large numbers of people, overwhelming the health care and public health systems; (iv) may cause public panic and social disruption; and (v) require special preparations such as enhanced surveillance, enhanced diagnostic capabilities in microbiology laboratories, and stockpiles of medicines and equipment to protect the public's health. Category B agents are moderately easy to disseminate, cause moderate morbidity and low mortality, and challenge the national capacity for surveillance and diagnosis. This category includes pathogens that are foodborne or waterborne (e.g., *Salmonella* species, *Shigella dysenteriae, Escherichia coli* O157:H7, *Vibrio cholerae,* and *Cryptosporidium parvum*). Category C agents are primarily emerging pathogens that could be engineered for mass dissemination in the future (8, 25, 30).

PREPAREDNESS AND RESPONSE TO BIOTERRORISM

The U.S. Department of Homeland Security (DHS) was created in 2002 to prevent and deter terrorist attacks, protect citizens from threats and hazards, and respond to possible attacks. As defined in the 2003 Homeland Security Presidential Directive/HSPD-5, DHS serves as the lead agency in managing and coordinating the national response to acts of terrorism, natural disasters, or other emergencies (http://www.dhs.gov, www.fema.gov/pdf/reg-ii/hspd_5.pdf). The Federal Emergency Management Agency (FEMA), responsible for planning for and responding to disasters and for helping communities mitigate and recover from catastrophes, became part of DHS in March 2003.

A National Response Plan (NRP), National Incident Management System (NIMS), and Interim National Preparedness Goal (NPG) have been developed to provide standards for planning and response. Bioterrorism preparedness has been integrated into all-hazards—chemical, biologic, radiologic, nuclear, explosive (CBRNE)—emergency response planning. Several Homeland Security Presidential Directives establish roles for other federal agencies, including the Department of Health and Human Services (HHS) and the Environmental Protection Agency, in prevention of and response to CBRNE. The Federal Bureau of Investigation (FBI) is the federal agency that leads criminal investigations.

The Department of Defense has created over 32 "weapons of mass destruction civil support teams" (WMD-CST) that help local and state authorities respond to CBRNE domestic incidents of terrorism. The WMD-CSTs identify agents and substances, assess consequences, advise local and state authorities about how to respond, and assist with requests for additional military support. Additional CST teams are being added to provide coverage in every state (http://www.globalsecurity.org/military/agency/army/wmd-cst.htm; http://www.defenselink.mil/news/Jan2004/n01202004_200401201.html).

Professional organizations for the first responder and medical communities have developed numerous training programs and online resources. The Association of Professionals in Infection Control and Epidemiology and the CDC developed a Bioterrorism Preparedness and Response Program for hospitals to use in creating institutional plans for disease surveillance, epidemiologic investigation, rapid laboratory diagnosis, communication, and assessing readiness (12; http://www.apic.org/Content/NavigationMenu/PracticeGuidance/Topics/Bioterrorism/APIC_BTWG_BTRSugg.pdf). In addition, ASM has included on its website a template that clinical microbiology laboratories can use to create a bioterrorism response plan.

Since 2000, HHS, through the CDC, has provided funding to state and city health departments to enhance local emergency preparedness. Public health laboratories have received funding to rebuild infrastructure and to improve their molecular detection capabilities and the biosafety and biosecurity in existing facilities (38). The CDC has also established a strategic national stockpile of supplies necessary for treating persons affected by bioemergencies, including therapeutics (e.g., chemical antidotes, antimicrobical agents, antitoxins, life support medications, and supplies and equipment for intravenous fluids, airway maintenance, and surgical procedures), vaccines, and personal protective equipment. Since 2002, the Health Resources and Services Administration (HRSA) has awarded funds that hospitals and communities have used to improve their capacity to care for mass casualties. Funds from CDC and HRSA have been used to provide training and reference materials for clinical sentinel laboratories and to strengthen communication and partnerships between clinical and public health laboratories (APHL Public Health Laboratory Issues in Brief: Bioterrorism Capacity; http://www.aphl.org/docs/bt_issue_brief_2005_final.pdf).

LRN

In 1999, the CDC, in collaboration with the Association of Public Health Laboratories (APHL) and the FBI, established a model in which clinical and public health laboratories would be linked and integrated into a network called the Laboratory Response Network (LRN). The goal of the LRN is to facilitate rapid detection and confirmatory testing of suspected agents of bioterrorism. As shown in Fig. 1, all laboratories have a defined role and level of responsibility (8, 14, 21, 26). Although the LRN was initially structured to test only

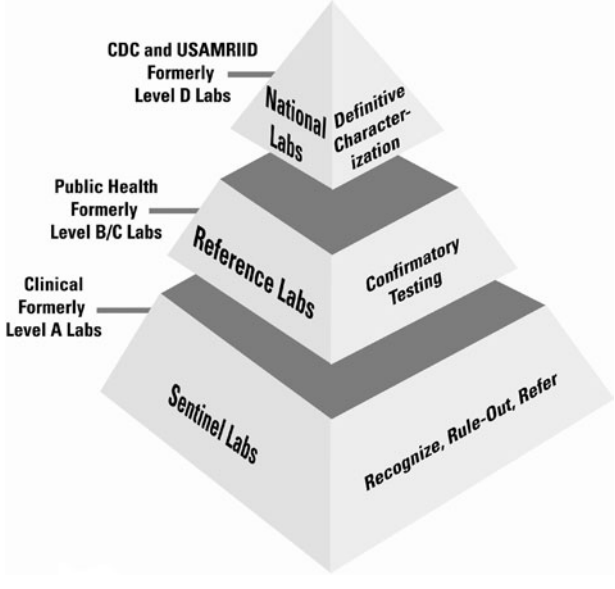

FIGURE 1 Laboratory Response Network (LRN).

clinical specimens for biologic agents, during the anthrax events of 2001, the LRN performed more than one million tests on clinical and environmental samples.

Most hospital and commercial reference laboratories have been classified as sentinel (formerly level A) laboratories. The primary role of sentinel laboratories is to "raise suspicion" when rule-out testing indicates that a targeted agent may be present in a clinical sample and to promptly refer suspicious isolates and specimens to an LRN reference laboratory for confirmatory testing (26, 34). For example, the microbiologists who initially isolated *B. anthracis* from the journalist in Florida were suspicious that the organism was the etiologic agent for anthrax but they could not confirm the species identification or definitively prove that this organism did not cause the infection. Thus, they referred the isolate to the Florida State Department of Health Laboratory, which confirmed the isolate to be *B. anthracis*. Sentinel laboratories are restricted to testing human specimens only and *must* forward or refer all other samples, e.g., environmental and animal, to a reference level (formerly level B/C; also known as confirmatory laboratories) laboratory (31, 34).

The nationwide network of LRN reference laboratories comprises local, state, and federal public health laboratories; food testing, veterinary diagnostic, and environmental testing laboratories affiliated with state and local public health departments and federal agencies; laboratories on military installations; and selected international laboratories. In general, these laboratories have biosafety level 3 (BSL-3) facilities, federally approved equipment, and standardized validated reagents for clinical and environmental testing so that they can respond to biological terrorism and other public health emergencies. Reference laboratories have established functional linkages with law enforcement, including the FBI, and employ chain-of-custody and LRN-approved testing protocols that are consistent with legal evidentiary requirements (4). Reference level laboratories perform rapid tests, such as PCR and fluorescent-antibody tests, to presumptively identify microorganisms or toxins; biochemical tests to confirm the identification of suspect isolates; and antimicrobial susceptibility tests of these isolates. National (formerly level D) laboratories, located at the CDC and USAMRIID, perform definitive characterization of biologic agents and have BSL-4 facilities in which highly infectious agents can be handled safely.

The success of the LRN depends on effective coordination and communication among all the laboratories in the network. Public health and clinical laboratories must establish working relationships in advance so that they can develop integrated response plans and effective lines of communication, exchange and share information, and test the system through exercises and drills. As any biothreat or bioterrorism event unfolds, information will flow from the CDC to public health laboratories, which, in turn, should transmit the information to the sentinel laboratories quickly.

Sentinel Lab Preparedness

To be successful in their role, sentinel laboratory personnel, including the laboratory director, must be aware that they might recover agents of bioterrorism from clinical samples. In addition, they must work with infection control staff and administrative personnel to develop both laboratory and institution-wide response plans. These plans should include (i) information regarding access to the LRN and use of the recommended diagnostic testing protocols; (ii) safety guidelines; (iii) protocols for internal and external communication and notification; (iv) criteria for packaging and transporting infectious substances safely; (v) measures to increase laboratory security; and (vi) telephone numbers for the local and state public health laboratories and the CDC (21, 34). A template for a laboratory response plan is available on the ASM website. If a bioterrorism event exposes a large number of people, clinical and public health laboratories will be overwhelmed with specimens. Thus, laboratory response plans should consider surge capacity needs for personnel and supplies (32).

Because most likely agents of bioterrorism are encountered rarely in clinical settings, laboratory personnel should be trained to recognize the targeted agents and apply the sentinel laboratory standardized testing protocols for ruling out these agents and for referring suspicious isolates (14). These protocols are available at the ASM website (http://www.asm.org/Policy/index.asp?bid=6342). In addition, because any clinical microbiology laboratory could have a sentinel role in detecting potential agents of bioterrorism, CDC, ASM, and APHL jointly recommend that, at a minimum, all sentinel clinical microbiology laboratories (i) meet facility and operational criteria for BSL-2, including the availability and use of a certified Class II biological safety cabinet (37); (ii) have appropriate Clinical Laboratory Improvement Amendments certification; (iii) enroll in proficiency testing (or an equivalent measurement) for Comprehensive Bacteriology and Laboratory Preparedness; and (iv) participate in training and exercises for bioterrorism agent rule-out testing sponsored by a state public health laboratory or other appropriate agency. Laboratories whose physical facilities do not meet these criteria must recognize that they may receive samples containing agents of concern, and thus, their staff should be trained and be familiar with rule-out and referral procedures and biosafety issues. In February 2006, ASM, CDC, and APHL approved a formal definition of sentinel laboratories; it can be found at http://www.asm.org/Policy/index.asp?bid=6342.

It is essential that clinical microbiology laboratories develop a relationship with their local and state health laboratories, many of which provide formal training in laboratory safety, procedures for ruling out targeted biological agents, characteristics of diseases produced by these agents, and packaging and shipping of infectious substances.

Safety

Laboratory personnel must be vigilant in case they isolate one of the targeted agents from what appears to be a routine specimen. Category A and B agents have caused laboratory-acquired infections (29, 31). To reduce the risk that laboratory personnel will be exposed to these agents, flowcharts for LRN sentinel laboratory procedures should be incorporated into standard operating procedures, and physicians should be taught to inform the laboratory when highly infectious agents are in the differential diagnosis (31, 33). If laboratory personnel suspect that a specimen or culture may contain a biothreat-related agent, they should conduct all manipulations in a biosafety cabinet to prevent transmission of the organism. Additional information regarding biosafety is available in chapter 8.

Environmental samples and "unknown packages" may contain very high concentrations of disease-causing agents or toxins, a volatile, toxic chemical, or a radioactive substance; such packages could even be explosive. Powders, in particular, may be highly contaminated and can be aerosolized easily. *Thus, to ensure that personnel and patients are not endangered, sentinel laboratories should not accept or process nonhuman specimens (animal or environmental) but should forward such specimens directly to the state public health laboratory as directed by law enforcement or public health authorities* (31, 34). Public health laboratories have worked with law enforcement

and first responders to develop procedures for evaluating the level of threat posed by environmental samples and to screen these samples for safety (http://www.bt.cdc.gov/planning/pdf/suspicious-package-biothreat.pdf).

Sentinel Laboratory Protocols

A partnership of subject matter experts from CDC, ASM, and APHL developed protocols for LRN sentinel laboratories, which describe a number of the targeted Category A and B agents of bioterrorism (Table 2) and provide standardized methods for ruling out critical agents and referring specimens to LRN reference laboratories. These detailed protocols are published on the ASM website (http://www.asm.org/Policy/index.asp?bid=6342). If sentinel laboratory testing fails to rule out an agent of bioterrorism, all suspicious specimens and isolates should be immediately sent to an LRN reference laboratory, where the specialized tests necessary to definitively identify these organisms (e.g., molecular detection methods, enzyme immunoassays, and direct and indirect fluorescent-antibody assays) are available. Clinical laboratories should maintain a subculture of all suspicious isolates that are forwarded for LRN reference testing until the reference laboratory has completed the definitive identification. Sentinel laboratories do not routinely process specimens following law enforcement chain-of-custody guidelines. However, they may be instructed by law enforcement or public health officials to implement specific procedures if a biocrime is suspected.

To simplify matters for hospital laboratories, the procedures provide practical conventional microbiological methods to rule out four of the most likely agents, *B. anthracis*, *Francisella tularensis*, *Brucella* species, and *Yersinia pestis*, using only eight simple procedures: oxidase, catalase, hemolysis, motility, satelliting, β-lactamase, Gram stain, and urease. The flowcharts from these procedures are reproduced here (Fig. 2 to 5). ASM, CDC, and APHL, as partners in the LRN, recommend that all sentinel laboratories use the LRN sentinel protocols to rule out bioterrorism agents, including *B. anthracis*, rather than using newly described molecular detection assays, new commercial detection and rule-out assays, or tests that will be developed in the near future. If personnel from sentinel laboratories choose to use the latter set of tests, they first must understand the limitations of the assays and the necessary quality control measures and the validation requirements.

TABLE 2 Sentinel laboratory protocols available at ASM website

Bacillus anthracis (anthrax)
Botulinum toxin
Brucella spp.
Burkholderia mallei and *B. pseudomallei*
Coxiella burnetii
Francisella tularensis (tularemia)
Staphylococcal enterotoxin B
Yersinia pestis (plague)
Unknown viruses
Packaging and shipping
Bioterrorism readiness plan for laboratories

Bacillus anthracis

Humans can become infected with *B. anthracis* by handling contaminated materials or consuming undercooked contaminated meat. Infection may also result from inhalation of *B. anthracis* spores from contaminated animal products, or following the intentional release of spores. Human-to-human transmission has not been reported. Three forms of anthrax occur in humans: cutaneous, gastrointestinal, and inhalational. Appropriate specimen types will depend on the disease

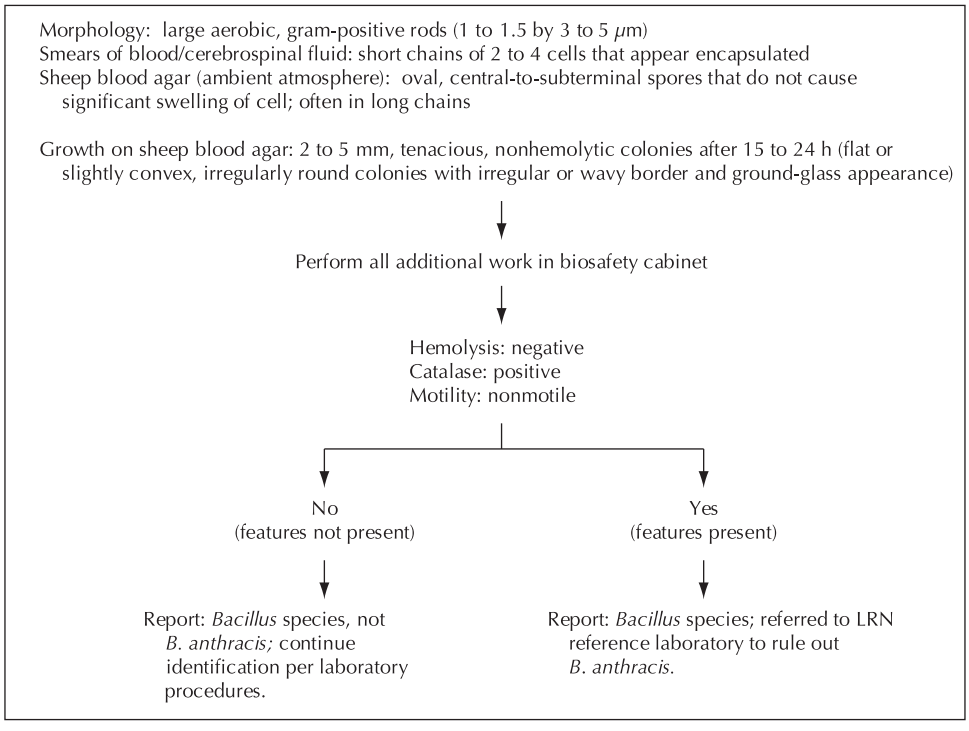

FIGURE 2 Sentinel rule-out testing for *B. anthracis*.

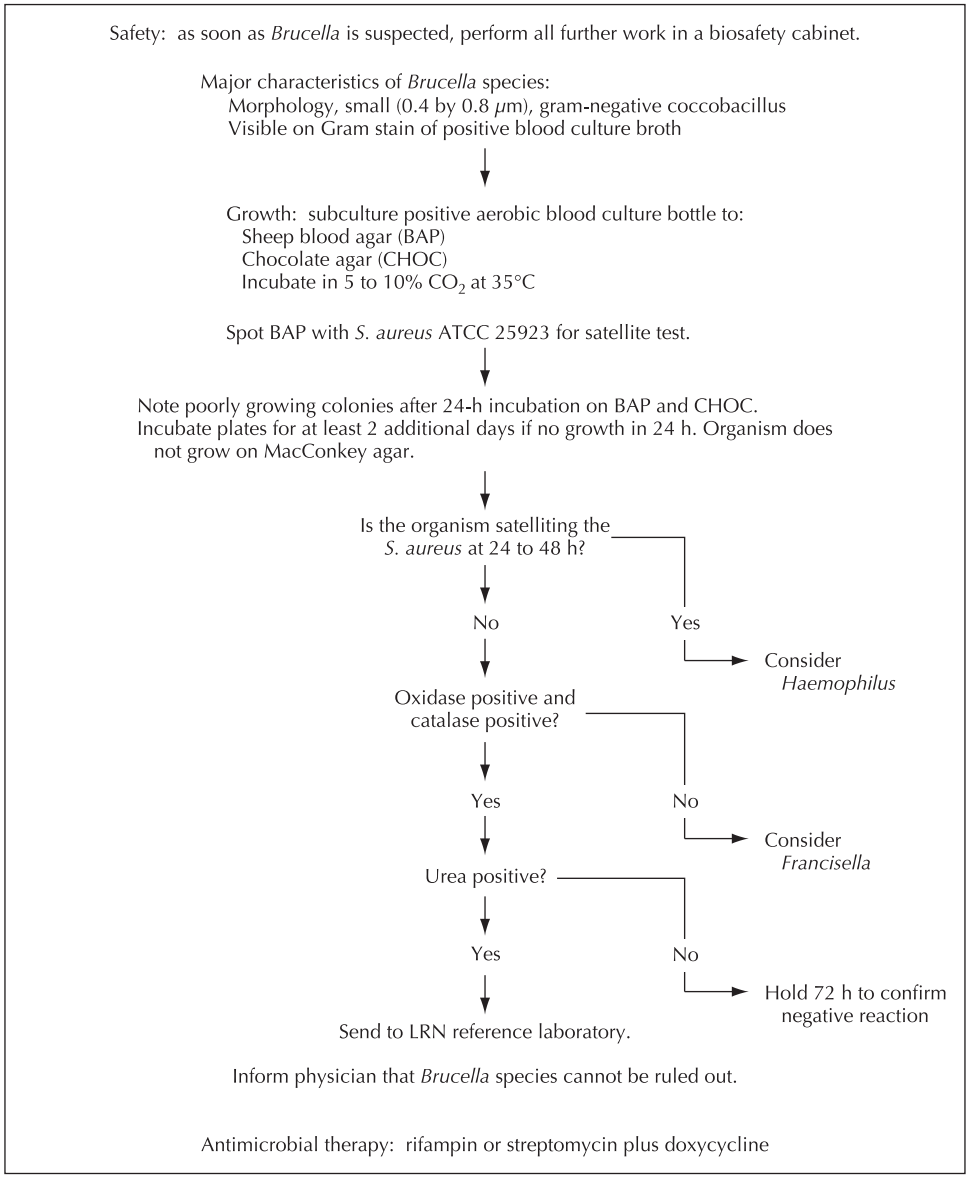

FIGURE 3 Sentinel rule-out testing for *Brucella* spp.

presentation. Clinicians should submit (i) blood, vesicular fluid, swabs from beneath lesions, or tissue/punch biopsy of eschars to diagnose cutaneous anthrax; (ii) stool and blood specimens to diagnose gastrointestinal anthrax; (iii) sputum and blood to diagnose inhalational anthrax; and (iv) cerebrospinal fluid if anthrax meningitis is suspected (15, 22, 29).

B. anthracis grows rapidly, producing 2- to 5-μm flat or slightly convex colonies that have a ground-glass appearance and often have comma-shaped projections from the colony edge (i.e., the "Medusa-head"). *B. anthracis* is nonhemolytic and has a tenacious consistency on blood agar. *B. anthracis* is a large gram-positive rod (1 to 1.5 by 3 to 5 μm). In Gram stains from blood or clinical material, vegetative cells are often encapsulated and appear in short chains. When grown on blood agar or a similar medium, the organism generally appears as long chains of bacilli; it is not encapsulated but may form oval, central-to-subterminal spores. *B. anthracis* is nonmotile and catalase positive. Hemolysis, Gram stain morphology, or motility can be used to rule out this organism when the result provides clear evidence that the isolate is not *B. anthracis* (e.g., a clearly visible zone of beta-hemolysis). In general, a combination of two level A tests is necessary to rule out this organism. Additional information about *B. anthracis* can be found in chapter 32 and in the sentinel laboratory protocol at the ASM website.

Some laboratories might consider using a commercially available, FDA-approved, culture-dependent method, the RedLine Alert (Tetracore Inc., Gaithersburg, Md.; http://www.tetracore.com) as an adjunct to the current sentinel tests (Gram stain, hemolysis, catalase, and motility) for rapid, presumptive identification of *B. anthracis* or ruling out of this organism. (Readers should not infer from this discussion that ASM, APHL, or the CDC endorse this test.) The test, a lateral-flow immunoassay housed in a plastic cassette, was designed

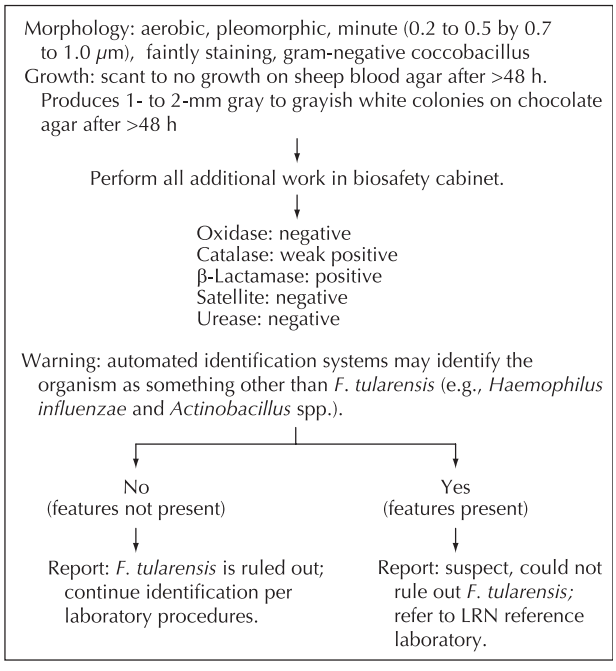

FIGURE 4 Sentinel rule-out testing for *F. tularensis*.

primarily to screen nonhemolytic *Bacillus* colonies cultured on sheep blood agar. The principal target of the test is a cell surface protein commonly found in *B. anthracis* vegetative cells, and the presence or absence of this protein can be used to differentiate *B. anthracis* from other nonhemolytic *Bacillus* colonies. A positive control (lyophilized antigen derived from the nonpathogenic Sterne strain of *B. anthracis*) and reconstitution buffer (Colony Isolation Buffer) are provided in the test kit. A non-*Bacillus* species, such as *Staphylococcus aureus*, or a nonhemolytic *Bacillus* species, such as *B. megaterium*, can be used as external negative controls. The Sterne strain (avirulent; devoid of plasmid pXO2) of *B. anthracis* has been excluded from the Select Agent Rule and can be used as an additional external positive control. Test results are available within 15 min. If the test is positive and the bacterial colony is nonhemolytic, *B. anthracis* cannot be ruled out and the sample must be sent to an LRN reference laboratory for confirmation. To ensure that the test is accurate and performs appropriately, external controls should be performed with each new test lot.

According to the manufacturer, the RedLine Alert test has been extensively evaluated against many strains of *B. anthracis*, non-*anthracis Bacillus* species, and non-*Bacillus* pathogens. The test's limitations include the following: (i) only colonies grown on sheep blood agar should be tested; (ii) hemolytic colonies, including *Bacillus* species, should not be tested; (iii) suspicious powders, other environmental samples, or spore preparations should not be tested; (iv) false-negative results may occur if the amount of specific antigen is below the sensitivity of the test; (v) the test cassette cannot be reused; and (vi) isolates that produce negative results but are suspected of being *B. anthracis* by other criteria (e.g., colonies that are flat or slightly convex and irregularly rounded, with edges that are slightly undulate, have a ground-glass appearance, or exhibit a tenacious consistency) should be forwarded to an LRN reference laboratory for confirmatory testing.

Brucella spp.

Brucellosis is a zoonotic infection; there are four species recognized as causing infection in humans: *Brucella abortus* (cattle), *Brucella melitensis* (goats, sheep, and camels), *Brucella suis* (pigs), and *Brucella canis* (dogs). Infection may occur via enteric, percutaneous, or respiratory exposure. The infective dose for these organisms is very low if acquired via the inhalation route, which makes them a potentially effective bioterrorism agent and also makes them hazardous in the clinical microbiology laboratory. Specimens suspected or known to contain *Brucella* spp. and *Brucella* spp. isolates should be handled in a biologic safety cabinet, and all culture plates

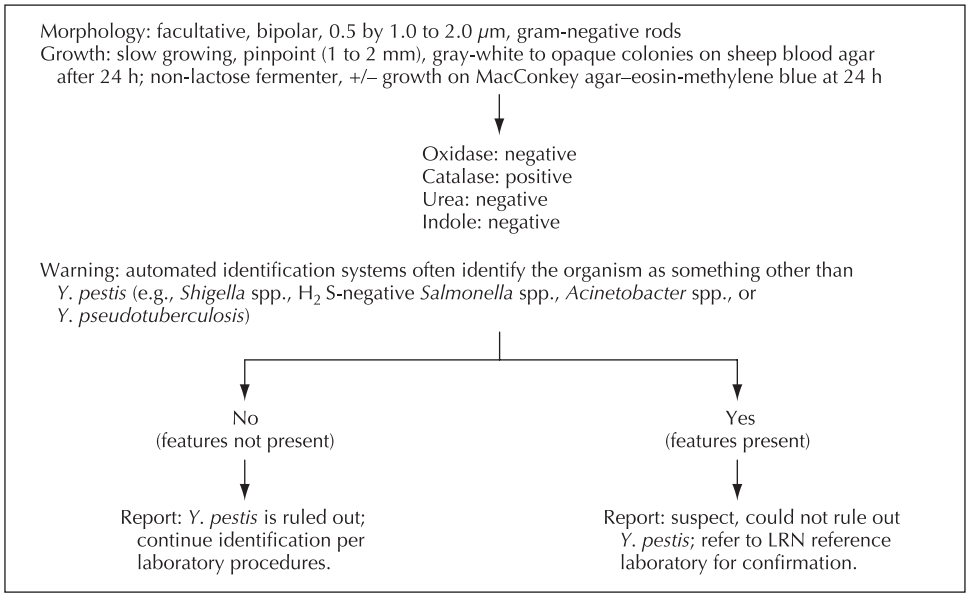

FIGURE 5 Sentinel rule-out testing for *Y. pestis*.

should be sealed. Blood and bone marrow are the best specimens for diagnostic cultures, but spleen, liver, joint fluid, samples from abscesses, and cerebrospinal fluid occasionally yield *Brucella* spp. Serologic studies are available; both acute- and convalescent-phase (>14 days after acute phase) serum samples should be collected (10, 15, 29).

Brucella spp. are tiny (0.5 to 0.7 μm by 1.5 μm), faintly staining gram-negative coccobacilli. Isolation of *Brucella* spp. in blood culture is often delayed, and incubation should be extended for 10 to 21 days if infection with this organism is suspected. On blood or chocolate agar, these organisms produce pinpoint, nonhemolytic, convex, smooth colonies after 48 h. To rule out these organisms, sentinel laboratories should perform the oxidase, catalase, and urea tests, all of which are positive for *Brucella* spp. With the Christensen's tube test, urea hydrolysis can be observed in as early as 15 min of incubation with *B. suis* strains, 1 day for most strains of *B. abortus* and *B. melitensis,* and more than 1 day for some *B. melitensis* strains. Refer to chapter 52 of this Manual and to the sentinel laboratory protocol for additional information.

Burkholderia mallei and *Burkholderia pseudomallei*

Burkholderia mallei is the etiologic agent of glanders, a febrile illness typically seen in horses, mules, and donkeys. Naturally occurring human infection, most often the result of exposure to an infected animal, presents as cutaneous nodules with lymphadenitis or as systemic disease with pneumonia and bacteremia. *Burkholderia pseudomallei* is an environmental organism found in soil and water and is most likely acquired by direct contact with or aerosols from environmental sources. This organism can cause melioidosis, a disease endemic to the tropical regions of the world, which can manifest as an asymptomatic, acute, subacute, or chronic process. Appropriate specimens for diagnosis of glanders and melioidois include blood or bone marrow, sputum or bronchoscopy specimens, material from abscesses, wound swabs, and urine. Acute- and convalescent-phase serum specimens should be collected for serologic diagnosis of *B. pseudomallei*. Currently, no serology test for *B. mallei* is available in the United States. All cultures suspected of containing *B. mallei* or *B. pseudomallei* should be handled in a biological safety cabinet (16).

B. mallei is a small gram-negative coccobacillus, which typically grows in 2 days on sheep blood agar as smooth, gray, translucent colonies, without pigment or distinctive odor. Colonies may or may not grow on MacConkey agar. Additional presumptive identification criteria include these test results: oxidase variable and indole and motility negative; catalase, arginine dihydrolase, and nitrate positive; and resistance to colistin and polymyxin B. Isolates suspected to be *B. mallei* based on colony and Gram stain morphology should be evaluated with these tests.

B. pseudomallei is a small gram-negative rod that often appears on sheep blood agar as small, smooth, creamy colonies in 1 to 2 days, which gradually change after a few days to dry, wrinkled colonies similar to *Pseudomonas stutzeri*. Colonies are neither yellow nor violet pigmented. The organism also grows on MacConkey agar. *B. pseudomallei* often produces a distinctive musty or earthy odor that is very pronounced on opening a petri dish or even opening an incubator door when a positive plate is present. Do not sniff plates, as this can be very dangerous.

B. mallei and *B. pseudomallei* are not in the databases used by some of the commercial identification systems; laboratory staff should consult with the manufacturer to determine whether the system they use includes this information. More details about these agents and their disease spectrum and diagnosis are discussed in chapter 49 and in the sentinel laboratory protocol.

Francisella tularensis

Tularemia is caused by the zoonotic agent *F. tularensis*. In humans, disease can occur in several forms, depending to some extent on the route by which the bacterium enters the body. If used for bioterrorism, the organism would most likely be dispersed via aerosol, resulting in pulmonary or typhoidal disease. Symptoms for both syndromes are often nonspecific. Human-to-human transmission is rare; however, numerous laboratory-acquired infections have been documented. Laboratory staff should manipulate suspicious cultures in a biosafety cabinet using BSL-3 practices; culture plates should be sealed. Appropriate specimens to diagnose pulmonary disease include sputum, bronchial aspirates or washes, and blood (10, 15, 31).

On Gram stain, *F. tularensis* characteristically appears as tiny (0.2 to 0.7 μm by 0.7 to 1.0 μm), pleomorphic, poorly staining, gram-negative coccobacilli. The organism is fastidious, requires cysteine for growth, and grows slowly, producing tiny grayish white colonies after 48 to 72 h. Isolates with characteristic Gram stain and culture morphology that are oxidase negative, catalase weakly positive, beta-lactamase positive, satellite or XV test negative, and urease test negative could be *F. tularensis* (cannot be ruled out) and should be immediately referred to the nearest LRN reference laboratory.

Additional information about other clinical manifestations of tularemia, the modes of transmission, and the organism's characteristics are discussed in chapter 52 as well as the sentinel laboratory protocol.

Yersinia pestis

Plague is a zoonotic disease caused by *Y. pestis*. Humans can acquire plague through the bite of infected fleas, direct contact with contaminated tissue, or inhalation of aerosolized bacteria. Plague presents in one of three clinical syndromes: bubonic, septicemic, or pneumonic. In a bioterrorism event, the agent would most likely be aerosolized, resulting in pneumonic disease, which has a high mortality rate and is highly transmissible from person to person. Appropriate specimens include tracheal or bronchial washes, sputum, blood, and aspirates or biopsy specimens of affected tissues (bubos). Acute- and, if necessary, convalescent-phase sera can be tested for antibodies to *Y. pestis* (3, 15, 29).

Gram stains of specimens and cultures containing *Y. pestis* often reveal plump, gram-negative rods (1 to 2 μm by 0.5 μm) with a bipolar or safety pin appearance. Bipolar staining may be more apparent with Wright stain. This appearance should trigger suspicion of *Y. pestis*. On routine media, pinpoint colonies can appear after 24 h. After incubation for 48 h, the small gray-white to slightly yellow colonies are opaque and produce little or no hemolysis. Under ×4 enlargement, colonies have a raised, irregular "fried egg" appearance, which becomes more prominent as the culture ages. Colonies also can be described as having a "hammered copper" shiny surface. *Y. pestis* grows best at 28°C. Isolates that are catalase positive and oxidase, urease, and indole negative and that exhibit classic Gram stain and growth characteristics suggestive of *Y. pestis* should be referred to an LRN reference laboratory for confirmatory testing. More details about this organism and disease manifestations can be found in chapter 44 and in the LRN sentinel laboratory protocol.

Smallpox (Variola Virus)

The CDC has developed an extensive smallpox response plan and a clinical algorithm to assist physicians as they assess patients and develop differential diagnoses. Varicella (chickenpox) is the infection most likely to be confused with smallpox. Guidelines for specimen collection and laboratory testing for variola, the causative agent of smallpox, and other look-alike diseases are also provided on the CDC website (http://www.bt.cdc.gov/agent/smallpox). If clinicians suspect that a patient has smallpox, the person designated by the facility should contact the public health laboratory and state health officials immediately.

Variola virus can grow and amplify easily in most routine cell lines used for cultivating herpesviruses such as varicella-zoster virus and herpes simplex virus (21, 29). While clinical microbiology/virology laboratories should never attempt to isolate this virus, which requires BSL-4, technologists may neither suspect nor recognize the potential hazard. If technologists manipulate a culture in the routine manner or passage the culture while trying to confirm the etiology of the cytopathic effects, they may increase the risk that personnel will be exposed to smallpox virus. Therefore, laboratory personnel should be familiar with the risks from the most likely viral agents of bioterrorism and understand appropriate safety practices (see the "Unknown Virus" protocol for sentinel laboratories on the ASM website for helpful materials). If a laboratory inadvertently isolates the smallpox virus, the laboratory director should notify both the state health laboratory and the CDC immediately.

Reporting

The sentinel laboratory staff should inform infection control personnel promptly if they identify suspicious isolates. Infection control staff should follow internal chain of command and communication policies for notifying local and state health officials, who are responsible to communicate with law enforcement. The chain of command should be clearly described in each institution's bioterrorism preparedness program (34). There are several reasons why sentinel laboratories should not report possible bioterrorism events externally. First, many potential agents of bioterrorism are found naturally in certain geographic areas and cause sporadic infections. Second, incorrect characterization of a suspect agent can cause public panic, placing undue burdens on public health and law enforcement agencies.

Regulatory Issues

Packaging and Shipping

Sentinel laboratories must refer suspicious isolates to reference laboratories. Therefore, proper packaging and shipping of infectious agents is one of their important functions (refer to chapter 5, "General Principles of Specimen Collection and Handling"). Cultures and clinical specimens known or suspected to contain infectious substances must be packaged according to domestic and international regulations on dangerous goods and infectious substances promulgated by the U.S. Department of Transportation (DOT), the International Air Transport Association, and the Canadian Transportation of Dangerous Goods Regulations. Recently various regulatory authorities have attempted to harmonize the requirements; updated regulations are published periodically. Anyone, including microbiologists, who ships infectious substances is required to complete formal training, become certified in the application of these regulations, and be familiar with current regulations. Formal training is available through the U.S. DOT and most commercial suppliers of approved packaging containers (see the DOT's and the commercial suppliers' websites).

Select Agent Program

In accordance with provisions of Public Law 107-188, the "Public Health Security and Bioterrorism Preparedness Response Act of 2002," the CDC and the U.S. Department of Agriculture Animal and Plant Health Inspection Service (USDA-APHIS) regulate the possession, use, and transfer of biological agents and toxins that could pose a severe threat to public health and safety (13). The CDC maintains a list of select agents that threaten humans, and the USDA-APHIS maintains a list of organisms that threaten animals; together they maintain a shared (overlap) list of organisms, primarily "high consequence" zoonotic agents that threaten humans and animals (42 CFR Part 73, 7 CFR Part 331, and 9 CFR Part 121). The Select Agent regulation requires all entities, including individuals, government agencies, universities, research institutions, and commercial facilities that possess, use, or transfer biologic agents and toxins that pose a significant threat to public health, to register with either CDC or USDA depending on the agents they possess. As a condition of registration, each entity must designate a Responsible Official to ensure that staff members comply with the regulation and to develop and implement a written security plan. Persons with access to select agents must submit required forms for a security risk assessment through the U.S. Attorney General, Department of Justice.

As described in 42 CFR Part 73.5, clinical or diagnostic laboratories that acquire a select agent from a specimen presented for diagnosis or verification are exempt from the regulation, provided that (i) laboratory personnel transfer or destroy the select agent within 7 days after the organism's identification has been confirmed; (ii) the agent is secured against theft, loss, or release during the period between identification and transfer or destruction; and (iii) laboratory personnel report the select agent to the CDC or USDA as defined in the regulation (usually within 7 days; viral hemorrhagic fever viruses, variola virus, and *Y. pestis* must be reported immediately). The laboratory must document that the organism was transferred or, if the organism was destroyed, the method of destruction and must maintain these records for 3 years. Additional exemptions apply to clinical and diagnostic laboratories that acquire a select agent as part of a proficiency testing exercise, provided that the agent is transferred or destroyed within 90 days; that the agent is properly secured against theft, loss, or release; and that the CDC or USDA is notified within 90 days.

Sources for Additional and Updated Information

Information and guidelines on bioterrorism continue to change and may be updated if a bioterrorism event is detected. Microbiologists are encouraged to remain current with local, state, and federal guidelines and should contact the local health department regarding emergencies and to report suspected or confirmed exposures to biological agents. In addition, laboratory personnel and clinicians can use the CDC Emergency Response Hotline (phone: 770-488-7100) at all hours to receive emergency consultation from subject matter experts in bioterrorism, chemical exposure, and natural disasters. Check http://www.bt.cdc.gov/emcontact/ for updated contact information.

Infection Control Epidemiology and Clinical Microbiology

DANIEL J. DIEKEMA AND MICHAEL A. PFALLER

10

In 2000, the Institute of Medicine issued a landmark report on medical errors, estimating that between 44,000 and 98,000 deaths per year in U.S. hospitals are a result of injuries or complications sustained during the delivery of health care (44). Health care-associated (or nosocomial) infections represent one of the most common complications of care, affecting approximately 2 million persons admitted to acute-care hospitals each year (8). For this reason, every health care facility should have an infection control program charged with monitoring, preventing, and controlling the spread of infections in the health care environment. Because infection control requires the ability to detect infections when they occur, the clinical microbiology laboratory is inextricably linked to any comprehensive infection control program. In this chapter we will discuss the impact of nosocomial infections, outline the organization of the hospital infection control program, and describe the important role of the clinical microbiology laboratory in the prevention and control of health care-associated infections.

NOSOCOMIAL INFECTION

Definition

A nosocomial infection is one that is acquired in a hospital or health care facility (i.e., the infection was not present or incubating at the time of admission). For most bacterial infections, an onset of symptoms more than 48 h after admission is evidence of nosocomial acquisition. To determine whether some infections such as legionellosis are hospital acquired, one must consider the usual incubation periods and determine whether the patient was hospitalized during that time period. Because hospital stays are getting shorter and more patients are treated in the outpatient setting, many health care-associated infections are not recognized during hospitalization. Infection control programs must therefore devise strategies for effective outpatient surveillance in order to accurately monitor nosocomial infection rates (38).

Infection Rates and Predominant Pathogens

At least 5% of patients may acquire an infection during hospitalization (6, 34). The urinary tract is the most commonly involved site, with 30 to 40% of all nosocomial infections occurring at this site. Surgical wound and lower respiratory tract infections are the next most frequent, with each accounting for about 15 to 20% of nosocomial infections, followed by bloodstream infections (5 to 15%). The vast majority of nosocomial infections are related to devices (e.g., urinary tract catheters, endotracheal tubes in ventilated patients, and central venous catheters). For this reason, and as a way to adjust for risk when comparing rates over time or between similar units in different facilities, the Centers for Disease Control and Prevention (CDC) recommends calculating nosocomial infection rates in the intensive care unit (ICU) by using device days as the denominator (Table 1 gives definitions of common epidemiology terms).

Table 2 lists the five most common bacterial pathogens isolated from various sites of nosocomial infection in U.S. hospital ICUs (17, 80). Over the past 3 decades, the spectrum of nosocomial pathogens has shifted from gram-negative to gram-positive organisms and *Candida* spp. have emerged as a major problem (55). The incidence of nosocomial infections caused by staphylococci and enterococci has increased, in part because these organisms are becoming increasingly resistant to antimicrobial agents (21).

Morbidity, Mortality, and Cost

Nosocomial infections cause or contribute to thousands of deaths annually (6, 76). Because patients with the most severe underlying illnesses are also those most vulnerable to nosocomial infections, it is very difficult to estimate the proportion of crude or overall mortality that is directly attributable to nosocomial infections. Studies that attempt to address this question by carefully controlling for many potentially confounding variables are called attributable mortality studies. Estimates of the attributable mortality associated with nosocomial bloodstream infections have ranged from 14% for infections caused by coagulase-negative staphylococci (49), 31 and 37% for infections caused by vancomycin-susceptible and vancomycin-resistant enterococci (26, 46), respectively, and 38 to 49% for infections caused by *Candida* spp. (32, 78) (Table 3).

Nosocomial infections also increase hospital costs and lengths of stay (LOS), thereby costing the health care system billions of dollars annually. At the University of Iowa, the median excess LOS for nosocomial bloodstream infections caused by coagulase-negative staphylococci and *Candida* spp. were 8 and 30 days, respectively (49, 78). Nosocomial bloodstream infections in the ICU were associated with an excess LOS of 24 days and excess hospital costs of $40,000

TABLE 1 Commonly used terms in health care epidemiology[a]

Term	Definition or Summary
Epidemiology	Study of the occurrence, distribution, and determinants of health and disease in a population. Hospital or health care epidemiology is the study of disease occurrence and distribution in the hospital or health care system.
Nosocomial infection	An infection acquired in a hospital or other health care facility.
Endemic infections	Infections occurring as part of the background or usual rate of infection in a specified population.
Epidemic infections	Infections occurring as part of an outbreak (or epidemic) of infection—defined as a significant increase in the usual rate of that infection in the specified population.
Incidence rate	Ratio of the number of new cases of infection in a specified population at risk during a defined time period to the overall number of people in the population at risk (the denominator).
Device-associated incidence rate	Ratio of the number of new cases of device-related infection in a specified population at risk during a defined time period to the number of days of device utilization in the population at risk.
Prevalence rate	Total number of cases of infection in the defined population at risk at one point in time (point prevalence) or in a given time period (period prevalence).
Observational or descriptive study	Study of the natural course of events, without an intervention in the process.
Case control study	Study frequently done as part of an outbreak investigation: a group of patients with the outcome of interest (e.g., cases of nosocomial infection) is compared to a control group of patients without the outcome. A comparison of specific factors between groups (e.g., exposures of interest) may suggest why infection occurred.
Crude or overall mortality rate	Ratio of the number of patients who die to the overall number of patients in a specified population.
Attributable mortality	Ratio of the number of patients who die as a direct result of the disease of interest to the overall population with the disease.

[a] Adapted from reference 50.

per survivor (60). Kirkland et al. found that surgical site infections increased LOS by more than 6 days and increased hospital costs by more than $3,000 per infection (42).

The premise upon which infection control programs operate is that many of these life-threatening and costly nosocomial infections are preventable. The Study of the Efficacy of Nosocomial Infection Control indicated that the presence of an active surveillance and infection control program was associated with a 32% decrease in nosocomial infection rates and that the absence of such a program was associated with an 18% increase in nosocomial infection rates (35). More recently, the CDC National Nosocomial Infection Surveillance (NNIS) system of hospitals reported a reduction in risk-adjusted infection rates in ICUs for all monitored infection sites (urinary tract, bloodstream, and lung) during the 1990s. The elements that were critical for reducing rates included targeted surveillance of high-risk populations (using standard definitions); adequate numbers of trained infection control professionals (ICPs), who inform health care providers of infection rates; and prevention efforts designed to address issues identified during evaluation of infection rates (18). Clearly, an effective infection control program improves patient care, saves lives, and decreases health care costs.

TABLE 2 Distribution of the five most common nosocomial pathogens isolated from major infection sites in the ICU

Pathogen	% of total at each infection site
Bloodstream infection[a]	
CoNS[b]	35.9
S. aureus	16.8
Candida spp.	10.1
Enterococcus spp.	9.8
Pseudomonas aeruginosa	4.7
Pneumonia[c]	
S. aureus	18.1
Pseudomonas aeruginosa	17.0
Enterobacter spp.	11.2
Klebsiella pneumoniae	7.2
Haemophilus influenzae	4.3
Urinary tract infection[c]	
Escherichia coli	17.5
Candida albicans	15.8
Enterococcus spp.	13.8
Pseudomonas aeruginosa	11.0
Klebsiella pneumoniae	6.2

[a] Data from SCOPE (80); collected between March 1995 and September 2002.
[b] CoNS, coagulase-negative *Staphylococcus* spp.
[c] Data from NNIS (17); collected between January 1990 and May 1999.

TABLE 3 Attributable mortality of nosocomial bloodstream infection due to selected pathogens[a]

Organism	Mortality among cases (%)	Mortality among matched controls (%)	Attributable mortality (%)	Reference(s)
CoNS[b]	31	17	14	49
Enterococcus spp.	43	12	31	46
VRE	67	30	37	26
Candida spp.	57–61	12–19	38–49	32, 78

[b] CoNS, coagulase-negative *Staphylococcus* spp.

THE HOSPITAL INFECTION CONTROL PROGRAM

The hospital infection control program should include surveillance and prevention of nosocomial infections, continuing education of medical staff, control of infectious disease outbreaks, protection of employees from infection, and advice on new products and procedures. The program is generally directed by a physician-epidemiologist and enforced by the infection control committee. Every hospital must also have a working infection control staff, comprising one or more ICPs. The ICPs should collect data on nosocomial infections and provide the data to the infection control committee.

Infection Control Committee

The infection control committee is responsible for reporting and evaluating nosocomial infection data and for drafting and implementing policies, procedures, and guidelines pertinent to the practice of infection control. Of note, in some hospitals the infection control program staff performs the functions just described and the infection control committee approves the reports, policies, procedures, and guidelines. The committee should be multidisciplinary, with representatives from all departments, including clinical microbiology, and should meet every 1 to 3 months to review hospital-specific nosocomial infection data and to formulate policy. The members bring the needs and perspectives of their departments to the committee and, in turn, take back important information about infection control initiatives and policies, etc. Other responsibilities of the committee include reviewing technical information about new products, devices, or procedures pertinent to infection control and instituting all necessary control measures in the event of an outbreak or other infection control emergency.

A clinical microbiologist must be on the infection control committee in order to provide expertise in the interpretation of culture results, advice about the appropriateness and feasibility of microbiological approaches to an infection control problem, and input regarding the laboratory resources necessary to accomplish the goals of the committee. One of the most important contributions of the clinical microbiologist is to inform the infection control committee of the strengths and limitations of methods employed to detect and characterize nosocomial pathogens. He or she should describe how changes in the methods used for detection, identification, and susceptibility testing of nosocomial pathogens would affect the infection control program. For example, if the laboratory introduces a urinary antigen detection test for diagnosis of legionellosis, the clinical microbiologist must inform the committee that the test is sensitive and specific only for detection of *Legionella pneumophila* serogroup 1 and that culture is required to evaluate for nosocomial legionellosis due to other species or serogroups. The committee should also be made aware of the budgetary and personnel constraints under which the laboratory operates to ensure that they do not expend valuable laboratory resources unless there is a clear epidemiologic indication to do so.

Nosocomial Infection Surveillance

Active nosocomial infection surveillance programs are associated with a reduction in infection rates and their consequent morbidity and mortality (22, 35), and national and state accrediting agencies require hospitals to do surveillance for nosocomial infections. Thus, systematic surveillance of nosocomial infections is the infection control program's most important activity. Surveillance is also the infection control program's most costly and time-consuming activity. Surveillance allows the infection control program staff to monitor the frequency and types of nosocomial infections, detect outbreaks, evaluate compliance with infection control guidelines, provide data for policy development, and monitor the effect of infection control interventions on nosocomial infection rates. To accomplish the overall goal of decreasing infection rates, the infection control program personnel must give the surveillance data and suggestions for improvement, including reminders to staff of existing infection control practices, back to the clinicians as soon as possible. Infection control programs that follow the CDC's advice about using device days as the denominator for calculating rates of nosocomial infection in ICUs can compare their rates with national benchmarks compiled and reported by the CDC NNIS system (17, 18). Figure 1 is a sample format for comparing infection rates in an ICU of a tertiary-care center with national benchmark data. The infection control program should provide infection rates, recommendations for improving rates, and assistance in

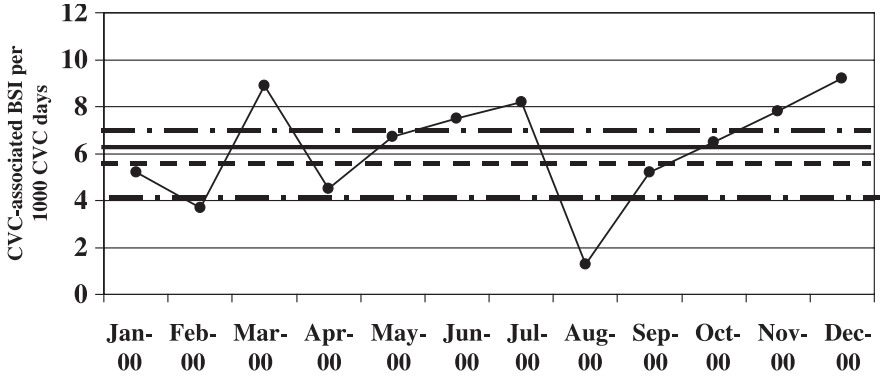

FIGURE 1 Medical ICU catheter-associated bloodstream infection rates. •———•, central venous catheter (CVC)-associated bloodstream infection rate per 1,000 catheter-days; ———, mean CVC-associated bloodstream infection rate in Hospital A medical ICU; – – – –, pooled mean CVC-associated bloodstream infection rate for the CDC NNIS hospital medical ICUs (n = 131); — ▪ —, 25th and 75th percentiles for CVC-associated bloodstream infection rate in NNIS hospitals.

implementing interventions to unit personnel such as medical directors, nurse managers, and clinicians.

The infection control program staff should design a surveillance system that is appropriate for the specific needs of the hospital and feasible based on the hospital's budget. For example, program personnel wishing to use device days as a denominator must develop a system for counting or accurately estimating device utilization in their ICUs. Because surveillance consumes more resources than any other infection control activity (27), infection control programs must devise the most efficient surveillance system possible. The most complete and accurate surveillance program might require an ICP to review charts of all hospitalized patients daily, but this approach obviously is not practical in any but the smallest of hospitals. Infection control programs should focus their limited resources on the highest-risk areas (e.g., intensive care, hematology-oncology, burn, and organ transplant wards) and use various screening techniques to increase surveillance efficiency. ICPs can use microbiology reports, nursing care plans, antibiotic orders, radiology reports, vital signs, and discharge diagnoses to determine which charts should be further reviewed.

Review of microbiology reports is probably the most common method for case finding, and it compares favorably in some circumstances with more comprehensive ward-based surveillance (31, 77). For example, Yokoe and colleagues reported that review of microbiology data alone was both more resource efficient and as effective as applying the CDC's definition of nosocomial bloodstream infection (85). Such laboratory-based surveillance allows the ICP to efficiently review a large amount of data. Moreover, medical information systems can enhance laboratory-based surveillance further by linking laboratory data with data from many sources (71), including pharmacies (e.g., antimicrobial use), radiology departments, billing departments (e.g., diagnostic codes), and nursing notes (e.g., vital signs and care plans).

Although reviewing microbiology reports is an essential part of surveillance, these data alone may not detect all nosocomial infections or all outbreaks. The sensitivity and specificity of laboratory-based surveillance depend upon both the frequency at which clinicians obtain cultures and the quality of the culture specimens received by the laboratory. In addition, while laboratory-based surveillance may quickly detect outbreaks due to unusual pathogens, or infections at unusual sites, outbreaks or clusters due to common pathogens at common sites (e.g., *Escherichia coli* urinary tract infection) may go undetected for longer periods of time. An optimal surveillance program will include data from more than one source (e.g., nursing care plans and microbiology reports) to help ICPs determine which charts deserve further review. The University of Iowa, Iowa City, previously validated a surveillance strategy using primarily microbiology reports and nursing care plans and found the sensitivity and specificity to be 81 and 98%, respectively (5). More recently, we introduced a computer-based screening algorithm that provides a list for each ICP each day of all patients in their units that had positive cultures or that had a *Clostridium difficile* toxin test or a respiratory syncytial virus antigen test ordered or one of the following combinations of tests ordered within a 24-h period: chest radiograph and culture of respiratory secretions or cultures from two or more body sites. After reviewing this information, the ICPs review the medical records of a small percentage of patients, thereby reducing the amount of time required for surveillance.

The frequency of surveillance of specific hospital units should be determined by the infection control committee based on the types of patients hospitalized, the procedures and treatments done in the facility, the resources available for surveillance, prevailing infection rates, and other factors. In addition, the infection control committee, in consultation with clinical microbiology personnel, should decide the mechanism by which the laboratory provides specific information needed for surveillance (e.g., all positive results or selected or sorted reports, etc.).

The recent movement toward public disclosure of nosocomial infection rates (16, 75, 81) has important implications for surveillance. If interhospital comparisons of nosocomial infection rates are to have any meaning, all hospitals must use the same methods for surveillance and risk adjustment (16, 75). Unfortunately, at the time this chapter was written, methods for nosocomial infection surveillance varied widely among hospitals and validated methods for risk adjustment rates were not available (40). Thus, although public disclosure of nosocomial infection rates is a laudable goal and the policy is being introduced by law in many states, much work needs to be done to ensure that such reporting improves, rather than hinders, efforts to prevent nosocomial infections.

Process Surveillance

Several recent studies clearly demonstrate that implementing evidence-based infection control practices, such as good hand hygiene (61) and guidelines for the placement and care of central venous catheters (4, 10), can dramatically reduce nosocomial infection rates (4, 61, 86). The obvious implication of these studies is that health care workers do not routinely adhere to the safest processes of care. For this reason, ICPs must now perform surveillance not only for important outcomes (infections) but also for important processes (e.g., rates of hand hygiene performance, use of maximal sterile barriers during central venous catheter placement, and elevation of the heads of beds to 30° for ventilated patients, etc.). Process measures can help infection control personnel understand some of the variation in nosocomial infection rates. In addition, reporting compliance rates to personnel may improve practices and reduce nosocomial infection rates.

ROLE OF THE MICROBIOLOGY LABORATORY IN INFECTION CONTROL

With this overview of the structure and activities of the hospital infection control program in mind, we will now focus on the most important specific roles played by the microbiology laboratory in the day-to-day practice of infection control.

Specimen Collection

Many nosocomial pathogens (e.g., coagulase-negative staphylococci) also commonly colonize patients' skin or mucous membranes and can easily contaminate cultures if specimens are not collected or handled properly. If contaminants are mistakenly considered to be infecting organisms, ICPs may inadvertently count these as representatives of nosocomial infections, thereby inflating the infection rates (2). Consequently, microbiologists must monitor specimen quality carefully and also set and enforce strict criteria for acceptable clinical specimens (see chapter 5).

Accurate Identification and Susceptibility Testing of Nosocomial Pathogens

Commercial identification and susceptibility testing systems allow most laboratories to identify microorganisms to the species level and perform antimicrobial susceptibility testing (AST). However, the expanding spectrum of organisms that colonize and infect seriously ill patients challenges the ability of the clinical microbiology laboratory to identify and characterize nosocomial pathogens accurately (56). For example, while many nosocomial pathogens (e.g., *Staphylococcus* spp. and the *Enterobacteriaceae*) are easily detected and identified with commonly used automated systems, many nonfermentative gram-negative organisms that cause nosocomial infections can be much more difficult to identify. Laboratories that identify nosocomial pathogens to the species level may find outbreaks that would otherwise have been undetected because clusters of unusual organisms or unusual clusters of common organisms may be clues to outbreaks. Thus, laboratories should establish a system for sending unusual nosocomial pathogens to a reference laboratory for definitive identification. In addition, viral, fungal, and mycobacterial pathogens can cause nosocomial infections and also can be difficult to identify to a level appropriate for infection control needs.

New antimicrobial resistances continue to emerge, and existing resistances are increasing in frequency. To guard against significant AST errors for some organism-antimicrobial combinations, laboratories must supplement automated systems with additional methods. AST errors are most likely for organisms that display heteroresistance or inducible resistance mechanisms or for newly emerging resistances. For example, some systems previously underestimated oxacillin resistance among *Staphylococcus* species (82) and did not adequately detect extended-spectrum beta-lactamase (ESBL) production by certain *Enterobacteriaceae* (3, 29, 70). Some automated systems have not detected all enterococci with certain vancomycin resistance phenotypes (68). More recently, investigators have found that automated systems were not adequate to detect vancomycin-resistant *Staphylococcus aureus* (VRSA), and therefore, laboratories must use new screening methods to detect this organism (67). If the laboratory uses methods that do not accurately identify organisms or particular resistance patterns, the infection control program may not identify serious problems or even outbreaks. Conversely, infection control personnel may investigate spurious problems, thereby diverting and wasting precious resources.

Laboratories that recognize such problems should bring them to the manufacturers' attention so that manufacturers can improve the instrumentation, panels, or software programs and, thereby, improve accuracy. This process of ongoing independent evaluation of automated systems and feedback to responsive industry representatives is extremely important. Unfortunately, in the era of managed care and shrinking laboratory resources, fewer laboratories have the ability to perform rigorous internal evaluations of new technology. The most important resistances emerging in nosocomial pathogens include ESBL production among *Enterobacteriaceae* (58, 64), glycopeptide resistance among enterococci (21) and staphylococci (9, 11, 12, 14, 19, 51, 65), and methicillin resistance among *S. aureus* strains (25). Moreover, four patients are known to have been infected with VRSA (11, 12, 14, 51), which is particularly concerning because *S. aureus* is a virulent organism and options for bactericidal therapy for infections caused by multiply resistant methicillin-resistant *S. aureus* (MRSA) are limited. The infection control program must implement control measures to prevent the spread of these important antimicrobial-resistant pathogens. However, the success of the program depends upon the ability of the laboratory to detect these organisms. Laboratory directors must read current literature regarding automated systems' ability to detect emerging resistances and implement, if necessary, additional methods to detect or confirm particular resistance patterns. The CDC website provides fact sheets summarizing current recommendations for detecting these resistances (http://www.cdc.gov/ncidod/hip/lab/lab.htm). Antimicrobial resistance detection is also reviewed in chapters 17, 74, and 78 of this Manual.

Laboratory Information Systems

An information system that can do prospective data mining and interface with other parts of the computerized patient record could help ICPs do surveillance, monitor patient-to-patient spread of pathogens, and detect outbreaks early (54, 59). Thus, persons choosing a laboratory information system must consult with both laboratory and infection control personnel before purchasing the best system for the hospital. Chapters 4 and 17 include more complete discussions of laboratory information systems and expert systems for data analysis.

Rapid Diagnostic Testing

During the past decade, numerous rapid diagnostic tests have been developed that use molecular or immunologic methods. For example, a variety of methods are now available for rapid detection of respiratory syncytial virus (41), *Clostridium difficile* (30), *Mycobacterium tuberculosis* (36, 39), and *Legionella pneumophila* serogroup 1 (62). Rapid methods for detecting important antimicrobial resistances are also being developed. Latex agglutination testing for the altered penicillin binding protein 2a (84)—or real-time molecular detection of the *mecA* gene coding for this protein (7, 73, 87)—detects MRSA more rapidly than traditional methods. Some hospitals, including that at the University of Iowa, are using methods that detect the *vanA* and *vanB* genes in real time to identify patients who carry vancomycin-resistant *Enterococcus* spp. (VRE) (24). A positive result from any of these tests will allow clinicians to implement appropriate isolation precautions quickly in order to prevent the spread of the organisms. Thus, such tests can help infection control programs control the spread of important pathogens. Of course, if clinicians order the tests indiscriminately or the laboratory has poor quality control, rapid diagnostic tests can lead to errors, including falsely positive tests that lead to inappropriate treatment and isolation of patients. Erroneous results may also cause the infection control program staff to waste time investigating a pseudo-outbreak (48). The clinical microbiologist must also assess the negative predictive value of any rapid tests provided by the laboratory. If the negative predictive value is not high enough, decisions to discontinue isolation precautions should not be based on the results of the rapid test.

Reporting of Laboratory Data

Culture and AST results are an important data source for infection control and are usually reviewed daily by ICPs. Thus, routine microbiology laboratory results should be readily accessible to ICPs. In most cases, results are stored in a computer database, facilitating retrieval and analysis. The laboratory should store the following information: specimen

type, date of collection, patient name, hospital number, hospital service, ward location, organisms identified, AST results, and the results of any specialized testing performed (e.g., typing). Both clinicians and ICPs benefit from periodic summaries of selected microbiology results such as an antibiogram specifically for nosocomial pathogens. These results can be presented in a table that includes the antibiograms of the most common nosocomial pathogens organized by anatomical site and hospital service and that also includes cost information for the most commonly used antimicrobials. This information will help clinicians choose empiric antimicrobial therapy for patients with nosocomial infections. The Clinical and Laboratory Standards Institute has developed guidelines for antibiogram preparation, which are discussed in chapter 4 (20).

Laboratory personnel should call the ICP directly to report some culture results to ensure that appropriate control measures are implemented. Examples include sterile-site cultures positive for *Neisseria meningitidis* and *Legionella pneumophila* and smears or cultures positive for acid-fast bacilli, enteric pathogens such as *Salmonella* and *Shigella* spp., and certain antimicrobial-resistant pathogens such as MRSA, VRSA, and VRE. In addition, new or unusual pathogens and potential agents of bioterrorism (e.g., *Bacillus anthracis*, *Yersinia pestis*, and orthopox viruses) should be reported promptly to the ICP.

In addition to providing printed and verbal reports, laboratory staff should meet regularly with infection control staff to ensure that their communication is direct and clear. They can discuss areas of mutual concern, such as the status of epidemiological and microbiological investigations of clusters or outbreaks. Together they can determine whether supplementary studies such as molecular typing or environmental cultures will be necessary. If these studies are necessary, they can determine exactly what needs to be done, who will perform these procedures, and when they will be carried out.

Outbreak Recognition and Investigation: Epidemic versus Endemic Infections

Most nosocomial infections are not associated with outbreaks, that is, they are endemic rather than epidemic infections. If rates of nosocomial infections are consistently defined by prospective surveillance, infection control personnel may occasionally identify outbreaks of nosocomial infections—an increase in infection rate beyond that expected during a defined time period—by reviewing these rates. However, more often infection control personnel learn about potential outbreaks while interacting with personnel in the ward, in clinics, or in the laboratory.

When the infection control team detects a cluster or outbreak of nosocomial infections, they must act promptly to identify the etiologic agent if it is not known, define the extent of the outbreak, learn the mode of transmission of the pathogen, and institute appropriate control measures. The clinical microbiology laboratory must provide appropriate laboratory support during this time. Table 4 outlines recommended steps in an outbreak investigation and points out the important role of the clinical microbiology laboratory at each step.

TABLE 4 Steps in nosocomial outbreak investigation, and the role of the laboratory at each step[a]

Investigative step	Role of the clinical microbiology laboratory
Recognize problem	Maintain surveillance and early-warning system—ideally part of the laboratory information system; notify infection control personnel of clusters of infections, unusual resistance patterns, and possible patient-to-patient transmission
Establish case definition	Assist and advise regarding inclusion of laboratory diagnosis in case definition
Confirm cases	Perform laboratory confirmation of diagnosis
Complete case finding	Characterize isolates with accuracy; store all sterile-site isolates and epidemiologically important isolates; search laboratory database for new cases
Establish background rate of disease, compare to attack rate during suspected outbreak	Provide data for use in ongoing surveillance, which provide baseline rates for selected units and infection sites; search laboratory database for all prior cases of the entity if baseline rate is not prospectively monitored
Characterize outbreak (descriptive epidemiology)	Perform typing of involved strains and compare to previously isolated endemic strains to determine if the outbreak involves a single strain (see chapter 11); this can be done only if selected pathogens are routinely stored (see above)
Generate hypotheses about causation: Identify potential reservoirs Identify potential modes of spread Identify potential vectors Perform case control study or cohort study	Perform supplementary studies or cultures as needed, but only if justified by epidemiologic link to transmission: personnel, patients, environment
Institute control measures	Adjust laboratory procedures as necessary
Perform ongoing surveillance to document efficacy of control measures	Maintain surveillance and early-warning function of the laboratory

[a] Adapted from reference 50.

Because the demands on the laboratory may be great during outbreaks, the laboratory staff should prepare in advance. Laboratory personnel periodically should ask ICPs what types of outbreaks have occurred in the past or may be anticipated in the future and what laboratory resources would be required should similar outbreaks occur. Laboratory staff should also anticipate the extra costs associated with outbreak investigations so that they can work with hospital administrators to include funds for these efforts in annual budgets. Costs should not be borne by the laboratory or charged to individual patients involved in the outbreak.

Some problems and potential pitfalls of outbreak investigation are pertinent to the clinical microbiology laboratory and bear specific mention. Foremost among these is the problem of determining when to proceed with an outbreak investigation in the first place. The number of cases necessary to constitute an outbreak depends upon the organism, the patient population, and the institution involved. For example, while numerous cases of *Escherichia coli* urinary tract infection in a long-term-care facility may not constitute an outbreak, even a single nosocomial case of group A streptococcal surgical wound infection or VRSA infection merits an outbreak investigation. Laboratories should consider instituting a computerized program that recognizes clusters of pathogens within the hospital. Organisms that appear to be part of a cluster could be further characterized to evaluate whether they are genetically related (see chapter 11), which would suggest patient-to-patient spread or exposure to a contaminated common source. Investigators at Northwestern University hospital implemented such a system and noted that their rates of nosocomial infections decreased in temporal association with this intervention (33).

A second important problem is that of a pseudo-outbreak. A pseudo-outbreak has occurred when an apparent outbreak turns out not to be an outbreak after all. The usual cause of a pseudo-outbreak is either misdiagnosis (e.g., infection has not actually occurred) or misinterpretation of epidemiologic data (e.g., infections have occurred, but clustering or epidemic transmission has not). The microbiology laboratory can be the source of pseudo-outbreaks (1, 28, 37, 45, 47, 66, 72, 83). Problems in the laboratory that lead to pseudo-outbreaks include contamination of reagents for stains (37), false AST results (28), and contamination of culture specimens (often from construction or renovation projects [47] or cross-contamination during specimen processing [83]). Careful attention to quality control, use of sterile techniques for specimen processing, and preventive measures during construction and renovation projects can decrease the likelihood of pseudo-outbreaks that originate in the laboratory.

Molecular Typing To Support Infection Control Activities

Outbreaks of nosocomial infection often result when a number of hospitalized patients are exposed to a contaminated common source or a reservoir of a pathogenic agent (e.g., water from a hot water tank colonized with *Legionella* spp.). The organisms causing such outbreaks would all derive from a single strain (i.e., they are clonally related). The infection control program team may, therefore, request that the microbiology laboratory characterize isolates that may be associated with outbreaks to determine whether they are genetically related. In the appropriate clinical setting, species-level identification and AST results (antibiogram) may provide strong evidence for an epidemiologic link. However, more sensitive methods of strain delineation are often necessary. In this setting, genotypic or DNA-based typing methods have essentially replaced phenotypic typing methods (e.g., AST, biochemical profiles, and bacteriophage susceptibility patterns), which discriminate poorly among isolates (52, 63, 74).

Genotypic typing methods provide meaningful data and are cost-effective only when they are used for well-defined epidemiologic objectives. These objectives include (i) determining the source and extent of an outbreak, (ii) determining the mode of transmission of a nosocomial pathogen, (iii) evaluating the efficacy of preventative measures, and (iv) monitoring transmission of pathogens in high-risk areas (e.g., ICUs), where cross-infection is a recognized hazard.

The ideal genotypic typing system should be standardized, reproducible, stable, sensitive, broadly applicable, readily available, and inexpensive. The typing method should also have proven value in previous epidemiologic investigations. Further discussion of the relative advantages and disadvantages of the many available typing systems is beyond the scope of this chapter and has been summarized in several reviews (52, 63, 69, 74) and in chapter 11 of this text.

Organism Storage

Of course, the laboratory cannot provide the infection control program with supplemental testing such as molecular typing if the appropriate isolates have not been saved. The laboratory should plan ahead and be sure to save all epidemiologically important isolates (see chapter 6). Laboratory and infection control personnel should decide which isolates should be banked and how long they should be stored based upon their epidemiological importance and the available resources. We recommend that all isolates from normally sterile sites (e.g., blood and cerebrospinal fluid), important antibiotic-resistant organisms (MRSA, VRE, and ESBL-producing *Enterobacteriaceae*) from any site, and other epidemiologically important pathogens (e.g., *Mycobacterium tuberculosis*) be saved for a period of 3 to 5 years.

Cultures of Specimens from Hospital Personnel and the Environment

The laboratory should perform cultures of specimens from hospital personnel and the environment (surfaces, air, and water) rarely and only when the epidemiologic evidence suggests that personnel or the environment was associated with transmission of a nosocomial pathogen. Various potential sources and appropriate culture methods are outlined in Table 5. Although infection control staff frequently consider obtaining such cultures, these cultures are labor-intensive, nonstandardized, and difficult to interpret and rarely provide useful information.

Because health care workers' hands can transmit nosocomial pathogens from patient to patient, hand cultures are sometimes useful in confirming the mechanism of cross-infection during an outbreak investigation (79). Similarly, because the anterior nares represent the usual reservoir for *S. aureus* (including MRSA) colonization in humans (43), nares cultures from patients and health care personnel are sometimes appropriate during an *S. aureus* infection outbreak.

Laboratory and infection control personnel should weigh two important factors before deciding to culture specimens from hospital personnel during an outbreak investigation: (i) finding the outbreak strain on the hands or in the nares of a health care worker does not establish the direction of transmission or definitively implicate a health care worker as the source or reservoir for the outbreak, and (ii) culturing specimens from hospital personnel indiscriminately can lead

TABLE 5 Cultures of personnel or environmental sources of infection in the hospital[a,b]

Source	Culture method	Comment
Blood products	Broth culture incubated aerobically and anaerobically at 30–32°C for 10 days	Following transfusion reaction; obtain simultaneous blood cultures by venipuncture
Environmental surfaces	Swab-rinse or impression plate	No evidence that any particular level of contamination correlates with nosocomial infection
Disinfectants and antiseptics	Plating of serial dilutions of the product with and without specific neutralizers	Organisms usually nonfermenting gram-negative aerobic bacilli
Air	Mechanical air sampler (preferred); settling plates (poor)	No uniform agreement on acceptable levels of contamination; lack of correlation with infection
Water (for *Legionella* spp.)	Membrane filter for water samples, swab of faucets and showerheads	Number of sites positive for *Legionella* spp. may correlate with risk for nosocomial cases; culture after confirmed case of nosocomial legionellosis; no consensus on performance of routine water cultures for *Legionella* (see text)
Hands of personnel	Broth-bag: 10–20 ml nutrient broth in sterile plastic bag; wash hands in broth and plate semiquantitatively	May confirm the mechanism of cross-infection; impress the importance of hand washing
Anterior nares of personnel	Swab culture	Carriage of outbreak strain may be eradicated by application of topical agent (e.g., mupirocin for *S. aureus*); recolonization with the same strain is frequent

[a] Cultures to be performed only if clearly indicated by epidemiologic data.
[b] Adapted from references 23 and 57, with permission.

to confusing results and can generate ill will toward the infection control program. In general, only specimens from health care workers epidemiologically linked to cases should be cultured. We recommend that infection control programs obtain cultures of specimens from hospital personnel only after consulting with a hospital epidemiologist experienced in outbreak investigation.

As a general rule, routine cultures of specimens from hospital personnel and the environment should not be performed. Exceptions include routine monitoring of sterilized items, infant formula, products prepared in the hospital, blood components (e.g., platelets) prepared in an open system, and hemodialysis fluid. The CDC and other experts have not reached a consensus about the utility of routine water cultures for the presence of *Legionella* spp. While the CDC suggests that such culturing may be an important aspect of preventing nosocomial legionellosis among very high risk patients (e.g., transplant recipients), the CDC has not made a recommendation about obtaining routine water cultures in health care settings other than transplant units if cases of nosocomial legionellosis have not been identified (13, 15). A complete discussion of this issue is beyond the scope of this chapter but can be found in the CDC guidelines (13, 15) and in a recent review by O'Neill and Humphreys (53).

Routine surveillance cultures should not be obtained from the following persons or items because the cost is high and the cultures rarely provide useful clinical or epidemiologic information: patients and hospital personnel, commercial patient care items, antiseptics and disinfectants that are in use, random blood units, respiratory therapy equipment, peritoneal dialysate, and air. Routine cultures from these sources are a burden to the laboratory and seldom, if ever, provide useful information or lead to specific interventions (13).

CONCLUSION

The clinical microbiology laboratory is an essential component of any effective infection control program. The development and application of new technologies in the clinical laboratory can greatly enhance infection control efforts. A good working relationship between clinical laboratory and infection control personnel will greatly facilitate the investigation and control of health care-associated infections.

Laboratory Procedures for the Epidemiological Analysis of Microorganisms

DAVID R. SOLL, CLAUDE PUJOL, AND SHAWN R. LOCKHART

11

In dealing with an infection, one often is faced with the need for species identification in order to prescribe effective treatment. In some clinical cases, however, one must pursue the identity of the infecting organism to the subspecies level. The typing techniques that have evolved for such discrimination at both of these levels of relatedness must be as rapid as possible. These techniques, therefore, usually focus on phenotypic characteristics and rarely provide the resolution necessary to obtain measurements of genetic relatedness among isolates of the same species or the same subspecies. Such resolution is essential for a number of epidemiological questions. In order to accurately identify the origin of a nosocomial infection, track the transmission of a disease, the emergence of a new hypervirulent or drug-resistant strain, or the microevolution of a commensal or infecting strain, and examine the general population structure of a pathogen, one must move from species typing to strain and substrain typing. Methods must be selected that provide information on the level of genetic relatedness. Methods have evolved that indeed provide such information, but researchers rarely validate the method they select for characterizing relatedness (135) or ask if the method they have selected has the resolving power for the question posed. Their results may, therefore, suggest stability when in fact the infecting organism is undergoing rapid microevolution. Alternatively, researchers may ask a question related to strain grouping that requires the genesis of deep-rooted dendrograms and then apply a method that relies mainly on hypervariable changes. Again, their results may not provide them with a valid answer, in this case because hypervariable changes will affect clustering due to homoplasy, which is the presence of identical characteristics in distinct phylogenetic lineages that are acquired not through descent, but rather through convergence, parallelism, or reversion. It is, therefore, imperative that one accurately formulate the question to be answered, define the level of genetic relatedness that must be assessed, and select a genetic fingerprinting method with the resolution necessary to answer that question (135).

BIOTYPING AND GENETIC FINGERPRINTING TECHNIQUES

Prior to the development of DNA-based techniques for assessing genetic relatedness, scientists relied on biotyping techniques, which measure phenotypic differences. The logic behind this approach was that phenotype reflects genotype, and so if one employs a number of phenotypic parameters, one can obtain a measure of genetic relatedness. In discriminating between genuses and species in both bacteria and fungi, biotyping still provides us with fast and reliable diagnostic methods. Kits measuring assimilation patterns (biochemical profiles) are still a mainstay for discriminating among a variety of bacterial and fungal species (25, 76, 78, 82, 106, 139, 163), antibody-based tests (serotyping) continue to be used to discriminate among groups within bacterial species and fungi like *Cryptococcus neoformans* (7, 132, 138, 174), and phage typing continues to be used to discriminate among groups within bacterial species (9, 70). However, these types of methods in general do not provide the kind of genetic discrimination usually necessary for addressing epidemiological questions. First, most of these tests do not provide enough unrelated parameters to obtain a good reflection of genotype. Usually they discriminate among only a limited number of groups, as in the case of serotyping. Second, and more important, the expression of many genes is affected by environmental changes and by developmental programs or reversible phenotypic switching (11, 54, 134, 143). In addition, phage and plasmids can be transmitted horizontally (23, 173). Most biotyping methods, therefore, fall short as genetic fingerprinting techniques. There is, however, one major exception, multilocus enzyme electrophoresis (MLEE) (105, 115). MLEE represents a robust genetic fingerprinting method that exhibits performance parity with many of the most effective DNA fingerprinting methods (111, 156).

DNA fingerprinting techniques, by virtue of the fact that they assess differences in genetic material, have been assumed to be the most accurate methods for genetic fingerprinting. This is not necessarily the case (135). As noted, some are as effective as MLEE and others fall short. Some are poor indicators of microevolution, and others are good indicators of microevolution but measure DNA sequences that are too hypervariable for deep-rooted cluster analyses (111). Some techniques are effective for analyzing bacteria but less effective for analyzing eukaryotes, and vice versa, because of inherent genomic differences. Finally, while some DNA fingerprinting techniques are excellent for cluster analyses of large collections of isolates, they are not favored by evolutionary biologists because they do not provide

codominant markers (150), although this requirement has been challenged quite effectively (154, 155).

What, then, are the general methods of DNA fingerprinting? The methods that will be reviewed in this chapter have, for the most part, been used for bacteria, fungi, and parasites. One of the earliest methods applied to bacteria and fungi took advantage of the fact that in the divergence of strains within a species, restriction sites identified by restriction enzymes, or endonucleases, change, leading to changes in the lengths of DNA sequences between sites. These changes accumulate as strains diverge during evolution, and the sum of the changes provides an indicator of evolutionary distance. The pattern of restriction fragments is referred to as the restriction fragment length polymorphism (RFLP) pattern. The comparison of the RFLP patterns between different isolates is referred to as RFLP analysis. This method has proved to be effective in DNA fingerprinting of bacteria, especially with the use of infrequent cutters in combination with pulsed-field gel electrophoresis (PFGE) (151), but less effective in fingerprinting of eukaryotic pathogens like the infectious fungi (10, 123). To obtain a more limited and more specific pattern, Southern blots can be hybridized with a DNA probe. Although this method is also referred to as RFLP analysis in the literature, we will distinguish it by calling it RFLP with a probe. The probes in this case must distinguish more than one fragment and, therefore, usually contain a repetitive sequence (124, 141, 145) or a combination of unique and repetitive sequences (41, 72, 91). The former are referred to as repetitive-element probes, and the latter are referred to as complex probes (135). A second approach to DNA fingerprinting takes advantage of PCR to amplify a variety of sequence fragments from the genome by utilizing sequences identified by the primers used in the PCR. The use of arbitrary primers for amplification has been referred to as random amplification of polymorphic DNA (RAPD) analysis (165, 167). This method has been used for DNA fingerprinting of a number of prokaryotic and eukaryotic pathogens (35, 77, 109, 156, 165). In recent years, PCR-based methods have been developed that employ primers that recognize identified sequences and in some cases these methods have been used in combination with RFLP analysis. Some of these methods are preferred by evolutionary biologists since the data they generate represent identified alleles (150). A third DNA fingerprinting method that has evolved in the last decade is based on PFGE methods for separating chromosome-sized DNA fragments (26, 126). This method has been successfully used to karyotype many fungi (14, 36, 79) and other eukaryotic microorganisms (69, 133) and, in the case of prokaryotes, to separate large fragments generated by endonucleases that identify infrequent restriction sites (3, 15, 35). Finally, sequencing of portions of one or several genes is a basic tool for answering evolutionary questions and a rapidly emerging tool for assessing epidemiological questions (42, 75, 95). Multilocus sequence typing (MLST) (95) has evolved rapidly in the past 5 years for DNA fingerprinting of both bacteria and lower eukaryotes (20, 37, 46, 149, 157). Finally, microarray typing based on probing oligonucleotides representing alleles of loci with PCR products provides a very new and potentially powerful method of discrimination (51, 56, 86, 140). Since MLEE and the variety of DNA fingerprinting methods outlined above are all tools for epidemiological studies of the genetic relatedness of isolates, we will refer to them as genetic fingerprinting methods.

GENERAL REQUIREMENTS OF AN EFFECTIVE GENETIC FINGERPRINTING METHOD

Before considering in detail each DNA fingerprinting method, a consideration of the general requirements of fingerprinting methods is in order. Although a list of requirements will be formulated, it should be realized that each epidemiological question posed will require different levels of resolution or stringency.

A Method Should Provide Data That Reflect Genetic Distance at the Level Necessary for Answering the Question Posed

An effective genetic fingerprinting system should do more than demonstrate that two isolates are nonidentical or that a collection of isolates differ. In many cases, a researcher must know how unrelated (or related) two or more isolates are. If one does not know the resolving power of the genetic fingerprinting method applied, one may conclude that because there are differences in the fingerprinting data, two isolates are unrelated or that because the fingerprinting patterns are identical, the isolates represent the same strain. However, if in the former case the method identifies hypervariable changes in the genome that can occur as frequently as 1 in every 200 cell divisions, the isolates may in fact be highly related, and in the latter case, if the method measures only rare changes, the isolates may in fact be quite unrelated. With this in mind, what are the levels of relatedness that we must consider? Because few methods provide a true measure of genetic relatedness, with some functioning better at discriminating one level than another, and since evolutionary time can only be estimated, we will categorize the levels rather than consider them as a continuum. The categories, diagrammed in Fig. 1, are "identical," "highly related but nonidentical," "moderately related," and "unrelated." The utility of using these categories will become evident in considering the effectiveness of the separate methods.

A Genetic Fingerprinting Method Should Be Resistant to Environmental Perturbations and High-Frequency Genomic Reorganization

As in the case of MLEE, the targeted sequences for a DNA fingerprinting method must be carefully selected. For instance, plasmid DNA and minichromosomal DNA may in

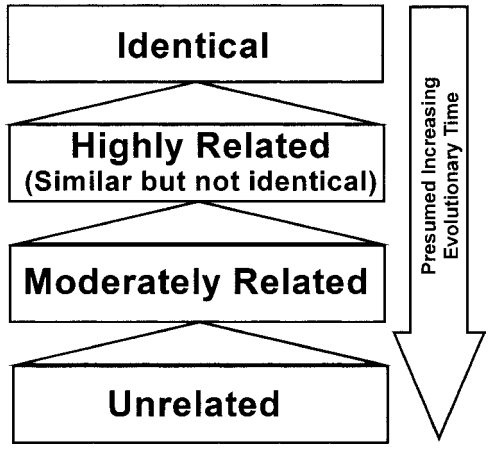

FIGURE 1 Categories of genetic relatedness for isolates within a species.

some cases be bad choices since growth rate and cellular phenotype may affect the maintenance of the genetic markers and the rate of reorganization (22, 27). Sequences involved in phase transitions in such bacteria as *Salmonella enterica* serovar Typhimurium and *Escherichia coli* undergo reversible transitions (61), as is also the case for the expressed mating type locus in *Saccharomyces cerevisiae* (65). In addition, some genomic reorganization events are repressed by silencing genes (58) and derepressed in mutants (63) and the frequencies of other reorganizational events are affected by the expressed phase in phenotypic switching systems (113).

In Most Cases, a Genetic Fingerprinting Method Should Be Fast, Feasible, Affordable, and Amenable to Computer-Assisted Analysis

In many instances, a genetic fingerprinting study involves few isolates and limited goals. If a study, however, involves large numbers of isolates requiring complex measurements of relatedness, and if retrospective use of the data in the future is entertained, one must select a method amenable to automatic computer-assisted analysis and storage. One must also select a method that is within one's technical abilities, that is affordable, that can be accomplished in a reasonable amount of time, and that will answer the question posed.

COMMON GENETIC FINGERPRINTING METHODS

There are several basic genetic fingerprinting methods that have been used repeatedly for prokaryotic and eukaryotic pathogens to answer a variety of epidemiological questions. In the sections that follow, the most commonly used methods are described and evaluated.

Multilocus Enzyme Electrophoresis

It is immediately obvious that a method based on enzyme electrophoresis is not DNA based. However, MLEE fulfills the requirements set forth for DNA-based fingerprinting systems (135) and has been demonstrated to attain resolution at all of the levels categorized in Fig. 1 (105, 111, 115, 156). The MLEE method relies on phenotypic polymorphisms, but these polymorphisms are rooted in protein structures that are reflections of the sequences of the structural genes that encode them. The MLEE method resolves polymorphisms through differences in the electrophoretic mobilities of the gene products of different alleles of the same gene. Electrophoretic mobility depends primarily on the net charge of the protein, which is a consequence of the primary protein structure but which is also influenced by secondary, tertiary, and quaternary structures. The latter levels of structure can conceal or reveal charged amino acid residues that contribute to the total charge of a protein and therefore to its exact electrophoretic mobility. In addition, MLEE detects polymorphisms only within the coding region of a gene. Even in coding regions, many mutations do not cause a polymorphism. It is, therefore, difficult to estimate what proportion of base changes leading to amino acid substitutions or other mutations in a protein is detected by the MLEE method, but it is generally accepted that only approximately 15% of the amino acid changes in an average protein can be resolved by MLEE (115). This level of sensitivity is sufficient for assessing the various levels of genetic relationships outlined in Fig. 1.

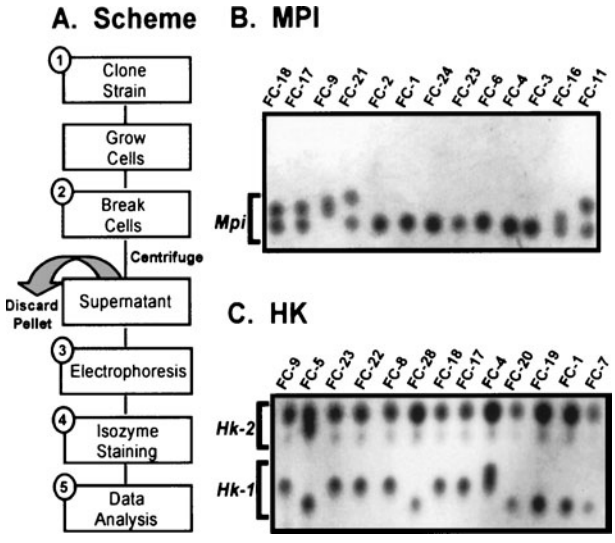

FIGURE 2 MLEE. (A) Generic version of the steps in the MLEE method. (B and C) Examples of enzyme phenotypes using starch gel electrophoresis for mannose-6-phosphate isomerase (MPI) (B) and hexokinase (HK) (C) in 13 *C. albicans* isolates (111). Note that there are two different HK genes, *Hk-1* and *Hk-2*.

In Fig. 2A, a generic version of the MLEE method is presented.

Preparation of Cells

One must begin with a clone. Primary isolates must be cloned, and each clone must be individually grown for protein extraction. For most infectious microorganisms, homogeneous cell populations can be grown in culture to the levels necessary for standard assays. Precaution must be taken, however, in the growth of the different isolates in a test set. Growth conditions for isolates must be uniform, which is not as stringent a requirement for DNA-based methods. If some isolates grow at different rates, reach stationary phase at different times, or express different general phenotypes under the same culture conditions, there may be effects on the isozyme patterns that would not represent changes in DNA sequence.

Preparation of Protein Extracts

Cells are harvested (e.g., pelleted by centrifugation) and washed (e.g., with distilled water). The cell sample (e.g., 200 μl of wet cells) is mixed with glass beads (e.g., 200 μl) and distilled water (e.g., 200 μl) in a 1.5-ml microcentrifuge tube and vortexed. The extraction solution must be appropriate for the maintenance of enzyme activity. Distilled water is in many cases appropriate for large, concentrated biological samples. In some cases, proteinase inhibitors must be employed. Bead friction during vortexing will produce heat that can denature proteins. To avoid this, cooling intervals (e.g., placing the tube in ice water) are interspersed with vortexing pulses. A number of different lysis methods are available, each with different attributes. Immediately after disruption, samples are centrifuged to remove insoluble materials. The supernatant containing the soluble enzymes of interest can then be divided into small aliquots (e.g., 50-μl aliquots) and immediately used or stored at ⩽20°C. Enzymes must be selected that retain activity through the extraction procedure.

Electrophoresis

Electrophoretic methods employing different supporting gels have been used in MLEE. These include methods utilizing cellulose acetate, agarose, starch, and polyacrylamide. In the case of cellulose acetate, migration of proteins occurs on the surfaces of gels, in the film created by the buffer. Proteins migrate as a function of their electrophoretic mobilities alone. In the cases of both starch and agarose, the supporting gels are made up of a network of constantly sized pores, large enough for the migration of most proteins without retardation due to friction. In both cases, proteins migrate as a function of their electrophoretic mobilities alone. In the case of polyacrylamide gels, it is possible to regulate pore size by changing the acrylamide/bisacrylamide ratio. Therefore, polyacrylamide gels can be used to separate proteins based both on electrophoretic mobility and on size or conformation. In specific cases, one of these four methods may be more effective in separating a particular set of isozymes than another. Urea and sodium dodecyl sulfate (SDS), used in denaturation gels, can never be included in the electrophoresis procedure. The electrophoretic temperature usually must be maintained at close to 4°C in order to avoid thermal denaturation of the protein. The composition of the electrophoresis buffer must be optimized empirically by the enzymes selected for analysis. Buffer characteristics that affect both activity and separation include pH, ionic strength, and the specific concentrations of cations and anions.

Staining of Enzymes for Visualization of Specific Activities

Once enzymes are separated, enzyme positions must be visualized. This is achieved by using the specific activities of the isozymes. This basic approach requires that the mutations that affect mobility do not affect enzyme activity. In visualizing enzyme activity, one of the enzyme products is usually stained by a second reaction. Examples of stained isozymes are presented in Fig. 2B and C.

Application and Analysis

If the patterns of a single set of isozymes for a particular gene are used to assess genetic relatedness, the information level is too meager. For a haploid organism, one band is obtained per sample, and for diploids, one or two bands are usually obtained. Electrophoretic patterns may be more complex if the enzyme is active in multimeric forms, but this does not increase the information that can be used to assess genetic relatedness. In the patterns generated by MLEE (Fig. 2B and C), the alleles are codominant, which means that for heterozygous loci in diploid organisms, both alleles are expressed. Electrophoretic conditions should, therefore, be developed that provide the best separation of the different isozymes of each gene. For monomeric enzymes (composed of a single polypeptide), a homozygote will exhibit one band and a heterozygote will exhibit two bands. For a dimeric enzyme (composed of two polypeptides) in diploid organisms, heterozygotes could show three bands. Similarly, a heterozygote for a tetrameric enzyme should show up to five bands. Such patterns are sometimes difficult to resolve. On rare occasions, enzymes are composed of two or more polypeptides encoded by independent genes, and even greater complications then arise. To generate complex enough data to assess relatedness at all levels (Fig. 1), several genes must be analyzed. On average, 10 to 20 genes should make up the data set for each microorganism (see, e.g., Table 1). The selected genes must exhibit variability between independent isolates. Therefore, for each organism, a set of enzymes must be established empirically. For well-studied organisms, this job usually has already been performed, so scrutiny of the literature should provide one with a list of enzymes and references to the chemical reactions for visualization. The general approach for selecting enzymes was recently described by Pujol et al. (110, 111) in developing an MLEE method for *Candida albicans*. In two independent studies, 21 enzyme loci were tested with collections of 55 and 29 isolates of *C. albicans*. In both studies, 13 loci (62%) exhibited variability among the test strains and their products were selected as the set of analytical enzymes. In MLEE studies of bacterial collections, 9 polymorphic enzymes were used to analyze *Campylobacter jejuni* isolates (103) and 16 were used to analyze the genetic diversity of *Helicobacter pylori* (66). In MLEE studies of fungal collections, 7 polymorphic enzymes were used to analyze *Aspergillus fumigatus* (17) and 12 were used to analyze *Cryptococcus neoformans* (16). In MLEE studies of parasite collections, 22 polymorphic enzyme loci were used to analyze *Trypanosoma cruzi* isolates (12) and 16 were used to analyze *Leishmania* spp. (8). Examples of sets of enzymes used effectively in an MLEE study of a bacterium (13), a fungus (111), and a parasite (2) are presented in Table 1.

The result of an MLEE analysis involving, for example, 10 analyzed genes is a phenotype composed of 10 sets of values for each isolate. Each analyzed test isolate must then be compared with every other isolate at every locus in order to obtain a summed similarity coefficient. The method for doing this will be dealt with later in this chapter.

Restriction Fragment Length Polymorphism without Hybridization

As previously noted, one of the earliest methods for DNA fingerprinting of infectious microorganisms was restriction enzyme analysis, more commonly referred to as RFLP analysis. RFLP has been useful in answering limited epidemiological questions posed for a number of lower eukaryotic pathogens, but because of the composition of eukaryotic genomes, RFLP as presently applied presents limitations as a DNA fingerprinting method. For this reason, the application of RFLP to eukaryotic microorganisms will first be described and discussed and a discussion of its application to bacteria, which has been far more effective, will follow separately. The basic method of RFLP has also been incorporated into a number of additional, more complex fingerprinting methods, usually involving repetitive-hybridization probes.

Use of RFLP To Analyze Lower Eukaryotic Pathogens

The general method of RFLP analysis is relatively straightforward (Fig. 3A). Total cellular DNA is extracted from cells, digested usually with one endonuclease, separated by agarose gel electrophoresis, and stained usually with ethidium bromide. The final banding pattern represents differences in the sizes of the digestion fragments. Differences between patterns are assumed to represent differences in genetic relatedness. Fragment polymorphisms are determined by the positions of restriction sites identified by the particular endonuclease(s) employed. Differences in the banding patterns of two isolates of the same species are due to differences in fragment sizes that can occur as a result of changes in restriction site sequences, secondary modifications of restriction sites, deletion or insertion of restriction sites, or deletion or insertion of sequences between

[a] Data from Bart et al. (13).
[b] Data from Pujol et al. (111).
[c] Data from Abderrazak et al. (2).
[d] Enzyme activities are indicated (with Enzyme Commission numbers). ADH, alcohol dehydrogenase; ME, malic enzyme; IDH, isocitrate dehydrogenase; G6PD, glucose-6-phosphate dehydrogenase; UDH, unidentified dehydrogenase; NAD-GDH, glutamate dehydrogenase (NAD^+ dependent); NADP-GDH, glutamate dehydrogenase ($NADP^+$ dependent); IPO, indophenol oxydase; AK, adenylate kinase; AKP, alkaline phosphatase; PEP, peptidase (the substrates are indicated for the different peptidases used with *C. albicans* and *P. falciparum*); ACO, aconitase; FUM, fumarase; SDH, sorbitol dehydrogenase; MDH, malate dehydrogenase; SOD, superoxide dismutase; AAT, aspartate aminotransferase; HK, hexokinase; PK, pyruvate kinase; EST, esterase; LAP, leucine aminopeptidase; MPI, mannose-6-phosphate isomerase; ALD, aldolase; GPI, glucose-6-phosphate isomerase; PGM, phosphoglucomutase; LDH, lactate dehydrogenase; 6PGD, 6-phosphogluconate dehydrogenase; GSR, glutathione reductase; NH-i, nucleoside hydrolase (substrate inosine); ADA, adenosine deaminase.

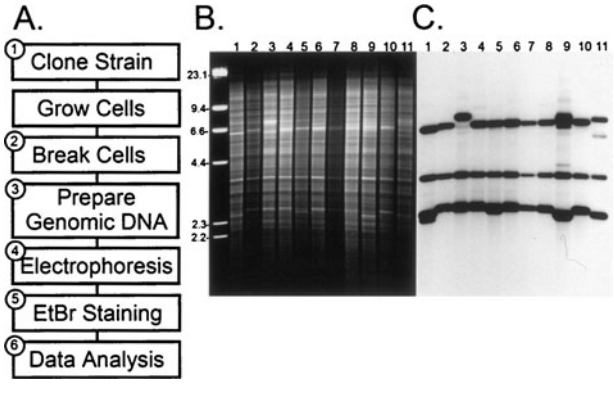

FIGURE 3 RFLP. (A) Generic version of the steps in the RFLP method as it is commonly applied to lower eukaryotic pathogens. EtBr, ethidium bromide. (B) Example of an ethidium bromide-stained gel of EcoRI-digested DNA from 10 test isolates of *C. albicans* (lanes 2 to 11) and a control isolate (lane 1). The first lane, not numbered, contains molecular mass standards. Molecular sizes (in kilobases) are indicated to the left. (C) The gel in panel B Southern blotted and hybridized with a ribosomal probe that identifies 28, 17, and 5S rRNA genes.

restriction sites. Therefore, selection of the most effective endonuclease for generating a pattern must be empirical. A good example of an RFLP pattern for isolates of the yeast pathogen *C. albicans* is presented in Fig. 3B. One should immediately recognize first that not all bands are easily resolvable. Because of the complexity of the eukaryotic genome, the number of digestion fragments is greater than that in prokaryotes. This reduces resolution between bands in an agarose gel and leads to the normally smeared nature of an average RFLP profile. The dominant bands are resolvable, but unfortunately, these bands represent primarily the repetitive ribosomal cistrons and to a lesser extent mitochondrial DNA sequences. Unlike those of prokaryotes, the ribosomal cistrons of eukaryotes are clustered on one or two chromosomes (62, 128). The cistrons are in tandem with interspersed spacer regions and are structurally quite homogeneous. Therefore, endonuclease digestion that results in a complex RFLP pattern results in a relatively simple rRNA gene pattern. To demonstrate this point, the ethidium bromide-stained gel with *C. albicans* whole-cell DNA in Fig. 3B was destained, Southern blotted, and hybridized with an rRNA gene probe containing the high-molecular-mass (28S), low-molecular-mass (17S), and 5S rRNA gene sequences (Fig. 3C). Only three intense bands and a few minor bands were resolved with a reasonable degree of resolution in each pattern. The number and variability of the major RFLP bands

among independent *C. albicans* isolates, therefore, do not provide enough complexity for resolving differences between moderately or highly related isolates and in some cases may not even be able to distinguish between unrelated isolates. In contrast, the complexity of the pattern of unique-sequence DNA, which should be great enough for assessing genetic distance, is blurred by the congestion of bands in a normal gel. Even so, the use of RFLP patterns for distinguishing between unrelated isolates or identifying different isolates of the same strains of eukaryotic pathogens continues and can sometimes be reasonably effective, if one does not demand resolution at the levels of moderate relatedness (Fig. 1).

In Fig. 3A, a generic version of the RFLP method (121) as applied to eukaryotic pathogens is presented. The major steps are dealt with individually below.

Preparation of Cells

As in the case of the MLEE method, one must begin with a clone. Each clone must be individually grown for DNA extraction. In contrast to MLEE, however, RFLP analysis does not require one to worry about uniform growth conditions since genotypes should be stable under different conditions.

Preparation of DNA

Many lower eukaryotic pathogens are encased in cell walls, and the walls must be removed prior to cell lysis. Here, a general protocol is described for infectious yeast. Cells from agar cultures are grown to stationary phase in a rich liquid growth medium. Cells are pelleted, washed, and resuspended in medium that removes cell walls and osmotically maintains the integrity of the resulting spheroplasts (cells that have had their walls removed). For generation of spheroplasts, cells are first suspended in the medium SPP, containing 1 M sorbitol and 50 mM potassium phosphate, pH 7.4. To remove the cell wall, a variety of enzymes are used, depending on the nature of the wall. To remove yeast cell walls, the snail enzyme Zymolyase can be used. For *C. albicans*, which has a very tough wall, 15 μl of a solution containing 100 mg of Zymolyase 20 T (Seikagaku America, Ijamsville, Md.) in 800 μl of 50 mM sodium phosphate (pH 6.5)–50% glycerol is added to 0.7 ml of SPP containing 10^8 cells. Cells are then incubated in suspension for 30 to 90 min at 37°C. The time for wall removal varies, even between strains of the same species. A preparation is assessed microscopically for spheroplast formation and is usually terminated when the proportion of spheroplasts in the population is >80%. The percentage of spheroplasts can be assessed by adding 1 μl of 10% KOH to a droplet of spheroplasts on a microscope slide and counting the proportion of lysed cells. At the time of 80% lysis, the spheroplasts are pelleted at 2,500 × *g* for 10 min at room temperature, washed in SPP, and finally resuspended in 500 μl of a lysis buffer containing 50 mM Tris-HCl, pH 7.4, and 20 mM EDTA. Fifty microliters of 10% SDS is added to the preparation, which is then incubated for 30 min at 65°C. Two hundred microliters of 5 M potassium acetate is then added, and the preparation is incubated in an ice bath for 1 h. The lysate is centrifuged at 10,000 × *g* for 10 min at 4°C, and the supernatant, containing DNA, is extracted with an equal volume of a 1:1 solution of phenol-chloroform. The DNA in the supernatant is precipitated with an equal volume of cold isopropanol. The DNA is then washed twice with 750 μl of 75% ethanol, dried, and resuspended in 100 μl of a solution containing 10 mM Tris-HCl, pH 7.5, and 1 mM EDTA. Contaminating RNA can be removed by adding 2 μl of a 10-mg/ml solution of RNase A and incubating for 1 h at 37°C. This solution is again extracted with phenol-chloroform and precipitated, as in earlier steps. The final precipitate is then resuspended in 100 μl of the Tris-HCl–EDTA solution and may be stored at 4°C. This solution should not be frozen.

Endonuclease Digestion

Three micrograms of DNA extracted from each test isolate is incubated in 25 μl of reaction buffer containing one or more selected endonucleases according to the manufacturer's instructions. The units of endonuclease should be threefold over the recommended value to ensure complete digestion, a necessary prerequisite for obtaining reproducible, well-separated RFLP patterns. Endonucleases, or restriction enzymes, identify precise sequences throughout the genome. For example, EcoRI identifies and cleaves (cuts) at sites with the sequence 5′GAATTC3′, BamHI cleaves at 5′GGATCC3′, and HinfI cleaves at 5′GANTC3′, where N is any nucleotide. Restriction sites vary in abundance. An infrequent cutter is an enzyme that identifies infrequent sites in a particular genome and is the basis for the RFLP method combined with PFGE that is frequently applied to prokaryotes. Two examples of infrequent cutters used in fungal studies are NotI, which cleaves sites with the sequence 5′GCGGCCGC3′, and SfiI, which cleaves sites with the sequence 5′GGCCNNNNNGGCC3′, where N is any nucleotide. In bacteria, SmaI is an infrequent cutter which cleaves sites with the sequence 5′CCCGGG3′. An infrequent cutter will generate a limited number of genomic fragments. These fragments may be too large to be separated by standard gel electrophoresis. On the other hand, some restriction sites are too common, resulting in patterns containing too many bands for good pattern resolution. It should be clear from this brief discussion that one must carefully choose the endonuclease or combination of endonucleases to be used in an RFLP analysis.

Electrophoresis

After digestion is complete and prior to electrophoresis, 3 μl of DNA loading dye (e.g., 40% Ficoll and 0.01% bromophenol blue) is added to each sample. The low-molecular-weight dye will migrate close to the front of the sample and, therefore, provide a measure of migration progress. Electrophoresis, in this case, is usually performed with agarose gels cast in and run with 1× TBE buffer, containing 89 mM Tris-HCl (pH 8.1), 89 mM H_3BO_3, and 2 mM EDTA. In a standard experiment, 3 μg of digested DNA is loaded into a well of a 13- by 24-cm gel containing 12 to 15 wells. A set of standards, DNA fragments of known sizes, should also be loaded onto each gel. The percent agarose used will depend upon the range of fragment sizes, which will in turn be a function of genome size and the selected restriction enzyme(s). For example, for the gel in Fig. 3B, digestion of *C. albicans* DNA with the restriction enzyme EcoRI generated a complex pattern separated in a 0.8% agarose gel. For these gel specifications, the dye front should migrate 16 cm from the loading well.

Staining

To visualize the banding patterns of RFLPs, the gel is soaked for 1 h in a solution of 0.2 μg of ethidium bromide/ml. The pattern is then viewed and photographed with a UV light source. It is suggested that a ruler be placed next to the gel when the gel is photographed so that migration distances can be assigned.

Analysis

The standard RFLP method for eukaryotic pathogens generates patterns that are sometimes difficult to compare. Because of band crowding, automatic computer-assisted analyses are difficult and too much information is lost due to the lack of discrimination. The positions of the major bands in RFLP patterns can be manually digitized into a database, but as noted above, the major bands represent primarily rRNA gene fragments. However, when RFLP studies involve small numbers of isolates, and all that is demanded from the data is an assessment of identity and nonidentity, qualitative interpretations can be sufficient. The problems of RFLP analyses of eukaryotic pathogens are resolved to some extent by applying hybridization probes, the subject of a later section of this chapter.

Use of RFLP To Analyze Prokaryotes

The bacterial genome is usually composed of a single DNA molecule (i.e., a single chromosome). These genomes can vary significantly in size and complexity, but in the majority of cases, bacterial genomes are less complex than lower eukaryotic genomes. One, therefore, may expect greater resolution in an RFLP pattern generated with a prokaryotic genome, but that is really not the case. When a frequent cutter is used, the ethidium bromide-stained pattern is still crowded. Standard RFLP analysis without probes has, therefore, not been a popular epidemiological tool for bacteria. Instead, bacterial epidemiologists have used infrequent cutters to generate a limited number of DNA fragments, which are then separated by an electrophoretic method customized for large fragments (33). In Fig. 4A, a generic version of this method is presented. A clone is grown to stationary phase in medium recommended for the particular species. In many cases, this represents an overnight growth culture. Cells are usually pelleted by centrifugation and resuspended in a medium customized for the species under analysis. For instance, in a procedure applied to *Staphylococcus aureus* (68), cells are washed in a solution containing 0.15 M NaCl and 10 mM EDTA, pH 8.0, and resuspended in a solution containing 1 M NaCl and 10 mM EDTA, pH 8.0. This cell suspension is then mixed with an equal volume of 1.2% low-melting-temperature agarose, and the mixture is allowed to solidify in 100-μl molds. The blocks are then incubated in lysis solution containing 1 M NaCl, 10 mM EDTA, 10 mM Tris-HCl (pH 8.0), and a lysis cocktail that includes 0.5% (wt/vol) Brij 58, 0.2% (wt/vol) deoxycholate, 0.5% (wt/vol) Sarkosyl, 1 mg of lysozyme/ml, and 4 mg of acromopeptidase/ml. The blocks are next incubated in a solution containing 0.25 M EDTA, 1% (wt/vol) Sarkosyl, and 0.1 mg of proteinase K/ml at 50°C, followed by a solution containing 10 mM Tris-HCl (pH 8.0), 1 mM EDTA, and 1 mM phenylmethylsulfonyl fluoride. Sections of blocks are then incubated with restriction enzyme and electrophoresed in a 0.9% agarose gel by using contour-clamped homogeneous electric field electrophoresis (29), the PFGE system of choice for this form of fingerprinting. Staining and data analysis are as described for RFLP analysis of lower eukaryotes. An example of the application of RFLP-PFGE to *Staphylococcus aureus* is presented in Fig. 4B. A standardized protocol for the refined preparation of DNA for PFGE analysis has been described by Chang and Chui (28) and should serve as a good starting point for individuals interested in an RFLP method for fingerprinting of bacteria. Chung et al. (30) give a protocol for PFGE analysis of *Staphylococcus aureus* with specific details on troubleshooting.

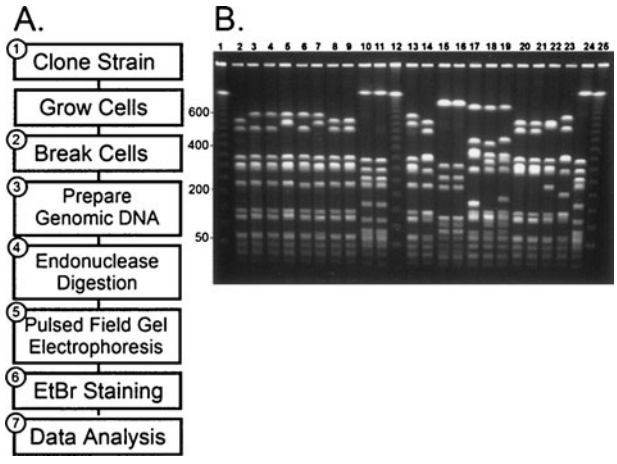

FIGURE 4 RFLP as it is commonly applied to prokaryotic pathogens, using PFGE to separate large DNA fragments. (A) Generic version of the steps in the RFLP-PFGE method. EtBr, ethidium bromide. (B) Example of RFLP-PFGE as it was applied to 22 *Staphylococcus aureus* isolates (provided by M. Pfaller, University of Iowa). Standards were run in lanes 1, 12, and 25. Molecular sizes are given in kilobases.

Restriction Fragment End Labeling

Restriction fragment end labeling was developed as a fingerprinting method for bacteria because of the compact size of the bacterial genome. In this method, total genomic DNA is digested with a restriction endonuclease and all of the fragments are end labeled using the Klenow fragment of DNA polymerase I. Following labeling, the fragments are separated by electrophoresis through a polyacrylamide-urea gel, such as what would be used for DNA sequencing. The number of bands will depend upon the species and isolates of the bacteria that will be analyzed and on the characteristics of the gel. van Steenbergen et al. (161) found that of the 11 species of bacteria that they analyzed, they could distinguish between 30 and 50 bands per isolate in the 100- to 400-bp size range. This method has been successfully applied to the molecular epidemiology of several bacterial species, including *Streptococcus pneumoniae* (19) and *Helicobacter pylori* (159).

Application of Hybridization Probes to RFLPs

Because hybridization probes allow visualization of a subset of fragments in an RFLP pattern, the resolution of the pattern increases over that with RFLP without a probe. The increase in resolution is evident in the comparison between the RFLP pattern (Fig. 3B) and the Southern blot pattern of the same gel hybridized with an rRNA gene probe (Fig. 3C). The success of this fingerprinting strategy has been mixed and depends upon the selected hybridization probe. Therefore, after a description of the general method, the caveats of the method will be reviewed. In Fig. 5A, a generic version of the RFLP method with a hybridization probe is presented.

Steps i to vi

Steps i through vi are identical to those already described for the RFLP method without a probe, and a description of them will not be repeated.

Steps vii and viii

To hybridize with a probe, the ethidium bromide-stained DNA is transferred onto a nitrocellulose or nylon membrane,

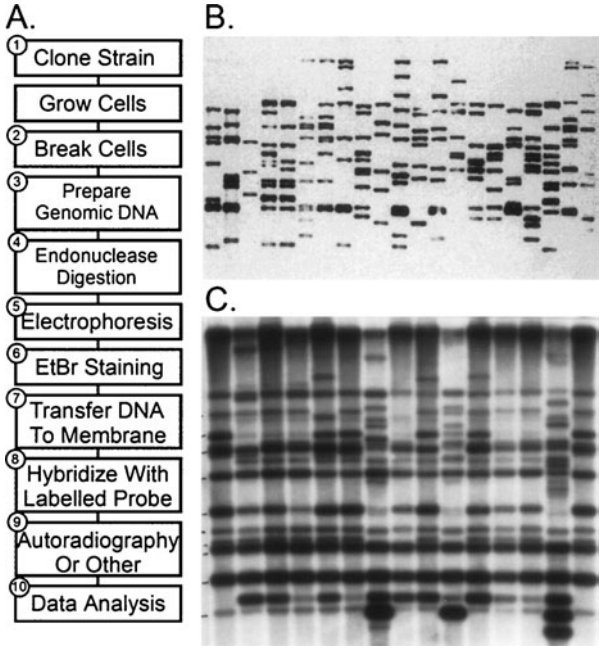

FIGURE 5 RFLP with probe. (A) Generic version of the steps in the RFLP-with-probe method. EtBr, ethidium bromide. (B) Example of RFLP with probe applied to a bacterium, in this case an IS probe applied to PvuII-digested *Mycobacterium tuberculosis* DNA (160). Molecular sizes are presented in kilobases to the left of the gel. (C) Example of RFLP with probe applied to a yeast, in this case the complex probe Ca3 applied to EcoRI-digested *C. albicans* DNA (S. Joly and D. R. Soll, unpublished results).

a process referred to as Southern blotting. The method for this process can be found in *Current Protocols in Molecular Biology*, volume 1 (6), or in *Molecular Cloning: a Laboratory Manual* (121). In brief, the gel is first treated with 0.25 M HCl. This step results in partial depurination and strand cleavage of DNA. The gel is rinsed in water and soaked in a solution containing 0.5 M NaOH and 1.5 M NaCl. This treatment denatures the DNA, a necessary step prior to hybridization. If a nitrocellulose membrane is used, the gel must then be neutralized to a pH below 9.0. The transfer to a membrane can then be achieved by a number of protocols, the most common ones based on upward or downward capillary transfer (60, 121). The Southern blot is then ready for the hybridization step. The probe must be labeled. The most common method is random priming with [α-^{32}P]dCTP or [α-^{32}P]dATP. A nonradioactive method employs a digoxigenin label (67), which can generate sharper banding patterns than radioactive probes but is usually less sensitive. For both methods, the gel must first be treated with hybridization buffer containing 150 μg of sheared, denatured salmon sperm, calf thymus, or other DNA per ml for approximately 4 h at 65°C to block nonspecific binding of the probe. Hybridization is then performed with the same prehybridization buffer containing the labeled probe. One standard hybridization buffer contains 50 mM NaH_2PO_4 (pH 7.5), 50 mM EDTA, 0.9 M NaCl, 5% dextran sulfate, and 0.3% SDS. The hybridization reaction is performed for 16 to 24 h at 65°C. Hybridization is terminated by washing the membrane at 45°C with a solution containing 0.3 M NaCl, 0.03 M sodium citrate (pH 7.0), and 2% SDS.

Step ix

The hybridization pattern generated by a radioactive probe is visualized by exposing the blot to X-ray film with the aid of intensifying screens. Examples of Southern blot hybridization patterns for bacteria and yeast are presented in Fig. 5B and C, respectively. To visualize digoxigenin-labeled patterns, one can treat the gel with anti-digoxigenin antibody conjugated to horseradish peroxidase (39). The antibody binds to digoxygenin. Next, one adds the substrate luminol under alkaline conditions. Horseradish peroxide and hydrogen peroxide catalyze luminol oxidation. Oxidized luminol decays, releasing light, which can be visualized with X-ray film.

Step x

Because hybridization is a result of ionic rather than covalent bonding, one can strip a Southern blot of a probe and rehybridize with additional probes.

Selection of a Hybridization Probe

Selection of a probe for a study should be based on a firm understanding of the exact information a particular probe will provide. Some of the first probes used for DNA fingerprinting of the infectious fungi included single gene sequences, rRNA genes, and mitochrondrial DNA. It should be evident that a single-gene probe will usually hybridize to only one band in a haploid organism and one or two bands in a diploid organism. Although differences in the sizes of the fragments carrying the gene may exist between isolates, the data are never sufficient for epidemiological studies that require measurements of moderate relatedness.

The use of rRNA genes as a fingerprinting probe for both prokaryotic and eukaryotic pathogens was predicated on the idea that single-copy DNA probes would not provide adequate data complexity. In bacteria, rRNA gene probes, which are the basis of the most popular automatic typing systems such as the Riboprinter microbial characterization system (Qualicon, Wilmington, Del.), are effective because rRNA cistrons are dispersed throughout the single chromosome (104). Variability in banding patterns results from changes in bordering sequences (34, 43, 97, 107, 169).

In contrast, the rRNA cistrons of eukaryotes are clustered, usually in only one chromosome (62, 128). These cistrons are separated by spacers. Endonuclease digestion usually results in a very limited number of bands, generating unexpectedly simple patterns (Fig. 3C) that are not much more complex than those generated by single-copy probes. Therefore, other repetitive sequences were sought that provided more complex patterns. In particular, repetitive sequences were sought that were dispersed throughout the genome. The expectation was that changes in the flanking sequences would generate differences in the patterns of different isolates that could be interpreted in terms of genetic distance. In some bacteria, transposable elements have been used as DNA fingerprinting probes. For instance, in *Mycobacterium tuberculosis*, insertion sequences such as IS*6110* (also known as IS*986*) have been used as probes (83). The copy number of IS*6110* per strain varies between 1 and 19, but the majority of strains carry between 8 and 15 copies dispersed throughout the chromosome (114). Therefore, patterns generated with the IS*6110* probe and PvuII-digested *Mycobacterium tuberculosis* DNA are relatively complex and vary between unrelated isolates (Fig. 5B).

For the fungi, a variety of moderately repetitive sequences have been used. For instance, poly(GT) and several oligonucleotides, such as $(GGAT)_4$, $(GTG)_5$, $(GATA)_4$, and

$(GACA)_4$, have been used for DNA fingerprinting of *Candida* species (142). These sequences, which identify microsatellite regions, generate complex patterns that may prove to be effective fingerprinting probes, but none have been fully verified. In *C. albicans*, the repeat sequence CARE2 (84), which is represented 10 to 14 times in the genome, generates a relatively complex Southern blot hybridization pattern. However, CARE2 and other repetitive sequences that reorganize at a rapid evolutionary rate are sometimes ineffective in identifying clusters of moderately related isolates of a species, a problem to which we will return.

For fungi, complex probes have been cloned that have proven effective at all levels of relatedness. Complex probes are genomic fragments between 10 and 20 kb in length that contain and therefore identify highly variable repetitive sequences, moderately variable sequences, and monomorphic sequences. These probes hybridize in a species-specific fashion and generate patterns that are complex but distinct enough for automatic computer-assisted methods of analysis. They have been cloned from every fungal species so far tested, including *C. albicans* (4, 89, 119), *C. tropicalis* (71), *C. glabrata* (91), *C. dubliniensis* (72), *C. parapsilosis* (41), *C. lusitaniae* (S. Lockhart and D. R. Soll, unpublished results), and *Aspergillus fumigatus* (60). The methods for cloning and characterizing complex probes have been recently reviewed by Lockhart et al. (88). An example of patterns obtained with the Ca3 probe for *C. albicans* is presented in Fig. 5C.

Random Amplification of Polymorphic DNA

RAPD is one of the most frequently used methods for DNA fingerprinting of eukaryotic organisms (24, 165, 167). As we shall see in a following section dealing with verification, this method, when developed correctly, is highly effective for assessing relatedness at all levels of resolution. However, in contrast to RFLP, RFLP-PFGE, and RFLP with a hybridization probe, the RAPD method is compromised by problems of reproducibility among laboratories. The method, presented in a generic form in Fig. 6A and B, is straightforward. With the use of random primers of approximately 10 bases in length, amplicons throughout the genome are amplified by PCR as described in Fig. 6A. The amplification products are separated on an agarose gel and visualized by ethidium bromide staining. Polymorphisms arise when the distances between primer hybridization sites change or when primer sites appear, disappear, or change location due to insertion, deletion, or recombination. If a primer hybridizes to a large number of sites on opposing Crick and Watson strands (i.e., identifies a significant number of amplicons), that primer will generate a complex pattern. Usually, however, each 10-bp primer will generate one or a few major bands and a few minor bands (Fig. 7). Because some minor bands may not be highly reproducible in repeat experiments in the same laboratory, only the major bands are usually used for analysis. This irreproducibility is probably the result of low annealing temperatures and short primer sequences, which result in mispairing. Several primers must be used and the data must be pooled to obtain the necessary level of complexity for epidemiological studies. As a general guideline, it is recommended that one use approximately eight primers, each generating at least two reproducible, strong bands, resulting in at least 16 polymorphic bands. Too low a degree of polymorphism will bias a study. Based on our experience with the RAPD method, we recommend the selection of polymorphic bands present in between 10 and 90% of isolates (41, 91, 111). To

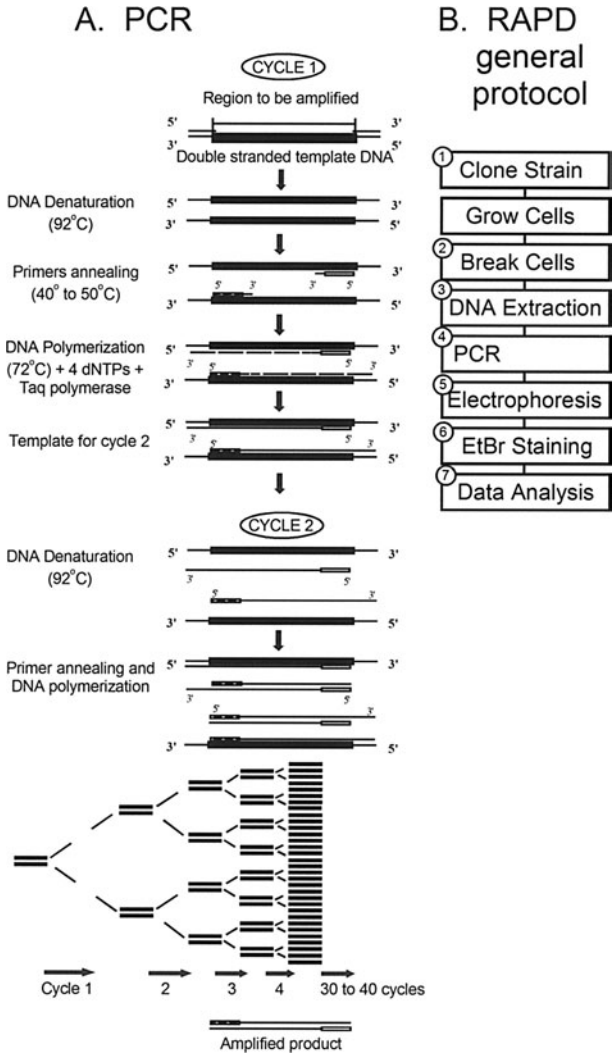

FIGURE 6 RAPD. (A) Description of PCR. (B) Generic version of the steps in the RAPD method. EtBr, ethidium bromide.

obtain an effective collection of primers, one should begin with 30 or 40 primers and test each with a representative collection of isolates if one is setting up one's own RAPD protocol. Primer collections can be readily obtained commercially. The test sequences can usually be obtained from collections used for studies of related organisms. In an analysis of *C. glabrata*, Lockhart et al. (91) selected the following nine primers: GGACTGCAGA, GTGACATGCC, CAGGCCCTTA, TGCCGAGCTG, AATCGGGCTG, GTGATCGCAG, TCGGCGATAG, AGCCAGCGAA, and AGGTGACCGT. In an analysis of *C. albicans*, Pujol et al. (111) selected the following eight primers: CCAGATGCAC, GTGACATGCC, TTATCGCCCC, GGACTGCAGA, ACGGCGTATG, AACGGTGACC, GGAAGCTTGG, and ACGGTACCAG. In an analysis of *Salmonella enterica* serovar Typhimurium isolates, Malorny et al. (96) selected 13 primers, and in an analysis of *Burkholderia pseudomallei* (85), 30 primers were tested for their efficacy in RAPD analysis. In contrast, in several studies, isolates have been grouped using a single primer (31). In some cases, a single primer can in fact provide enough data to generate a dendrogram (see, e.g., reference 112).

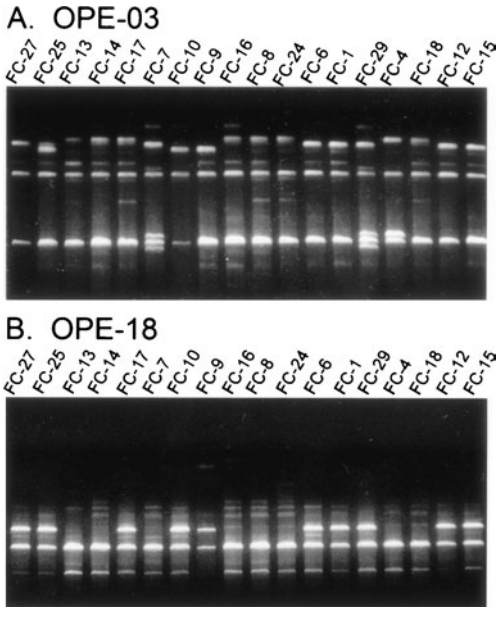

FIGURE 7 Examples of RAPD patterns with the primers OPE-03 (A) and OPE-18 (B) applied to 18 isolates of the yeast *C. albicans*. Reprinted from reference 111 with permission.

Once a primer or primers are selected, the method of RAPD analysis is relatively straightforward. In Fig. 6B, a generic version of the RAPD method is presented.

Preparation of Cells

As in the case of the MLEE, RFLP, and RFLP-with-probe methods, one must begin with a clone. In contrast to the MLEE method, but similar to the RFLP and RFLP-with-probe methods, the RAPD method does not require one to be too concerned about uniform growth conditions.

Preparation of DNA

The preparation of DNA is similar to that for RFLP, with some modifications. First, since the DNA has to be pure to facilitate the PCR, several chloroform extractions are necessary. To prevent DNA degradation, EDTA can be added during extraction, but EDTA should be absent from the final DNA suspension solution since 0.1 μM EDTA can affect the efficiency of *Taq* polymerase in the PCR. The following protocol is relatively simple, has been successfully used for the analysis of several fungal species, and can be adapted for other organisms. A 500-μl suspension of cells (5×10^9 cells per ml) in a solution of 10 mM Tris-HCl (pH 8.0)–1 mM EDTA is mixed with an equal volume of glass beads (0.45 mm in diameter) in a 1.5-ml microcentrifuge tube and disrupted in a bead beater. SDS is then added to a final concentration of 2% (wt/vol), and the suspension is mixed by repeatedly inverting the tube. DNA is then purified by two rounds of phenol extraction followed by three rounds of chloroform extraction. DNA is precipitated in 0.3 M sodium acetate (pH 4.5) and 2 volumes of 100% ethanol. The final DNA precipitate is resuspended in distilled water.

PCR Amplification

The following is a simple version of PCR amplification. To a 0.5-ml microcentrifuge tube is added 25 μl of a reaction mixture containing 5 ng of genomic DNA, 2.5 μl of 10× buffer provided by the manufacturer with purchased *Taq* DNA polymerase, 1.5 mM $MgCl_2$, 0.5 to 1.5 U of *Taq* DNA polymerase, 250 μM (each) dATP, dCTP, dGTP, and dTTP, and 0.2 mM selected 10-bp primers. Amplification is performed in a thermal cycler programmed for 45 cycles of 1-min duration at 94°C, 2 min at 36°C, and 2 min at 73°C. Amplification products are separated by electrophoresis in a 1.5% agarose gel run for 4 h at 110 V so that the bromophenol blue marker dye migrates approximately 10 cm. For the separation of low-molecular-mass (<500 bp) amplification products, acrylamide gels can be used.

Visualization of Bands

The gel is stained with ethidium bromide as described for RFLP gels and viewed with a UV light box.

Problems Inherent in the RAPD Method and Controls That Must Be Applied

Because there is a problem of reproducibility not only between laboratories but also within the same laboratory over time, one must be cognizant of the pitfalls in the procedure. Most aspects of PCR affect reproducibility, including small differences in the primer-to-template ratios, the concentrations of magnesium, and temperatures (40, 94, 99). Second, variation can occur as a result of the source of *Taq* enzyme (94, 99).

The following steps should, therefore, be taken to obtain reproducible banding patterns. First, DNA from different strains should be tested at a variety of dilutions to assess the impact of dilution on pattern stability. Second, the DNA of a single strain should be extracted several times to test whether minor variations in the preparation of DNA affect patterns. Finally, the amplification reaction should be performed in parallel and in sequence for a single DNA preparation that will be used as a control to test intralaboratory reproducibility.

Other PCR-Based Methods for DNA Fingerprinting

A variety of additional DNA fingerprinting methods have been developed that are PCR based. One modification to RAPD is the amplified fragment length polymorphism method, in which restriction fragments are selected for amplification (130, 158, 164). In this method, DNA is first digested with a restriction enzyme and random restriction fragments are singled out by using a specific base sequence at the 3′ ends of the primers. While the amplified fragment length polymorphism method has been developed to target restriction sites, PCR methods have also been developed to target other known sequences distributed throughout the genome, such as microsatellite sequences and spacer regions between tRNAs or rRNAs. In interrepeat PCR, the variable-length segments found between consecutive repeat elements, rather than the repeat elements themselves, are amplified. Oligonucleotide primers are designed such that they hybridize to the 5′ and/or 3′ ends of repetitive elements, but instead of amplifying the elements, they face outward from the elements and amplify the internal spacer sequences. PCR fragments are separated by agarose gel electrophoresis following amplification and are viewed by staining with ethidium bromide. The number of bands produced is dependent upon the number of repetitive elements within the genome as well as the number that are adjacent and close enough for *Taq* DNA polymerase to amplify the sequences between them (usually around 5,000 bp). Single-primer interrepeat PCR using the M13 core sequence or the microsatellite primers

$(GTG)_5$ and $(GACA)_4$ has been successfully used for a number of fungal species, including *Candida* spp. (101) and *Cryptococcus neoformans* (100), and the parasite *Leishmania* spp. (125). In bacteria, there are at least two commonly used inverted-repeat elements, BOX and the enterobacterial repetitive intergenic consensus (ERIC) sequence. These elements have been successfully used for typing of *Streptococcus pneumoniae* with the single BOXA primer (80) and *Pseudomonas aeruginosa* with both BOXA and primers ERIC1 and ERIC2 (146). A specific protocol for fingerprinting of *Mycobacterium tuberculosis* strains called double repetitive element PCR utilizes two sets of primers, two of which amplify out from the repetitive element IS*6110* and two of which amplify out from the polymorphic GC-rich repetitive sequence PGRS element, in order to generate patterns for isolates with small numbers of IS*6110* repetitive elements (53). Another typing method that has been applied to *Mycobacterium* is spoligotyping. This method uses interrepeat PCR to amplify the regions between a repetitive element known as DR. Rather than separating the interrepeat regions on a gel, one of the primers is end labeled and the products are hybridized to an array of oligonucleotides corresponding to 43 known inter-DR regions (38, 73, 81).

Variable-number-of-tandem-repeat elements (VNTRs) or microsatellites are very short tandem repetitive elements found within the genomes of both prokaryotes and eukaryotes. The VNTR fingerprinting method is PCR based and relies on the amplification of specific VNTRs by using primers specific to the outside flanking regions of the elements. The bands that are generated are distinguished by size following gel electrophoresis. In an article by Lott et al. (93), VNTR profiles were generated for one dimorphic and three polymorphic loci from 114 isolates of *C. albicans* and the methodology was verified by comparing the deduced phylogeny to that which was found using some of the same strains in a previously verified fingerprinting system (111). Mazars et al. (98) identified 12 VNTR regions within the *Mycobacterium tuberculosis* genome that had from two to eight alleles each in the 72 isolates that were tested. This corresponds to a potential for more than 16 million combinations of alleles. VNTR typing has also been successfully applied to the parasite *Plasmodium falciparum*. Anderson et al. (5) described 12 variable-length microsatellite loci and were able to do a population structure analysis of isolates from 465 cases of infection.

Because some evolutionary biologists believe that patterns must account for identified alleles (i.e., a change in a band size in a pattern must be attributed to a change in the size or another aspect of a known sequence), PCR-based methods have been developed that employ genetic markers, either identified or anonymous. Karl and Avise (74) have devised a method that has been applied to a number of lower eukaryotic pathogens, in which arbitrary primers are used to identify monomorphic amplicons, which are then partially sequenced. Customized pairs of primers are then developed for specific bands. Changes in these identifiable bands are then assessed through either RFLP or single-strand conformational polymorphism (SSCP) analysis, which involves the identification of single base pair changes in a sequence through nonhomologous renaturation of DNA and separation on a sequencing gel. For the use of these markers in fungi, see the review by Taylor et al. (150). For *C. albicans*, both PCR-SSCP (52, 64) and PCR-RFLP (171, 172) have been used with equally good results. PCR and the use of specific allelic probes have also been applied to *C. albicans* (32). Similar approaches have also been developed that target the noncoding regions of loci. Development of primer pairs is based on published sequences, and polymorphisms can again be identified by SSCP or RFLP. In these types of PCR-based methods, several pairs of primers must be employed and the pairs must be selected not only because they identify a known sequence but also because they produce the necessary levels of variation between strains. Although these methods have been argued to be superior to standard RFLP because one knows the identity of bands in different strains, analyses of the efficacy of RAPDs in band identification have demonstrated levels of identity between patterns that far exceed those required for effective analysis. Reiseberg (116) tested the homology of 220 pairs of comigrating RAPD fragments from three closely related species (not strains!) of sunflower and found that 91% exhibited homology. Thormann and coworkers (152) demonstrated an extremely high degree of similarity of hybridization patterns of RAPD bands within several plant species. Both these interspecies and intraspecies analyses support the conclusion that RAPD fragment size within a plant species is a strong indicator of homology, and by inference, this should be true for microbial pathogens. More important, verification of the RAPD method through comparison of its clustering abilities with those of unrelated methods has demonstrated its efficacy, as will be discussed in a later section of this chapter. The bottom line is that it is not necessary to identify the RAPD bands being analyzed to use the RAPD method in genetic fingerprinting, as has been amply argued by Tibayrenc (154–156).

Electrophoretic Karyotyping

Since lower eukaryotes possess multiple chromosomes within the size separation range of PFGE technology, this method (26, 126) has been used as a way of fingerprinting eukaryotic pathogens (Fig. 8). If the cell possesses a wall, the wall must be removed. The resulting spheroplasts are embedded in an agarose plug. Detergent and proteinase are added, which removes membrane, digests protein, and releases nucleic acid. The agarose matrix reduces shear forces and thus protects the large chromosomal DNAs from fragmenting. The agarose plug is placed in a well of an agarose slab gel, and electrophoresis is

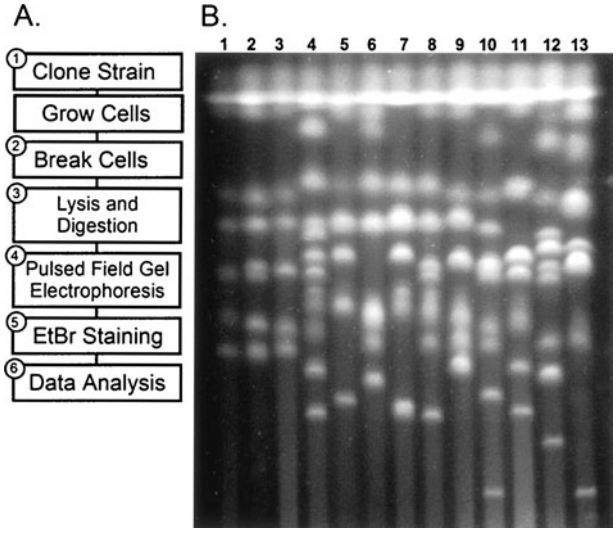

FIGURE 8 PFGE. (A) Generic version of the steps in the PFGE method. EtBr, ethidium bromide. (B) Example of ethidium bromide-stained chromosomes of isolates of the yeasts *C. albicans* (lanes 1 to 3) and *C. dubliniensis* (lanes 4 to 13).

carried out according to the protocol for the specific system used (e.g., orthogonal-field-alternation gel electrophoresis [127], contour-clamped homogeneous electric field electrophoresis [29], or transverse alternating-field electrophoresis [57]). After electrophoresis, chromosomal DNAs are visualized by ethidium bromide staining. Chromosomes can then be identified by Southern blot hybridization with chromosome-specific probes. For infectious yeast, Sangeorzan et al. (122) demonstrated that patterns were reproducible among experiments and relatively insensitive to the method of preparation. However, there have been other studies that demonstrate pattern variability due to reagents, sample preparation, and eletrophoretic conditions. Thrash-Bingham and Gorman (153) demonstrated that in spite of karyotypic variability between strains, the general organization of the genome was maintained, although some chromosomal translocations contributed to karyotypic variability between strains of *C. albicans*. In addition, it has been demonstrated that the frequency of changes in electrophoretic karyotypes can be dramatically influenced by high-frequency phenotypic switching (113). In a sequence of high-frequency switching, the electrophoretic karyotype of a strain diverged from and then reverted to the original pattern, a process that would invalidate the use of this method for assessing moderate levels of relatedness (113). There are reasons to believe that the majority of changes in the chromosome harboring rRNA cistrons in *C. albicans* were due to a release from silencing (113), a process involving *SIR* genes in *Saccharomyces cerevisiae* (58, 63). Whatever the mechanism proves to be, the problem that arises from these observations is that the rate of change identified by PFGE methods may not always reflect genetic distance.

Multilocus Sequence Typing

Although nucleotide sequencing provides the most exact data for assessing polymorphisms within a species, until recently it has been used primarily to analyze mutations associated with phenotypic change and to generate single-locus phylogenetic trees at the interspecies level. At the intraspecies level, multiple loci must be sequenced and the combined data must be analyzed. Recent advances in automated sequencing and the complete sequence data of genomes of select microorganisms have led to the use of sequence data to type isolates and perform population genetic studies of bacteria and fungi. MLST (95) has evolved rapidly over the past several years for DNA fingerprinting of bacteria and fungi (20, 21, 37, 45, 49, 157). It replaces MLEE, providing more alleles per locus and resulting data that are highly reproducible between laboratories. In addition, sequence data can be easily stored and shared via the Internet for comparison and use in large-scale epidemiology studies (1).

A general protocol for MLST has recently been described by Lockhart et al. (90). For template DNA extraction, the protocol proposed for the RAPD method is appropriate. Alternatively, commercial DNA extraction kits can also be used. PCR fragments should be around 500 bp in length to be easily sequenced in both directions. The PCR products must be purified by using any commonly available PCR cleanup kit before sequencing.

Choice of Loci

A selection of six to seven genes is commonly used. These are usually selected among core metabolic genes (housekeeping genes) that are believed to be unaffected by selection. Their use, therefore, precludes microevolutionary analysis. In a few studies, microevolutionary changes have been assessed by using hypervariable genes or genes that are known to be affected by selection. Morelli et al. (102) have analyzed the microevolution of a clonal lineage of *Neisseria meningitidis* by sequencing multiple DNA fragments, including genes encoding cell surface antigens and intergenic regions. Similarly, Feavers et al. (44) used antigen sequences to analyze an outbreak of *Neisseria meningitidis* infection. More recently, Robinson and Enright (117) have used surface-associated genes to supplement their MLST data in order to document the emergence of methicillin-resistant *Staphylococcus aureus* isolates. While MLST schemes have been used to fingerprint fungi (21, 37, 55, 149), the MLST approach was originally designed for bacterial analyses. The use of coding sequences is appropriate for the majority of bacteria because many bacterial species present a high number of polymorphisms. If noncoding sequences were to be used, homoplasy may render interpretations difficult. However, for some microorganisms, and fungi in particular, this approach may not be optimum due to lower genetic variability than that in bacteria. For instance, in the yeast *C. parapsilosis*, three distinct genetic groups can be distinguished (41, 87, 147). Group I strains are the most pervasive and account for between 60 and 90% of isolates (41, 87). Groups II and III are less frequently found and have recently been considered distinct species (147). Tavanti et al. (147) have sequenced a total of 7.5 kb over 11 genes for 21 *C. parapsilosis* group I isolates. They found limited genetic variability, with only two polymorphic nucleotide positions in their entire collection.

MLST and Heterozygosity

The MLST method has been used primarily for fingerprinting of species with haploid genomes. MLST has been successfully used for at least one diploid species, the yeast *C. albicans* (20, 21, 148). While direct sequencing of PCR products identifies single alleles in haploid species, in diploid species, the sequences obtained reflect the combination of two homologous alleles. Heterozygosities are revealed by double peaks in the sequencing traces. Thus, where heterozygosities exist at multiple nucleotide sites in any particular locus, assignment of individual alleles is not possible. This issue may be overcome by cloning the PCR product into a suitable plasmid vector and sequencing one cloned allele. The remaining allele may then be inferred. In diploid genomes, loci containing insertion or deletion polymorphisms need to be avoided. Where such polymorphisms are present, the sequences of the two alleles will be out of phase and the sequencing traces will be unreadable.

Microarray Typing

The latest development in typing techniques has evolved from advances in genome sequencing and DNA microarray technology. Microarray typing methods are rapidly emerging as powerful high-throughput typing strategies. The general method is based on the use of oligonucleotides of around 30 bp in length. These oligonucleotides are selected to target variable single nucleotide polymorphism sequences based on the presence of known polymorphisms. A set of specific oligonuclotides representing each allele of a given locus is used to detect polymorphisms in PCR products of the respective loci. It is a multilocus-based method with which several loci can be analyzed simultaneously. This approach has been used to fingerprint several bacteria (56, 129, 144, 168), viruses (59, 86), parasites (140), and fungi (51). The method has been shown to be effective in detecting heterozygosities in diploid organisms (51).

VERIFYING THE EFFICACY OF A GENETIC FINGERPRINTING METHOD

As noted earlier, one must be sure that a fingerprinting method provides the correct level of genetic resolution for the question posed. Therefore, one must select a method that has already been verified or perform tests to verify the method. The most straightforward test is comparison with an unrelated method by using a set of test isolates with known or implied relatedness. The levels to be tested are (i) identical, (ii) highly similar but nonidentical, (iii) moderately related, and (iv) unrelated (Fig. 1). The test collection is fingerprinted by the individual methods, and similarity coefficients are computed by the same analytical method for every pair of isolates. Dendrograms based on the independent sets of data are then generated and compared. If the unrelated methods both identify known identical isolates as identical, presumed highly related isolates as similar but nonidentical, and presumed unrelated isolates as dissimilar and if the independent methods group isolates into the same clusters, they in essence cross-verify each other's efficacy at every level of relatedness. If they identify as identical presumably identical isolates and identify as similar but nonidentical highly related isolates but do not cluster in a similar fashion moderately related to unrelated isolates, then one or both methods may be ineffective in assessing lower levels of relatedness. This general method of cross-verification has been used to assess the efficiency of a variety of fingerprinting methods for bacterial, fungal, and parasitic pathogens (see, e.g., references 81, 111, and 156). It should be emphasized that without cross-verification, a genetic fingerprinting method is always suspect for the different levels of relatedness (Fig. 1), no matter how valid the system seems to be. One must realize, however, that such cross-verification is possible only for microorganisms with clonal population structures (111, 154–156).

DATA ANALYSIS

Computing Similarity Coefficients

Genetic fingerprinting data come in different forms. MLEE provides multiple spot patterns, RAPD provides single or multiple banding patterns, RFLP, RFLP with a probe, and PFGE provide single or multiple banding patterns, and MLST provides sequence data. Regardless of the data form, the goal of a genetic fingerprinting method is to compute similarity coefficients (S_{AB}s) for every pair of isolates in order to generate a dendrogram, or tree. The formula for computing S_{AB}s and the formula for generating a tree from the S_{AB}s must be carefully selected, and excellent reviews of these computations are available (47, 131, 166). Here, we will review only the most common of these. For a detailed description of these methods, the reader is referred specifically to Sneath and Sokal's *Numerical Taxonomy: the Principles and Practice of Numerical Classification* (131). The challenges of MLST data analysis will be dealt with in a separate section.

Band Positions Alone

For methods that produce patterns of bands, the presence or absence of a band is described by the binary value 1 or 0, respectively, n_{AB} is the number of common bands in the two patterns A and B (coded 1, 1), a is the number of bands in A with no counterpart in B (coded 1, 0), b is the number of bands in B with no counterpart in A (coded 0, 1), and c is the number of bands absent in A and B (coded 0, 0). The sample size x represents the total number of bands, described by the following formula: $x = n_{AB} + a + b + c$. The number of matches (m) is, therefore, $m = n_{AB} + c$, and the number of mismatches (u) is $u = a + b$. Using this basic logic, a number of formulas for S_{AB}s based on band position alone have been developed, most notably those for the coefficient of Jaccard (S_j):

$$S_j = \frac{n_{AB}}{n_{AB} + a + b}$$

the coefficient of Dice (S_D):

$$S_D = \frac{2n_{AB}}{2n_{AB} + a + b}$$

the sample-matching coefficient (S_m):

$$S_m = \frac{n_{AB} + c}{n_{AB} + a + b + c}$$

the Pearson coefficient (S_Ψ):

$$S_\Psi = \frac{(n_{AB}c - ab)}{\sqrt{[(n_{AB} + a)(n_{AB} + b)(b + c)(a + c)]}}$$

and others such as mean square difference/total bands. It should also be noted that data such as those obtained by MLEE or RAPDs, in which a series of primers provide binomial data, can be converted into binary values to generate a matrix similar to that obtained with banding data that can then be used to compute S_{AB}s for every pair of isolates. The same formulas for S_{AB}s can then be considered.

Band Position and Intensity

In many cases, the information garnered from band intensity is added to that of band position. In these formulas, X_{iA} and X_{iB} represent the intensities of bands in patterns A and B, respectively, $\bar{X}_{iA}$ and $\bar{X}_{iB}$ represent the respective means of all intensities, and n represents the total number of bands. A number of formulas for S_{AB}s based on band position and intensity have been developed, most notably those for Pearson's product-moment correlation coefficient (S_r):

$$S_r = \frac{\sum_{i=1}^{n}[(X_{iA} - \bar{X}_{iA})(X_{iB} - \bar{X}_{iB})]}{\sum_{i=1}^{n}(X_{iA} - \bar{X}_{iA})^2 \sum_{i=1}^{n}(X_{iB} - \bar{X}_{iB})^2}$$

absolute difference/total area (S_{AB}):

$$S_{AB} = 1.0 - \frac{\sum_{i=1}^{n}|X_{iA} - X_{iB}|}{\sum_{i=1}^{n}|X_{iA} + X_{iB}|}$$

and others such as absolute difference/maximum intensity similarity coefficient, mean square difference/intensity similarity coefficient, and mean square difference/maximum intensity similarity coefficient.

In selecting a method for computing S_{AB}s, several points should be kept in mind. First, if the reproducibility of band intensities is not good, then an S_{AB} based on band positions

alone is obviously more accurate. Second, if a method involves the presence or absence of bands as if they were alleles, S_{AB}s based on band position alone are used. One must realize, however, that in most of the DNA fingerprinting methods employed, allelism is not always verified. Third, it must be realized that in methods based on repeat sequences, band intensities may provide as much or more information on relatedness as position, and a method based on both may, therefore, be preferable.

The different similarity coefficients described above do not require the identification of alleles at given loci. For this reason, they are favored when cross-verifying methods are applied since one or more of the methods may rely on dominant markers. Genetic similarity can also be assessed by using genetic distances based on the frequencies of codominant markers (see references 47, 131, and 166).

Generating Dendrograms

The computation of S_{AB}s leads to a matrix of values generated for every pair of isolates in an epidemiological study. These values are the basis for generation of a dendrogram. The most commonly used method for connecting isolates into a tree is the unweighted-pair group method using arithmetic averages (UPGMA) first employed by Rohlf (118). This method generates a rooted tree. The Fitch-Margoliash method with evolutionary clock (50) also generates a rooted dendrogram, with the additional feature that it tests alternative topologies for the tree by rearranging nodes to minimize the sum of squares computed between genetic distances and branch lengths, making it more time-consuming to perform. There are also methods that do not assume a common molecular clock for all strains and, therefore, generate unrooted trees. These methods, which include the neighbor-joining method (120) and the Fitch-Margoliash method without evolutionary clock (50), generate unrooted trees that in fact should have more exact topographies. Because the neighbor-joining method and more particularly the UPGMA are faster than the other methods, they may be preferable for large experimental samples. There are, therefore, tradeoffs among methods. It should be realized that these methods were developed for generating trees at the species level rather than subspecies levels of relatedness, but they still result in interpretable trees at the subspecies and strain levels. If the data are robust, similar dendrograms should be generated no matter which method is applied. Dendrograms generated for intraspecies analysis should not be considered a purely phylogenetic representation of lineages but rather a practical tool that provides a visual description of genetic similarities and divergence between strains and that may be useful in identifying groups, or clades. The derived dendrograms represent true phylogenies only when each strain is derived through a purely clonal lineage (i.e., with no genetic exchange) and homoplasy is negligible. These conditions are rarely verified for the markers used in epidemiological studies.

Let us consider how the UPGMA is performed. The S_{AB} matrix is scanned for the most similar isolates. If more than one group (two or more) are identified, the first is arbitrarily taken as group one. The isolates are joined at the appropriate position along the S_{AB} axis. The matrix is scanned once again for the next most similar isolate or group of isolates, which is then connected along the S_{AB} matrix to the first group, and this function is repeated over and over again until all isolates are incorporated into the tree. A sample dendrogram that includes 67 *C. albicans* isolates is presented in Fig. 9. In this dendrogram, thresholds and

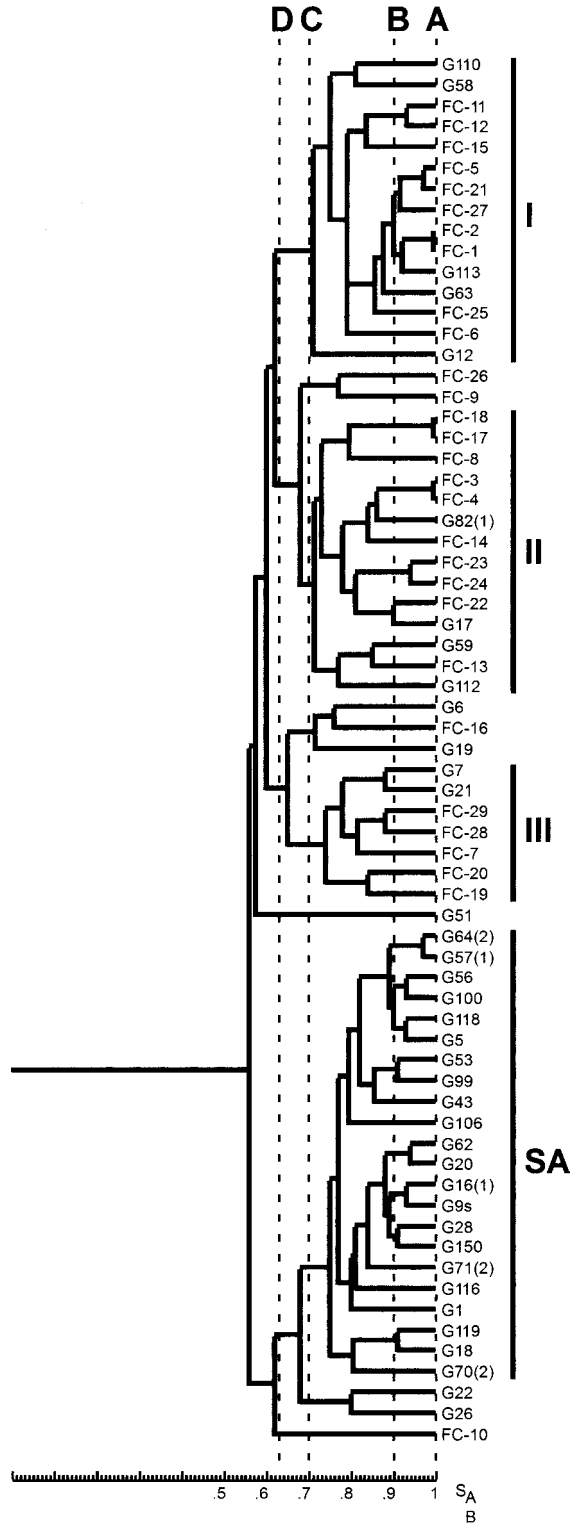

FIGURE 9 Example of a dendrogram. The similarity coefficients (S_{AB}s) were generated from the patterns of 67 isolates of *C. albicans* fingerprinted with the complex Ca3 probe. The value A represents identicalness, at an S_{AB} of 1.00; threshold B demarcates highly related isolates at an S_{AB} of 0.90; threshold C demarcates clades at an S_{AB} of 0.70; and the value D represents the average S_{AB} at 0.63. In this example, a South African-specific clade of *C. albicans* (SA) was identified in addition to the three clades (I, II, and III) present in U.S. collections (18).

landmarks are noted, one (A) which represents identity, at an S_{AB} of 1.00; one (B) which demarcates highly related isolates, at an S_{AB} of 0.90; one (C) which demarcates moderately related groups, in this example at an S_{AB} of 0.70; and one (D) which denotes the average S_{AB} for all strains in the dendrogram, in this example at an S_{AB} of 0.63. The C threshold is the one which best demarcates clades. The selection of thresholds and landmarks in a dendrogram is sometimes somewhat arbitrary (135) but extremely important in interpreting a tree. Confidence in these values comes with increased familiarity with the origins of isolates and assumptions of relatedness based on those origins.

Testing the Integrity of Clusters and Statistical Analyses

Although the selection of a threshold for defining clusters may be somewhat arbitrary, one can demonstrate that the content of a cluster is stable and that the identity of the cluster is in fact valid. First, the order in which isolates are chosen in the generation of a dendrogram can be randomized (2), an important control when the UPGMA is used since this method is prone to mistakes in higher-order clusters. For instance, one can apply 10 random starts to assess whether a cluster remains intact. Second, "noise" can be introduced by adding or subtracting a set percentage of the S_{AB}s in every pairwise comparison (108). Noise can affect and, therefore, be used to assess the stability of second-tier groupings. Third, one can use the comparison of clustering patterns generated by two independent genetic fingerprinting methods to assess the stability of a cluster (81, 111, 156).

The most common method used by evolutionary biologists to analyze the integrity of clusters is bootstrapping (48). In this process, one generates deletions and duplications by random sampling. This process is normally performed 1,000 times. A consensus tree of all dendrograms is then generated, and a "majority rule consensus" algorithm is used to compute the percentage of occurrence of each node. A percentage above 80% suggests a stable node. In a second common method called jackknifing (170), subsets of the collection are randomly selected approximately 100 times, a consensus dendrogram is generated, and the percentage of occurrence at each node is computed. These methods, however, were developed for DNA fingerprinting methods in which the data represent alleles of identified loci, not for patterns like those generated by RFLP or RAPD. They are, therefore, not commonly used in general epidemiological studies. They can, however, be used for RAPD data if each primer is considered an independent gene.

For comparing the relatedness of different populations of isolates, it is often the case that the mean S_{AB} of an entire collection is not informative, although comparisons of mean S_{AB}s of different collections may be informative. The Student *t* test can assess whether mean S_{AB}s are significantly different. In applying the Student *t* test, a probability value of 0.05 (i.e., less than 5%) usually represents significance.

Challenges of MLST Data Analysis

MLST data have also been typically represented by dendrogram-based methods. In addition to that approach, an increasingly popular method, called eBURST (for "based upon related sequence types"), has been developed to accommodate the specific needs associated with the analysis of large MLST data sets (46, 137). The eBURST approach was developed to provide a simple representation of relationships between closely related isolates. As such, eBURST does not try to represent relationships among all analyzed isolates. The development of eBURST was warranted by the fact that dendrograms based on the bifurcating of lineages cannot correctly represent patterns of evolutionary descent within closely related strains from a clonal group. In addition, dendrograms of thousands of strains are hard to display and to analyze. The solution proposed by Feil et al. (46) and Spratt et al. (137) is based on a simple evolutionary model in which clonal lineages are assumed to be founded by a parental clone that, as it increases in frequency, will diversify by accumulation of mutations or by recombination. The eBURST algorithm identifies clonal lineages, predicts their founding genotypes, and displays the most parsimonious pattern of descent for the isolates of each clonal group from the putative founding genotype.

The eBURST algorithm first divides the collection analyzed into groups of closely related strains. The level of relatedness used is user defined. As a general rule, members assigned to the same group share identical alleles at a minimum of one locus with at least one other member of the group. This is the most stringent definition for clonal groups. A threshold of two (or fewer) loci can also be used, but the outcome may be harder to interpret. This step results in a set of nonoverlapping groups of related strains. Then, based on the number of single-locus variants, strains that differ at a single locus, observed for each strain, the algorithm predicts which genotype is the founder for each group. The strain with the highest number of single-locus variants will be defined as having the founder genotype. This process can be supplemented by bootstrap analysis in troublesome cases. The descent from the founder genotype to all of the other genotypes of a given group is then inferred and represented as a radial diagram. The eBURST approach can be used to analyze large samples of thousands of isolates (46, 137).

While the eBURST method is becoming very popular in bacterial MLST studies due to its attractive and convenient representation of evolutionary descent in clonal groups, users should be aware of a few limitations. The eBURST analysis will perform better on large samples. In small samples, clonal groups may not be correctly inferred due to the absence of intermediary genotypes that may have connected groups otherwise deemed independent. Even in larger samples, however, this problem may persist if the missing link has become extinct. Because the founder genotype is inferred from the genotypes present in the sample, predictions of the founder genotype may be affected by sampling biases. Again, this problem should be more limited in large samples. The eBURST method, therefore, offers a useful representation that complements the more commonly used dendrogram-based methods.

ROLE OF COMPUTERS IN GENETIC FINGERPRINTING

For epidemiological studies in which only a few isolates are compared or in which qualitative comparisons are sufficient to obtain an answer, it is simple enough to interpret results, including the computation of similarity coefficients, without the use of computers. However, when dealing with bigger collections, one must recruit a customized computer program. Computer programs are available that can assist in virtually every step in a cluster analysis. For fingerprinting methods that create complex patterns, the systems will automatically acquire the original image and with the assistance of the user will remove distortion, identify lanes, normalize to a universal standard, identify bands, measure the intensity of bands, compute similarity coefficients, generate dendrograms, identify clusters, and perform statistical tests (135). Computer systems will also store data at any or all levels of analysis for

retrospective studies and future comparisons with new collections. An automatic genetic fingerprint analysis system can perform searches based on any aspect of the fingerprinting data (e.g., a particular band length), any characteristic of a patient (e.g., human immunodeficiency virus positivity), or any characteristic of the infecting organism (e.g., drug susceptibility). An outline of the steps for computer-assisted analysis of generic complex RFLP, RFLP-with-probe, and select PCR-based patterns follows. The generic software will be referred to simply as the Program.

Digitizing the Pattern

The pattern of an autoradiogram or its equivalent is digitized into the computer's hard drive (Fig. 10A) by using a scanner with software that supports grayscale scanning that saves the image in the correct format (e.g., bitmap or tiff). The scanner should be sensitive to a reasonable range of grayscales (e.g., around 256 grayscales).

Local Standard

In order to straighten a pattern for automatic analysis and compare patterns obtained on different gels, landmark bands must exist in a set of standards either run in lanes alongside test samples, added to the test samples, or incorporated as components of the pattern (e.g., monomorphic bands). In all three cases, standards must include bands that span the entire molecular-weight range of bands in test patterns.

Global Standard

For studies in which the patterns of multiple gels are compared, each test pattern must be normalized to a global standard in the database. The global standard must share bands in the local standard.

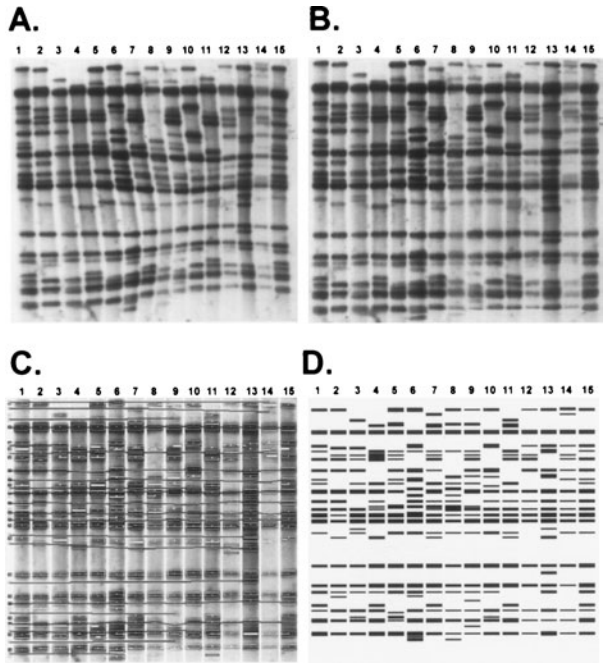

FIGURE 10 Computer-assisted processing and analysis of DNA fingerprint patterns generated with the complex Ca3 probe of 15 isolates of *C. albicans*. (A) Original digitized image with inherent distortions; (B) straightened patterns; (C) correlations of bands with universal standards; (D) model generated from data.

Initial Image Processing

The need for processing stems from artifacts that distort the pattern. First, because of uneven polymerization or electrophoresis, the entire gel pattern may contain "smiles," "frowns," skews, and other linear or nonlinear distortions (Fig. 10A). Unwarping is the process of pattern straightening. Local standards are essential for unwarping. Horizontal lines are drawn between common bands for horizontal distortions, and vertical lines are drawn through spaces for vertical distortions. Once lines are drawn, the Program reconstructs the processed pattern (Fig. 10B). Second, because of unequal loading, the pattern in a single lane can be intensified or deintensified.

Automatic Lane and Band Detection

The Program scans and automatically detects lanes and separates them by spaces to facilitate band identification. At this point, the Program should allow editing for final band alignment that includes lane sliding, stretching, or compressing. This may be necessary if lanes were loaded unequally, which can result in slightly different migration rates for bands of the same molecular weight. Next, the Program should perform a densitometric analysis of grayscales along the lane, subtracting background intensity. Integration at peaks or an intensity threshold can be used for band identification, and band intensity can be categorized (e.g., from 0 to 5), directly measured, or converted according to a normalization curve. Models of the gel can then be generated from band position and intensity (Fig. 10D).

Calibrating to the Global Standard and Linking

The local standard is calibrated to the global standard (Fig. 10C), providing molecular weights of the standard bands. The Program then automatically links bands in test lanes to bands in the local standard. The user must specify a degree of tolerance for considering bands to be the same size. Bands with no correlate in the standard can be linked, and the option should exist for adding new bands to the global standard, if desired.

Creating the Basic Data File

The preceding data provide a text map in which the band number, molecular size, or pixel distance of each band is listed in descending order along the vertical axis for each labeled isolate. At each position, either the binary value 0 or 1 for position alone or the band intensity is listed. If one has collected binary data by using MLEE, RAPD, MLST, or other multilocus methods, one can manually generate the data file at this point in the computer program, or the software can combine the data automatically.

Computing Similarity Coefficients and Generating Dendrograms

The Program must provide the user with a choice of formulas for computing S_{AB}s. Once a particular formula is selected, the Program generates a matrix of S_{AB}s for all pairs of isolates. The Program must then provide the user with a choice of algorithms for generating a dendrogram from the S_{AB} matrix and software for separating groups by thresholding, testing of the stability of clusters, and statistical analyses (Fig. 9).

Other Useful Functions

The Program should provide accessible storage and comparative capabilities so that every new set of genetically fingerprinted isolates can be compared with previously

fingerprinted isolates in the database. It must also allow searches based on other elements such as patient and isolate characteristics. The former include disease state, treatment, geographical location, anatomical origin of the isolate, age, sex, weight, and predisposing conditions. The latter include growth characteristics, sugar assimilation patterns, antigenicity, drug susceptibility, switching repertoire, and other phenotypic traits, most notably those involved in virulence and pathogenicity. One must also be able to mine the genetic fingerprint database for particular characteristics, such as the presence of a particular MLEE allele or RFLP fragment.

THE COLLECTION

Because genetic fingerprinting is time-consuming, one must carefully consider the original collection. Yet, this first step is often the most poorly conceived. This problem stems no doubt in part from the assumption that colonizing populations of pathogens are genetically homogenous. It has become increasingly apparent that in many cases, infecting populations, especially in immunocompromised patients, may consist of multiple species, multiple strains of the same species, or diverging substrains. Species heterogeneity has been demonstrated in recurrent infections and commensals (92, 162). In each case in which heterogeneity was demonstrated, care was taken in obtaining the original collection.

In most standard methods of collection, the primary samples are aspirates, tissue, blood, other fluids, or swabs. These materials may be transported to a microbiology laboratory for anaerobic or aerobic culturing. In some cases, the microorganism must be released from the material. Blood cells may be lysed, tissue may be minced, and fluids may be filtered or centrifuged. The problem is clonality. If the sampled colonizing population is homogeneous (i.e., consists of one genetically homogenous strain), there is no problem. However, if the population is heterogeneous (consists of multiple species, strains, or substrains), several problematic scenarios can arise. First, if the culture is genetically heterogeneous at the time of genetic fingerprinting, a mixed fingerprint will arise. Second, if the primary culture contains mixed strains or substrains and is mass cultured, the strain or substrain that grows fastest under the culture conditions employed will enrich. Finally, a problem arises when a primary culture containing mixed strains or substrains is cultured and only one clone is picked for analysis. The single clone may not represent the majority genotype of the infecting population. The solutions to these problems are straightforward. First, the primary sample should be clonally plated, which may entail assessment of concentration, serial dilution, or knowledge of approximate density. Second, indicator agars can be used for initial screening of species. Third, more than one colony can be picked for genetic fingerprinting. The number picked and analyzed will depend on the size of the collection and the objectives of the study. These considerations apply mainly to bacteria and fungi. The problems may be harder to resolve for many parasites that cannot be grown as isolated colonies on agar media.

In addition to sample homogeneity, a second problem arises in some cases that is related to space and time. There is growing evidence of body location specificity in commensalism, geographical specificity of strains, and rapid microevolution (88, 89, 108, 135). It is prudent to consider what body location is sampled, since a pathogen like *C. albicans* can colonize multiple sites (136). It is also important to realize that if one is testing strain specificity for a particular disease, geographical differences may outweigh disease specialization. For instance, within a geographical region, one might find that isolates from a particular disease state are genetically similar, but when isolates from that disease state are collected from different geographical regions and compared, they may prove to be genetically dissimilar (108). One must, therefore, consider restricting the geographical boundaries of the collection or choosing distinct multiple populations. Finally, one must consider the speed of microevolution and the timing of sampling. If one is analyzing substrain specialization, the linear rate of microevolution may outweigh substrain differences related to different disease states or antibiotic resistance. One must, therefore, consider restricting the time window of collection.

CONCLUDING REMARKS

The preceding survey of methods used to fingerprint microbial pathogens should demonstrate that there is no dominant method that has emerged for all of the pathogen categories (bacteria, fungi, and parasites) or even for all species within a category. For instance, in bacteria, although RFLP-PFGE is the most commonly used method for *Streptococcus pneumoniae* and *Staphylococcus aureus*, RFLP with a probe is the most commonly used method for *Mycobacterium tuberculosis* (Table 2). The same variability holds true between fungal and parasite species (Table 2). The reason is twofold. First, differences between the genomes of different species warrant in some cases different methods. Second, different methods are effective for measuring different levels of relatedness. Third, and maybe

TABLE 2 Rough estimates of the use of the most common genetic fingerprinting methods[a]

Pathogen category	Genus or species	Most common genetic fingerprinting methods
Bacteria	*Streptococcus pneumoniae*	42% RFLP-PFGE; 17% RepE1 PCR; 10% restriction fragment end labeling
	Mycobacterium tuberculosis	54% RFLP + probe: 23% spoligotyping
	Staphylococcus aureus	56% RFLP-PFGE; 13% PCR-RFLP; 11% RAPD
Fungi	*Candida*	30% RAPD; 29% karyotyping; 22% RFLP + probe; 12% RFLP
	Aspergillus	71% RAPD; 18% MLEE; 11% RFLP + probe
	Cryptococcus	53% RAPD; 21% karyotyping; 18% RFLP + probe
Parasites	*Trypanosoma*	47% MLEE; 30% RAPD
	Leishmania	69% MLEE; 16% RAPD
	Plasmodium	81% PCR-RFLP; 11% RAPD

[a] Estimates were made from a literature search beginning in 1996.

not as scientific, a particular method may take hold for a particular species due to a consensus of the scientists working in that area and the history of the methods first applied. Fourth, selections may be based on expediency. Whatever the reason, the take-home message of this chapter should be clear. Select a fingerprinting method that will answer the question posed. Make sure that the method has been verified for efficacy at the level of genetic relatedness necessary. Use computer-assisted systems, and save data in a format accessible for retrospective analyses and comparisons with new data. Finally, carefully consider the methods used for obtaining the collection.

Investigation of Foodborne and Waterborne Disease Outbreaks*

TIMOTHY F. JONES

12

Each year approximately 4 billion cases of diarrhea occur worldwide (26). In 2002, foodborne and waterborne diarrheal diseases were estimated to have killed 1.8 million people, most of whom were under 5 years of age. In the United States alone, foodborne diseases are estimated to cause 76 million illnesses, 325,000 hospitalizations, and 5,000 deaths each year (21). Food and water safety issues are complex, and foodborne and waterborne diseases can have a myriad of potential causes. Because outbreaks can affect large numbers of persons, prompt and thorough investigations of potential outbreaks can prevent substantial morbidity. In addition, outbreak investigations provide information that increases our understanding of the epidemiology of these diseases and allows us to develop preventive measures.

Foodborne and waterborne disease outbreaks are generally defined as clusters of two or more persons with a similar illness resulting from ingestion of a common food (6) or epidemiologically linked to recreational or drinking water (10). Foodborne and waterborne disease outbreaks may be caused by bacteria, viruses, protozoa, fungi, helminths, prions, and biologic or environmental toxins. Viral agents cause two-thirds of foodborne disease outbreaks in the United States, bacteria cause approximately one-third, and parasites are relatively uncommon etiologic agents. Of viruses, noroviruses are by far the most common cause of foodborne disease outbreaks. The most common bacterial causes are *Salmonella* and *Campylobacter* (21).

Many foodborne and waterborne diseases are self-limited and characterized by gastrointestinal symptoms such as vomiting and diarrhea. Others, however, may manifest as systemic or neurological disease and result in substantial morbidity and mortality. Examples include infection with *Escherichia coli* O157:H7, which can be associated with hemolytic-uremic syndrome; *Helicobacter pylori,* which has been linked to gastric cancers; *Listeria,* which can cause meningitis and miscarriage; *Salmonella,* which can cause reactive arthritis; and prions, which cause invariably fatal new-variant Creutzfeldt-Jakob disease.

Improved basic sanitation, medical care, and diagnostic capabilities have helped substantially reduce both the risks for foodborne and waterborne diseases and the frequency of complications. However, other factors have allowed old scourges to persist and new threats to emerge. Noroviruses, rotaviruses, astroviruses, *Cryptosporidium parvum, Campylobacter* spp., *E. coli* O157:H7, hepatitis E, and the prion associated with bovine-spongiform encephalopathy are among foodborne and waterborne pathogens identified since 1972. The population of vulnerable persons is growing, and new populations are being exposed to potential pathogens because more people are living longer, are living with immunosuppressive conditions, or are traveling internationally. Moreover, the food supply has been globalized so that people are eating at home foods that travel medicine physicians tell them not to eat when they are traveling abroad. Outbreaks of cryptosporidiosis in Milwaukee, Wis., in 1993, which sickened 400,000 persons and led to 100 deaths, primarily in human immunodeficiency virus-infected persons (20), and *E. coli* O157:H7 in Japan, which caused over 6,000 illnesses among persons who ate radish sprouts from a single supplier (24), are examples demonstrating the large and dramatic sequelae of such social changes.

It is important to investigate foodborne outbreaks so that the etiology, vehicle, and mechanisms associated with disease can be identified and similar outbreaks can be prevented in the future. This chapter provides a framework for understanding the general principles and strategies of outbreak investigations. Details on the clinical and epidemiologic characteristics of specific pathogens can be found in other chapters of this Manual. Additional information on outbreak investigation and testing of environmental and food specimens is available from other published sources (http://www.cdc.gov/foodborneoutbreaks/, http://www.cdc.gov/ncidod/dpd/healthywater/professional.htm, and http://www.cdc.gov/healthyswimming/outbreak.htm) (5, 12–14, 16–18).

EPIDEMIOLOGY OF FOODBORNE AND WATERBORNE DISEASE OUTBREAKS

Beginning in 1938, the U.S. Public Health Service has maintained and reported data on foodborne and waterborne disease outbreaks (6). Between 2001 and 2003, the Centers for Disease Control and Prevention (CDC) received an annual mean of 1,214 reports of outbreaks from federal, state, and local epidemiologists throughout the United States who conducted outbreak investigations (http://www.cdc.gov/foodborneoutbreaks/report_pub.htm) (11). These outbreaks involved approximately 24,000 persons. Of reported

*This chapter contains information presented in chapter 13 by John Besser, James Beebe, and Bala Swaminathan in the eighth edition of this Manual.

outbreaks during this period, approximately one-fifth were due to bacterial pathogens, about one-eighth were due to viruses, and less than one-twentieth were due to chemicals and parasitic agents. It is noteworthy that the etiology of two-thirds of the outbreaks was not identified. The pathogens most commonly identified in outbreaks reported in 2003 are shown in Fig. 1.

In the United States over one-half of the outbreaks of foodborne and waterborne disease are associated with restaurants. In contrast, nearly 90% of the global burden of diarrheal disease is attributable to unsafe water supplies (25). In 2001–2002, 96 waterborne disease outbreaks in the United States were reported to the CDC, of which 31 were associated with drinking water and 65 were associated with recreational water (10). Figure 2 illustrates the etiologic agents causing outbreaks associated with drinking water, and Fig. 3 describes the clinical syndromes seen in outbreaks related to recreational water.

The response to preventive measures and the treatment of clinical infections vary markedly depending on the etiologic agent involved. It is therefore of concern that the etiologic agents were not identified for nearly two-thirds of foodborne disease outbreaks reported to the CDC in 2001–2003 and for one-fourth of drinking-water-associated outbreaks reported in 2001–2002. This deficit is due in part to the fact that stool specimens are rarely tested in such outbreaks. In fact, stool specimens were tested for only one of seven waterborne outbreaks of acute gastrointestinal illness for which the etiology was unknown (10) and stool specimens were not collected for laboratory testing in two-thirds of foodborne disease outbreaks of unknown etiology occurring at seven sites in 1998 and 1999 (19). While many factors can impede investigators as they work up outbreaks, laboratory testing is usually necessary to confirm an etiology.

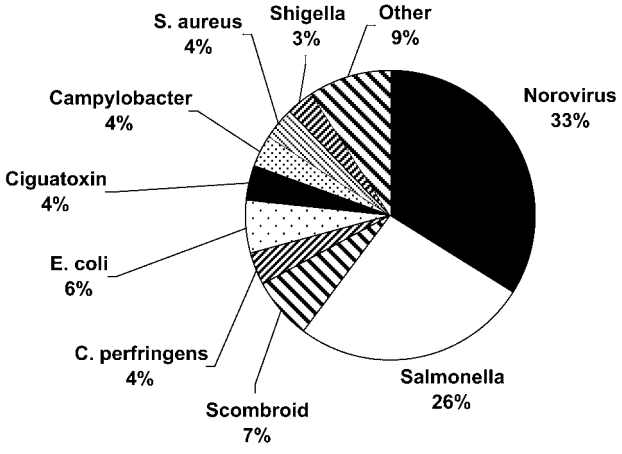

FIGURE 1 Causes of foodborne disease outbreaks with a confirmed etiology, among those reported to the Centers for Disease Control and Prevention, 2003.

GENERAL APPROACH TO AN OUTBREAK INVESTIGATION

Standard steps in an outbreak investigation are outlined in Table 1. Potential foodborne and waterborne disease outbreaks may come to the attention of health authorities through a number of mechanisms. Laboratorians, clinicians, or public health agencies may recognize unusual numbers or types of illness and report them, or patients may report illnesses to public health agencies directly. Foodborne and waterborne disease outbreaks must be reported to public health departments in most jurisdictions, and public health personnel frequently coordinate community-wide investigations, although clinicians, laboratorians, environmentalists, and institutional representatives all may play important roles in outbreak investigations. Local and state public health authorities generally have legal responsibility for outbreak investigations and may involve the CDC or other local, state, and federal agencies as appropriate. The roles of various government agencies in outbreak investigations are outlined in Table 2.

One of the first steps in responding to a possible foodborne or waterborne disease outbreak is confirming whether an "outbreak" has actually occurred. The CDC defines a foodborne disease outbreak as "the occurrence of two or

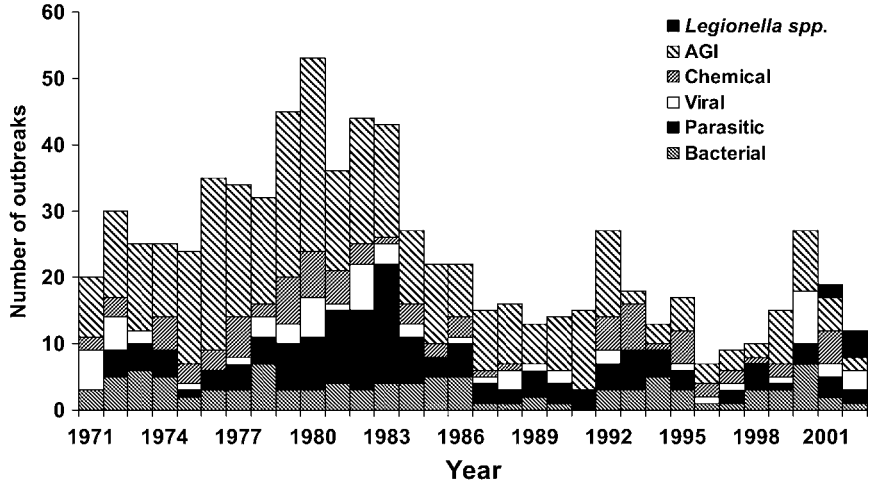

FIGURE 2 Drinking-water-associated outbreaks, by year and etiologic agent—United States, 1971–2001 (n = 764). AGI, acute gastrointestinal illness of unknown etiology. For *Legionella* spp., Legionnaires' disease was added to the surveillance system (and *Legionella* spp. were classified separately) beginning with 2001. Adapted from reference 10.

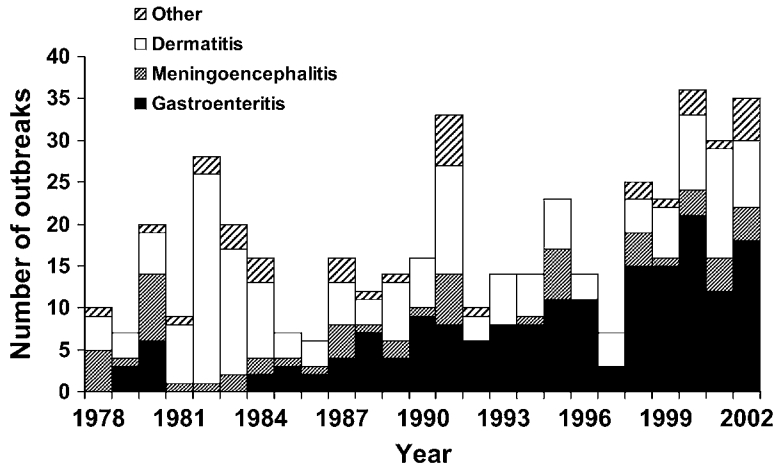

FIGURE 3 Waterborne-disease outbreaks ($n = 65$) associated with recreational water, by etiologic agent—United States, 1978–2002. "Other" includes keratitis, conjunctivitis, otitis, bronchitis, meningitis, hepatitis, leptospirosis, Pontiac fever, and acute respiratory illness. "Meningoencephalitis" also includes data from report of ameba infections (28). Adapted from reference 10.

TABLE 1 Steps of an outbreak investigation[a]

1. Establish the existence of an outbreak.
2. Verify the diagnosis.
3. Define and count cases.
4. Determine the population at risk.
5. Describe epidemiology.
6. Develop hypotheses.
7. Evaluate hypotheses.
8. Perform additional epidemiologic, environmental, and laboratory studies, as necessary.
9. Implement control and prevention measures.
10. Communicate findings.

[a]Adapted from references 5 and 14, with permission.

more cases of a similar illness resulting from ingestion of a common food" (6). The CDC defines a recreational water-associated outbreak as ≥2 persons experiencing a similar illness after exposure to water or air encountered in a recreational water setting (this criterion is waived for single cases of laboratory-confirmed primary amebic meningoencephalitis, wound infections, or chemical poisoning if water quality data indicate contamination by the chemical), with epidemiologic evidence implicating recreational water or a recreational water setting as the probable source of the illness (10). Drinking-water outbreaks are defined similarly, with the implication of drinking water rather than recreational water. Information on local and federal water quality standards is available from a number of government agencies (http://www.cdc.gov/nceh/ehhe/water/data.htm). Outbreaks caused by contamination of water or ice at the point of use (e.g., a contaminated faucet or serving container) are not classified as drinking-water-associated outbreaks (10). As these definitions suggest, it is important to quickly ascertain whether apparent clusters of patients with similar symptoms or laboratory-confirmed disease are linked epidemiologically by exposure to a common food or water source. In practical terms, many outbreaks are recognized through routine surveillance for diseases that must be reported (Table 3). If public health officials identify unusual numbers of cases clustered by time or place, they often investigate further and identify a previously unrecognized epidemiologic link between cases. To recognize unusual clusters of illness, public health officials obviously must have knowledge of what "normal" or baseline rates of a disease are in the affected community. This important information may be available from routine disease surveillance performed by public health authorities and institutional infection control personnel. To decide whether a potential cluster of disease warrants further investigation, one needs basic epidemiologic data about the potential cluster and one must consider other factors such as the resources available for an investigation, the severity of the disease, the community affected, and the likelihood that useful data can be obtained from an investigation.

To recognize and characterize a potential outbreak, one must identify the persons affected by the outbreak ("cases") and organize data about these cases by time, place, exposure history, and other characteristics. Investigators should develop a "case definition," or criteria by which a person will be judged to be part of an outbreak (or not), early in their inquiry. While this definition may change as additional information is collected, it is critical to collect sufficient data on all possible cases to determine whether each is part of the group of interest. Typically, cases are defined by criteria including symptoms, time of onset, and the time and place of potential exposure. Examples include "a case is defined as any person reporting vomiting or diarrhea within 5 days of consuming food from Restaurant A between March 2 and 5" or "a case is defined as any person seeking medical care for a rash illness, with or without fever, within 2 weeks of swimming at Lake X."

The incubation period (time from exposure to an etiologic agent until onset of symptoms) provides an important clue to the possible etiology of an outbreak. Textbooks and references frequently categorize infectious agents by incubation period. It is important to remember, however, that a definitive incubation period can rarely be determined based on a single patient's history. Typical signs and symptoms and the mean incubation period and duration of illness are most useful when evaluated in aggregate, for a number of ill patients. In addition, patients often assume that recent meals or particular events caused their illnesses, when

TABLE 2 Roles of selected government agencies in responding to possible foodborne or waterborne disease outbreaks in the United States[a]

Agency	Responsibilities	Product or situation of interest
Local and state health departments	Generally authorized under state laws to be responsible for surveillance for notifiable diseases and investigation of most foodborne and waterborne outbreaks in their jurisdiction. Often responsible to inspect and regulate restaurants within jurisdiction. State health laboratories support outbreak investigations.	Any legally notifiable disease or outbreak of public health importance.
Local and state water regulatory agencies	Generally authorized under state laws to have oversight of surface water, municipal water systems, wells, and other water supplies. Responsibility may be under the jurisdiction of different agencies, including health, agriculture, or environmental safety departments.	Regulation of recreational and drinking water supplies including surface water, wells, source water protection, and public water systems.
State department of agriculture	Enforce state food safety laws and perform investigations associated with facilities or products they regulate.	Farms, food production facilities and warehouses, milk production facilities, water bottling facilities, grocery stores, and many retail food establishments within the state.
Federal Centers for Disease Control and Prevention (CDC)	Assists state and local authorities in outbreak investigations, by invitation. May provide extensive laboratory and epidemiology support. Frequently participates in multistate and international outbreaks.	Any disease or outbreak of public health importance.
U.S. Food and Drug Administration (FDA)	May assist local authorities in investigations associated with products they regulate, perform interstate or international product tracebacks, and provide laboratory and regulatory support.	Manufacturers, processors, and distributors of human and animal foods (except meat, poultry, and processed egg products); potable water, bottled water, and dietary supplements shipped in interstate commerce.
U.S. Department of Agriculture, Food Safety and Inspection Service (FSIS)	May assist local authorities in investigations associated with products they regulate, perform interstate or international product tracebacks, and provide laboratory and regulatory support.	Domestic and imported meat, poultry, and egg products, including soups, stews, pizzas, and frozen foods which contain meat or poultry.
Environmental Protection Agency (EPA)	Works with other agencies in responding to outbreaks associated with contaminated water or environmental contaminants.	Drinking water, toxic substances, and wastes to prevent their entry into the environment and food chain.
Law enforcement	Federal Bureau of Investigation (FBI) has the authority to lead the investigation of any outbreak suspected of being associated with terrorism. Works with other health and regulatory agencies on the investigation.	Outbreaks involving criminal actions, including acts of terrorism.

[a]This table provides a general outline of typical responsibilities for different agencies involved in investigation of food- and waterborne outbreaks. All states have unique food and water safety laws, policies, and organizational structures that will affect investigations, and many other agencies and organizations may play important roles in certain situations. Additional information is available at the Gateway to Government Food Safety Information website (http://www.foodsafety.gov/) and the EPA website (http://www.epa.gov/ebtpages/water.html).

further epidemiologic investigation implicates earlier exposures. Moreover, many foodborne and waterborne infections present with clinical signs and symptoms that are indistinguishable from those of other common diseases, and few have pathognomonic clinical features. Thus, clinicians evaluating individual patients may have difficulty identifying the source of the infection, and persons investigating an outbreak should not jump to conclusions regarding the source of infection. In any epidemiologic study of a potential outbreak, the investigators must systematically and completely assess the population of affected persons and systematically identify the involved cohort or well controls, which may be challenging. Laboratories can assist the investigators by reporting all laboratory-confirmed cases of the disease of

Trichinellosis

[a]Adapted from reference 9. Additional diseases and conditions may be reportable at the state level, and outbreaks of public health importance are reportable regardless of etiology.

interest within a specific geographic area or time period. Public health authorities may augment routine surveillance for notifiable diseases by contacting medical providers, hospitals, and laboratories directly or by pursuing other means of active surveillance. Media reports can encourage ill persons to report their illnesses directly to public health authorities, and known cases may be able to identify other ill persons or well persons with similar exposures who could be controls for epidemiologic studies.

To identify the entire exposed group, investigators may need to collect information on all persons who attended a large function, residents of an institution, patrons of a restaurant, or other potentially exposed groups. Public health authorities have substantial legal authority to gather data from individuals, groups, and institutions when investigating outbreaks that threaten the public health. For example, they may at times review credit card receipts to identify patrons of a restaurant, use records generated by grocery stores' frequent-shopper discount cards, or make public announcements to identify enough cases or controls for an investigation. However, epidemiologists must assess potential biases introduced into a study by the mechanisms through which they identify the cases or controls.

EPIDEMIOLOGIC INTERVIEWS

After confirming the existence of an outbreak, investigators must interview affected persons to identify demographic characteristics of cases, the nature and timing of symptoms, and potential causative exposures. As noted previously, interviews can also help investigators identify other ill persons or well persons with similar characteristics who may be enrolled in the epidemiologic studies. The initial broad-based and open-ended interviews provide data that allow investigators to generate hypotheses about the suspected etiologic agents and exposures (e.g., particular foods, restaurants, water sources, etc.) in order to efficiently focus subsequent investigations.

Standardized written questionnaires can help investigators collect data consistently and completely from all study participants. The CDC and others maintain sample templates of questionnaires, which can be modified, for preliminary outbreak investigations (http://www.cdc.gov/foodborneoutbreaks/standard_questionnaire.htm). While standard templates are a useful starting point, a "one-size-fits-all" approach is rarely optimal, and questionnaires likely will need to be modified depending on the suspected etiology, affected population, and particular details surrounding a specific outbreak. Moreover, investigators inevitably want to be comprehensive, but this desire must be balanced by practical considerations including the ease with which support staff can use the questionnaire and its acceptability to study participants. Complete answers to reasonably limited questions are generally preferred over incomplete answers to an unreasonable number. The design of a questionnaire should be tailored for the population to whom it is directed, the mode of administration, and the sophistication of those collecting the data. Collection of data via telephone, face-to-face interview, written survey, self-administered questionnaire, and electronic data capture all have associated advantages and disadvantages that must be considered in the planning stages of a study. Before the study begins, all persons who will collect data must be taught how to introduce the study to participants and answer questions. Data collectors must also be given guidelines for obtaining data and standard definitions so that the data are elicited consistently and completely, thereby minimizing bias and erroneous information.

Data on cases can be organized in various formats for different purposes. Basic information about cases is frequently entered on a "line-listing" or spreadsheet. The distribution of cases over time (frequently categorized by date or time of symptom onset) can be represented graphically as an "epidemic curve" (Fig. 4), and the geographic distribution of cases can be plotted on a map. The line-list, the epidemic curve, and the map can give the investigator clues about the source of an outbreak. For example, if these representations suggest that the outbreak is acute and associated with an exposure at a single time and place ("point source outbreak"), such as all patrons of a single restaurant on a single day, the outbreak may have been caused by a contamination event that is relatively easy to identify and correct. In contrast, if the line-list, epidemic curve, and map indicate that the outbreak has occurred over a large area or over a prolonged time period, the investigators may need to search for contaminated food or water products distributed over a wide area, a source of intermittent or low-level contamination, a means by which products are recurrently contaminated during production, storage, or serving, or a component of person-to-person spread (i.e., secondary cases) following an initial food or water-related source, and a potential ongoing threat to the public health.

The intensity of an investigation may vary widely, depending on the nature of an outbreak, the population involved, the etiologic agent, and available resources. In some cases, basic laboratory testing and interviews of a limited number of ill persons may provide investigators with sufficient information to identify the source of the outbreak and institute adequate interventions and preventive measures. In many cases, more extensive epidemiologic investigation is required. If the population affected by the outbreak is well defined, such as attendees of a church picnic or patrons of a single restaurant within a 3-day period, a retrospective cohort study can be performed. In this situation, all members or a representative sample of the affected group (the "cohort")

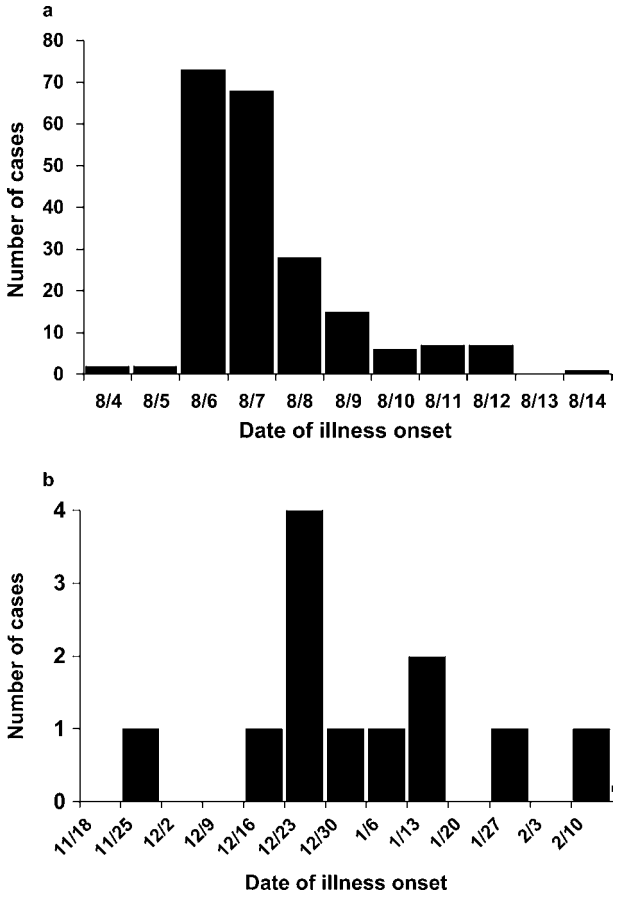

FIGURE 4 (a) Epidemic curve, point-source outbreak of *Salmonella* associated with a restaurant in Tennessee. All ill patrons ate at the establishment on the same day, and the distribution of illness onset times reflects natural variation in incubation period. (b) Epidemic curve, continuing common-source outbreak of *Yersinia* associated with chitterlings in Tennessee. The distribution of dates of illness onset suggests that the source of infection was a contaminated product handled over several weeks. Under different conditions, a similar epidemic curve might reflect a propagated outbreak, in which earlier cases were the source of infection for subsequent cases.

are interviewed to assess whether they were ill and what foods or water they consumed. Rates of illness among persons who did or did not consume particular foods (or among persons who were or were not exposed to other factors of interest) are compared by appropriate statistical methods to help investigators identify likely causes of an outbreak (5, 14). If the affected population is not well defined or a cohort study is not practical, a case-control study may be performed. In such outbreaks, persons with the illness of interest (cases) are compared to those without it (controls).

Statistical analyses can help investigators summarize their findings from the epidemiologic investigation and help them draw conclusions from data that may be complicated. Basic descriptive statistics should include the number of ill persons, a summary of the characteristics of cases and the population at risk, the proportion of ill persons experiencing particular symptoms, mean and/or median incubation period (time between exposure and onset of symptoms), and mean and/or median duration of illness. Data from cohort studies may be used to calculate the attack rate (proportion of persons exposed to an etiologic agent who subsequently developed disease). Data from cohort and case-control studies can be used to estimate the risk (using "risk ratios" and "odds ratios," respectively) of developing disease after exposure to particular foods, water sources, or other risk factors. Basic two-by-two tables or comparisons of relative risks of illness among those exposed to and those not exposed to particular foods frequently suffice to support the most imperative decisions during an outbreak investigation. More advanced statistical techniques, such as stratified analyses, regression modeling, and sensitivity analyses, may also be appropriate. Detailed information on doing and interpreting statistical analyses of epidemiologic data is available from multiple sources (5, 14, 22, 23). While statistical analytic techniques can be powerful tools, investigators must remember that all statistics must be interpreted cautiously and with a component of judgment. The obvious cause of a foodborne or waterborne disease outbreak should not be discounted simply because its associated "*P* value" (a commonly cited measure of statistical significance) is greater than 0.05, and likewise measures of statistical significance (particularly in larger studies) do not necessarily prove that a result is biologically plausible or meaningful in a given situation.

LABORATORY INVESTIGATION

Laboratory testing is usually needed to confirm the etiology of an outbreak. In most foodborne or waterborne outbreaks, the etiologic agent should be isolated from the stool specimens of two or more ill persons or from the epidemiologically implicated food (Table 4). In a few situations, such as mushroom poisoning, ciguatera fish poisoning, or other chemical intoxications, it is sufficient to document the clinical syndrome among affected persons. *Staphylococcus* can also be problematic because the organism may not be viable in stool or food samples and most laboratories cannot test for enterotoxin. Thus, investigators must collect sufficient numbers of specimens (potentially including stool and other clinical specimens and also food, water, or environmental specimens) and handle them appropriately to ensure that laboratory testing identifies the etiologic agent.

Epidemiologists, environmentalists, or others participating in outbreak investigations should communicate early and openly with laboratorians to ensure that the specimens collected can be tested for all suspected etiologic agents and that appropriate specimens are collected. Many organisms (including most bacterial causes of foodborne and waterborne diseases) can be isolated from both clinical and environmental specimens. In such cases, molecular methods (such as pulsed-field gel electrophoresis [PFGE]) can be used to demonstrate similarities between isolates from affected persons and the putative source, thereby confirming the epidemiological studies. Other common agents, such as norovirus, are not recovered easily from food or water, whereas many toxins are more readily identified in food than in clinical specimens. Moreover, if the laboratory needs to identify or quantify pathogens in food, the epidemiologic investigators must tell the laboratory which pathogens are suspected so that resources are not wasted.

Most clinical laboratories currently cannot test specimens for norovirus, which is the most common cause of foodborne disease in the United States. Most state health department laboratories offer reverse transcriptase (RT)-PCR testing for norovirus and can help coordinate appropriate testing of

TABLE 4 Typical characteristics of foodborne and waterborne disease outbreaks and guidelines for confirmation[a]

Etiologic agent	Incubation period	Clinical syndrome	Typical vehicle	Diagnostic testing	Confirmation of outbreak etiology
Bacterial					
Bacillus cereus					
Preformed toxin	1–6 h	Vomiting; some patients with diarrhea; fever uncommon	Improperly stored cooked or fried rice, meats	Clinical diagnosis; clinical laboratories do not routinely identify; stool and food specimens may be tested at a reference laboratory for culture and toxin identification	Isolation of organism from stool of two or more ill persons and not from stool of control patients OR Isolation of 10^5 organisms/g from epidemiologically implicated food, provided specimen is properly handled
Diarrheal toxin	10–16 h	Diarrhea, abdominal cramps, and vomiting in some patients; fever uncommon	Cereal products, soups, custards and sauces, meatloaf, sausage, cooked vegetables, reconstituted dried potatoes, refried beans	Stool and food specimens may be tested at a reference laboratory for culture and toxin identification	Isolation of organism from stool of two or more ill persons and not from stool of control patients OR Isolation of 10^5 organisms/g from epidemiologically implicated food, provided specimen is properly handled
Brucella	7–21 days	Weakness, fever, headache, sweats, chills, arthralgia, weight loss, splenomegaly, bloody stools	Raw milk, goat cheese from unpasteurized milk, contaminated meats	Blood cultures and serology	Two or more ill persons and isolation of organism in culture of blood or bone marrow OR Greater-than-fourfold increase in standard agglutination titer (SAT) over several weeks OR Single SAT of 1:160 in person who has compatible clinical symptoms and history of exposure
Campylobacter jejuni/coli	2–10 days; usually 2–5 days	Diarrhea (often bloody), abdominal pain, fever, vomiting	Unpasteurized milk, raw and undercooked poultry, contaminated water	Routine stool culture; requires special media and incubation at 42°C	Isolation of organism from clinical specimens from two or more ill persons OR Isolation of organism from epidemiologically implicated food
Clostridium botulinum (toxin)	12–72 h	Vomiting, diarrhea, blurred vision, diplopia, dysphagia, descending muscle weakness	Canned low-acid foods, smoked fish, cooked potatoes in foil, garlic in oil, fish, marine mammals	Stool, serum, and food tested for toxin; stool and food cultured for organism; testing available at state health department or CDC laboratories	Detection of botulinum toxin in serum, stool, gastric contents, or implicated food OR

					Isolation of organism from stool or intestine
Clostridium perfringens (toxin)	8–16 h	Watery diarrhea, nausea, abdominal cramps; vomiting and fever uncommon	Meats, poultry, gravy, dried or precooked foods, time- and/or temperature-abused foods	Stools tested for enterotoxin and cultured; because C. *perfringens* can normally be found in stool, quantitative cultures must be done	Isolation of 10^6 organisms/g from stool of two or more ill persons, provided specimen is properly handled OR Demonstration of enterotoxin in the stool of two or more ill persons OR Isolation of 10^5 organisms/g from epidemiologically implicated food, provided specimen is properly handled
Escherichia coli					
Enterohemorrhagic *E. coli* (EHEC) including *E. coli* O157:H7 and other Shiga toxin-producing *E. coli* (STEC)	1–8 days	Diarrhea (often bloody), abdominal pain, vomiting; fever is rare	Undercooked beef (especially hamburger), unpasteurized milk and juice, raw fruits and vegetables (e.g., sprouts), contaminated water	Stool culture; Shiga toxin may be detected using commercial kits; positive isolates should be forwarded to public health laboratories for confirmation and serotyping	Isolation of *E. coli* O157:H7 or other Shiga-like toxin-producing *E. coli* strains from clinical specimen from two or more ill persons or from epidemiologically implicated food
Enterotoxigenic *E. coli* (ETEC)	1–3 days	Watery diarrhea, abdominal cramps; vomiting and fever less common	Water or foods contaminated with human feces	Stool culture; special laboratory techniques are required to identify ETEC; if suspected, request specific testing	Isolation of organism of same serotype that produces heat-stable and/or heat-labile enterotoxin from stool of two or more ill persons
Enteropathogenic *E. coli* (EPEC)	Variable	Diarrhea, fever, abdominal cramps	Water, fecal-oral contamination	Stool culture; special laboratory techniques are required to identify EPEC; if suspected, request specific testing	Isolation of organism of same enteropathogenic serotype from stool of two or more ill persons
Enteroinvasive *E. coli* (EIEC)	Variable	Diarrhea (might be bloody), fever, abdominal cramps	Salads and other foods not subsequently heated, water	Stool culture; special laboratory techniques are required to identify EIEC; if suspected, request specific testing	Isolation of same enteroinvasive serotype from stool of two or more ill persons
Listeria monocytogenes					
Invasive disease	2–6 weeks	Meningitis, neonatal sepsis, fever	Coleslaw, milk, soft cheese, pâté, turkey franks, processed meats	Blood or cerebrospinal fluid cultures; asymptomatic fecal carriage occurs; antibody to listerolysin O	Isolation of organism from normally sterile site
Diarrheal disease	Unknown	Diarrhea, abdominal cramps, fever	Corn salad, chocolate milk	Stool culture	Isolation of organism of same serotype from stool of two or more ill persons exposed to food that is epidemiologically implicated or from which organism of same serotype has been isolated

(Continued on next page)

TABLE 4 Typical characteristics of foodborne and waterborne disease outbreaks and guidelines for confirmation[a] *(Continued)*

Etiologic agent	Incubation period	Clinical syndrome	Typical vehicle	Diagnostic testing	Confirmation of outbreak etiology
Salmonella Non-Typhi	1–3 days	Diarrhea, often with fever and abdominal cramps	Poultry, eggs, meat products, raw milk or juice, cheese, contaminated raw fruits and vegetables (sprouts, melons)	Stool culture	Isolation of organism of same serotype from clinical specimens from two or more ill persons OR Isolation of organism from epidemiologically implicated food
Serovar Typhi	3–60 days; usually 7–14 days	Fever, anorexia, malaise, headache, and myalgia; sometimes diarrhea or constipation	Shellfish, any food contaminated by infected person, raw milk, meat contaminated after processing, cheese, watercress, water	Stool culture, blood culture.	Isolation of organism from clinical specimens from two or more ill persons OR Isolation of organism from epidemiologically implicated food
Shigella spp.	24–48 h	Diarrhea (often bloody), often accompanied by fever and abdominal cramps	Any food contaminated by infected person; frequently salads, poi, water	Stool culture	Isolation of organism of same serotype from clinical specimens from two or more ill persons OR Isolation of organism from epidemiologically implicated food
Staphylococcus aureus (preformed toxin)	1–6 h	Sudden onset of severe nausea and vomiting, diarrhea; fever may be present	Unrefrigerated or improperly stored meats, potato and egg salads, cream pastries	Normally a clinical diagnosis; stool, vomitus, and food can be tested for toxin	Isolation of organism of same phage type from stool or vomitus of two or more ill persons OR Detection of enterotoxin in epidemiologically implicated food OR Isolation of 10^5 organisms/g from epidemiologically implicated food, provided specimen is properly handled
Streptococcus, group A	1–4 days	Fever, pharyngitis, scarlet fever, upper respiratory infection	Raw milk, egg-containing salads	Throat culture, culture of food	Isolation of organism of same M- or T-type from throats of two or more ill persons OR Isolation of organism of same M- or T-type from epidemiologically implicated food
Vibrio cholerae O1 or O139	24–72 h	Profuse watery diarrhea and vomiting; dehydration and death can occur within hours	Raw fish, shellfish, crustaceans, contaminated water	Stool culture; special media required to isolate the organism; request specific testing if suspected	Isolation of toxigenic organism from stool or vomitus of two or more ill persons OR Significant rise in vibriocidal, bacterial agglutinating, or antitoxin antibodies in acute- and early

					convalescent-phase sera among persons not recently immunized OR Isolation of toxigenic organism from epidemiologically implicated food
Non-O1 and non-O139	1–5 days	Watery diarrhea	Shellfish, fish	Stool culture; special media required to isolate the organism; request specific testing if suspected	Isolation of organism of same serotype from stool of two or more ill persons
Vibrio parahaemolyticus	2–48 h	Watery diarrhea, cramps, nausea, vomiting	Undercooked or raw seafood or cooked seafood contaminated with seawater or by utensils used on raw seafood	Stool culture; special media required to isolate the organism; request specific testing if suspected	Isolation of Kanagawa-positive organism from stool of two or more ill persons OR Isolation of 10^5 Kanagawa-positive organisms/g from epidemiologically implicated food, provided specimen is properly handled
Yersinia enterocolitica and *Y. pseudotuberculosis*	24–48 h	Diarrhea, abdominal pain (often severe), appendicitis-like symptoms	Undercooked pork, unpasteurized milk, tofu, contaminated water, chitterlings	Stool, vomitus or blood culture; special media required to isolate the organism; request specific testing if suspected; serology available in reference laboratories	Isolation of organism from clinical specimen from two or more ill persons OR Isolation of pathogenic strain of organism from epidemiologically implicated food
Chemical					
Marine toxins					
Ciguatera toxin	1–48 h; usually 2–8 h	Usually gastrointestinal symptoms followed by neurologic symptoms (including paresthesia of lips, tongue, throat, or extremities) and reversal of hot and cold sensation	Numerous varieties of tropical fish, e.g., barracuda, grouper, red snapper, amberjack, goatfish, skipjack, parrotfish	Radioassay for toxin in fish or a consistent history	Demonstration of ciguatoxin in epidemiologically implicated fish OR Clinical syndrome among persons who have eaten a type of fish previously associated with ciguatera fish poisoning (e.g., snapper, grouper, or barracuda)
Scombroid toxin (histamine)	1 min–3 h; usually <1 h	Flushing, dizziness, burning of mouth and throat, headache, gastrointestinal symptoms, urticaria, and generalized pruritis	Fish: tuna, mackerel, Pacific dolphin (mahi mahi), bluefin, marlin, escolar	Detect histamine in food or clinical diagnosis	Demonstration of histamine in epidemiologically implicated fish OR Clinical syndrome among persons who have eaten a type of fish previously associated with histamine fish poisoning (e.g., mahimahi or fish of order Scombroidei)

(Continued on next page)

TABLE 4 Typical characteristics of foodborne and waterborne disease outbreaks and guidelines for confirmation[a] *(Continued)*

Etiologic agent	Incubation period	Clinical syndrome	Typical vehicle	Diagnostic testing	Confirmation of outbreak etiology
Paralytic or neurotoxic shellfish poison	30 min–3 h	Paresthesia of lips, mouth, or face and extremities; intestinal symptoms or weakness, including respiratory difficulty	Mussels, clams, scallops	High-pressure liquid chromatography to detect toxin in food or water where fish are located	Detection of toxin in epidemiologically implicated food OR Detection of large numbers of a dinoflagellate species associated with shellfish poisoning in water from which epidemiologically implicated mollusks are gathered
Puffer fish, tetrodotoxin	10 min–3 h; usually 10–45 min	Paresthesia of lips, tongue, face, or extremities, often following numbness; loss of proprioception or floating sensations	Puffer-type fish	Toxin testing of fish	Demonstration of tetrodotoxin in epidemiologically implicated fish OR Clinical syndrome among persons who have eaten puffer fish
Heavy metals: antimony, cadmium, copper, iron, tin, zinc	5 min–8 h; usually <1 h	Vomiting, often metallic taste	High-acid foods and beverages, metal-colored cake decorations	Testing foods	Demonstration of high concentration of metal in epidemiologically implicated food
Monosodium glutamate (MSG)	3 min–2 h; usually <1 h	Burning sensation in chest, neck, abdomen, or extremities; sensation of lightness and pressure over face or heavy feeling in chest	Foods seasoned with MSG	Clinical diagnosis; testing food	Clinical syndrome among persons who have eaten food containing MSG (e.g., usually 1.5 g of MSG)
Mushroom toxins					
Shorter-acting toxins	2 h	Vomiting and diarrhea; other symptoms differ with toxin	Many species of wild mushrooms	Typical syndrome, identify mushroom, detect toxin	Clinical syndrome among persons who have eaten mushroom identified as toxic type OR Demonstration of toxin in epidemiologically implicated mushroom or food containing mushroom
Muscimol		Confusion, visual disturbance			
Muscarine		Salivation, diaphoresis			
Psilocybin		Hallucinations			
Coprinus artrementaris		Disulfiram-like reaction			
Ibotenic acid		Confusion, visual disturbance			

Longer-acting toxins (e.g., *Amanita* spp.)	6–24 h	Diarrhea and abdominal cramps for 24 h followed by hepatic and renal failure	Wild mushrooms	Typical syndrome, identify mushroom, detect toxin	Clinical syndrome among persons who have eaten mushroom identified as toxic type OR Demonstration of toxin in epidemiologically implicated mushroom or food containing mushrooms
Parasitic					
Cryptosporidium parvum	2–28 days; median, 7 days	Diarrhea, nausea, vomiting, fever	Water, any uncooked food or food contaminated after cooking	Request specific examination of stool, food, or water for *Cryptosporidium*	Demonstration of organism or antigen in stool or in small-bowel biopsy specimens of two or more ill persons OR Demonstration of organism in epidemiologically implicated food
Cyclospora cayetanensis	1–11 days; median, 7 days	Fatigue, protracted diarrhea, often relapsing	Produce including raspberries, lettuce, basil; water	Request specific examination of stool, food, or water for *Cyclospora*	Demonstration of organism in stool of two or more ill persons
Giardia lamblia	3–25 days; median, 7 days	Diarrhea, gas, cramps, nausea, fatigue	Any uncooked food or food contaminated by ill food-handler, water	Stool examination for ova and parasites; may require at least 3 specimens	Two or more ill persons and detection of antigen in stool or demonstration of organism in stool, duodenal contents, or small-bowel biopsy specimen
Trichinella spp.	1–2 days for intestinal phase; 2–4 weeks for systemic phase	Fever, myalgia, periorbital edema, high eosinophil count	Pork, bear meat, walrus flesh, cross-contaminated ground beef, lamb	Positive serology, demonstration of larvae in muscle biopsy specimen, increase in eosinophils	Two or more ill persons and positive serologic test or demonstration of larvae in muscle biopsy OR Demonstration of larvae in epidemiologically implicated meat
Viral					
Hepatitis A	15–50 days; median, 28 days	Jaundice, dark urine, fatigue, anorexia, nausea	Water, raw shellfish, any food contaminated by infected person	Increase in ALT, bilirubin; positive IgM and anti-hepatitis A antibodies	Detection of immunoglobulin M anti-hepatitis A virus in serum from two or more persons who consumed epidemiologically implicated food
Noroviruses (and other caliciviruses)	12–48 h	Vomiting, cramps, diarrhea, headache, fever	Shellfish, any food contaminated by infected person	Routine RT-PCR and electron microscopy on fresh unpreserved stool samples; negative bacterial cultures; stool negative for white blood cells	Detection of viral RNA in stool or vomitus by RT-PCR OR Visualization of small, round-structured viruses that react with patient's convalescent-phase sera but not

(Continued on next page)

TABLE 4 Typical characteristics of foodborne and waterborne disease outbreaks and guidelines for confirmation[a] *(Continued)*

Etiologic agent	Incubation period	Clinical syndrome	Typical vehicle	Diagnostic testing	Confirmation of outbreak etiology
					acute-phase sera by immune-electron microscopy OR More than fourfold rise in antibody titer to Norwalk virus or Norwalk-like virus in acute and convalescent sera in most serum pairs
Astrovirus	15–77 h; usually 24–48 h	Vomiting, cramps, diarrhea, headache	Ready-to-eat foods contaminated by infected food-handler	Identification of virus in early acute-phase stool specimen, serology; commercial enzyme-linked immunosorbent assay kits available	Detection of virus antigen by enzyme immunoassay OR Detection of viral RNA in stool or vomitus by RT-PCR OR Visualization of viruses with characteristic surface morphology by electron microscopy

[a] Adapted from references 6 and 18.

specimens if this agent is suspected as the cause of an outbreak. Likewise, many laboratories do not serotype *Salmonella,* and few can definitively identify enterotoxigenic *E. coli,* non-O157:H7 enterohemorrhagic *E. coli* strains, or staphylococcal enterotoxin. Consequently, investigators should notify the appropriate health departments early in the course of an outbreak investigation if such laboratory services are necessary.

Guidelines for collecting appropriate specimens during an outbreak investigation are listed in Table 5. It can be difficult to collect adequate specimens for laboratory testing. If the outbreak is not reported promptly or the investigation is delayed, affected persons may have recovered and appropriate clinical specimens may not be available for testing. Investigators may need to expend substantial effort convincing patients to provide stool specimens and may need to provide transportation for the patients or the specimens, convenient collection materials, and free testing so that sufficient specimens are obtained. Investigators should promptly contact laboratories that may have received previous specimens from outbreak-associated patients to ask that the original specimens be held for possible additional testing. Suspected "vehicles," such as water or food samples, should be collected as soon as possible after an outbreak is recognized. If possible, investigators should collect specimens from the batches or lots of food or water that cases actually ate or drank. If this is not possible (as is often the case in outbreaks caused by pathogens with long incubation periods), the investigators should collect food or water from stored products, leftovers, suppliers, or other sources that represent as closely as possible what was consumed by the cases. If investigators suspect that the source of an outbreak is contaminated packaged food, they should collect unopened packages from the implicated lot. In such cases, investigators should work with the appropriate regulatory authorities to ensure that specimens are handled and tested properly because the specimens might provide important evidence for product tracebacks or other regulatory interventions. If specimens, such as leftovers from an implicated meal, have been handled and stored by ill persons, investigators must interpret the results cautiously, because the case may have contaminated the products after becoming infected.

Molecular microbiology technology has markedly changed the nature of many acute-disease epidemiology investigations. For example, PFGE can provide DNA fingerprints of bacterial isolates from clinical and food specimens. If the PFGE patterns are the same, the investigators have evidence that the suspected food item is implicated in the event. PFGE can also help investigators include related cases and exclude concurrent cases that are epidemiologically unrelated to the outbreak. PulseNet, a CDC-sponsored program that allows PFGE patterns to be shared nationally, has greatly helped public health officials recognize multistate outbreaks affecting small numbers of persons scattered over time or large geographic areas. In the absence of this technology, the epidemiologic link between cases is often missed.

Bender et al. evaluated the PFGE patterns of *E. coli* O157:H7 isolates obtained during a 2-year period in Minnesota (2). These investigators identified 10 outbreaks, of which 40% were identified solely based on subtype-specific surveillance. In addition, 8 of 11 (73%) "apparent outbreaks" (i.e., increases in numbers of reported cases) were not associated with clonal outbreaks, and 2 of the remaining 3 outbreaks were actually multiple clonal outbreaks occurring within the same time period. The same group studied the molecular epidemiology of *Salmonella enterica* serovar Typhimurium and identified 16 outbreaks over a 5-year period, including 10

TABLE 5 Guidelines for collection and handling of stool specimens during a foodborne or waterborne disease outbreak investigation[a]

Procedure	Instructions regarding specimens to be tested for:			
	Bacteria	Parasites[c]	Viruses[d]	Chemicals
Collection[b]				
When to collect	During period of active diarrhea (preferably as soon as possible after onset of illness).	Anytime after onset of illness (preferably as soon as possible).	Within 48–72 h after onset of illness.	Soon after onset of illness (preferably within 48 h of exposure to contaminant).
How much to collect	Two rectal swabs or swabs of fresh stool from 10 ill persons; whole stool is preferred if testing for nonbacterial pathogens is considered.	A fresh stool sample from 10 ill persons; to enhance detection, 3 stool specimens per patient can be collected >48 h apart.	As much stool sample as possible from 10 ill persons (a minimum of 10 ml of stool from each).	A fresh urine sample (50 ml) from 10 ill persons; samples from 10 controls also can be submitted; collect vomitus, if vomiting occurs within 12 h of exposure; collect 5–10 ml of whole blood if a toxin/poison that is not excreted in urine is suspected.
Method of collection	For rectal swabs, moisten 2 swabs in an appropriate transport medium (e.g., Cary-Blair, Stuart, Amies; buffered glycerol-saline is suitable for *E. coli, Salmonella, Shigella,* and *Y. enterocolitica* but not for *Campylobacter* and *Vibrio*); insert swabs 1–1.5 inches into rectum and gently rotate; place both swabs into the same tube deep enough that medium covers the cotton tips; break off top portion of sticks and discard; alternatively, swab whole stools and put the swabs into Cary-Blair medium.	Collect bulk stool specimen, unmixed with urine, in a clean container; place a portion of each stool sample into 10% formalin and polyvinyl alcohol preservative at a ratio of one part stool to three parts preservative; mix well; save portion of the unpreserved stool placed into a leakproof container for antigen or PCR testing.	Place fresh stool specimens (liquid preferable), unmixed with urine, in clean, dry containers, e.g., urine specimen cups.	Collect urine, blood, or vomitus in prescreened containers[e]; if prescreened containers are not available, submit field blanks with samples[f]; most analyses from blood require separation of serum from red cells; cyanide, lead, and mercury analyses require whole blood collected in prescreened EDTA tubes; volatile organic compounds require whole blood collected in a specially prepared gray-top tube.
Storage	Refrigerate swabs in transport media at 4°C; when possible, test within 48 h after collection; otherwise, freeze samples at −70°C; refrigerate whole stool, process it within 2 h after collection; store portion of each stool specimen frozen at less than −15°C for antigen or PCR testing.	Store specimen in fixative at room temperature or refrigerate unpreserved specimen at 4°C; a portion of unpreserved stool specimen may be frozen at less than −15°C for antigen or PCR testing.	Immediately refrigerate at 4°C; store portion of each stool specimen frozen at less than −15°C for antigen or PCR testing.	Immediately refrigerate at 4°C and if possible freeze urine, serum, and vomitus specimens at less than −15°C; refrigerate whole blood for volatile organic compounds and metals at 4°C.

(Continued on next page)

TABLE 5 Guidelines for collection and handling of stool specimens during a foodborne or waterborne disease outbreak investigation[a] *(Continued)*

Procedure	Instructions regarding specimens to be tested for:			
	Bacteria	Parasites[c]	Viruses[d]	Chemicals
Transportation	For refrigeration, follow instructions for viral samples. For frozen samples, place bagged and sealed samples on dry ice. Mail in insulated box by overnight mail.	For refrigeration, follow instructions for viral samples. For room-temperature samples, mail in waterproof container.	Keep refrigerated; place bagged and sealed specimens on ice or with frozen refrigerant packs in an insulated box; send by overnight mail. Send frozen specimens on dry ice for antigen or PCR testing.	Place double-bagged and sealed urine, serum, and vomitus specimens on dry ice; mail in an insulated box by overnight mail. Ship whole blood in an insulated container with prefrozen ice packs. Avoid placing specimens directly on ice packs.

[a] Adapted from reference 7.
[b] Put the samples in sealed, waterproof containers (i.e., plastic bags). Label each specimen container in a waterproof manner. Batch the collection and send by overnight mail to arrive at the testing laboratory on a weekday during business hours unless other arrangements have been made in advance with the testing laboratory. Contact the testing laboratory before shipping, and give the testing laboratory as much advance notice as possible so that testing can begin as soon as samples arrive. When etiology is unclear and syndrome is nonspecific, consider collecting all four types of specimens.
[c] For more detailed instructions on how to collect specimens for specific parasites, please see the CDC DPDx website (http://www.dpd.cdc.gov/dpdx/).
[d] For more detailed instructions on how to collect specimens for viral testing, please see http://www.cdc.gov/mmwr/PDF/RR/RR5009.pdf.
[e] The containers must be tested for the presence of the chemical of interest prior to use.
[f] Unused specimen collection containers that have been brought to the field and subjected to the same field conditions as the used containers. These containers are then tested for trace amounts of the chemical of interest.

FIGURE 5 Patterns of PFGE of isolates of *Salmonella enterica* serovar Typhimurium collected in Minnesota during 4 months in 1995. Molecular subtyping allowed investigators to recognize three concurrent outbreaks caused by different strains and associated with different restaurants and to associate particular strains with particular outbreaks or document that particular strains are not associated with particular outbreaks. Adapted from reference 3, with permission.

institutional outbreaks with small numbers of cases. Four of six larger community outbreaks would not have been recognized without molecular subtyping (Fig. 5) (3).

Genetic sequencing technology has become more readily available and has been useful for assessing the relatedness of various pathogens involved in food- and waterborne outbreaks. For example, sequencing of hepatitis A viruses collected during three large outbreaks associated with green onions demonstrated that similar virus strains caused all three outbreaks and that this strain was related to hepatitis A strains commonly isolated from patients living in the region of Mexico where the green onions were grown (8). Sequencing of noroviruses is also becoming increasingly useful in identifying relatedness among potential outbreak-associated viruses.

CONTROL AND PREVENTION

The most immediate priorities for anyone investigating outbreaks of foodborne or waterborne disease are to implement appropriate measures to control the outbreak, mitigate associated morbidity, and prevent recurrences. While the steps of an outbreak investigation (Table 1) are listed sequentially, in practice many of those steps will be addressed concurrently. Not infrequently, public health officials must institute substantial and occasionally controversial control measures before the investigation is complete and before all desired data are available because there appears to be considerable potential for continued transmission of infection and thus continued morbidity or mortality. Control measures may include confiscating food products from markets, excluding foodhandlers or ill cases from work, closing retail food establishments or implicated venues, and publicly notifying persons who may have been exposed. Because such interventions can have important medical, emotional, and economic implications for all parties involved, investigators, laboratorians, regulatory partners, and other involved groups must assimilate available data rapidly and communicate effectively with each other and the public. Such collaboration is imperative to ensure that

ongoing transmission is eliminated while minimizing the adverse consequences associated with control measures.

The causes of foodborne and waterborne disease outbreaks can be multifactorial and complex. A single incident or event, such as an ill foodhandler with poor hygiene who prepared cake frosting barehanded or chlorination that was not adequate to disinfect well water contaminated by agricultural runoff, may be identified as the proximate cause of an outbreak. Frequently, however, seemingly simple explanations may belie complex underlying factors that contributed to the final outcome. For example, foodhandlers may be poorly educated regarding proper techniques for preparing food, may not understand English, or may lose their jobs if they miss work because they are ill. In addition, food may be prepared at temperatures inadequate to kill organisms, food may be stored at temperatures that encourage microbial growth, or equipment for preparing or storing food may fail to reach the appropriate temperature. These and other such factors can contribute to the immediate cause of an outbreak. The CDC attempts to capture some data on "contributing factors" on the standard reports it uses for foodborne disease outbreaks (http://www.cdc.gov/foodborneoutbreaks/report_f.htm). To ensure that similar incidents do not recur after an outbreak, investigators should identify modifiable contributing factors and recommend measures to correct them.

INTENTIONAL OUTBREAKS

Most foodborne and waterborne disease outbreaks have resulted from unintentional contamination of food or water sources at any of innumerable points in the long food production and service chain. In recent years public health officials and the public have become concerned that the food supply system is a potential target of intentional acts of contamination, sabotage, or terrorism. In fact, the food and water supply is considered a high-risk target for potential terrorist activity because it is difficult to protect the myriad stages from "farm-to-fork," tremendous volumes of product are rapidly distributed worldwide, and techniques for detecting intentional events are inadequate. Virtually all governmental agencies associated with food safety are increasing efforts to improve security at all stages of the food supply chain (http://www.foodsafety.gov).

Given the existence of active terrorist groups, persons investigating outbreaks of foodborne or waterborne disease must consider intentional contamination as a possible cause. Several outbreaks related to intentional contamination of food have been identified in the United States (1). In 1984, a religious group deliberately contaminated food at salad bars in Oregon with *S. enterica* serovar Typhimurium in an attempt to influence a local election. In total, 751 persons became ill. In 1996, a disgruntled laboratory employee in Texas deliberately contaminated doughnuts with a laboratory strain of *Shigella*, leading to illness in 12 coworkers. In 2003, a Michigan supermarket employee intentionally contaminated 200 pounds of ground beef with a nicotine-containing pesticide, causing illness in 92 persons (http://www.fda.gov/ora/training/orau/FoodSecurity/). In another incident that year, a parishioner put arsenic in coffee served at a church in Maine, causing 12 persons to become ill; one person died (15). While these have been isolated incidents, they demonstrate the range of agents and modes by which persons could deliberately cause an outbreak.

In some instances of intentional contamination, the perpetrators may claim responsibility for the subsequent outbreak. In general, however, these outbreaks are likely to be identified and reported in the same way that unintentional foodborne and waterborne disease outbreaks are reported. Thus, continued surveillance is necessary and standard epidemiologic methods remain essential to the investigations. Potential clues that might suggest bioterrorism or intentionally caused outbreaks are described in Table 6. If purposeful contamination is suspected as a cause, investigators must include law enforcement officials in the investigation. In any instance involving food- or water-related terrorism, the Federal Bureau of Investigation will lead the investigation and will coordinate the response.

TABLE 6 Potential clues that might increase suspicion that intentional contamination is the cause of a foodborne or waterborne disease outbreak

Occurrence of a rare or novel disease
Outbreak due to a disease occurring outside its normal range of endemicity
Disease occurring during unusual season
Unusual drug resistance
Unusual epidemiologic characteristics
Unusual demographic population affected
Unusual clinical presentation of disease
Widespread contamination without apparent explanation
Claims or social context suggesting intentional contamination

REPORTING AND SUMMARIZING OUTBREAKS

Under the law in most states, all suspected foodborne and waterborne disease outbreaks must be reported to the public health department. Public health authorities will work with other involved parties to determine whether further investigation is warranted and who will perform those investigations. Whether public health authorities or other agencies or institutions perform the investigation, health departments have the authority and obligation to ensure that the response to a potential outbreak protects the public's health. By mutual agreement, state or local departments of health collect basic descriptive data on all foodborne and waterborne disease outbreaks in their jurisdictions and share reports with the CDC, which periodically summarizes those data. Examples of the forms, the electronic database used for foodborne disease outbreaks, and recent data are accessible online (http://www.cdc.gov/foodborneoutbreaks/info_healthprofessional.htm). Organizations other than the CDC regularly monitor outbreaks reported via public health agencies and other venues (4).

Public health and regulatory agencies and most other institutions involved in outbreak investigations adhere to strict guidelines protecting the confidentiality of data collected during those investigations. Although confidentiality laws may vary by jurisdiction and agency, personally identifiable medical information regarding involved case patients is strictly protected in all cases. In the absence of a court subpoena or permission from the patient, personally identifiable information cannot be released to other parties. Such assurances of confidentiality are necessary to ensure that persons involved in the outbreak trust the investigators and provide critical information during investigations. In many cases, proprietary information and the names of institutions involved in outbreaks are also protected from public dissemination. Occasionally, such information may be disseminated publicly if it is necessary to protect people from infection.

TABLE 7 Recommended components of an outbreak investigation summary report

List of participants in the investigation and contact information for lead investigator
Dates of outbreak and investigation
Description of process by which outbreak was recognized and reported
Description of the epidemiologic steps followed in the investigation
Definition of cases included in the outbreak
Summary of total number of affected persons and description of the population exposed
Description of clinical syndrome, including proportion of persons experiencing common symptoms, summary of incubation period, duration of illness, and indicators of morbidity such as proportion seeking medical care or mortality rates
Description of results from epidemiologic studies, including numbers of cases or controls enrolled in cohort or case-control studies, and results of analyses assessing possible sources
Summary of supporting laboratory data obtained by testing clinical, food, or environmental specimens
Summary of findings of various groups contributing to the investigation, including epidemiologists, environmentalists/sanitarians, regulatory agencies, institutional representatives, medical providers, or others not primarily writing report
Conclusions about the etiology, vehicle, cause, and underlying contributing factors leading to the outbreak
Lessons learned during the investigation, which may benefit others in similar situations in the future
Limitations of the investigation
Specific recommendations made and control measures implemented (including dates and how and when communicated)
Results of intervention, if known
Recommendations for preventing similar incidents in the future

For example, media announcements may be used to notify restaurant patrons potentially exposed to hepatitis A from a foodhandler that they should get prophylactic immune globulin. In such cases, public health authorities and regulators work closely with other involved parties to ensure that appropriate measures are taken to avoid an inappropriate breach of confidentiality.

Investigators frequently summarize the results of outbreak investigations in narrative reports, which are maintained locally and disseminated based on institutional policy. These reports are an important medical, legal, and scientific resource for documenting the process of an investigation, nature of an outbreak, conclusions about its causes and control, and preventive measures instituted. Sufficient detail is required in those reports to ensure that the audience understands the outbreak and investigation, while maintaining confidentiality of protected information. An example of the components that should be in an outbreak investigation report is shown in Table 7. Summary reports should be shared with appropriate persons and agencies, and outbreak descriptions should be published in peer-reviewed literature when the information can contribute to improving future investigations or the general understanding of diseases, epidemiology, laboratory methods, or other aspects of outbreak response.

Microscopy

DANNY L. WIEDBRAUK

13

The history of microscopy is closely linked to the beginning of microbiology; Hooke, Divini, Kircher, and van Leeuwenhoek were among the first individuals to describe microscopic life-forms (7). Hooke, in his 1665 treatise, "*Micrographica,*" included illustrations of mold forms and the anatomy of the flea (7). Antonie van Leeuwenhoek provided detailed descriptions of protozoa and bacteria in his letters to the Royal Society in London. His descriptions of "very small animalcules" included drawings of basic organism shapes and movement (7). Today, light microscopy is used not only in microbiology and cell biology but also in metallurgy, computer chip design, and microsurgical applications. This chapter attempts to describe the basic concepts of light microscopy as they are practiced in the microbiology laboratory.

TECHNICAL BACKGROUND AND DEFINITION OF TERMS

Aberration

Aberrations are unwanted artifacts in the microscopic image that are caused by elements in the optical path. Aberration can be caused by physical objects such as dust or oils on the optical surfaces, by alterations in the light path caused by improper alignment or aperture settings, and by imperfections in the lens systems. Two main types of optical aberrations can occur when white light passes through a convex lens: spherical aberration and chromatic aberration. Spherical aberration is hallmarked by images that appear to be in focus in the center of the field and out of focus at the periphery (5). Chromatic aberration occurs because shorter light wavelengths are refracted to a greater extent than longer wavelengths (5). This wavelength separation (also called dispersion) produces color fringes within the image field. Chromatic aberration is reduced or eliminated in optical systems by combining two lenses with different color dispersion characteristics (5).

Contrast

Contrast is a measure of the differences in image luminance that provides gray-scale or color information. Contrast is expressed as the ratio of the difference in luminance between two points divided by the average luminance in the field (1). Under optimum conditions, the human eye can detect the presence of 2% contrast (1).

Depth of Field and Depth of Focus

Depth of field is a subjective measure of the vertical distance between the nearest and farthest objects in the specimen that appear to be in sharp focus. Depth of field decreases as the numerical aperture (NA) of the lens increases (3). Depth of focus is the area around the image plane where the image appears to be sharply focused. The image plane is formed within the microscope tube at or near the level of the ocular lenses. Microscopes with greater depth of focus allow the user to employ ocular lenses with different working distances, magnification factors, and visual compensation systems without losing image sharpness. Like depth of field, depth of focus depends on the NA of the objective. However, depth of focus increases as the NA increases (3).

Immersion Fluid (Immersion Oil)

Immersion fluid is a term used to describe any liquid that occupies the space between the object and microscope objective lens. Immersion fluids are usually required for objectives that have working distances of 3 mm or less (5). Many microscopy applications employ immersion fluids that possess the same refractive index as the glass slide (refractive index = 1.515) (3, 5). This procedure produces a homogeneous optical path which minimizes light refraction and maximizes the effective NA of the objective lens. Immersion fluids are also used between the condenser and the microscope slide in transmitted light fluorescence microscopy and in dark-field microscopy to minimize refraction, increase the NA of the objective, and improve optical resolution (3, 5).

Köhler Illumination

Köhler illumination was first introduced in 1893 by August Köhler of the Carl Zeiss corporation as a method of providing the optimum specimen illumination (5). In this procedure, the collector lens projects an enlarged and focused image of the lamp filament onto the plane of the aperture diaphragm. Because the light source is not focused at the specimen, the specimen is bathed in a uniformly bright, glare-free light that is not seriously affected by dust or imperfections on the glass surfaces of the condenser. Köhler illumination is required to produce the maximum optical resolution and high-quality photomicrographs (4, 5).

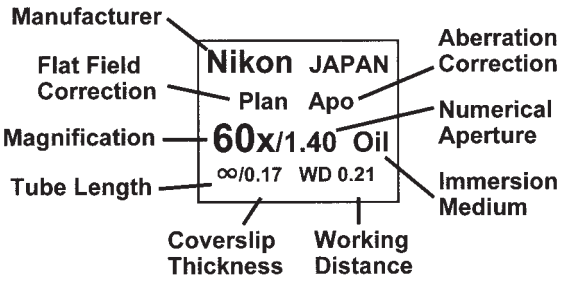

FIGURE 1 Objective lens labeling. Objective lenses are labeled with information on the manufacturer, correction factors, NA, tube length, coverslip thickness, working distance, and expected immersion medium. Objectives without a listed aberration correction are considered achromats. Objectives without a listed immersion medium (Oil, Oel, W, Gly) are considered dry objectives and are meant to operate with air between the lens and the specimen.

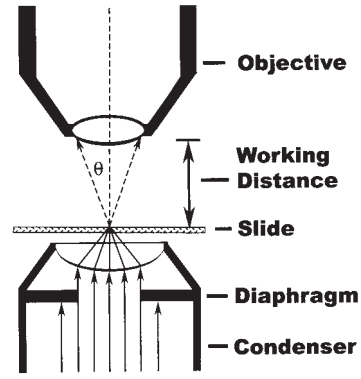

FIGURE 2 Typical configuration for bright-field microscopy. The column of light generated by the field lens and the field diaphragm enters the bottom of the condenser and is focused on the slide by the condenser lens. The condenser diaphragm controls the angle of the light, the NA of the condenser, and the amount of contrast in the image. The working distance is the vertical distance from the top of the specimen to the leading edge of the objective lens. The semiangle of the objective aperture (θ) is used to calculate the NA. Modified from reference 7.

Mechanical Tube Length

Mechanical tube length describes the light path distance within the microscope body tube. Tube length is measured from the objective opening in the nosepiece to the top edge of the observation tube. Tube length is usually inscribed on the barrel of the objective as the length in millimeters (e.g., 160, 170, 210, etc.) for fixed lengths, or the infinity symbol (∞) for infinity-corrected tube lengths (Fig. 1). Many of the newer objectives are infinity corrected, whereas older objectives are corrected for 160-mm (Nikon, Olympus, Zeiss) or 170-mm (Leica) tube lengths (5).

Numerical Aperture

NA is a measure of the light-gathering capability of a lens or condenser. Higher NA objectives have better resolving power and brighter images than lower NA objectives. Higher NA objectives also have shallower depth of field. The equation for determining NA is as follows: $NA = n \cdot \sin(\theta)$, where n is the refractive index of the imaging medium between the objective and the specimen and θ is one-half the angular aperture of the objective (Fig. 2) (3, 5, 7, 12).

Refractive Index (Index of Refraction)

Index of refraction is the ratio of the velocity of light in a vacuum to its velocity in a transparent or translucent medium (3, 5, 7, 11, 12). As the refractive index of a material increases, light beams entering or leaving a material are deflected (refracted) to a greater extent. The refractive index of a medium depends upon the wavelength of light passing through it. Light beams containing multiple wavelengths (e.g., white light) are dispersed when they move into a different medium because each wavelength in the beam is refracted to a slightly different degree. Light dispersion causes chromatic aberration in microscope objectives (5). Refractive index is also an important variable in calculating NA (see "Numerical Aperture" above). Moving from a high-dry microscope objective that uses air as the imaging medium (refractive index of air = 1.003) to an oil immersion objective of the same power (refractive index of immersion oil = 1.515) increases the maximum theoretical NA of a given lens from 1.0 to 1.5, producing a 50% increase in light-gathering capability (3, 5).

Resolution (Resolving Power)

The resolution of an optical microscope is defined as the shortest distance between two points that can be distinguished by the observer or camera system as separate entities (3, 7, 12). The resolving power of a microscope is the most important feature of the optical system because it defines our ability to distinguish fine details in a specimen. The theoretical limit of resolution for a given lens is defined mathematically as $r = \lambda/(2NA)$, where r is the resolution, λ is the imaging wavelength, and NA is the numerical aperture of the lens (3, 7, 12). From this equation it is obvious that only the light wavelength and NA directly affect the resolving power. Thus, a 40× oil objective with an NA of 1.30 can have the same resolving power as a 100× oil objective (Table 1). In the same manner, the resolving power of a 100× oil objective is higher when using UV wavelengths than it is when using visible light (Table 1).

TABLE 1 Resolving power of selected lenses with different NAs

Lens system	NA	Light color	Avg wavelength (nm)	Medium	Resolution (μm)
Eye		White	550	Air	700
Hand magnifier	0.03	White	550	Air	10
10× objective	0.30	White	550	Air	0.92
40× objective	0.75	White	550	Air	0.37
40× objective (oil)	1.30	White	550	Oil	0.21
100× objective	1.30	White	550	Oil	0.21
100× objective	1.30	UV	400	Oil	0.15

Working Distance

Working distance is the distance between the objective front lens and the top of the cover glass when the specimen is in focus (Fig. 2). The working distance of an objective generally decreases as magnification increases (3). The working distance of an objective may not be inscribed on the barrel of older objectives, but newer objectives often contain the working distance in millimeters (Fig. 1). Longer working distance objectives are important when examining the inside surface of glass tubes (tube cultures) and cell culture flasks.

SIMPLE MICROSCOPE

Common objects such as jewelers' loupes, photographic slide viewers, and simple magnifying or reading glasses are all examples of simple microscopes in routine use today. A simple microscope is composed of a single biconvex magnifying lens which is thicker in the center than at the periphery. In contrast with compound microscopes, simple microscopes produce a magnified image that is in the same orientation as the original object. Because of their low NA, simple microscopes have limited resolution and magnifying power. Most commercial magnifiers are able to produce a magnification of ×2 to ×30, and the better lenses have a resolution of about 10 μm. Simple magnifiers are useful for dissection, examination of bacterial colonies, and interpretation of agglutination reactions.

COMPOUND MICROSCOPE

The first compound microscopes were constructed around 1590 by Dutch spectacle makers Zaccharias Janssen and Hans Janssen. The Janssen microscope consisted of an object lens (objective) that was placed close to the specimen and an eye or ocular lens that was placed close to the eye. The lenses were separated by a body tube. In this microscope, the objective lens projected a magnified image into the body tube and the eyepiece magnified the projected image, thereby producing a two-stage magnification. Modern compound microscopes still use this general design and have two separate lens systems mounted at opposite ends of a body tube.

The stereoscopic microscope combines two compound microscopes which produce separate images for each eye. Stereoscopic microscopes may have one or two separate objectives, and many have a zoom magnification function. These microscopes are used for reflected or transmitted illumination, but the absence of a substage condenser limits their NA and resolution. Stereomicroscopes are useful in examining colonial morphology of bacteria, fungi, and cell cultures (12).

The modern light microscope is composed of optical and mechanical components that, together with the mounted specimen, make up the optical train. The optical train of a typical bright-field microscope consists of an illuminator (light source and collector lens), a substage condenser, a specimen, an objective, an eyepiece, and a detector. The detector can be a camera or the observer's eye.

Specimen illumination is one of the most critical elements in optical microscopy. Inadequate or improper sample illumination can reduce contrast in the specimen and significantly decrease the resolving power of any microscope. There are numerous commercially available illuminators for microscopes, but 50- or 100-W tungsten halogen lamp systems are frequently used due to their low cost and long life. Light generated by the light source is passed through a collector and a field lens (Fig. 3) before being directed into the substage condenser and onto the specimen. Image-forming light rays are captured by the microscope objective and passed into the eyepieces or a camera port. Alignment of the optical components of a microscope is critical to produce a good image.

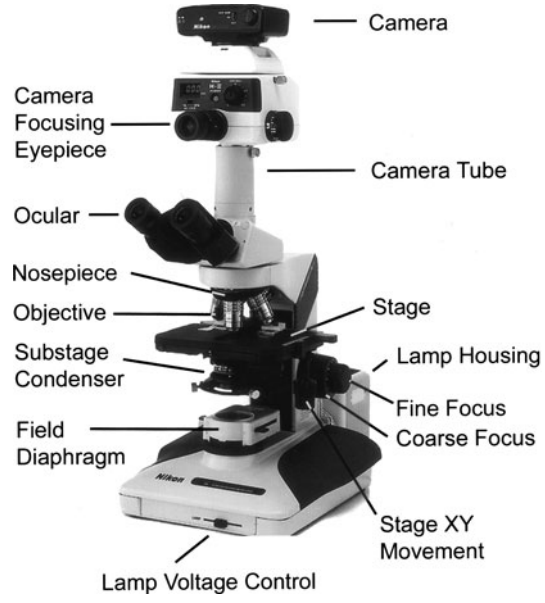

FIGURE 3 Anatomy of a typical clinical microscope with an integral camera.

Field Diaphragm

The field diaphragm is located in the light path between the light source and the substage condenser (Fig. 3). This iris-like mechanism controls the width of the light beam that enters the substage condenser. The field diaphragm does not affect the optical resolution, NA, or the intensity of illumination. However, the field diaphragm should be centered in the optical path and opened far enough that it just overfills the field of view. This adjustment is important for preventing glare and loss of contrast in the observed image. When the field diaphragm is opened too far, scattered light and reflections can degrade image quality.

Substage Condenser

The substage condenser is typically mounted beneath the microscope stage in a bracket that can be raised or lowered independently of the stage (Fig. 3). The substage condenser gathers light from the field diaphragm and concentrates it into a cone of light that illuminates the specimen with uniform intensity over the entire field of view. Adjustment of the substage condenser is probably the most critical element for achieving proper illumination, and it is the main source of image degradation and poor-quality photomicrography. The condenser light cone must be properly adjusted to optimize the intensity and angle of light entering the objective. Because each objective has different light-gathering capabilities (NA), the substage condenser should be adjusted to provide a light cone that matches the NA of the new objective. This is done by adjusting the aperture (or condenser) diaphragm control. Substage condensers on newer microscopes have a scale embossed on the condenser and an index mark on the aperture control that allows the user to quickly switch from one NA range to another. Many manufacturers

are now synchronizing the NA gradations to correspond with the approximate NA of the objectives.

In clinical laboratory practice, the condenser aperture is often made smaller to improve the contrast of wet mounts of some stained preparations (7). This practice, while effective for some applications, results in decreased resolution (1, 7). It should be noted that the intensity of illumination should not be adjusted by opening and closing the condenser aperture diaphragm or by moving the condenser laterally in the light path. Illumination intensity should be controlled through the use of neutral density filters placed into the light path or by reducing voltage to the lamp. Reducing the voltage, however, also alters the color of the incoming light. For this reason, lamp voltage changes are not recommended for photomicroscopy (4).

Objectives

The objective lens is the most important single determinant of the quality of the image produced by a particular microscope (12). When choosing a microscope, the purchaser must select the magnification factor, NA, and the level of correction for each objective. Lenses with higher NA values have higher resolution and produce a brighter field of view. The level of optical correction in the objective depends on the ultimate use of the microscope. Achromatic (achromat) objectives are the least expensive objectives found on laboratory microscopes. Achromat objectives are corrected for axial chromatic aberration in two wavelengths (red and blue), and they are corrected for spherical aberration in one color (green) (5). The limited correction of achromatic objectives can cause a number of optical artifacts when specimens are examined and photographed in color (e.g., green images often have a reddish magenta halo) (5). Achromat objectives produce the best results with light passed through a green filter and when performing black and white photomicroscopy. Flatness of field is also a problem when using straight achromat objectives because the center of the field is in focus while the edges are out of focus (5). In the past few years, most manufacturers have begun providing flat-field corrections for achromat objectives. These objectives are called plan-achromats.

The next higher level of correction and cost is found in objectives called fluorites or semiapochromats. Fluorite objectives are produced from advanced glass formulations that allow for greatly improved correction of optical aberration. Like the achromat objectives, the fluorite objectives are also corrected chromatically for red and blue light (5). Fluorites are also corrected spherically for two or three colors instead of a single color, like achromats (5). The superior correction of fluorite objectives compared to achromats enables these objectives to be made with a higher NA. Fluorite lenses therefore produce brighter images than achromats. Fluorite objectives also have better resolving power than achromats and provide a higher degree of contrast, making them better suited for color photomicrography in white light (3, 5).

Apochromats

Apochromats are the most highly corrected microscope lenses and the most costly. Apochromats are corrected chromatically for three colors (red, green, and blue), almost eliminating chromatic aberration, and are corrected spherically for either two or three wavelengths (5). Apochromat objectives are the best choice for color photomicrography in white light. Because of their high level of correction, apochromat objectives usually have, for a given magnification, higher numerical apertures than do achromats or fluorites (3, 5).

Fluorescence Objectives

Fluorescence objectives are designed with quartz and other special glasses that have high transmission rates of UV, visible, and infrared light. These objectives are extremely low in autofluorescence and use specialized optical cements and antireflection coatings that protect the lens and allow it to operate with a wide variety of excitation wavelengths. The correction for optical aberration and NA values in UV fluor objectives usually approaches that of apochromats, which contributes to image brightness and enhanced image resolution (2, 5). The primary drawback of high-performance fluorescence objectives is that many are not corrected for field curvature and produce images that do not have uniform focus throughout the entire field of view. This is not a large problem when performing direct or indirect fluorescent-antibody testing, but it can be troublesome if you have to use the same objectives to do bright-field and phase-contrast microscopy.

Microscope objectives that use air as the medium between the coverslip and the objective lens are considered dry objectives. The maximum working NA of a dry-objective system is limited to 0.95, and greater values can be achieved only by using optics designed for immersion media. Immersion media have the same refractive index and dispersion values as glass (refractive index = 1.51). The use of immersion media produces a homogeneous light path from the coverslip to the lens so that light is not refracted away from the objective. The use of immersion fluids and lenses significantly increases the NA and the optical resolution of the system. In addition to "oil" lenses, specially corrected objective lenses designed for glycerin and water immersion are available commercially. The proper immersion fluid type is always stamped on the side of the objective. The advantages of oil immersion objectives are severely compromised if the wrong immersion fluid is utilized. Microscope manufacturers produce immersion objectives with tight refractive index and dispersion tolerances (5). It is therefore advisable to use only the immersion fluid recommended by the objective manufacturer. Mixing of immersion fluids from different manufacturers should be avoided because mixing can produce unexpected crystallization artifacts or phase separations that compromise image quality.

Many high-power (NA, $\geq$0.8) dry objectives are engineered to operate through 0.17-mm coverslips (designated as number 1½). In practice, however, the total thickness of the specimen-coverslip sandwich can be greater or less than 0.17 mm due to variations in coverslip and/or mounting fluid thickness (3, 5). Under these conditions, there will be noticeable spherical aberration in the microscopic image (3, 5). A 0.2-mm deviation in coverslip thickness produces an 8% decrease in image intensity when using a 0.79 NA objective and 57% with a 0.85 NA high-dry objective (5). Therefore, some of the more advanced dry objectives are engineered with a coverslip correction collar that adjusts the objective lens elements to compensate for coverslip thickness variations. Objectives with a coverslip correction collar are labeled Corr, w/Corr, or CR. However, this labeling is usually unnecessary because the objective has a distinctive knurled ring and graduated scale on the side. The expected coverslip thickness for an objective is etched on the barrel of the objective (Fig. 1).

The eyepiece or ocular objective contains the final lens system in the optical train. The purpose of the ocular objective is to magnify and focus the projected image onto the eye of the viewer. Ocular lenses generally have a magnification factor of $\times$10 to $\times$20 and the total magnification of the microscope is the product of the objective magnification and the ocular magnification. (5, 7, 11, 12). Thus, a microscope

with a 40× objective and a 10× ocular lens would have a magnification value of ×400. Many eyepieces have a shelf at the level of the fixed eyepiece diaphragm that allows for the insertion of ocular micrometers, pointers, or crosshairs. This shelf is located at the focal plane of the image projected by the objective lens so that the inserted element is in focus when the specimen image is in focus.

DARK-FIELD MICROSCOPY

Dark-field microscopy is a specialized illumination technique that is used in the clinical laboratory to detect thin organisms such as spirochetes and *Leptospira* (refer to chapters 61 and 63). High-resolution dark-field microscopy utilizes a specialized high-NA cardioid dark-field condenser that blocks the central light path light and produces a hollow cone of illumination that is directed away from the objective lens at an oblique angle (Fig. 4). Bacteria on the slide have a refractive index slightly different from that of the surrounding medium, and light rays passing through the organism are refracted into the objective lens. Light rays that do not pass through an organism do not enter the lens. This type of illumination produces bright organism profiles against a dark background. Dark-field microscopy requires careful alignment of the condenser and the placement of immersion oil between the slide and the substage condenser. Dark-field microscopy, when done correctly, increases the resolution of the microscope to 0.1 μm or less (1, 7). The resolution of bright-field microscopy is 0.2 μm (7, 12).

PHASE-CONTRAST MICROSCOPY

Many unstained biological specimens are virtually transparent when observed under bright-field illumination. To improve visibility in wet mounts and cell cultures, microscopists often reduce the opening size of the substage condenser iris diaphragm (7), but this maneuver is accompanied by a serious loss of resolution and the introduction of diffraction artifacts (1, 5). Phase-contrast microscopy significantly improves the contrast in these specimens without significant loss in resolution (1).

In phase-contrast microscopy, a ring annulus is placed directly under the lower lens of the condenser to produce a hollow cylinder of light. This light is essentially unchanged as it passes into the objective, and it arrives at the rear focal plane of the objective in the shape of a ring. Light that goes through the specimen is refracted and slowed slightly so that it is out of phase with the unchanged light by about one-quater wavelength. This light is spread over the entire focal plane. Light passing through the rear focal plane of the objective interacts with a ring-shaped phase plate that alters the direct light path by one-quarter wavelength (1). When the direct light and the refracted light arrive at the image plane, they are out of phase by one-half wavelength. This out-of-phase light interacts destructively so that specimen details appear as dark areas against a lighter background (1). Because the phase-shifting calculations are based upon on a one-quarter wavelength of green light, the phase image has the best resolution when a green filter is placed in the light path (1). Green filters also allow the microscopist to use less expensive achromat lenses that are spherically corrected for green light. Phase microscopy is an important tool for examining living and/or unstained material in wet mounts and cell cultures. However, phase-contrast microscopy has lower resolution than bright-field microscopy of stained specimens (1). In addition, viewed objects are often surrounded by halos that can obscure boundary details. Phase-contrast microscopy does not work well with thick specimens because the phase shift may be greater than the expected one-quarter wavelength.

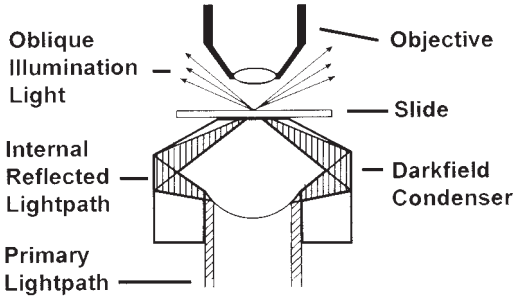

FIGURE 4 Dark-field illumination. The central light path interacts with the silvered dome located at the bottom of the condenser and is reflected away from the specimen. Peripheral light is reflected into the condenser and is reflected again by the internal condenser surfaces to produce a cone of light that is directed obliquely away from the objective.

FLUORESCENCE MICROSCOPY

The fluorescence microscope was developed in the early 1900s, and many of the initial microscopic studies involved identification and localization of compounds that autofluoresced when irradiated with UV light. In the 1930s a number of investigators began using fluorescent compounds to identify specific tissue components and infectious agents that did not autofluoresce (2). These stains are not organism specific, but rather, they bind to and stain specific structures within the organism. Examples of this type of staining include acridine orange (intercalcates into DNA and RNA), auramine-rhodamine (mycolic acids), calcofluor white (fungal cell wall polysaccharides), Evans blue (cytoplasm of fixed cells), and Hoechst 33258 (minor groove of AT-rich double-stranded DNA).

The use of fluorochrome-antibody conjugates (immunofluorescence) was first described in the 1940s when Coons et al. (8, 9) used fluorescein-labeled antibodies to detect pneumococcal polysaccharide antigens in tissue sections of infected mice. Fluorescent antibody staining expanded significantly with the development of fluorescein isocyanate in 1950 (10) and the more stable fluorescein isothiocyanate (FITC) derivative in 1958 (13, 15, 16, 22, 24). Today fluorescence microscopy is also used in conjunction with nucleic acid hybridization to visualize the location of fluorescent in situ hybridization (FISH) and multicolor FISH probes (23, 26).

Fluorescence microscopy is dependent on the ability of fluorescent substances to absorb near-UV light energy and reemit that energy (light) at a lower wavelength (2). To work properly, the fluorescence microscope must irradiate the specimen with UV excitation light and separate the much weaker emitted light from the brighter excitation light so that only the emitted light reaches the eye. The resulting image consists of brightly shining areas against a dark background (2). Older fluorescent microscopes are configured for dark-field illumination. In these instruments, UV excitation light enters a dark-field condenser and the light is directed onto the specimen at an oblique angle (Fig. 4). Fluorescent compounds in the specimen absorb the excitation light, and the emitted light is collected by the objective lens. The emitted light then passes through a barrier filter to remove any

excitation light that may enter the objective. These microscopes are difficult to use for routine diagnostics because the condenser and the objective must be carefully oiled. The dark-field condenser also reduces the effective NA of the objectives, thereby producing dim images that lack resolution (2). Most modern fluorescence microscopes use reflected light (epifluorescence). In these instruments, the excitation light is directed downward through the objective and onto the specimen. The emitted light and the reflected excitation light are collected by the objective, and they pass through a dichroic mirror which removes the excitation light and allows the longer-wavelength emitted light to form an image. With epifluorescence, the objective acts as a condenser and the alignment and oiling issues associated with a dark-field condenser are eliminated (2). The visual field is brighter with epifluorescence, the resolution is higher, and fluorescence quenching occurs only in the field of view (2).

Fluorescence microscopy requires high levels of illumination because the quantum yield of most fluorochromes is low. The most common lamps are mercury vapor (HBO) lamps, ranging in wattage from 50 to 200 W, or xenon vapor (XBO) lamps, which range from 75 to 200 W. It should be noted that lamp wattage is not necessarily a measure of usable brightness in a fluorescence lamp. The HBO 100-W lamp is 4 times brighter than the 200-W HBO lamp and 11 times brighter than the XBO 150-W lamp (2). When purchasing a fluorescence microscope, it is also important to determine whether the emission spectrum of the lamp is compatible with the fluorochromes used in the laboratory. HBO and XBO lamps are under high pressure, and care must be taken to prevent the lamps from exploding. One should never touch these lamps with bare hands because oils on the fingers can etch or discolor the glass.

Fluorochromes must be excited by specific light wavelengths in order to generate the maximum amount of emitted light. Therefore, specific exciter and barrier filter combinations are used to maximize the quantum yield of the fluorophore. Exciter filters are used to select the required light wavelengths from the spectrum of light generated by the lamp (2). Excitation filters are provided in narrow, medium, and wide bandpass configurations that pass a narrower and wider range of light frequencies, respectively. Barrier filters block shorter light wavelengths and allow longer wavelengths to pass through the filter. Barrier filters are important because they remove the high-intensity excitation light that could overwhelm the low-intensity emitted light. Barrier filters also prevent UV light from entering the eye, where it can cause cataracts and retinal damage. Wide bandpass barrier filters generally produce brighter images, but care must be taken to prevent the introduction of background light that could overwhelm the emitted light. Epifluorescence microscopes also have a dichromatic mirror (beam splitter) that reflects the incoming excitation light to the objective and allows the emitted light to pass to the barrier filter and on to the objectives. In most modern epifluorescence microscopes, the barrier filter, the excitation mirror, and the beam splitter are housed in removable optical blocks and several of these blocks can be installed in the microscope at one time. This configuration allows the user to quickly change the excitation and barrier filters to accommodate different fluorochromes. Care must be exercised when selecting optical blocks. The excitation filter should match the excitation wavelength of the fluorophore (Table 2), and the emission barrier should allow the emitted light to pass through. For example, direct fluorescent-antibody testing for viral antigens in cell smears typically employs FITC-labeled antibodies and an Evans blue counterstain. Choosing an optical block with a 450- to 490-nm excitation filter and a 515-nm-wide bandpass barrier filter produces a bright field of view, and the counterstained cells will appear orange-red. By selecting a more restricted bandpass barrier filter (520 to 560 nm), the field of view will be darker and the red emitted light from the Evans blue counterstain will not be visible. The images produced by this optical block have more contrast because the background is darker. Both filter combinations are appropriate for this task, but the final choice depends on user preference.

One of the major problems in the use and examination of fluorescent microscopic images is the tendency of fluorophores to lose fluorescence when exposed to excitation light for several minutes. This loss of fluorescence is caused by two mechanisms, photobleaching and quenching. Photobleaching (fading) is a permanent loss of fluorescence that is caused by chemical damage to the fluorophore (2). Quenching is caused by the presence of free radicals, salts of heavy metals, or halogen compounds (2). Quenching can also be caused by transfer of emission light energy to other fluorescent molecules in close proximity to the fluorophore in a process called fluorescent resonance energy transfer. To lessen the effect of quenching, slides should be stored in the dark at 2 to 8°C. In addition, the user should block the excitation light path when not viewing or photographing the specimen. Most epifluorescence microscopes have a shutter in the light path for this purpose. Quenching can be a significant problem when photographing fluorescent images because the shutter may be open for 1 min or more. Quenching can be reduced somewhat

TABLE 2 Excitation and emission wavelengths of commonly used fluorochromes[a]

Fluorescent compound	Excitation wavelength (nm)	Emission wavelength (nm)
Acridine orange (single-stranded nucleic acid)	500	526
Acridine orange (double-stranded nucleic acid)	460	640
Auramine O	460	550
Calcofluor white	440	500–520
Ethidium bromide	545	605
Evans blue	550	610
FITC	490	525
Hoechst 33258	352	461
Rhodamine B	540	625
TRITC[b]	555	580

[a] Excitation and emission wavelengths can vary depending on the solvent and the pH of the solution.
[b] TRITC, tetramethylrhodamine isothiocyanate.

by adding free-radical scavengers such as *p*-phenylenediamine (16), 1,4-diazabicyclo(2,2,2)-octane (DABCO) (17), or *n*-propylgallate (14) to the mounting fluid. *P*-Phenylenediamine and *n*-propylgallate can be used to reduce quenching in FITC and rhodamine. DABCO is slightly less effective than *p*-phenylenediamine for FITC fluorescence, but unlike *p*-phenylenediamine, DABCO does not darken when exposed to light and it is safer to use. Quench-resistant mounting media are also available from Vector Laboratories (Burlingame, Calif.), Molecular Probes Inc. (Carslbad, Calif.), and Bio-Rad Laboratories (Hercules, Calif.).

LINEAR MEASUREMENTS (MICROMETRY)

The first reported micrometric procedures were credited to Antonie van Leeuwenhoek, who used fine grains of sand as a gauge to determine the size of human erythrocytes. Since then, a variety of methods have been used to determine the dimensions of microscopic organisms. The crudest method for determining size in the clinical laboratory involves comparing the object size to the measured or calculated view field size. Other micrometric techniques include the addition of polystyrene beads of known size into the specimen. Comparative measurements are then performed utilizing a photomicrograph or digital image. The accuracy of this method is variable and depends on the homogeneity of the comparison objects. Direct measurements of microorganisms can be done by placing them on calibrated microscope slides or counting chambers. The accuracy of this method depends on the separation distance between ruled lines but averages between 10 and 50 μm. The most common procedure used in the clinical laboratory utilizes a graduated scale (reticle) located within one of the eyepieces (21). Reticles must be calibrated against a stage micrometer for each objective (21). The accuracy of this type of measurement is approximately 2 to 10 μm (3 to 5%), depending on magnification and the resolution of the stage micrometer (21).

PHOTOMICROSCOPY

Microscopists began capturing microscopic images on film shortly after the photographic process was invented (4). Micrographic images have long been used for investigations of morphology, in scientific publications and lectures, and in teaching. Modern film technologies have high resolution and clarity, but the use of photomicrographs in day-to-day microscopy has been hampered by long turnaround times associated with film development and printing. Reacquiring fluorescence images is a particular concern because the fluorescence can fade (2). The availability of high-quality digital cameras has significantly changed how photomicrographs are used in the microbiology laboratory. Today it is not unusual for digital photomicrographs to be shared with experts via the Internet. This process significantly extends the capabilities of the on-site microbiologist and can enhance patient care. Microscope-based digital cameras and video systems are also used to perform "plate rounds" in remote hospitals and clinics within a multihospital system. Newer Internet technologies involving robotic microscopes and high-resolution video systems now allow microbiologists to change the focus and the slide positioning of a microscope located anywhere in the world and view the resulting images on a monitor in their office. The availability of digital photomicroscopy has significantly enhanced the microbial identification process and has helped to standardize microbe identification.

A wide variety of microscopes that have integrated camera systems and sophisticated light metering and exposure controls are currently available. Accessory cameras are also available from a large number of aftermarket manufacturers. The performance and optical characteristics of these systems are too diverse to discuss in a single chapter. Photographs are a stern judge of microscopic quality (4), and the purchase of an expensive camera system does not automatically confer the ability to produce high-quality images. High-quality photomicrographs require proper specimen illumination and optical train alignment to achieve its ultimate potential (4). Color photography can be very demanding because specimens may appear yellow or blue under tungsten halogen (3200K color temperature) light depending on whether the lamp voltage is above or below the recommended 9-V setting. Photographs will also appear blue if the daylight blue filter is not removed from the light path. Photographs can also appear yellow when tungsten halogen (3200K) illumination is used in conjunction with daylight (5500K) film or digital cameras designed for daylight photography. Under these conditions, a Kodak 80A (3200K to 5500K) color conversion filter should be placed in the light path to achieve the proper 5500K color temperature (4).

Not all microbiologists can afford a microscope with an integrated camera system. Simple eyepiece cameras can also be used to capture bright-field images. The simplest configuration for eyepiece photography involves the use of a point-and-shoot digital camera. Some improvisation may be necessary with this method because few adapters are available for coupling a fixed-lens camera to the microscope eyepiece. Instead, the microscopist can use a camera tripod or some other support bracket to hold the camera in its proper position. Entry of stray light can be minimized by using a piece of black polyvinyl chloride pipe with an appropriate diameter and a black camera cloth. During photography, the camera lens system should be set to infinity focus (the default in fixed-lens cameras) and the lens should be positioned so that it is at the eyepoint (focal point) of the eyepiece. Location of the eyepoint can be determined by holding a piece of white paper just above the objective with the microscope turned on and focused (4). A bright circle of light will be projected onto the paper. The eyepoint is the position where the light circle is smallest (4). Photographs produced under these conditions are often acceptable, but they may be dark. Cameras with adjustable aperture settings should be set to the largest aperture value (smallest f-stop number) to maximize the amount of light entering the camera. This method also produces some chromatic aberration (due to different lens correction factors) and vignetting (pipe view effect).

Another method for photomicroscopy is to use the camera port on microscopes fitted with a trinocular head. Olympus and Nikon have introduced adapters that allow their digital cameras to attach to the camera tube of their microscopes. In addition, camera tube and eyepiece adapters for a number of digital cameras are available from Microscope Depot (Tracy, Calif.). Photography under these conditions is best done using a camera with through-the-lens exposure metering. These devices work well if the exposure is not longer than several seconds or shorter than one-third of a second (4). Many of these cameras have built-in flashes that should be turned off during photomicroscopy. These cameras may have problems with fluorescence microscopy due to the extreme contrast of fluorescent images and the tendency of metering systems to average exposure values over the entire field (4).

CARE AND USE OF THE MICROSCOPE

Proper care and maintenance of the microscope will prolong the usable life of the instrument and allow for more accurate interpretation of microbiological images. The microscope should be kept in a low-vibration, low-dust environment to facilitate viewing and decrease damage to the optical systems. The optical elements should be kept completely free of dust, dirt, oil, solvents, and any other contaminants (21). Ideally, the microscope should be covered and the lamp should be turned off when the microscope is not in use. Do not touch the optical surfaces with your fingers (21). Keep the lenses clean and be sure to remove oil or mounting fluid from the objectives, condenser, and mechanical stage after each session. Avoid dragging the high-dry objective through oil or fluorescence mounting fluid. One way to avoid accidental contact with these fluids is to place the high-dry objective and the oil immersion objective in the nosepiece on opposite sides of the low-power objective (4). Lenses should be dusted with residue-free compressed air and cleaned with lens paper and a commercial lens cleaner that is approved by the microscope manufacturer. Organic solvents such as alcohols and acetone should not be used on the lenses because the solvent may dissolve the optical mounting cement (7). Unused spaces in the nosepiece (Fig. 3) should be plugged, and the eyepieces should remain installed at all times to prevent introduction of dust into the body tube. The stage should be cleaned regularly and any spilled immersion oil must be removed or else slides will stick when they are moved across the stage. Spilled immersion oil also collects dust and grit that can damage the optical and mechanical parts. Microscopists should not attempt to remove or disassemble the objectives, as this increases the potential for damage (7, 21). This is a job that is best left to professionals (21). The gears and rackwork should be cleaned and treated with new grease at intervals specified by the manufacturer. Do not use light oil on the gears or bearing surfaces because this may cause the condenser and stage to sink from their own weight (21). Periodic cleaning and adjustment by a professional microscope repair person also help to extend the usable life of the microscope.

ERGONOMICS

Peering into a microscope eyepiece for long periods is not an activity for which the body is well adapted. Microscope work requires the head and arms to be locked in a forward position and inclined toward the microscope with rounded shoulders. This unusual positioning is further exaggerated when the feet are placed on the ring-style footrests that are common to many laboratory stools. Poor posture and awkward positioning during microscopy can cause pain or injury to the neck, wrists, back, shoulders, and arms. In one regional survey of cytotechnologists, Kalavar and Hunting (18) found that 70.5% of respondents reported neck, shoulder, or upper back pain during microscopy and 56% had an increased prevalence of hand and wrist symptoms. Eyestrain and leg and foot discomfort have also been documented with long-term microscope use (6). When using older microscopes, users often have their heads inclined up to 45° from vertical and their upper backs may be inclined by as much as 30°. Even 30° inclinations of the head can produce significant muscle contractions, fatigue, and pain (6). For this reason, microscopists should be taught to sit upright and hold their head in a neutral position (25).

During microscopy, the laboratorian should sit erect and maintain the natural curve of the spine (25). The lower back and shoulder blades should be supported by the chair and a lumbar support cushion should be used if necessary. The legs and feet should rest firmly on the floor or a footrest. The chair should have a pneumatic height adjustment (21), and the seat should have a sloping front edge to prevent undue pressure on the thighs. The backrest should be adjustable for both height and angle, and the chair should have a five-pointed star base with caster wheels. Knee spaces, which are often used for laboratory storage, should be free from obstructions, and there should be a minimum of 2 in. of clearance between the thigh and the bottom of the desk or counter (18). Obstructions that prevent the microscopists from holding their shoulders perpendicular to the ocular axis of the microscope should be removed (27). The upper arms should be perpendicular to the floor with the elbows close to the body. The forearms should be parallel with the floor, and the wrists should be straight. The head should be upright and the neck should bend as little as possible, preferably no more than 10 to 15°. The eyepieces should be just below the eyes, and the eyes should look downward at a 30 to 45° angle. The use of tilting microscope heads can significantly improve the comfort of the microscopist (18, 19, 27). Repetitive motions of the hands and the contact stress of arms resting on (the edge of) a hard surface can cause pain and nerve injury, leading to repetitive stress injuries and/or carpal tunnel syndrome. The use of padded arm rests can moderate some of these problems. In addition, microscopes should not be placed under an air vent in order to prevent stiffening of the muscles during microscopy.

Most laboratory microscopes are used by multiple individuals, and it is often a challenge to find conditions or microscope configurations that satisfy everyone. Some laboratories place microscopes on books or heavy blocks of wood to accommodate taller microscopists (21). This configuration creates a number of problems. If the microscope is raised to a sufficient height to prevent neck flexion, users may be forced to bend their wrists into an unnatural position. If the microscope is lowered to allow the forearms to remain parallel to the floor, the neck is forced to bend. Lowering the chair to its lowest position causes leg discomfort. Vertically challenged individuals may have to raise the chair to a level where their feet no longer touch the floor. Foot rests can ameliorate this problem, but some individuals may have insufficient space under the bench top to accommodate their legs. In practice, most laboratories will elect to use a suboptimum but workable microscope configuration that all users can employ. Under these conditions, microscopists can reduce stress and fatigue by taking 1-min "microbreaks" every 10 to 15 min during which they can stand, stretch, and allow the eyes to focus at a distance.

Eye fatigue can be a major problem for microscope users, especially if they have poor vision. The diopter adjustment provided on most microscope eyepieces can be adjusted to compensate for minor near- and far-sightedness, thereby allowing the users to remove their glasses during microscope use. The diopter adjustments do not adjust for astigmatism, and users with moderate to severe astigmatism should wear glasses when using the microscope. Most microscope manufacturers now produce high-eyepoint eyepieces that move the visual observation point further from the eyepiece, thereby facilitating the use of glasses during microscopy. Ensuring that the microscope images are as bright, sharp, and crisp as possible will also help to reduce eye fatigue and associated headaches. The importance of proper alignment of the microscope and optical components cannot be overstressed. Proper optical alignment and the use of newer objectives with higher NA values will produce brighter

images and better resolution, which eases the strain of searching for tiny specimen details. The use of a neutral blue (daylight) filter during bright-field microscopy can also help to lessen eyestrain when examining microbiological specimens. In the future, many new microscopes will display the specimen image on a computer monitor. This innovation could alleviate many of the eyestrain problems that develop during extended microscope use (27).

Microscopes are as different as the people who use them, and the previous comments should not be construed as a prescription for alleviating strain or repetitive motion injuries in every situation. When purchasing a microscope, every effort should be made to allow microscopists to evaluate the new microscope under their normal working conditions. Some microscopes will be comfortable for some users and uncomfortable for others. In the long run, the feel and fit of the microscope are just as important as the optical characteristics.

CONCLUSION

Advances in the design, resolution, and ergonomics of modern microscopes have greatly enhanced our ability to study and identify microorganisms. Microscopy still has a central role in the detection of infectious agents despite highly publicized advances in DNA and RNA detection systems. Microscopic examination of clinical specimens provides a rapid and inexpensive "first pass" in the detection and identification of infectious agents. Thus, clinical microscopy will continue to be a core competency in clinical microbiology laboratories for the foreseeable future.

Principles of Stains and Media*

KIMBERLE C. CHAPIN

14

DIRECT EXAMINATION OF SPECIMENS

The first step in the processing of most clinical material is the microscopic examination of the specimen. Direct examination is a rapid and cost-effective diagnostic aid developed to reveal and enumerate microorganisms and eukaryotic cells. Visible microorganisms or the lack thereof may denote the presumptive etiologic agent, guiding the laboratory in the selection of the appropriate isolation media and the physician in the selection of the appropriate empirical antibiotic therapy. The quality of the specimen and the measure of the inflammatory response can also be evaluated. In addition, the direct smear serves as a quality control indicator for attempts to cultivate observed organisms (18). The first part of this chapter discusses the principles of staining methods used in the direct examination of specimens. Tables 1 to 3 give a brief overview of all commonly performed staining methods noted in this Manual. Procedures for performance of the stains are available in the chapters on reagents, stains, and media for bacteriology (chapter 21), virology (chapter 81), mycology (chapter 117), and parasitology (chapter 134). Technical aspects of microscopy are described in chapter 13. An excellent website with exquisite detail containing all aspects of microscopy is available at http://www.zeiss.com.

CHEMICAL BASIS OF STAINING

Simple wet mounts, consisting of clinical material in a drop of saline, allow determination of cellular composition, morphology, and motility. However, cellular material and organisms are usually transparent and best distinguished by the use of dyes or biological stains. Antonie van Leeuwenhoek was the first to attempt the differentiation of bacteria with the use of natural colored agents such as beet juice in 1719 (16). Staining procedures and the understanding of the chemical basis of staining developed extensively in the area of histology, where cellular constituents were desired to be more clearly demarcated. The specific chemical basis of many stains used in clinical microbiology is described in detail in histology texts (10, 12, 13, 21). Additionally, websites pertaining to the basic properties of stains for histology are helpful, including the following site that lists stains alphabetically, http://focosi.immunesig.org/histochemistry.html.

Metachromasia is a characteristic color change which natural dyes (aniline dyes or products of such natural products) exhibit when bound to certain substances either in tissue or in aqueous solution. With the exception of hematoxylin, natural dyes have for the most part been replaced by artificial dyes. Artificial dyes are products of chemical derivatives from substances in coal tar, especially benzene. Two other important chemical groups, the chromophore and auxochrome, complete the dye compound (12, 13).

A chromophoric group is the group of atoms within a dye molecule responsible for its color. Benzene, an aromatic organic compound, undergoes substitution reactions with radicals to form these new compounds, which constitute the dye resonance system. Some of the molecular changes result in a colored product. The most important chromophoric groups are C=C, C=O, C=S, C=N, N=N, N=O, and NO_2. The number of chromophores in a compound determines the intensity of the compound color. Benzene plus a chromophore group is a chromogen. Although the chromogen is colored and typically ionic, it does not have great affinity for bacteria or tissues, and washing or mechanical processes will readily remove the compound. Thus, this group does not in itself constitute a dye. The molecule must also possess an ionizing group called an auxochrome, which allows the dye molecule as a unit to have affinity (cationic or anionic) for a compound and to function as a dye. The auxochrome group gives the compound the property of electrostatic dissociation, or the ability to form salt linkages with the ionizable radicals on proteins, glycoproteins, and lipoproteins on tissue or organism cellular components. This process can occur either directly or through a chelating action of a mordant (13). Commonly occurring auxochromes are amino groups ($-NH_2^+$), hydroxyl groups (–OH), sulfates ($-SO_3^-$), and carboxyl groups (–COOH). With the exception of the amino groups, which ionize to produce a positive charge and are considered basic (cationic), all of these auxochromes ionize to produce negative charges and are acidic (anionic). Some dyes have more than one auxochrome. Even in combinations with basic and acid auxochromes, the negative charge typically predominates (10, 12, 21).

Dyes are usually sold as salts; thus, it is the auxochrome group that usually determines whether a dye is classified as cationic (basic) or anionic (acidic). Most dyes will retain their cationic or anionic properties throughout the pH range of

*This chapter contains information presented in chapter 18 by Kimberle C. Chapin and Patrick R. Murray in the eighth edition of this Manual.

staining (pH 3 to 9) and thus reliably stain those structures that are oppositely charged. For example, DNA phosphate groups and mucopolysaccharides, which are negatively charged and acidic, will be stained with a basic dye. Basic (positively charged) components in cytoplasm will stain with an acid dye. Crystal violet, methylene blue, and safranin are typical cationic (basic) dyes, and eosin, acid fuchsin, and picric acid are typical anionic (acid) dyes.

WET MOUNTS AND SINGLE-STAIN METHODS

Wet-mount preparations are used to determine the cellular composition of a specimen as well as the morphology of organisms, their gross structure, and their biological activity, including motility (Table 1). The specimens can be examined by bright-field, phase-contrast, or dark-field microscopy. True wet mounts do not involve fixation of the clinical material and are viewed immediately upon preparation. Single-stain methods, such as methylene blue or iodine, enhance visualization of organisms by increasing the contrast of structures and can be performed either as a wet mount or with fixed material (e.g., M'Faydean stain) (3, 4). All organisms and cellular components stain shades of a similar color.

DIFFERENTIAL STAINING

While direct visualization of specimens in various wet mounts is useful, differentially stained specimens are the most helpful for presumptive grouping of the majority of pathogens. The

TABLE 1 Wet mounts and single-stain methods

Direct-examination method	Applications	Principle	Time required (min)	Advantages	Disadvantages
Wet mount	Direct clinical examination of stool, vaginal discharge, urine sediment, aspirates	Used to detect organism motility and morphology of parasitic forms and fungi	1	Rapid	Limited contrast and resolution; Brownian movement may be confused with motility; experienced microscopist required
10% KOH	Direct examinations of specimens for fungi, e.g., skin scrapings, fluid aspirates	Proteinaceous host cell components are partially digested by alkali; fungal cell walls stay intact	5–10	Rapid detection of fungi	Background material may cause confusion; experienced microscopist required
10% KOH with lactophenol cotton blue	Direct examination of specimens for fungi, e.g., skin scrapings, fluid aspirates	Adds contrast for detection of fungi	5–10	Dye enhances detection of fungi	Background material may cause confusion; experienced microscopist required
Colloidal carbon (India ink, nigrosin)	Direct examination of CSF[a] and other body fluids for *Cryptococcus neoformans*	Polysaccharide capsule excludes ink particles producing a halo appearance	1	Rapid; diagnostic in CSF when present	Not as sensitive as cryptococcal antigen; cells and artifacts may cause confusion; experienced microscopist required
Lugol's iodine	Direct examination of stool	Nonspecific contrast dye to help differentiate parasitic cysts from leukocytes; cysts retain dye and appear light brown	1	Rapid; enhances differentiation	Background material may cause confusion; experienced microscopist required
Methylene blue staining	Direct examination of stool for leukocytes; detection of bacteria, particularly poorly staining gram-negative organisms, spirochetes, and *Corynebacterium diphtheriae*	Leukocytes and bacteria stain blue	1; up to 10 min if *C. diphtheriae*	Rapid; enhances differentiation	Leukocytes may disintegrate if stool is not examined promptly; overstaining may mask granules
M'Fadyean staining	Fixed examination of clinical specimens from patients suspected to have anthrax	Methylene blue dye stains *Bacillus anthracis* deep blue and demarcated pink capsule zone	4	Rapid; enhances differentiation of capsule	Stain rarely performed

[a] CSF, cerebrospinal fluid.

Gram stain and acid-fast stain are examples of differential stains. In addition, fluorescent stains (see below) may aid in the identification of organisms when specific attachment of fluorochromes occurs with organism components: auramine, calcofluor white, and fluorescein isothiocyanate (FITC) bound to monoclonal antibodies or synthetic protein nucleic acids (PNAs) (19).

In fixed differential smear preparations, four components are typically used in a progressive manner: the primary stain, a mordant, a decolorizing agent(s), and a secondary stain or a counterstain. The primary stain usually stains all cellular components and organisms in the specimen the same color, as seen in simple procedures with a single stain (e.g., methylene blue). The mordant aids in the attachment of a dye to cellular components. Heat, phenol, and iodine are examples of mordants. Decolorizing agents are typically acids and alcohols, such as the acetone and alcohol mixture used in the Gram stain and sulfuric acid used in the modified Kinyoun (modified acid-fast) stain. Removal of the primary stain with the decolorizing agent allows a secondary stain (counterstain) to be taken up by any decolorized organisms and background material. The secondary stain differentiates between those cells that retain the primary stain and those that do not. Examples include the purple (primary stain) and pink (counterstain) organisms seen with the Gram staining procedure or the organism and the background, as seen with a pink acid-fast organism (primary stain) in a blue-counterstained background.

Gram Stains

The Gram stain is the most commonly performed differential fixed stain in microbiology. The Gram reaction, morphology, and arrangement of the organisms give the physician clues to the preliminary identification and significance of the organisms. Gram-positive organisms are thought to retain the crystal violet dye because of the increased number of cross-linked teichoic acids and the decreased permeabilities of their cell walls to organic solvents because they contain little lipid. While the gram-positive organisms take up the counterstain, their color is not altered. The cell walls of gram-negative organisms, because of the higher lipid content associated with the cell wall, show increased permeability to decolorizer, and these organisms lose the crystal violet dye and take up the counterstain dye, safranin (6).

Some enhancement techniques are basic modifications of more standard differential or single-stain methods. These include the use of tartrazine and light green (enhanced Gram stain [Remel]) in place of safranin in the Gram stain and the addition of basic fuchsin to methylene blue (Wayson stain). Many other combinations and manipulations exist (Table 2). The main purpose of these stains is to make organisms that are normally difficult to detect by the Gram staining method stand out more prominently. Typically, these enhancement techniques are used for the better visualization of gram-negative organisms. This is done by two methods. One method is to simply use a stain that will make the organism a darker color so that the normally weakly staining gram-negative organisms are visible (4, 9, 17). The second method is to make the background inflammatory cells and mucus, which often masks gram-negative organisms, a different color than the usual red-pink. This method is used with the tartrazine-light green stain, which makes the background gray or green and the organism easily visible. In this staining method the Gram reaction of the organisms is preserved (J. Kee, A. Hill, and K. Chapin, *Abstr. 94th Gen. Meet. Am Soc. Microbiol. 1994*, abstr. C-242, 1994).

Acid-Fast Stains

The cells of certain organisms contain long-chain (34- to 90-carbon) fatty acids (mycolic acids) that give them a coat impervious to crystal violet and other basic dyes. Heat or detergent must be used to allow penetration of the primary dye fuchsin into the bacterium. Once the dye has been forced into the cell, it forms a stable complex and the usual acid-alcohol solvent cannot decolorize the organism. The acid-fast stain is useful for identification of a specific group of bacteria (e.g., *Mycobacterium, Nocardia, Rhodococcus, Tsukamurella, Gordonia, and Legionella micdadei*) and the oocysts of *Cryptosporidium, Isopora, Sarcocystis*, and *Cyclospora*. A number of modifications have been developed from the original acid-fast stains described by Ziehl in 1882 and Neelsen in 1883. The modifications most commonly used are the Kinyoun and modified Kinyoun (modified acid-fast). Age of the organisms or slight differences in the fatty acids between species can also alter the stain choice (1, 14; J. Brown, CDC, personal communication).

FLUORESCENT MICROSCOPY

See Table 3 and chapter 13 for technical aspects of fluorescent microscopy.

ANTIBODY STAINING METHODS

See chapter 18 on immunoassays.

HISTOLOGICAL TISSUE SPECIMEN INTERPRETATION

The clinical microbiologist is often asked to consult on smear interpretation of blood and body fluid specimens and histologically stained sections of tissue. The differences between organisms stained directly from blood and those stained in fixed tissues need to be noted. In general, it should be remembered that most fungi, parasites, viral inclusions, and bacteria in histological preparations cannot be identified definitively. For instance, the stain typically used in the hematology laboratory for blood and body fluids is the Wright-Giemsa preparation, which uniformly stains all bacteria blue. Thus, one must not call a blue coccus a gram-positive coccus until Gram staining can be done to help in differentiation. In addition, in stained tissue preparations, pathogens may be significantly different in appearance owing to the staining and fixative practices used in the histology laboratory. For instance, vacuolated areas may give the appearance of a capsule in a nonencapsulated organism. However, some organisms, such as *Borrelia, Anaplasma*, and *Ehrlichia,* are best visualized in direct blood smears of buffy coats with Wright-Giemsa.

Histological preparations often stain organisms similarly to the stains used in microbiology but have been modified for tissue. The Brown-Brenn (Gram) stain and Fite-Faraco (acid-fast) stain are examples of tissue stains with which the organisms retain the color appearance seen with their microbiology counterpart (2, 15). Other common tissue stains often viewed by microbiologists include silver stains, such as Warthin-Starry or Dieterle, and the Wright-Giemsa stain. The Wright-Giemsa stain does not stain bacteria or fungi reliably in tissue, with the important exception of *Histoplasma capsulatum*, which will stain by Wright staining of bone marrow and peripheral blood. These histological preparations, as well as others, can also be used to stain infected cell culture monolayers and aid in the visualization of viral and

TABLE 2 Differential fixed staining methods

Differential fixed staining method	Application	Principle	Time required	Advantages	Disadvantages
Gram staining (conventional or Atkins' modification)	Differential bacterial and yeast stains; used to assess suitability of specimen for bacterial culture	Gram-positive organisms retain crystal violet and stain blue; gram-negative organisms do not retain crystal violet and stain pink due to the counterstain safranin	3 min	Rapid; commonly performed; can aid in choice of antibiotic therapy; used to assess specimen for culture and compare smear result to culture result	Organisms with damaged cell walls will stain unpredictably; *Nocardia* and fungi may not take up crystal violet completely; background and cellular elements stain pink, often masking gram-negative organisms
Anaerobic Gram staining variation	Differential stain used to detect anaerobic organisms (especially gram-negative bacteria) not easily seen with regular Gram stain	0.1–0.5% basic carbol fuchsin used as counterstain instead of safranin; enhances detection of gram-negative organisms	3 min	Darker staining of gram-negative anaerobes such as *Fusobacterium* as well as other slender gram-negative organisms, such as *Helicobacter* and *Campylobacter*	
Tartrazine-fast green Gram staining variation	Differential bacterial stain that enhances detection of organisms because cellular background is green	Use of fast green and tartrazine before safranin counterstain allows significant suppression of red-pink color of the background material; organisms still stain purple (gram positive) or pink (gram negative)	3 min	Allows excellent enhancement of small gram-negative organisms and detection of mixed cultures	Slight change in color appearance of organisms compared with regular Gram stain may be confusing
Spore staining (Wirtz-Conklin)	Differential stain for detection of bacterial spores	Spores take up the malachite green stain and the cellular debris, and bacteria appear pink from the safranin counterstain.	Slides can be stained for 45 min or gently heated to steaming for 3–6 min.	Facilitates detection of bacterial spores which may otherwise be difficult to observe. While a heating step is more cumbersome, it enhances uptake of the stain into the spore.	Gentle heating of slide may be difficult to control
Wayson staining	Direct examination of CSF[a] and other specimens for bacteria and amebae	A mixture of the dyes basic fuchsin and methylene blue that results in contrast staining between bacteria that stain deep blue and other material that stains light blue or purple	3 min	Rapid; enhances differentiation	Staining reagents unstable; slides cannot be restained with Gram stain
Acid-fast staining (Ziehl-Neelsen, Kinyoun, modified Kinyoun)	Detection of acid-fast and weakly acid-fast organisms (e.g., *Mycobacterium, Nocardia, L. micdadei, Rhodococcus, Tsukamurella, Gordonia, Cryptosporidium, Isospora, Cyclospora,* and *Sarcocystis*)	Presence of long-chain fatty acids (mycolic acids) in cell wall or cystic forms makes organisms resistant to decolorization; organisms retain the carbol fuchsin dye and appear pink	2 h	Used to detect acid-fast and partially acid-fast organisms; presence generally significant from direct specimens	Low organism number makes slide examination tedious; tissue homogenates often mask presence of organisms because of deeply staining background

(Continued on next page)

TABLE 2 Differential fixed staining methods *(Continued)*

Differential fixed staining method	Application	Principle	Time required	Advantages	Disadvantages
Periodic acid-Schiff staining	Detection of fungi, specifically yeast cells and hyphae, in tissue specimens. *Tropheryma whipplei* bacilli appear as inclusions in macrophages.	Combination of acid hydrolysis and staining of cell wall carbohydrates; fungi stain pink-magenta or purple, and background appears orange or green if picric acid or light green, respectively, is used as the counterstain. Diastase-resistant, magenta-stained inclusions within macrophages are pathognomic of Whipple's disease.	1 h	Most fungi stain	Time-consuming; respiratory specimens must be digested or mucin will also stain pink-magenta. Inclusion staining pattern seen in diseases other than Whipple's disease.
Toluidine blue O staining	Rapid examinations of lung biopsy imprints and respiratory specimens for *P. jiroveci*	Background material removed by sulfation reagent and appears light blue; *P. jiroveci* cysts stain reddish blue or dark purple against the lighter background	20 min	Rapid method for detection of *P. jiroveci* cysts from appropriate specimen, such as bronchoalveolar lavage specimen	Differentiation of *P. jiroveci* from yeast may be difficult; cysts often appear crescent shaped; trophozoites are not discernible
Wright-Giemsa staining	Detection of parasites from blood smears, viral and chlamydial inclusions, toxoplasmosis, *Pneumocystis carinii* trophozoites, *Histoplasma* yeast forms in tissue, *Yersinia, Helicobacter, Ehrlichia,* and *Rickettsia*	Differential staining of basophilic and acidophilic material. Combination of stains allows uptake by multiple structures.	10 min–1 h	Detection of multiple organisms and cellular inclusions	Not specific for inclusions (*Chlamydia* is the exception); cannot determine bacterial Gram reaction
Gimenez staining	Intracellular organisms, especially *Coxiella, Rickettsia* from cell cultures, and *Legionella pneumophila*	Gram-negative organisms take up the carbol fuchsin and appear red against a green background with the counterstain that contains malachite and fast green.	3 min	Provides enhanced contrast of the gram-negative cell wall not able to be achieved with the Gram stain	Stain needs to be heated to 37°C 48 h prior to use and then filtered. Not commonly available in microbiology laboratories. Not specific.
Trichrome staining, Wheatley	Detection of intestinal protozoan cysts and trophozoites	Provides contrast between parasite cytoplasm (blue-green tinged) and internal structures (red or purplish red) and background debris (green to blue-green) by using chromotrope 2R and light green combination	1 h	Permits detection of diagnostic internal structures of protozoa	Helminth eggs are generally stained very dark; human cells, yeast, and artifacts may also stain.

(Continued on next page)

TABLE 2 *(Continued)*

Differential fixed staining method	Application	Principle	Time required	Advantages	Disadvantages
Trichrome staining, modified (Weber-Green) (Ryan-Blue)	Detection of microsporidial spores	Increase in chromotrope 2R stain concentration and staining time permits detection of pink microsporidial spores.	2 h	Permits detection of pink microsporidial spores against a green (Weber) or blue (Ryan) background	Time-consuming stain
Iron hematoxylin staining (Delafield's)	Detection of microfilariae	Provides contrast so internal filarial structures can be visualized. Hematein, an amphoteric dye, when combined with iron that acts as a mordant, creates an ionically charged dye lake that has affinity for cellular components.	45 min	Permits greater detection of nuclei and sheath of microfilaria compared to Giemsa or Wright's stains	Stain not available commercially and involves extensive aging process
Iron hematoxylin staining	Detection of intestinal protozoan cysts, inclusions, nuclei, and trophozoites	Provides contrast between parasites and background debris. Cytoplasm will have a blue-gray color, sometimes with a tinge of black; cysts tend to be slightly darker; nuclei and inclusions have a dark gray-blue color. Background is pale gray or blue.	60 min	Permits detection of diagnostic structures of protozoa	Helminth eggs are generally stained too dark to discern specific structural differences.

Chlamydia inclusion bodies, *Coxiella, Ehrlichia,* and *Toxoplasma* in tissue. Silver stains provide a differential stain that is best for detection of fungi and *Pneumocystis jiroveci* cyst walls in tissue (20). However, the stain also can detect bacteria and parasites. Differentiation of various yeast forms of *P. jiroveci* as well as other yeasts such as *Cryptococcus* is difficult, and interpretation should be done with caution and in conjunction with the use of other specific stains, such as Fontana-Mason (melanin) and mucicarmine (mucopolysaccharide). Thus, for the best outcome in the histological diagnosis of infectious etiologies, good communication among the surgical pathologist, hematologist, microbiologist, and primary physician will result in the securing of tissue for staining as well as for culture.

PRINCIPLES OF MEDIA

The purposes and descriptions of media for bacteriology, virology, mycology, and parasitology are provided in chapters 21, 81, 117, and 134, respectively. This chapter focuses on the principles of media used mainly for the isolation of bacteria.

General Considerations

Many components optimize the growth of microorganisms on media. The basic requirements for a medium include a nutrient source, a solidifying agent (for solid media), a specific pH, and any number of specific additives. The nutritional requirements of most microorganisms are complex. Most utilize an array of nutrient sources including nitrogen, carbon, inorganic salts, minerals, and other diverse substances. While some organisms can utilize a very simple medium such as nitrate or ammonia, most require protein hydrolysates or peptones. Peptones are the most common nutrient additives in media and are water-soluble materials prepared by enzymatic or acid hydrolysis of animal tissues or products and vegetable substances. Meat infusions were the initial growth-supporting components in media, but because they are cumbersome to prepare and lack batch-to-batch consistency, they are not truly defined. However, meat infusions are still used in some media. Agar serves as the solidifying agent and is derived from red seaweed. The acidity or alkalinity (pH) of a medium is important because microorganisms have strict pH requirements, with most growing in the range of pH neutrality. Components may be added to a medium for purposes of evaluating the pH. These include dyes that change color at a specific pH secondary to the production of acid or alkaline by-products by the organism and buffers that allow determination of the hydrogen ion concentration. Other selective agents, such as antibiotics, dyes, and other nutrients, can be incorporated

TABLE 3 Fluorescent staining methods

Fluorescent stain	Application	Principle	Time required	Advantages	Disadvantages
Acridine orange stain (8, 11)	Detection of bacteria in blood cultures, CSF,[a] buffy coats, and corneal scrapings; detection of fungi	Fluorochrome intercalates nucleic acid in both native and denatured states; bacterial and fungal DNA fluoresces orange and mammalian DNA fluoresces green with UV excitation	3 min	Sensitive method of detection in blood, CSF, and tissues; detects organisms difficult to see with Gram stain and low numbers of organisms such as *Bartonella* and *Helicobacter;* thick or bloody smears can be used; can Gram stain same slide to confirm result	Cellular specimens with an abundance of DNA may be difficult to interpret; interobserver variability seen with some specimens (e.g., buffy coat smears)
Auramine-rhodamine stain	Detection of mycobacteria and other acid-fast organisms	Nonspecific fluorochromes that bind to mycolic acids and resist decolorization by acid-alcohol (identical to acid-fast stains); organisms fluoresce orange-yellow with UV excitation and use of the secondary potassium permanganate stain	30 min	Allows rapid screening of specimens at lower magnification; is more sensitive than other acid-fast stains; can use other acid-fast stains on the same slide to confirm suspicious organisms	Low numbers of organisms may be difficult to confirm with routine acid-fast procedures
Calcofluor white stain (7)	Detection of fungi, *P. jiroveci* cysts, and parasites, such as microsporidia and cysts of free-living amebae in clinical specimens	Nonspecific fluorochrome that binds to cellulose and chitin. Organisms fluoresce blue-white or green if a barrier filter is used. Optimal fluorescence occurs with UV and blue-violet excitation. For eye protection, barrier filters of 510–530 nm are recommended.	KOH clearing if necessary, and then immediate viewing after adding stain	Can be mixed with KOH to clear specimens such as hair, skin, and nails for dermatophytes; rapid, sensitive, and inexpensive screening test. Smears can be restained with conventional stains such as Gram stain.	Difficulty in interpretation with cellular specimens that contain fluorescing collagen and elastic fibers. Variable fluorescence is seen with darkly pigmented fungi. Use with Evans blue helps to suppress green background fluorescence and imparts a red color when blue-violet excitation is used.
Fluorescein-conjugated antibodies and PNA probes	Identification of specific organisms in clinical material; used to confirm specific organism identification from cultures (CMV,[b] *Erhlichia, Francisella*) and growth from blood culture broth (yeast and bacteria)	Monoclonal antibodies or probes bound to the fluorochrome FITC to detect antigens or nucleic acids for specific pathogens in clinical specimens; pathogens fluoresce apple green or red depending on barrier filters used	1–3 h	Rapid and specific organism identification; especially useful for commonly occurring blood culture isolates, specifically staphylococci, *Candida albicans,* enterococci, *Bordetella, Legionella, Pneumocystis*, and viruses.	Adequate clinical specimen must be submitted if done with direct specimen

[a] CSF, cerebrospinal fluid.
[b] CMV, cytomegalovirus.

into media for the isolation of a particular organism. Other considerations that allow optimal microorganism growth include the incubation temperature and the gas in the growth environment. Most clinically significant organisms are mesophiles, which means that they will grow optimally at temperatures of between 25 and 40°C. In addition, most species grow in ambient air, but others require CO_2 or the total removal of O_2. Liquid media require all of the ingredients and conditions described above but lack a solidifying agent (e.g., agar).

Medium Types

Transport Media and Preservatives

Transport media are used in the collection and transport of specimens and were devised initially because fastidious organisms would not survive transport from the bedside to inoculation in the laboratory. Now transport media are even more crucial in providing an appropriate environment for specimens as more and more specimens are transported from distant sites and for long periods.

Generally, bacterial transport media come packaged in a plastic tube sleeve or in tubes with a small amount of liquid medium. A single or a double swab attached to a cap is used for collection of the specimen, which is then placed into the tube and secured. The cap allows the swab(s) to be easily removed from the transport medium for inoculation. The swab component and shaft material, such as Dacron versus rayon and aluminum versus calcium alginate, respectively, may be significant depending on the organism targeted for isolation or the assay system used. Generally, transport media provide a nonnutrient source that sustains the viability of both aerobic and anaerobic organisms without allowing significant growth. Most transport media have specific ingredients that accomplish these goals. These include a small amount of agar or sponge to allow a solid base to which the organisms can attach and to reduce desiccation, an indicator oxidation-reduction agent which shows when oxidation has occurred, and reagents that maintain the pH. Other additives allow the survival of specific organisms, such as sodium thioglycolate for anaerobes or charcoal, which reduce the effects of toxic metabolic products and which subsequently enhance the growth of the pathogens. Other ingredients are added for specific purposes and are noted below. Transport media generally allow stability of specimens for 6 to 12 h at ambient temperatures and should not be refrigerated because some organisms do not survive at colder temperatures. When the specimen arrives in the laboratory, it should be plated as soon as possible. The material in the swab is extracted and placed onto the medium of choice. Care should be taken to inoculate the material from the swab itself when it is extracted from the tube and not the material that may have been in the swab system, such as the gel.

Viruses and chlamydiae have different transport requirements. Viral and *Chlamydia* transport media are designed to provide an isotonic solution containing protein, antibiotics to control bacteria, and a buffer to control pH. The media come in polypropylene centrifuge tubes that contain approximately 1 to 3 ml of medium, 1-dram freezer vials with up to 2 ml of medium, and a tube and swab form with a gel base. While separate transport media for viral pathogens and *Chlamydia* exist, more often laboratories use systems that can accomplish the culture of both of these types of pathogens as well as the *Ureaplasma* and *Mycoplasma* groups. The antibiotics used in these media are not inhibitory to the bacterial pathogens desired or viruses.

Parasitology transport media are actually preservatives meant to maintain the integrity of the parasite and not to maintain viability.

General-Purpose, Enriched, Selective, Differential, and Specialized Media

General purpose, enriched, selective, differential, and specialized are the general categories of media that are used for growth and cultivation of microorganisms. Each type of medium is not exclusive; e.g., many selective media are also differential media. An example is MacConkey agar, which is selective for gram-negative organisms but which is also differential in that it is used to identify lactose-fermenting organisms. Descriptions of each type of medium follow.

General Purpose

General-purpose media are those media capable of detecting most aerobic and facultatively anaerobic organisms. An example of a medium in this category is sheep blood agar, which is commonly used for the general isolation of organisms directly from primary specimens inoculated onto the agar.

Enriched

Enriched media are media that allow fastidious organisms to grow. These organisms may not grow well on general media. An example in this category is the growth of *Francisella* on chocolate agar because the agar is supplemented with cysteine.

Selective

Selective media are media that contain additives that enhance the detection of the desired organism by inhibiting other organisms. Most commonly, selection is attained with a dye or with the addition of an antibiotic. Examples include MacConkey agar that contains crystal violet, which inhibits most gram-positive organisms, and colistin-nalidixic acid agar, which contains antibiotics that inhibit most gram-negative organisms. The effectiveness of selective media varies and is not always complete. Thus, small colonies of partially inhibited organisms may be present on the media. In addition, the ingredients that make media highly selective may actually inhibit the desired pathogen, e.g., a vancomycin-supplemented medium that is selective for *Neisseria gonorrhoeae* (gonococci [GC]) may inhibit some strains of GC.

Differential

Differential media aid in the presumptive identification of organisms based on the organisms' appearance on the media. This can be demonstrated by colony color or a precipitate that forms on or around the colony. Examples include the agars used for the isolation of enteric pathogens (e.g., MacConkey, Hektoen enteric, and xylose-lactose-desoxycholate agars). In the case of MacConkey agar, lactose fermentation by the organism and exhibition of a bright pink magenta color by the colony mean that the organism is utilizing lactose. Further enhancements of differential media exist, such as specific chromogenic media that are also very selective, and allow groups of organisms within a genus to be more clearly recognized than with use of the usual primary media alone. See chromogenic media in chapter 21 for specific descriptions.

Specialized

Specialized media are those media developed with additives for the purpose of isolating a specific pathogen. Such media include buffered charcoal yeast extract medium (BCYE), which is designed for the purpose of isolating *Legionella* species. Specialized media typically include nutrients that the specific pathogen requires but that are not found in general-purpose or enriched media. In the case of BCYE, cysteine and ferric pyrophosphate are provided. Other examples include virology culture media with essential amino acids that are required for the maintenance of cell lines and growth of viruses and anaerobic media that typically include vitamin K, hemin, and reducing agents.

Susceptibility Media

Susceptibility testing media have well-defined formulations designed to support the growth of the most common bacterial

and fungal isolates. Hydrolysates of casein and beef extract with low concentrations of thymidine and thymine are used because excess amounts of thymine and thymidine can make organisms appear to be more susceptible to sulfonamides and trimethoprim. Adjustment of small ion concentrations may be necessary for correct susceptibility reporting. Calcium and magnesium ion concentrations are adjusted to allow correct interpretations of *Pseudomonas* susceptibility results with the aminoglycosides, colistin, and tetracycline.

Mycobacteriology Media

Most of the nonselective media used for the isolation and cultivation of mycobacteria are enriched media that are egg based or agar based and that contain additives with fatty acids essential for growth of the organism. Common additives include albumin, which protects the tubercle bacilli from toxic agents; inorganic salts essential for growth; glycerol as a carbon and an energy source; and malachite green, which partially inhibits contaminating bacteria other than mycobacteria and acts as a pH indicator. Because malachite green is a photosensitive dye, a medium with this ingredient should be stored in the dark. Mycobacteria prefer moisture, and tubes of media should be tightly sealed before inoculation. Liquid media are used for the optimum recovery of mycobacteria and for decreasing the time to detection of the organisms. The broths are also used to subculture stock strains and for other tests, such as susceptibility testing and tests with DNA probes.

Anaerobic Media

All general-purpose nonselective anaerobic blood agar media have similar formulations and include peptones, yeast extract, vitamin K (which is required for some *Porphyromonas* spp.), hemin (which enhances the growth of some *Bacteroides* spp.), 5% sheep blood (which allows for the detection of hemolysis), and reducing agents. All allow the isolation and cultivation of both strictly anaerobic and fastidiously anaerobic organisms. The difference in each of the media is the small variation in the peptones used and the inclusion of dextrose in some media as an energy source. These differences may make some of the media better for gram-negative or gram-positive organisms with slight variations in colonial characteristics. Additives used with some of these media allow the media to have both selective and differential properties. Enrichment broths are available in a number of formulations but are increasingly less commonly used for the routine isolation of anaerobes. It should be noted that media are available that are prepared and stored in a prereduced atmosphere specifically for optimization of anaerobic isolation (prereduced anaerobically sterile [PRAS] media).

Preparation of Media

When preparing media from dehydrated materials, the manufacturers' instructions should be followed closely. Chemically cleaned glassware and distilled and/or demineralized water should always be used unless specified otherwise. Care in terms of accuracy should be taken when measuring liquid and dry ingredients. Mixing and solubilization of ingredients are typically done on hot plates, with magnetic stir bars placed in the bottom of the flask or beaker. Excessive heating should be avoided. Autoclaving or filtration sterilizes the media. Autoclaving of volumes of up to 500 ml at 121°C for 15 min is adequate. Larger volumes may require up to 20 to 30 min. The stir bars should be removed before sterilization. For quality control of autoclaving, specialized tape or paper is placed on the medium flask at the time of autoclaving. Enrichments such as blood and other labile additives such as filter-sterilized antibiotics should be added aseptically after the base medium has cooled.

Quality Control

The Clinical and Laboratory Standards Institute has specific requirements for quality assurance of commercially prepared media, which have been updated and documented in standard M22-A3 (3). However, these recommendations do not apply to all media. In addition, any medium that is prepared by the user requires its own specific quality control. Storage of media should be in the dark at 2 to 8°C. Storage in the dark is preferred because additives, such as dyes, will deteriorate faster in the light. This is especially true for chromogenic media that rely heavily on color differentiation between organisms in the same genus. The date that the medium was received in the laboratory and the medium expiration date should be marked and easily visible when stored. Media should be in use only up to the expiration date. Prolonged or incorrect storage of media, including transport media, can lead to desiccation of the medium and to changes in the composition of nutrients and selective agents, and it can compromise organism isolation.

Manual and Automated Systems for Detection and Identification of Microorganisms*

KAREN C. CARROLL AND MELVIN P. WEINSTEIN

15

The last two decades have seen a trend away from the use of conventional, tube-based methods for the detection and identification of microorganisms and toward the use of instrument-based methods. Automation in microbiology first occurred in the early 1970s with the introduction of the first semiautomated blood culture instruments, followed by the early instrumented systems for identification and susceptibility testing of bacteria. In the 1980s, an instrumented screening device for the detection of bacteriuria was introduced. The trend toward automation has accelerated with the introduction and development of automated continuous-monitoring blood culture systems (CMBCSs) and more rapid systems for antimicrobial identification and susceptibility testing. Improvements to these instruments have included expansion of databases, implementation of combinations of technologies to decrease time to detection, and significant improvements in expert computer systems that provide laboratories with the ability to interpret, store, and manipulate data. Commercially available platforms have made improvements in their databases to incorporate or improve identification of category A and B potential agents of bioterrorism. Since the last edition of this manual, few publications have appeared evaluating these conventional methods, with the exception of the literature on a new automated identification and susceptibility testing instrument (Phoenix; BD Diagnostics, Sparks, Md.) (16, 50, 66). More has been published on susceptibility testing performance of some of these instruments (reviewed in chapter 17).

Progress has been made in the development of molecular platforms that provide real-time and simultaneous detection of multiple pathogens, most of which target viruses and agents of sexually transmitted diseases. However, it is unlikely that molecular technologies will completely replace the less expensive phenotypic methods in the short term. Regardless of whether a laboratory is using manual, automated, or molecular methods, the fundamental principles that provide the scientific bases for both detection and identification of microorganisms remain important.

This chapter reviews the systems used for the detection of microorganisms in clinical specimens, with primary emphasis on the underlying principles and systems for blood cultures, systems for microorganism identification, and criteria for assessing and selecting a system. For an expanded review and discussion of the blood culture issues, the reader is referred to more detailed reviews (5, 48, 63, 67). Discussions relevant to systems for antimicrobial susceptibility testing (chapter 17), immunoassays (chapter 18), molecular diagnostics (chapter 16), and rapid detection of mycobacteria (chapter 36) are found elsewhere in this Manual.

BLOOD CULTURE DETECTION SYSTEMS

Development and introduction of automated CMBCSs during the 1990s accelerated the trend away from conventional manual methods. However, the fundamental principles that provide the scientific basis for modern blood culture methods remain important, even with the new, automated technologies. The key variables will be reviewed briefly. For expanded review and discussion of these issues, the reader is referred to more detailed treatises (5, 55, 74).

Technical Variables That Affect Blood Cultures

Volume of Blood Cultured

The volume of blood obtained for culture is one of the most important variables in the detection of bloodstream infections (BSIs) (12, 56, 87). It has been well documented that BSIs in adults may be characterized by fewer than a single microorganism per 10 ml of blood. Studies have shown a direct relationship between the diagnostic yield of blood cultures and the volume of blood obtained for culture (12, 23, 30, 52, 69). Consensus guidelines recommend obtaining 20 to 30 ml per culture from adults (5). This cannot be accomplished with the use of a single blood culture set, and laboratories that accept single sets should discourage this practice (see discussion below). The importance of volume for detecting BSIs in infants and small children has become evident in recent years as well. Isaacman et al. (31) showed that the detection rate with 6 ml of blood was double that with 2 ml of blood from the same blood sample. Kellogg et al. (32) documented that low-level bacteremia occurs in children and recommended that

* This chapter contains information presented in chapter 14 by Caroline Mohr O'Hara, Melvin P. Weinstein, and J. Michael Miller in the eighth edition of this Manual.

4 to 4.5% of a child's blood volume be obtained for optimal detection of BSIs in this patient population. With tiny, premature infants, however, it may be impossible to obtain the volumes recommended by Kellogg et al. (32).

Culture Medium

No one medium or commercial product is capable of optimally detecting all microorganisms. Decisions by microbiologists as to medium formulations should be based on data from well-controlled field trials in which large numbers of cultures were assessed. The most widely used medium for blood cultures is soybean casein digest broth; brain heart infusion (BHI) broth may be equivalent or even superior for the recovery of yeasts and some bacteria (88).

Ratio of Blood to Broth

A number of substances in human blood are capable of inhibiting microbial growth, including leukocytes, complement, and lysozyme. Moreover, nearly one-third of patients from whom blood samples were obtained in a recent study (84) already were receiving antimicrobials at the time the blood samples were obtained. Dilution of blood in broth by a ratio of at least 1:5 has been shown to enhance detection (3, 58), probably by reducing the concentrations of the natural inhibitory substances and antimicrobial agents to subinhibitory levels. Some commercial media, notably those containing resins, may have blood-to-broth ratios of less than 1:5; however, these media have been shown to have sufficiently improved recovery rates such that the suboptimal blood-to-broth ratios are overcome.

Some manufacturers have marketed "pediatric" blood culture bottles with decreased volumes of broth medium designed to maintain a blood-to-broth ratio of 1:5 to 1:10 when only small volumes of blood can be obtained from young children. The broth media in these bottles are supplemented with X and V factors to enhance the yield of *Haemophilus influenzae* and have reduced concentrations of sodium polyanetholsulfonate (SPS) for improved detection of *Neisseria* species. Although these bottles have become popular, there are few objective data to indicate that they provide higher yields or detect microorganisms earlier than conventional blood culture bottles. Moreover, with the availability of the *H. influenzae* type b vaccine, *H. influenzae* bacteremia in children is now rare. Thus, whether the use of pediatric blood culture bottles is truly necessary remains an unanswered question for clinical microbiology laboratories.

Anticoagulants

The yield from blood cultures may be reduced if the blood clots. Therefore, all broth-based blood culture medium formulations contain anticoagulants, the most common being SPS in concentrations of 0.025 to 0.050%. In addition to inhibiting clotting, SPS inhibits lysozyme, inactivates aminoglycoside antibiotics, and inhibits parts of the complement cascade and phagocytosis. SPS has some negative attributes, albeit fewer than some other anticoagulants used in blood culture media over the years. SPS has been shown to inhibit the growth of *Neisseria gonorrhoeae, Neisseria meningitidis, Gardnerella vaginalis, Streptobacillus moniliformis, Peptostreptococcus anaerobius, Francisella tularensis,* and *Moraxella catarrhalis* (19, 54, 55, 65). In general, higher concentrations of SPS have enhanced the growth of gram-positive cocci but inhibited the growth of gram-negative bacteria. Although SPS has its limitations, no other anticoagulant has been shown to be superior.

Neutralization and Inactivation of Antimicrobials

Because many patients are already being treated with antimicrobials before blood samples are obtained (84), potentially reducing test sensitivity, some manufacturers market media designed to bind, absorb, or inactivate these agents. Some medium formulations include additives designed to bind or absorb antimicrobial agents, thereby enhancing the yield of microorganisms. The BACTEC blood culture system (BD Diagnostics) utilizes antibiotic-binding resins on tiny glass beads, whereas the BacT/Alert blood culture system (bioMerieux Inc., Durham, N.C.) uses activated charcoal. In both systems, culture media containing these additives have been shown to have improved abilities to detect microorganisms overall, especially staphylococci and yeasts, and improved yields for patients receiving theoretically effective antimicrobial therapy (41) compared to medium formulations without the additives (15, 63, 77, 88). More coagulase-negative staphylococcal contaminants may be detected in the media containing the resins and activated charcoal than in the media without these additives (77, 88).

Atmosphere of Incubation

Traditional blood cultures have consisted of two blood culture bottles, one designed to support the growth of aerobes and facultative anaerobic bacteria and the other designed to support obligate anaerobes as well as facultative microorganisms. Aerobic blood culture bottles usually contain an ambient atmosphere in the bottle headspace to which various amounts of carbon dioxide have been added to support the growth of certain microorganisms. Anaerobic blood culture bottles usually contain carbon dioxide and nitrogen but no oxygen in the bottle headspace. With the decrease in the proportion of bacteremias caused by obligate anaerobes in recent decades (5, 17, 38, 48), some investigators have concluded that the routine use of anaerobic blood culture bottles in a culture set is not necessary (46, 48, 61, 91). Rather, use of a second aerobic bottle is recommended to enhance the detection of the more common aerobic and facultative organisms and yeasts and to ensure that at least 20 ml of blood from adults will be cultured. An anaerobic bottle would be used only selectively for patients deemed at high risk for anaerobic bacteremia. However, a recent study using media with activated charcoal that compared two aerobic bottles with an aerobic and anaerobic pair of bottles found improved overall detection of microorganisms with the aerobic-anaerobic pair (57). A potential limitation of the study was the presence of few fungemias in the study population. Whether to use only aerobic bottles or to use a more traditional aerobic and anaerobic pair of bottles remains controversial (5, 74).

Bottle Agitation

Several studies have assessed the value of bottle agitation, documenting an enhanced yield and improved speed of detection of positive blood cultures from aerobic bottles (27, 53, 75). All of the commercially available CMBCSs agitate aerobic bottles, and most agitate anaerobic bottles as well.

Subcultures

The processing of conventional manual blood cultures includes Gram staining and blind subculturing of the aerobic culture bottles, usually after the first overnight incubation and, if the cultures remain negative, at the end of the

incubation period. Blind subcultures of the anaerobic culture bottles in manual systems and of all bottles in instrumented systems are unnecessary (5).

Length of Incubation

In routine situations, manual blood cultures need not be incubated for more than 7 days. Studies of the instrumented blood culture systems have shown that 5 days of incubation is sufficient for the detection of most pathogens (12, 20, 25, 39, 86). Some investigators have suggested that incubation periods of 4 days (14) and even 3 days (8, 24) may be sufficient for certain systems and media. However, the current standard remains a 5-day duration of incubation. Although it has been common to extend the incubation period when infective endocarditis is suspected, Washington (71) noted that this practice rarely increases the ability to detect the etiologic agent. A recent study from the Mayo Clinic, using a CMBCS, demonstrated that 99.5% of nonendocarditis BSIs and 100% of endocarditis episodes were detected within the standard 5-day incubation period (12). Similarly, in the best medium formulations of the modern CMBCSs, extended incubation periods appear not to be necessary for the detection of the most common *Candida* species. However, published data for *Candida glabrata* and *Cryptococcus neoformans* are lacking.

Clinical Practices That Affect Blood Cultures

Skin Antisepsis and Prevention of Contamination

The probability that a positive blood culture represents infection rather than contamination is a function of the effectiveness of skin antisepsis at the time of the venipuncture or, when blood is obtained from an indwelling device, a function of the effectiveness of antisepsis of that device. Growth of blood culture contaminants, especially coagulase-negative staphylococci, which are the most common etiologic agents of catheter-associated bacteremia as well as the most common blood culture contaminants, not only may be confusing to clinicians but also is associated with substantial expense (6). Thus, reducing contamination is a key issue for both the microbiology laboratory and the health care system in general. For many years, contamination rates (number of contaminated blood culture sets/total number of blood culture sets obtained) of $<3\%$ were considered the benchmark for good blood culture practices. A 1998 report from the College of American Pathologists of 640 institutions determined that the median contamination rate was 2.5% (60). In that study, the contamination rate for laboratories in the 10th percentile was 5.4% and that for laboratories in the 90th percentile was 0.9%.

The traditional recommendation for skin preparation has been the application of 70% alcohol followed by either povidone-iodine or 2% iodine tincture. Povidone-iodine preparations require 1.5 to 2 min of contact time for maximum antiseptic effect (74), whereas iodine tincture requires 0.5 min (34). Two studies have documented lower contamination rates with the use of iodine tincture rather than with an iodophor (37, 68). Recently, chlorhexidine has been recommended for use prior to venipuncture. One study demonstrated lower contamination rates with this preparation than with an iodophor (43). Another report compared chlorhexidine tincture with iodine tincture and found equivalent contamination rates (4).

Regardless of the type of skin preparation used, meticulous care and an aseptic technique are required to reduce contamination. Studies have demonstrated that a dedicated blood culture team and/or phlebotomists are less likely than other health care workers to contaminate blood cultures (73; R. B. Sivadas, B. Vazirani, S. Mirrett, and M. P. Weinstein, *Abstr. 101st Gen. Meet. Am. Soc. Microbiol.,* abstr. C10, 2001). Lastly, blood samples for culture obtained by peripheral venipuncture are less likely than those obtained from indwelling catheters to grow contaminating microorganisms (11, 90; Sivadas et al., *Abstr. 101st Gen. Meet. Am. Soc. Microbiol.*).

Number of Blood Samples Cultured

Studies with manual blood culture systems into which 20 ml of blood was inoculated for culture provided good evidence that culture of two or three blood samples will detect virtually all ($\geq$99%) BSIs in adults (70, 83). A recent study using the same volume of blood obtained from adults and inoculated into one of the CMBCSs reported a nonendocarditis BSI detection rate of 96% with culture of three blood samples (12).

Culture of a single blood sample should be discouraged if not forbidden altogether (2). A single sample will provide insufficient blood volume for detection of some infections. Moreover, the growth of a coagulase-negative staphylococcus, a viridans group streptococcus, or a diphtheroid in a single blood culture most often represents contamination but may represent a clinically important infection (84). Interpretation of the positive result under these circumstances is very difficult.

Timing of Blood Cultures

Few studies have systematically addressed the timing of collection of blood for culture. Although bacteremia is associated with rigors (7), this physiologic event usually precedes fever, and it is the latter that most often triggers the request for a blood culture. Some authorities have recommended that blood for culture be drawn at arbitrary intervals (67). However, in a retrospective study, Li et al. (35) showed no difference in yields whether blood samples obtained during a 24-h period were drawn simultaneously or at spaced intervals. The clinician and microbiologist should be guided by the patient's clinical status and suspected diagnosis. With a septic, unstable patient, blood samples should be cultured promptly so that therapy can be instituted. Conversely, if subacute infective endocarditis is suspected in an otherwise stable patient, several blood samples can be obtained at spaced intervals.

BLOOD CULTURE SYSTEMS

Manual Systems

Only three manual blood culture systems are currently marketed in the United States: Septi-Chek (BD Diagnostics), Signal (Remel Inc., Lenexa, Kans.), and Isolator (Wampole Laboratories, Cranbury, N.J.). The Septi-Chek system originally was developed as a labor-saving alternative to conventional blood cultures, which had to be subcultured manually. It consists of a conventional aerobic broth blood culture bottle to which is attached an agar-coated paddle in a clear plastic cylinder, creating a biphasic system similar to that of the classic Castaneda bottle. After blood is inoculated into the bottle, the paddle is attached and the blood-broth mixture is inverted to flood the agar, inoculating onto the agar any microorganisms that may be present. A companion anaerobic bottle that does not use the paddle

attachment, which is permeable to oxygen, can be used as well and processed manually. The bottles are incubated with or without agitation and inspected macroscopically for evidence of microbial growth once or twice daily. The agar paddle can be removed from its cylinder for better inspection. Following each examination of the agar paddle, the bottle is inverted, in effect repeating the subculture. There are several Septi-Chek broth medium formulations. The paddles contain three agars: chocolate, MacConkey, and malt. The Septi-Chek system performed well in published clinical trials (10, 51, 80–82).

The Signal is a one-bottle manual blood culture system that also was developed as a labor-saving alternative to conventional manual blood cultures. After blood is inoculated into the bottle in a conventional fashion, a clear plastic signal device is attached to the top of the bottle. An outer plastic sleeve that slides over the neck of the bottle anchors this signal device. Within the device is a long needle that extends beneath the level of the blood-broth mixture. If microbial growth occurs in the bottle, gases are produced in the bottle headspace. This creates increased atmospheric pressure, which forces some of the blood-broth mixture through the needle and into the clear plastic signal cylinder, where it can be detected visually by the microbiologist who inspects the bottles daily. Only one medium formulation has been marketed. In published controlled clinical trials done in the United States, the Signal system performed less well than its competitors (47, 75, 76, 78).

The Isolator blood culture system is unique as the only commercial system that does not utilize a broth culture medium. Rather, it is based on the principle of lysis-centrifugation. Blood is inoculated into an Isolator tube that contains a lysing solution consisting of saponin, the anticoagulant EDTA, and a fluorocarbon that acts as a cushion during the centrifugation step of blood processing. After the blood is lysed and centrifuged, the tube is placed into the Isostat system, which applies a disposable cap that penetrates the rubber stopper, permitting access to the contents of the tube. The disposable supernatant pipette is used to remove the supernatant, and the concentrate pipette is used to transfer the sediment from the tube directly to culture media that will support the growth of the pathogens of which detection is desired. The Isolator can be used for detection of routine bacterial pathogens; however, it has been reported to have a reduced ability to detect anaerobes, *Haemophilus* species, and pneumococci if specimens are not processed within 8 h (28, 29, 33, 72). The Isolator is an excellent system for detecting yeasts and dimorphic fungi, mycobacteria, and *Bartonella* species (9). The system is labor-intensive compared to the newer automated CMBCSs, especially during the initial processing of specimens in the laboratory.

Instrumented Systems

All of the commercially available CMBCSs have a number of characteristics in common. Some of the relevant information pertaining to these systems is shown in Table 1.

The CMBCSs have been adapted or modified so that they can be used to detect the growth of mycobacteria; additional information is provided in chapter 36 of this Manual. The CMBCSs have also been used, as have manual and earlier automated systems, to detect the growth of microorganisms from other normally sterile body fluids, for example, peritoneal fluid (22, 62).

The BacT/Alert system (bioMerieux Inc.) was the first CMBCS and was marketed in 1990; the system was updated in 1999 as the BacT/Alert 3D, which has a smaller instrument footprint than the original and a computer touch screen to ease technologist manipulations. Each incubator module has a capacity of 240 culture bottles. At the base of each bottle is a colorimetric CO_2 sensor that is separated from the blood-broth mixture by a CO_2-semipermeable membrane that monitors the amount of CO_2 in the bottle. At the base of each bottle's holding cell in the incubator unit are light-emitting and light-sensing diodes. With microbial

TABLE 1 Commercially available continuous-monitoring blood culture systems[a]

System (manufacturer)	Method for detecting growth	Capacity per module (no. of bottles)	Maximum no. of modules (no. of bottles) per system	Test cycle (min)	Agitation type/speed (no. of back-and-forth strokes/min)	Dimensions (cm)
BacT/Alert 240 (bioMerieux Inc.)	CO_2, colorimetric	240	6 (1,440)	10	Rocking/34	175 by 87 by 66
BacT/Alert 120	CO_2, colorimetric	120	6 (720)	10	Rocking/34	87 by 87 by 55
BacT/Alert 3D	CO_2, colorimetric	240	12 (2,880)	10	Rocking/34	90 by 49 by 61
BACTEC 9240 (BD Diagnostics)	CO_2, O_2,[b] fluorescence	240	5 (1,200)/20 (4,800)/ 50 (12,000)[c]	10	Rocking/30	93 by 128 by 55
BACTEC 9120	CO_2, O_2,[b] fluorescence	120	5 (600)/20 (2,400)/ 50 (6,000)[c]	10	Rocking/30	61 by 129 by 56
BACTEC 9050	CO_2, O_2,[b] fluorescence	50	1 (50)	10	Continuous rotation	61 by 72 by 65
VersaTREK (TREK Diagnostic Systems)	Manometric	96–240	6 (1,440)	12 (aerobic), 24 (anaerobic)	Vortexing, aerobic only	40 by 52 by 36
VersaTREK	Manometric	528	6 (3,168)	12 (aerobic), 24 (anaerobic)	Vortexing, aerobic only	76 by 52 by 31

[b] O_2 detection is for Myco/F-Lytic medium only.
[c] Maximum number of bottles accommodated depends on data management system selected (core, Vision, or Epicenter).

growth and production of CO_2, the bottle's sensor changes color, altering the amount of light reflected. The change in reflectance is measured by the instrument, and the information is transmitted to the instrument's computer. The computer has several algorithms to report the detection of a positive culture that is noted when (i) the reflectance exceeds an arbitrary threshold, (ii) the instrument recognizes a linear increase in the CO_2 level, or (iii) there is a change in the rate of CO_2 production. Several medium formulations are available: (i) standard aerobic (SA) and anaerobic (SN) media that contain 40 ml of supplemented tryptic soy broth (TSB) and accept up to 10 ml of blood; (ii) aerobic FAN (FA) and anaerobic FAN (FN) media that contain 30 and 40 ml, respectively, of peptone-enriched TSB, supplemented with BHI solids, and activated charcoal designed to inactivate or bind antimicrobial agents and other inhibitory substances in the blood; and (iii) a FAN medium with a lower volume (20 ml) of peptone-enriched TSB, supplemented with BHI solids, and activated charcoal marketed for use with pediatric patients and those elderly patients from whom it is difficult to obtain larger volumes of blood. A detailed review of published comparative clinical trials is beyond the scope of this chapter, and more comprehensive reviews can be found elsewhere (57, 79, 89). Overall, the system is equivalent to the other commercially available CMBCSs with regard to the yield and speed of detection of microorganisms (79, 89). BacT/Alert media now are available in clear, shatter-resistant, plastic bottles that have performance characteristics equivalent to those of glass bottles.

The BACTEC 9000 (BD Diagnostics) CMBCS offers three instrument formats. The incubator module for the 9240 instrument holds 240 bottles, versus 120 bottles per module in the 9120 instrument. For small laboratories, the company markets the bench-top 9050 instrument that holds 50 bottles. Similar to the BacT/Alert system, the BACTEC system features a CO_2 sensor at the base of each culture bottle, but unlike BacT/Alert, the BACTEC instrument uses a fluorescence-sensing mechanism to detect the growth of microorganisms. When the amount of CO_2 increases, the concomitant increase in fluorescence is detected by the instrument; the principal detection criteria are a linear increase in fluorescence and an increase in the rate of fluorescence. The BACTEC system has multiple medium formulations: (i) standard aerobic and anaerobic media that contain 40 ml of soybean casein digest broth, (ii) aerobic and anaerobic Plus media that contain 25 ml of soybean casein digest broth plus antibiotic-binding resins on glass beads, (iii) an anaerobic lytic medium that contains 40 ml of soybean casein digest broth plus a lysing agent, (iv) a resin medium formulated for pediatric patients, and (v) a medium designated Myco/F-Lytic designed for improved detection of fungi and mycobacteria but which also supports the growth of bacterial pathogens. All BACTEC bottles accept up to 10 ml of blood, except the pediatric bottle, which accepts up to 5 ml. Published comparative clinical evaluations of the BACTEC 9000 system versus other CMBCSs have demonstrated that the system performs in a fashion relatively equivalent to those of its competitors in terms of both sensitivity and speed of detection of positive cultures (79).

The VersaTREK (TREK Diagnostic Systems) blood culture system uses the same technology as its commercial predecessor, the ESP system, and differs from BacT/Alert and BACTEC 9000 in several ways. In this system, bottles are placed into the instrument and monitored with a transducer for pressure changes within the bottle headspaces as gases (oxygen, hydrogen, nitrogen, and carbon dioxide) are either produced or consumed by metabolizing microorganisms. Aerobic (REDOX 1) bottles are monitored every 12 min, and anaerobic (REDOX 2) bottles are monitored every 24 min. Pressure is plotted against time to yield growth curves, and positive cultures are signaled according to the instrument's proprietary algorithms. Aerobic bottles are agitated by vortexing of the blood-broth mixture with a small, stainless-steel stir bar within each bottle, whereas agitation is accomplished by gentle rocking in the other two systems. Anaerobic bottles are not agitated, whereas anaerobic bottles in the other two systems are agitated in the same manner as their aerobic counterparts. In the VersaTREK system, the basal culture medium is supplemented soy casein-peptone broth in the aerobic bottle and modified proteose-peptone broth in the anaerobic bottle. As of this writing, there are no published comparative clinical evaluations of the VersaTREK system versus either the BacT/Alert or BACTEC 9000 system. The ESP blood culture system, which was marketed by the same manufacturer and which preceded VersaTREK, was shown to compare favorably with BacT/Alert and earlier BACTEC instrument systems in studies where the latter two systems utilized their standard medium formulations (45, 79, 92). However, fewer staphylococci and enteric gram-negative rods were detected by using ESP aerobic bottles than by using BacT/Alert aerobic FAN bottles (14, 45, 92).

Interpretation of Positive Blood Cultures

In most general hospitals, 8 to 14% of blood samples obtained will be positive by culture. Of the isolates in these positive blood cultures, one-half to two-thirds will be isolates that are the causes of bacteremia or fungemia and the remainder will be contaminants or isolates of unknown clinical significance. Thus, interpretation of the clinical significance of positive blood cultures is sometimes a vexing clinical problem. Misinterpretation of positive results can be expensive for both the patient and the institution (6). Several useful criteria may assist in interpretation. These include the identity of the microorganism itself, the presence of more than a single blood culture positive for the same microorganism, and growth of the same microorganism as that found in the blood from another normally sterile site.

Microorganisms that almost always represent true infection when isolated from blood include *Staphylococcus aureus*, *Escherichia coli*, and other members of the family *Enterobacteriaceae, Pseudomonas aeruginosa, Streptococcus pneumoniae,* and *Candida albicans* (84). Isolates from blood that rarely represent true bacteremia include *Corynebacterium* species, *Bacillus* species, and *Propionibacterium* species (84). Coagulase-negative staphylococci are perhaps the most problematic group with regard to interpreting clinical significance, in part because of their ubiquity and also because 12 to 15% of blood isolates are pathogens rather than contaminants (84). The number of positive culture bottles in a blood culture set is not a reliable criterion for decisions regarding the clinical significance of coagulase-negative staphylococci (44; S. J. Peacock, I. C. J. W. Bowler, and D. W. M. Crook, Letter, *Lancet* **346:**191–192, 1995).

A useful interpretive factor is the number of culture sets that are positive relative to the number of sets obtained. If most or all sets are positive for the same microorganism(s),

clinical significance is virtually assured (83). Although, ultimately, it is the physician who must make the final judgment, the microbiologist may provide important guidance regarding the clinical significance of blood isolates.

ORGANISM IDENTIFICATION SYSTEMS

Overview of Methods and Mechanisms of Identification

From the early years of diagnostic methods in microbiology until the 1960s, when advances in microbial identification began to emerge, skill in interpretive judgment and the use of tubed and plated media were the bases of microbial identification. Organisms were identified by what we now refer to as "conventional procedures," which include reactions in tubed media and observation of physical characteristics, such as colony morphology and odor, coupled with the results of Gram staining, agglutination tests, and antimicrobial susceptibility profiles. These conventional procedures eventually defined the genera and species of bacteria and yeasts and became the reference methods by which we confirm the identities of isolates.

The next step in the evolution of identification methods simply miniaturized commonly used biochemical reactions into a more convenient format (26). A system-dependent approach became the industry standard, and it remains the approach upon which most currently used substrate profile systems rely. In a system-dependent methodology, a set of substrates that will allow positive and negative reaction patterns to emerge is carefully selected. These patterns create a metabolic profile that can be compared with an established database profile. In many systems, it is necessary to use different sets of substrates to identify rapidly growing members of the family *Enterobacteriaceae,* slower-growing gram-negative non-*Enterobacteriaceae,* gram-positive cocci, gram-negative cocci, and anaerobes. Yeasts require yet another profile set.

Biochemical profiles are determined by the reactions of individual organisms with each of the substrates in the system. The accuracy of the reactions is dependent upon the users' following the directions of the manufacturer regarding inoculum preparation, inoculum density, incubation conditions, and test interpretation. Most systems rely upon one or a combination of several indicators. These include (i) pH changes resulting from utilization of the substrate, (ii) enzymatic reactions that allow the release of a chromogenic or fluorogenic compound, (iii) tetrazolium-based indicators of metabolic activity in the presence of a variety of carbon sources, (iv) detection of volatile or nonvolatile acids, and (v) recognition of visible growth (Table 2). Additional tests for microbial identification that use other means of detecting a positive response for a given substrate may also be included.

Although no formal definition of "rapid" exists for describing the time required for results to be generated, most microbiologists expect rapid systems to provide usable results within 2 to 4 h of incubation. Clearly, the generation times of microbes (usually 30 min or longer) will not allow growth-dependent methods to generate detectable biochemical responses within this time. To overcome the problem of generation times, manufacturers of rapid systems use novel substrates with which preformed enzymes, produced by the organisms to be tested, may react to elicit responses detectable within 2 to 4 h.

Most recently, molecular methods that amplify particular gene targets novel enough to distinguish among genera and species and automated sequencing technology have

TABLE 2 Basis of identification system reactivity

System reactivity	Need for growth	Analyte	Indicator of positive result	Examples of system
pH-based reactions (mostly 15–24 h)	Yes	Carbohydrate utilization	Color change due to pH indicator; carbohydrate utilization = acid pH; protein utilization or release of nitrogen-containing products = alkaline pH	API panels, Crystal panels, Vitek cards, MicroScan conventional panels, Phoenix panels, Sensititre panels
Enzyme profile (mostly 2–4 h)	No	Preformed enzymes	Color change due to chromogen or fluorogen release when colorless complex is hydrolyzed by an appropriate enzyme	MicroScan rapid panels, IDS panels, Crystal panels, Vitek cards, Phoenix panels, Sensititre panels
Carbon source utilization	Yes	Organic products	Color change as a result of metabolic activity transferring electrons to colorless tetrazolium-labeled carbon sources and converting the dye to purple	Biolog
Volatile or nonvolatile acid detection	Yes	Cellular fatty acids	Chromatographic tracing based on detection of end products, which are then compared to a library of known patterns	MIDI
Visual detection of growth	Yes	Various substrates	Turbidity due to growth of organism in the presence of a substrate	API 20C AUX panels

supplanted phenotypic methods for microbial identification for difficult-to-identify microorganisms. These methods have expanded our knowledge of pathogenesis and have expanded and resolved erroneous taxonomic classifications in some cases. Where appropriate throughout this text, more detailed descriptions of molecular methods for detection and identification of pathogens are provided in discussions of particular organism groups. The future will likely see more widespread implementation of these platforms as costs decrease and technologies improve.

System Construction

Microbial identification systems are either manual or automated. Manual methods offer the advantage of using the analytical skills of the technologists for reading and interpreting the tests, whereas automated systems offer a hands-off approach, allowing more technologist time for other duties. For all systems, the backbone of accuracy is the strength and utility of the database. Databases are constructed by using known, clinically relevant strains and include the type strains of most taxa. In some cases, before an organism is added to the database, it is evaluated to confirm its relationship to other strains in the same taxon by using the likelihood fraction. This compares the biochemical characteristics of the new strain to those of a typical culture of the same species.

The number of species included in a database may vary from just a few for some manual assays to over 1,900 for some of the automated systems, particularly if the system is to be used not only in clinical laboratory settings but also in environmental and research settings. For most commercial systems, database maintenance is a continuous process and software upgrades incorporating major taxonomic changes are provided by the manufacturer at intervals of up to every 4 years. Some systems may allow users to make minor changes at the local workstation.

System identifications are supported by algorithm-based decision making that is generally available through a computer. Occasionally, these identifications are compiled into a preprinted index, which is used to manually convert the organism's biochemical profile number into an identification. Bayes's theorem, or modifications of it, is often the basis of algorithm construction from data matrices.

Bayes's theorem is one of the statistical methods that manufacturers use to arrive at an identification of a certain taxon based on the reaction profile produced by the unknown clinical isolate (85). Bayes's theorem considers two important issues in order to arrive at an accurate conclusion: (i) $P(t_i/R)$ is the probability that an organism exhibiting test pattern R belongs to taxon t_i, and (ii) $P(R/t_i)$ is the probability that members of taxon t_i will exhibit test pattern R. Before testing, we make the assumption that an unknown isolate has an equal chance of being any taxon and that each test used to identify the isolate is independent of all other tests. In this case, Bayes's theorem can be written as

$$P\left(t_i / R\right) = \frac{P\left(R / t_i\right)}{\sum_i P\left(R / t_i\right)}$$

By observing reference identification charts derived by conventional biochemical tests, we know the expected pattern of the population of taxon t_i (e.g., *Escherichia coli* is indole positive and citrate negative). R in the formula is the test pattern composed of $R_1, R_2, \ldots R_n$, where R_1 is the result for test 1 and R_2 is the result for test 2, etc., for a given taxon. We can then incorporate the percentages (likelihoods that t_i will exhibit R_1, etc.) into Bayes's theorem to arrive at an accurate taxon.

Clinical microbiologists must not, however, become dependent upon these likelihoods and percentages when interpretive judgment would suggest an alternative taxonomic conclusion. Bacteria often tend to stretch the rules of nomenclature when isolated from clinical specimens, and they may not react as expected in a commercial system, even though a legitimate result is produced (e.g., lactose-positive *Salmonella* spp. or H_2S-positive *Escherichia coli*). The result from the most reliable system can be misleading. In these cases, an alternative method of identification must be used. D'Amato et al. (13) have described how the systems use the database profiles and probability matrices to arrive at an identification of an unknown taxon.

The manufacturers of commercial identification systems rely heavily on input from their customers. Laboratories are encouraged to communicate with the product manufacturer about problems such as unusual organism identifications that develop when a method or system is being used. Manufacturers depend on customer satisfaction, and most are willing to assist in problem solving or in projects that could add strength to their systems. These companies, like their users, are clearly interested in the highest quality of cost-effective patient care. Tables 3 to 8 provide a detailed summary of the available identification systems and compare the features offered by the automated and nonautomated organism identification methods.

CRITERIA FOR SELECTING INSTRUMENTED SYSTEMS

Whether selecting a blood culture system or a method for identification and susceptibility testing, the laboratorian must consider several important issues. Criteria for determining the need for an instrument-based system and its selection are provided in detail in the chapter on laboratory management (chapter 2). Supervisors and managers in the laboratory should make such major decisions carefully and with expert consultation. The process begins by answering key questions about the needs for a new system in the context of laboratory versus patient benefits.

Once these questions are answered, the next step is to begin the search for the right instrument or system to meet the needs of the laboratory and the medical staff. As a general rule, it is best not to be the first to purchase a new system without having seen in the peer-reviewed literature the results of evaluations performed by reputable clinical laboratories. If microbiology journals are unavailable, the manufacturer's representative can be asked to supply peer-reviewed articles about the ability of the system to correctly identify the range of isolates usually seen in your laboratory in the case of identification and susceptibility testing instruments or the results of well-designed, controlled comparative clinical evaluations with large numbers of observations (e.g., more than 5,000 comparisons and more than 500 positive cultures) in the case of blood culture systems. This phase requires demonstrations and conversations regarding space requirements, technical applications, manufacturer issues such as interface capabilities and service contracts, and personnel-related concerns such as sample preparation and throughput.

It is often helpful to visit other laboratories similar to one's own that are using the system under consideration to

[a] Cards are filled automatically but read visually.
[b] BD, BD Diagnostics.
[c] Microbact 12A and 12B are in a strip format; the 12E and 24E have microplate formats.
[d] Also available are combination identification and susceptibility panels: NMIC/ID and PMIC/ID for gram-negative and gram-positive organisms, respectively.
[e] RT, room temperature.
[f] For one sample and three samples, respectively.
[g] Part of the N/F system which also includes the N/F Screen 42P and the N/F GNF screen which are tubed media that are used for the identification of pigmented strains of *Pseudomonas aeruginosa* and the *Pseudomonas fluorescens-Pseudomonas putida* group.
[h] Part of the yeast system which also contains the C/N screen for *Cryptococcus neoformans*; GBE tube for presumptive identification of *Candida albicans* and *C. stellatoidea*, and the SAM tube for differentiation of *Candida albicans* and *Candida stellatoidea.*
[i] Off-line incubation required.

[a] Modified from O'Hara (50) and Stager and Davis (64) and updated in 2005.
[b] Manufacturer: bioMerieux Inc., 100 Rodolphe St., Durham, NC 27712. Phone: (800) 682-2666. http://www.bioMerieux.com.
[c] A compact model of this instrument (capacity 30/60) was released in 2005. It uses the same cards as Vitek 2.
[d] Manufacturer: Dade Behring, MicroScan, Inc., 1717 Deerfield Rd., Deerfield, IL 60015. Phone: (847) 267-5300. http://www.dadebehring.com.
[e] Manufacturer: BD Diagnostics, Inc., 1 Becton Drive, Franklin Lakes, NJ 07417. Phone: (201) 847-6800. http://www.bd-com/us/.
[f] Manufacturer: TREK Diagnostic Systems, Inc., 982 Keynote Circle, Suite 6, Cleveland, OH 44131. Phone: (800) 871-8909. http://www.trek.com.
[g] Manufacturer: Biolog, Inc., 21124 Cabot Blvd., Hayward, CA 94545. Phone: (510) 785-2564. E-mail: info@biolog.com.
[h] Manufacturer: MIDI, 125 Sandy Dr., Newark, DE 19713. Phone: (800) 276-8068.
[i] Based upon whether the rapid or standard method is used.
[j] Species in database indicates the groups, genera, or species identified.
[k] Conventional identification panel.
[l] Fluorogenic identification panel.
[m] NA, not applicable.
[n] U.S. clinical database (veterinary database not included).
[o] Although these panels have off-line incubation, they use the Vitek filling module for inoculation and the data management system for generation of identification.
[p] RT, room temperature.
[q] All rapid identification panels.
[r] DMS, data management system.

ask if they like the system, whether they would buy it again, how much downtime they have experienced, whether the service from the manufacturer has been acceptable, and whether the system has been mechanically reliable.

The laboratory should select a system that has been fully evaluated and whose accuracy exceeds 90% in its overall ability to identify common and uncommon bacteria normally seen in your hospital or laboratory. The system should be able to identify commonly isolated organisms with at least 95% accuracy compared with conventional methods.

The accuracy of antimicrobial susceptibility testing for combination panels is as important as the accuracy of identification, perhaps more so. Chapter 17 of this Manual discusses the issues involved in instrument susceptibility test methods.

EVALUATING AN INSTRUMENT OR SYSTEM

Several references provide useful information on the approach to evaluation, verification, and validation of kits, assays, and instruments in the clinical laboratory (18, 40, 42, 49, 64). Anytime an identification system is added to the laboratory, it is necessary to document that the system performs as described by the manufacturer. The first evidence of acceptable performance should be found in published reports by other laboratories that have evaluated the system in a sound, scientific manner (64). The next evidence of acceptable performance by a new identification instrument should be in-laboratory verification of performance by the purchasing laboratory. Verification is the documentation of test accuracy in the laboratory where the instrument will be used (40). The Clinical Laboratory Improvement Amendments of 1988 (21) specify the conditions for systems placed into service (see chapter 2).

Smaller laboratories will have fewer resources than larger laboratories for verification of the accuracy of an identification system. Laboratory size, however, has no bearing on the need to ensure the accuracies of laboratory identification methods and of the work performed by a laboratory in support of patient care. The role of verification by the purchasing laboratory should be to ensure that the personnel using the system can make it perform at the levels of accuracy already documented by the manufacturer and published in the literature. The laboratorian should expect a level of 95% agreement with the existing system or reference method and accept, in the final analysis, no less than 90% agreement. This takes into account the fact that the new system may be more accurate than the old one.

As of early 1998, the Food and Drug Administration (FDA) no longer does premarket [510(K)] evaluations to "clear" automated or manual phenotypic identification systems, nor does it receive or approve quality control protocols from these devices to meet the 1988 Clinical Laboratory Improvement Amendment requirements. Laboratorians must be aware that the identification component of the new or modified system that they are using is not cleared by the FDA because this approval is no longer required. This makes it even more important for laboratorians to search the literature for valid evaluations of their chosen instrument and to conduct their own in-house validation to make sure that the instrument meets the claims of the manufacturer regarding identification.

[a] Some products give a choice between two or more species; the alternate species is in parentheses.
[b] Includes the ability to differentiate between serogroups O111 and O157.
[c] #, genus designation only.
[d] "Group" indicates *Yersinia* group.

Devices and methods incorporating probes, nucleic acid amplification, and other genetic methods, as well as the susceptibility test component of commercial instruments, will continue to be reviewed by the FDA for clearance.

LIMITATIONS OF MICROORGANISM IDENTIFICATION SYSTEMS

The databases of microbial identification systems must be revised frequently to accommodate newly named species. For example, had *Enterobacter sakazakii* (the yellow-pigmented variant of *Enterobacter cloacae*) not been added to the databases of these instruments, the clinical correlation of *E. sakazakii* with neonatal meningitis would likely be obscured if only *E. cloacae* was reported. Laboratorians must be aware that the accuracy of a system is limited to the claims of the manufacturer for the version of the database currently in the instrument and that the database may be outdated.

The laboratory procedure manual must stipulate the action to be taken when a result is questionable either because of the unusual biochemical profile of the organism or because of the appearance of an unexpected susceptibility profile. A backup method must be used to achieve an accurate identification profile. Otherwise the isolate should be sent to a reference laboratory for analysis.

The biochemical properties of closely related species may make it difficult or impossible for the algorithms of the identification process to separate these organisms accurately; however, the inability to distinguish all species within a genus does not always have a negative effect on patient outcome. For example, accurate identification of all of the newly recognized *Citrobacter* species may not be possible for some of the systems. In this case, the effect on patient outcome because of the inability of a system to recognize *Citrobacter werkmanii* may be negligible, and a simple report of "*Citrobacter* species" may provide adequate data for patient management. Where such distinctions may be critical is in the recognition of a potential agent of bioterrorism. This has implications not only for the individual patient, but also for public health. Although some commercial systems have these organisms in their databases (Table 9), the inability to identify members of some of the genera to the species level (e.g., *Yersinia* spp.) makes these systems unreliable for identification (36). Users of these systems should be aware of the limitations of commercial products with respect to their biopreparedness plans and substitute other tests for presumptive diagnosis per recommended guidelines (1). Suspicious pathogens should be referred to a public health or other reference laboratory for definitive identification. Table 9 summarizes the agents of bioterrorism included in the databases of the more frequently used identification systems.

As pathogens continue to evolve and taxonomic classifications are revised, laboratorians must pay attention to the manufacturer's communications about products, such as letters, notices, or test exclusions regarding the accuracy of their methods, as well as the published literature describing the potential problems encountered by others using these identification systems. Likewise, the user has a responsibility to report continued problems with a system or product where poor performance may lead to adverse patient outcomes.

Molecular Detection and Identification of Microorganisms

FREDERICK S. NOLTE AND ANGELA M. CALIENDO

16

Since the publication of the eighth edition of this Manual, significant changes have occurred in the practice of diagnostic molecular microbiology. Nucleic acid amplification techniques are now commonly used to diagnose infectious diseases and manage patients with infectious diseases. The growth in the number of commercially available test kits and analyte-specific reagents (ASRs) has facilitated the use of this technology in the clinical laboratory. Technological advances in real-time PCR techniques, nucleic acid sequencing, DNA microarrays, and proteomics have invigorated the field and created new opportunities for growth.

Molecular microbiology is the leading area in molecular pathology in terms of both the numbers of tests performed and clinical relevance. This technology has reduced the dependency of the clinical microbiology laboratory on culture-based methods and created new opportunities for the clinical laboratory to affect patient care. This chapter covers amplified and nonamplified probe techniques, postamplification detection and analysis, clinical applications of these techniques, and the special challenges and opportunities that these techniques provide for the clinical laboratory. Molecular methods used in epidemiological investigations are covered in chapter 11. A more comprehensive discussion of many of the topics covered in this chapter is found in Persing et al., *Molecular Microbiology: Diagnostic Principles and Practice* (96).

NONAMPLIFIED NUCLEIC ACID PROBES

Nucleic acid probes are segments of DNA or RNA labeled with radioisotopes, enzymes, or chemiluminescent reporter molecules that can bind to complementary nucleic acid sequences with high degrees of specificity. Although probes can range from 15 to thousands of nucleotides in size, synthetic oligonucleotides of <50 nucleotides are most commonly incorporated into commercial kits. The probes can be designed to identify microorganisms at any taxonomic level. A number of commercially available DNA probes have been developed for direct detection of pathogens in clinical specimens and identification of pathogens after isolation by culture.

The commonly used formats for probe hybridization include liquid-phase, solid-phase, and in situ hybridization. The leading method used in clinical microbiology laboratories is a liquid-phase hybridization protection assay (Gen-Probe, Inc., San Diego, Calif.). In this method, a single-stranded DNA probe labeled with an acridinium ester is incubated with the target nucleic acid. Alkaline hydrolysis follows the hybridization step, and probe binding is measured in a luminometer after the addition of peroxides. For a positive sample, the acridinium ester on the bound probe is protected from hydrolysis and, upon the addition of peroxides, emits light. The hybridization protection assay can be completed in several hours and does not require removal of unbound single-stranded probe or isolation of probe-bound double-stranded sequences (3).

In solid-phase hybridization, target nucleic acids are bound to nylon or nitrocellulose and are hybridized with a probe in solution (122). The unbound probe is washed away, and the bound probe is detected by means of fluorescence, luminescence, radioactivity, or color development. Although solid-phase hybridization is a powerful research tool, the length of time required and the complexity of the procedure limit its application in clinical practice.

In situ hybridization is another type of solid-phase hybridization in which the nucleic acid is contained in tissues or cells which are affixed to microscope slides and is governed by the same basic principles described previously (44). In most clinical applications, formalin-fixed, paraffin-embedded tissue sections are used. The sensitivity of in situ hybridization is often limited by the accessibility of the target nucleic acid in the cells.

In general, due to the poor analytical sensitivities of nonamplified probe techniques, the application of these techniques to direct detection of pathogens in clinical specimens is limited to those situations in which the number of organisms is large. Such situations include cases of group A streptococcal pharyngitis and genital tract infections with *Neisseria gonorrhoeae* and *Chlamydia trachomatis*. These techniques are used most effectively in culture confirmation assays for mycobacteria and systemic dimorphic fungi. These culture confirmation tests have a positive effect on patient management by providing rapid and accurate detection of these slowly growing, often difficult to identify pathogens.

Nucleic acid probes for direct detection of group A streptococci, *C. trachomatis*, and *N. gonorrhoeae* are available from Gen-Probe. Probes for identification of *Blastomyces dermatitidis, Coccidioides immitis, Histoplasma capsulatum, Campylobacter* spp., enterococci, group A streptococci, group B streptococci, *Haemophilus influenzae, Listeria monocytogenes,* mycobacteria, *N. gonorrhoeae, Staphylococcus aureus,* and

Streptococcus pneumoniae isolated in culture are also available from Gen-Probe.

Peptide nucleic acid (PNA) probes are DNA mimics in which the negatively charged sugar phosphate backbone of DNA is replaced with a noncharged polyamide or "peptide" backbone. PNA probes contain the same nucleotide bases as DNA and follow standard Watson-Crick base pairing rules when hybridizing to complementary nucleic acid sequences (115). Because PNA probes are noncharged, they do not have to overcome the destabilizing electrostatic repulsion that occurs when two negatively charged DNA molecules hybridize. As a result, PNA probes bind more rapidly and tightly to nucleic acid targets. In addition, the relatively hydrophobic character of the PNA probes enables them to penetrate the hydrophobic cell membrane following preparation of a standard smear.

PNA probes have been used for identification of *S. aureus*, *Escherichia coli*, *Pseudomonas aeruginosa*, and *Candida albicans* directly from positive blood culture bottles (90, 102, 112) and direct detection of *Mycobacterium tuberculosis* in smear-positive sputum samples (116). PNA probes for direct identification of *S. aureus, Enterococcus faecalis*, and *C. albicans* from positive blood culture bottles are available from AdvanDx, Woburn, Mass.

AMPLIFIED NUCLEIC ACID TECHNIQUES

The development of the PCR by Saiki et al. (108) was a milestone in biotechnology and heralded the beginning of molecular diagnostics. PCR had its 20th birthday in 2005 and has stood the test of time. Although PCR is the best-developed and most widely used nucleic acid amplification strategy, other strategies have been developed, and several have clinical utility. These strategies are based on signal, target, or probe amplification. Examples of each category will be discussed in the sections that follow. These techniques have sensitivity unparalleled in laboratory medicine, have created new opportunities for the clinical laboratory to have an effect on patient care, and have become the new "gold standards" for laboratory diagnosis of several infectious diseases.

SIGNAL AMPLIFICATION TECHNIQUES

In signal amplification methods, the concentration of the probe or target does not increase. The increased analytical sensitivity comes from increasing the concentration of labeled molecules attached to the target nucleic acid. Multiple enzymes, multiple probes, multiple layers of probes, and reduction of background noise have all been used to enhance target detection (59). Target amplification systems generally have greater analytical sensitivity than signal amplification methods, but technological developments, particularly in branched DNA (bDNA) assays, have lowered the limits of detection to levels that may rival those of target amplification assays in some applications (57).

Signal amplification assays have several advantages over target amplification assays. In signal amplification systems, the number of target molecules is not altered, and as a result, the signal is directly proportional to the amount of the target sequence present in the clinical specimen. This reduces concerns about false-positive results due to cross contamination and simplifies the development of quantitative assays. Since signal amplification systems are not dependent on enzymatic processes to amplify the target sequence, they are not affected by the presence of enzyme inhibitors in clinical specimens. Consequently, less cumbersome nucleic acid extraction methods may be used. Typically, signal amplification systems use either larger probes or more probes than target amplification systems and, consequently, are less susceptible to errors resulting from target sequence heterogeneity. Finally, RNA levels can be measured directly without the synthesis of a cDNA intermediate.

bDNA Assays

The bDNA signal amplification system is a solid-phase, sandwich hybridization assay incorporating multiple sets of synthetic oligonucleotide probes (86). The key to this technology is the amplifier molecule, a bDNA molecule with 15 identical branches, each of which can bind to three labeled probes.

The bDNA signal amplification system is illustrated in Fig. 1. Multiple target-specific probes are used to capture the target nucleic acid onto the surface of a microtiter well. A second set of target-specific probes also binds to the target. Preamplifier molecules bind to the second set of target probes and up to eight bDNA amplifiers. Three alkaline phosphatase-labeled probes hybridize to each branch of the amplifier. Detection of bound labeled probes is achieved by incubating the complex with dioxetane, an enzyme-triggerable substrate, and measuring the light emission in a luminometer. The resulting signal is directly proportional to the quantity of the target in the sample. The quantity of the target in the sample is determined from an external standard curve.

Nonspecific hybridization of any of the amplification probes and nontarget nucleic acids leads to amplification of the background signal. In order to reduce potential hybridization to nontarget nucleic acids, isocytidine (isoC) and isoguanosine (isoG) were incorporated into the preamplifier and labeled probes were used in the third-generation bDNA assays (21). IsoC and isoG form base pairs with each other but not with any of the four naturally occurring bases (97). The use of isoC- and isoG-containing probes in bDNA assays increases target-specific signal amplification without a concomitant increase in the background signal, thereby greatly enhancing the detection limits without loss of specificity. The detection limit of the third-generation bDNA assay for human immunodeficiency virus type 1 (HIV-1) RNA is 75 copies/ml. bDNA assays for the quantitation of hepatitis B virus (HBV) DNA, hepatitis C virus (HCV) RNA, and HIV-1 RNA are commercially available (Bayer HealthCare, Diagnostics Division, Tarrytown, N.Y.). The System 340 analyzer for bDNA assays automates the incubation, washing, reading, and data-processing steps.

Hybrid Capture Assays

The hybrid capture system is a solution hybridization-antibody capture assay that uses chemiluminescence detection of the hybrid molecules. The target DNA in the specimen is denatured and then hybridized with a specific RNA probe. The DNA-RNA hybrids are captured by antihybrid antibodies that are used to coat the surface of a tube. Alkaline phosphatase-conjugated antihybrid antibodies bind to the immobilized hybrids. The bound antibody conjugate is detected with a chemiluminescent substrate, and the light emitted is measured in a luminometer. Multiple alkaline phosphatase conjugates bind to each hybrid molecule, amplifying the signal. The intensity of the emitted light is proportional to the amount of target DNA in the specimen. Hybrid capture assays for detection of *N. gonorrhoeae, C. trachomatis,* human papillomavirus (HPV) (23), and cytomegalovirus (CMV) (76) in clinical specimens are commercially available (Digene Corp., Gaithersburg, Md.).

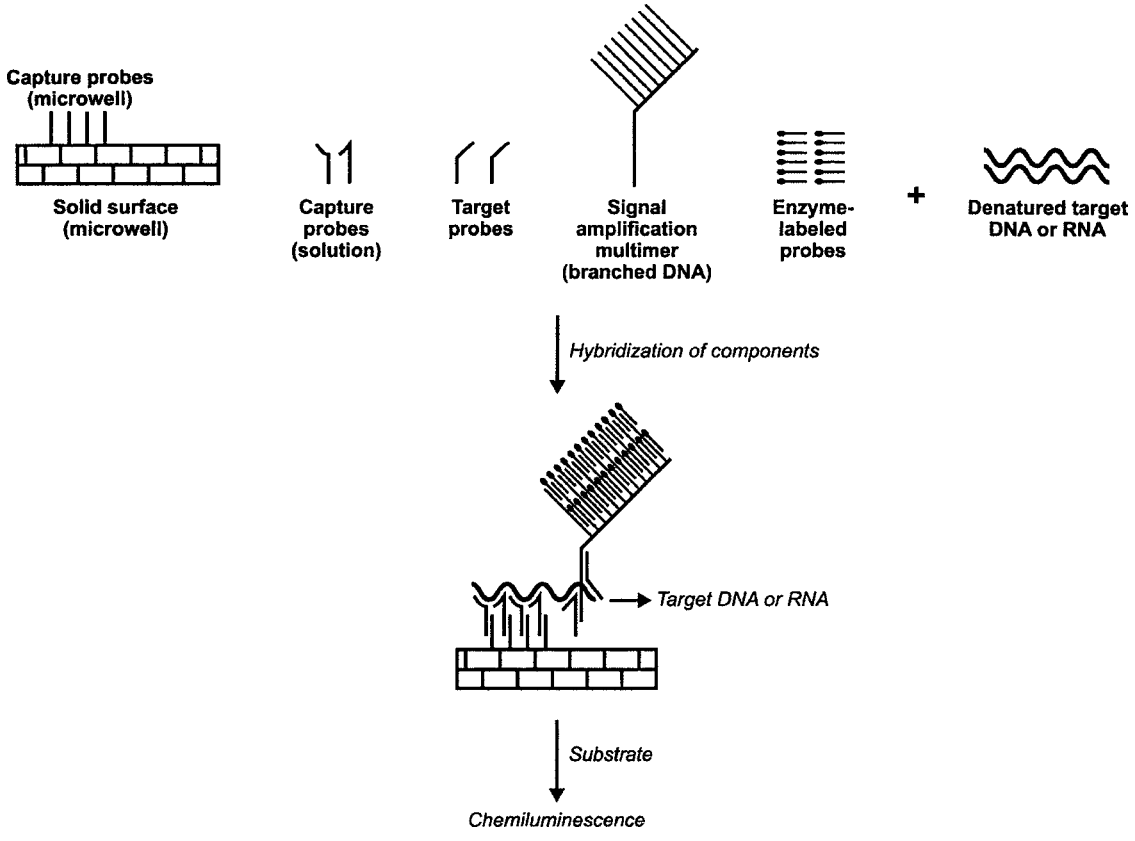

FIGURE 1 bDNA signal amplification (reprinted with permission of Elsevier from reference 134).

TARGET AMPLIFICATION TECHNIQUES

All of the target amplification systems share certain fundamental characteristics. They use enzyme-mediated processes, in which a single enzyme or multiple enzymes synthesize copies of target nucleic acid. In all of these techniques, the amplification products are detected by two oligonucleotide primers that bind to complementary sequences on opposite strands of double-stranded targets. All the techniques result in the production of millions to billions of copies of the targeted sequence in a matter of hours, and in each case, the amplification products can serve as templates for subsequent rounds of amplification. Because of this, all of the techniques are sensitive to contamination with product molecules that can lead to false-positive reactions. The potential for cross contamination is real and should be adequately addressed before any of these techniques are used in the clinical laboratory. However, the occurrence of false-positive reactions can be reduced through special laboratory design, practices, and workflow.

PCR

PCR is a simple, in vitro, chemical reaction that permits the synthesis of essentially limitless quantities of a targeted nucleic acid sequence. This is accomplished through the action of a DNA polymerase that, under the proper conditions, can copy a DNA strand (Fig. 2). At its simplest, a PCR consists of target DNA, a molar excess of two oligonucleotide primers, a heat-stable DNA polymerase, an equimolar mixture of deoxyribonucleotide triphosphates (dNTPs; dATP, dCTP, dGTP, and dTTP), $MgCl_2$, KCl, and a Tris-HCl buffer. The two primers flank the double-stranded DNA sequence to be amplified, typically <100 to several hundred bases, and are complementary to opposite strands of the target.

To initiate a PCR, the reaction mixture is heated to separate the two strands of target DNA and is then cooled to permit the primers to anneal to the target DNA in a sequence-specific manner. The DNA polymerase then initiates extension of the primers at their 3′ ends toward one another. The primer extension products are dissociated from the target DNA by heating. Each extension product, as well as the original target, can serve as a template for subsequent rounds of primer annealing and extension.

At the end of each cycle, the PCR products are theoretically doubled. Thus, after n PCR cycles the target sequence can be amplified 2^n-fold. The whole procedure is carried out in a programmable thermal cycler that precisely controls the temperature at which the steps occur, the lengths of time that the reaction mixture is held at the different temperatures, and the number of cycles. Ideally, after 20 cycles of PCR a 10^6-fold amplification is achieved and after 30 cycles a 10^9-fold amplification occurs. In practice, the amplification may not be completely efficient due to failure to optimize the reaction conditions or the presence of inhibitors of the DNA polymerase. In such cases, the total amplification is best described by the expression $(1 + e)^n$, where e is the amplification efficiency ($0 \leq e \leq 1$) and n is the total number of cycles.

RT-PCR

As it was originally described, PCR was a technique for DNA amplification. Reverse transcriptase PCR (RT-PCR) was

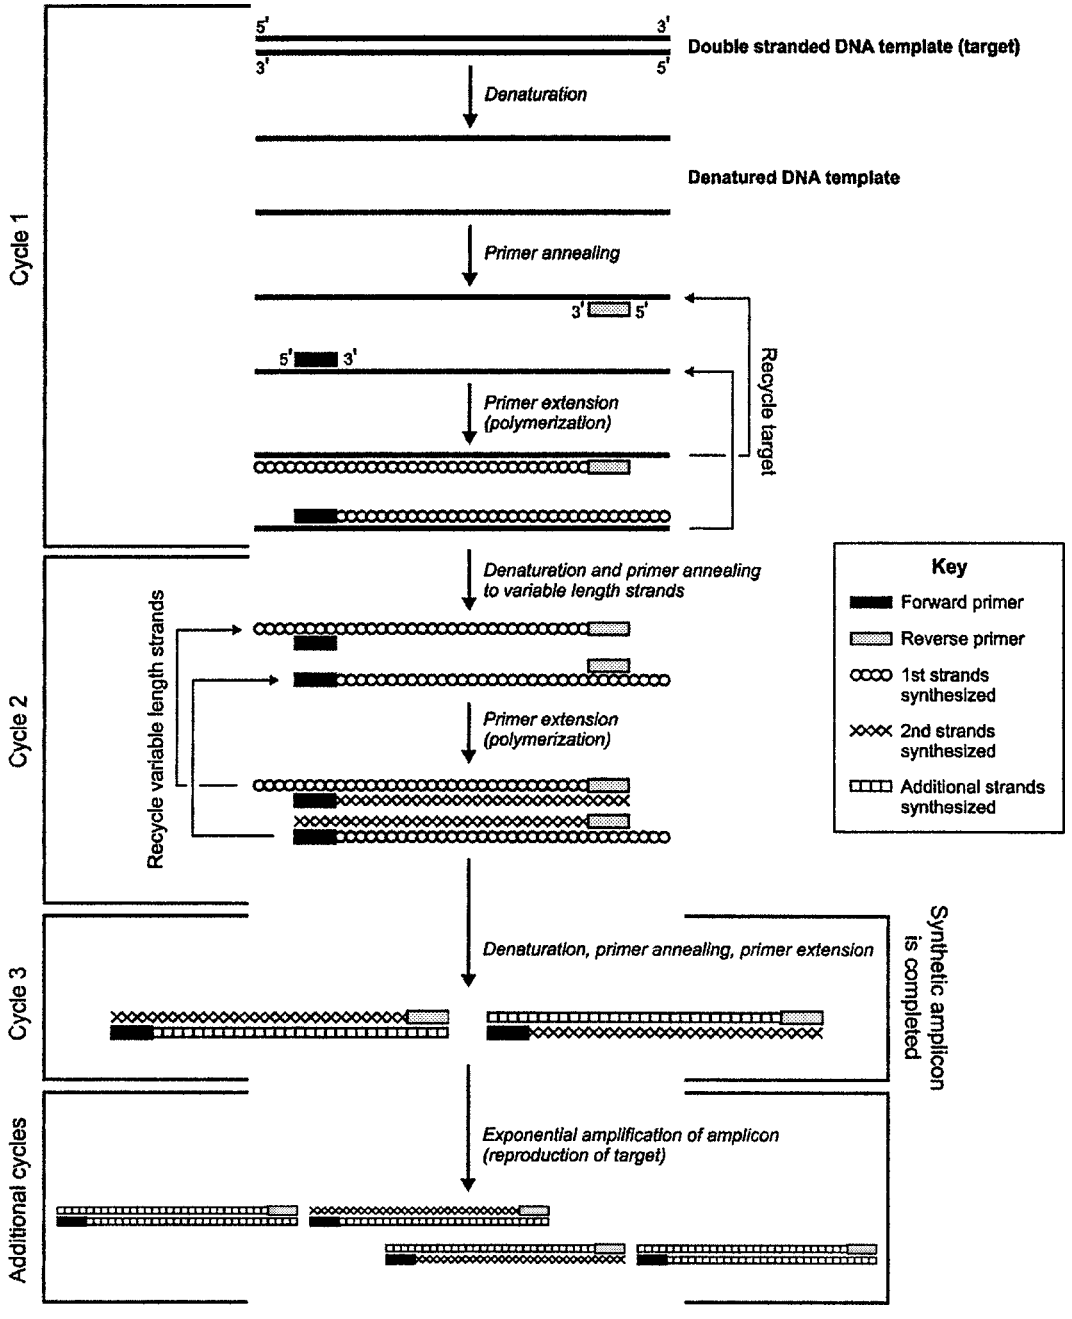

FIGURE 2 PCR target amplification (reprinted with permission of Elsevier from reference 134).

developed to amplify RNA targets. In this process, cDNA is first produced from RNA targets by reverse transcription and then the cDNA is amplified by PCR. As it was originally described, RT-PCR used two enzymes, a heat-labile RT such as avian myeloblastosis virus RT and a thermostable DNA polymerase. Because of the temperature requirements of the heat-labile enzyme, cDNA synthesis had to occur at temperatures below the optimal annealing temperatures of the primers. This presented problems in terms of both nonspecific primer annealing and inefficient primer extension due to the formation of RNA secondary structures. These problems have largely been overcome by the development of a thermostable DNA polymerase derived from *Thermus thermophilus* that under the proper conditions can function efficiently as both an RT and a DNA polymerase (82). RT-PCRs with this enzyme are more specific and efficient than previous protocols with conventional, heat-labile RT enzymes. Commercially available kits (Roche Diagnostics, Indianapolis, Ind.) that use this single-enzyme technology are available for detection of HCV RNA and for quantitation of HIV-1 and HCV RNA in clinical specimens.

Nested PCR

Nested PCR was developed to increase both the sensitivity and the specificity of PCR (45). It uses two pairs of amplification primers and two rounds of PCR. Typically, one primer pair is used in the first round of PCR for 15 to 30 cycles. The products of the first round of amplification are then subjected to a second round of amplification with the second set of primers that anneal to a sequence internal to the sequence amplified by the first primer set. The increased sensitivity arises from the high total cycle number, and the increased specificity arises from the annealing of the second primer set to sequences found only in the first-round products, thus verifying the identity of the first-round product. The major disadvantage of nested PCR is the high rates of contamination that can occur during the transfer of first-round products to the second tube for the second round of amplification. This contamination can be avoided either by physically separating the first- and second-round amplification mixtures with a layer of wax or oil or by designing single-tube amplification protocols. In practice, the enhanced sensitivity afforded by nested PCR protocols is rarely required in diagnostic applications, and the identity of an amplification product is usually confirmed by hybridization with a nucleic acid probe.

Multiplex PCR

In multiplex PCR, two or more primer sets designed for amplification of different targets are included in the same reaction mixture (12). By this technique, more than one target sequence in a clinical specimen can be coamplified in a single tube. The primers used in multiplexed reactions must be carefully selected so that they have similar annealing temperatures and lack complementarity. Multiplex PCRs have proved to be more complicated to develop and are usually less sensitive than PCRs with single primer sets.

Many multiplex assays have been developed, especially for the detection of central nervous system (9, 24) and respiratory (58, 121) pathogens. Multiplex PCR assays for bacterial and viral respiratory pathogens are commercially available from Prodesse, Inc., Waukesha, Wis.

A promising new platform for multiplex PCR analysis is the LabMAP system (Luminex Corp., Austin, Tex.). The LabMAP system incorporates a proprietary process to internally dye polystyrene microspheres with two spectrally distinct fluorochromes. By using precise ratios of these fluorochromes, an array is created consisting of 100 different microsphere sets with specific spectral addresses. Each microsphere set can possess a different reactant on its surface. For nucleic acid analysis, oligonucleotide probes would be covalently bound to the microsphere surface by carbodiimide coupling. Since each microsphere set can be distinguished by its spectral address, the sets can be combined, allowing up to 100 different analytes to be measured simultaneously in a single reaction vessel. A third fluorochrome coupled to a reporter molecule quantifies the biomolecular interaction that occurs at the microsphere surface.

Microspheres are investigated individually in a rapidly flowing liquid stream as they pass by two separate lasers in the Luminex 100 flow cytometer. High-speed digital signal processing classifies each microsphere based on its spectral address and quantifies the reaction on its surface. Thousands of microspheres are investigated per second, resulting in an analysis system capable of analyzing and reporting up to 100 different reactions in a single reaction vessel in a few seconds. The technology has been adapted to a wide variety of applications in bacteriology (27), mycology (25), and virology (111, 129).

Real-Time (Homogeneous, Kinetic) PCR

The term real-time PCR describes methods in which the target amplification and detection steps occur simultaneously in the same tube (homogeneous). These methods require special thermal cyclers with precision optics that can monitor the fluorescence emission from the sample wells. The computer software supporting the thermal cycler monitors the data throughout the PCR at every cycle and generates an amplification plot for each reaction (kinetic).

Figure 3 shows a representative amplification plot and defines the terms used in real-time PCR quantitation. The amplification plot shows the normalized fluorescence signal from the reporter at each cycle number. In the initial cycles of PCR, there is little change in the fluorescence signal. This initial signal level defines the baseline for the plot. An increase above the baseline indicates the detection of accumulated PCR product. A fixed fluorescence threshold can be set above the baseline. The cycle threshold (C_T) is defined as the cycle number at which the fluorescence passes the fixed threshold. A plot of the log of the initial target concentration versus C_T for a set of standards is a straight line (49). The amount of the target in an unknown sample is determined by measuring the sample C_T and using a standard curve to determine the starting copy number. Alternatively, the cycle number corresponding to the maximal change in fluorescence, the second derivative maximum, has a similar relationship to the initial target concentration.

In its simplest format, the PCR product is detected as it is produced by using fluorescent dyes that preferentially bind to double-stranded DNA. SYBR Green I is one such dye that has been used in this application (81). In the dye's unbound state, the fluorescence is relatively low, but when the dye is bound to double-stranded DNA, the fluorescence is greatly enhanced. The dye will bind to both specific and nonspecific PCR products. The specificity of the detection can be improved through melting curve analysis. As the temperature is slowly raised, the two strands of the amplicon will melt apart and the amount of fluorescence will decrease. The data are transformed and analyzed by plotting the first derivative of the fluorescence on the y axis and the temperature on the

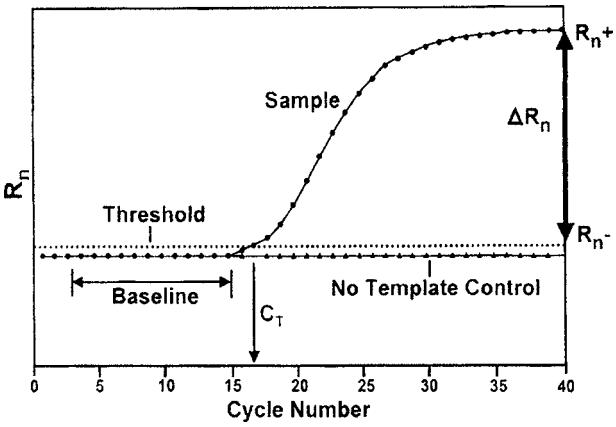

FIGURE 3 Real-time PCR amplification plot with commonly used terms and abbreviations. R_n, normalized fluorescent signal from reporter dye. (From *TaqMan Universal PCR Master Mix Protocol*, Foster City, Calif.: Applied Biosystems; 2002:5–94. Reprinted with permission.)

x axis. The specific amplified product will have a characteristic melting peak at its predicted melting temperature (T_m), whereas the primer dimers and other nonspecific products should have different T_ms or give broader peaks (103).

The specificity of real-time PCR can also be increased by including fluorescent resonance energy transfer (FRET) probes in the reaction mixture. These probes are labeled with fluorescent dyes or with combinations of fluorescent and quencher dyes. In 5′ exonuclease PCR (TaqMan) assays, the 5′ to 3′ exonuclease activity of *Taq* DNA polymerase is used to cleave a nonextendable hybridization probe during the primer extension phase of PCR (50). This approach uses dual-labeled fluorogenic hybridization probes and is illustrated in Fig. 4. One fluorescent dye serves as a reporter, and its emission spectrum is quenched by the second fluorescent dye. The nuclease degradation of the hybridization probe releases the

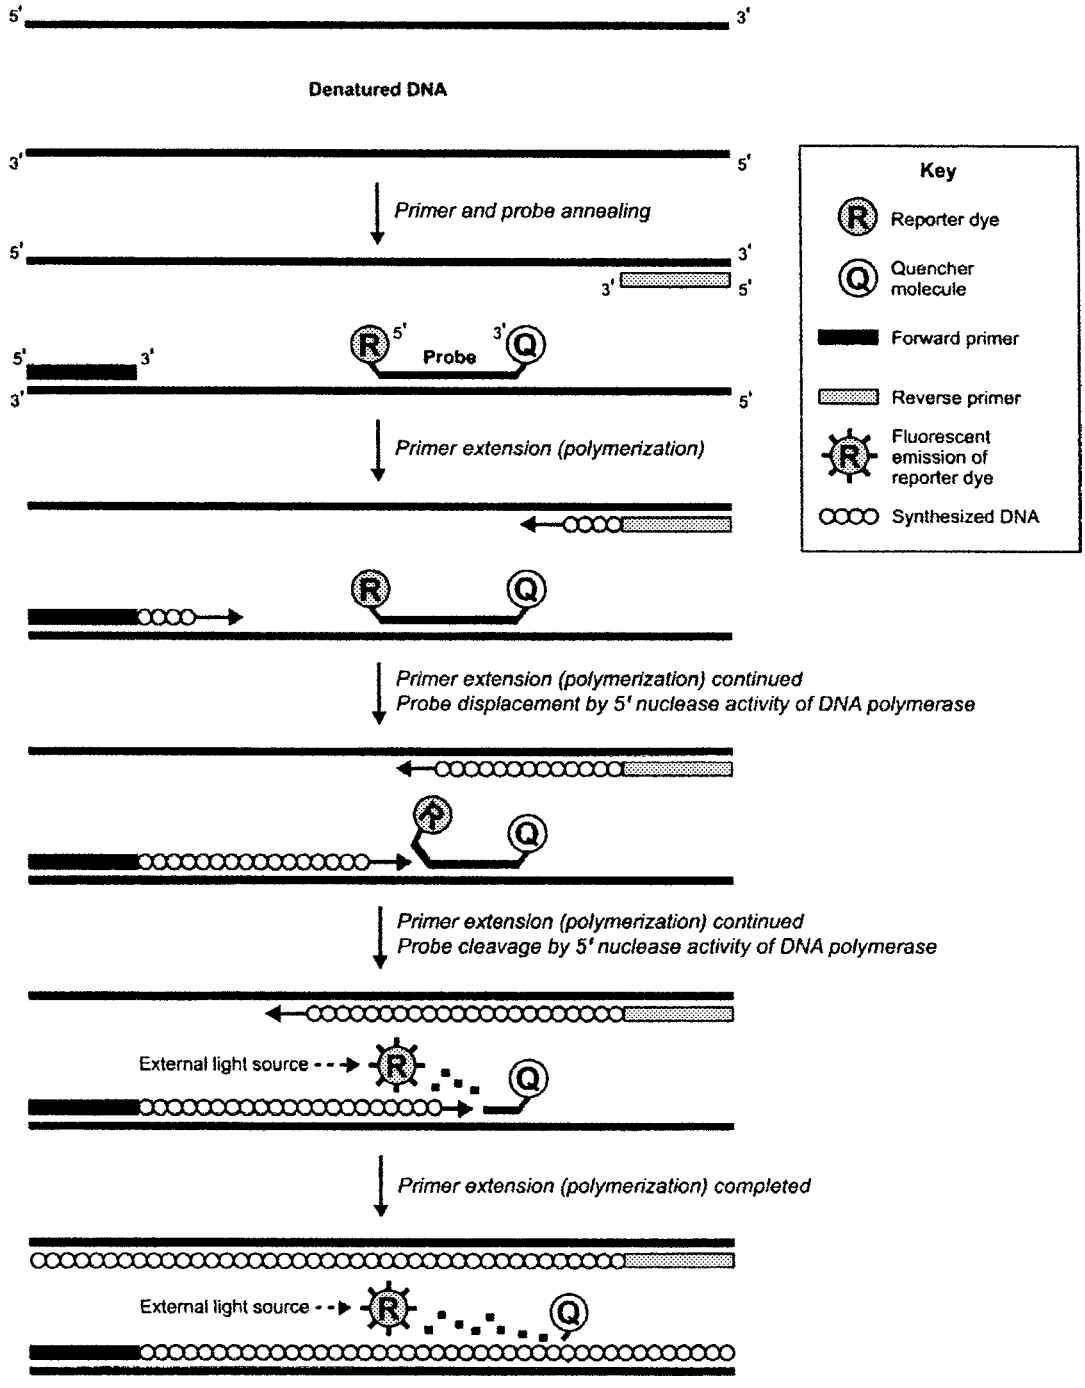

FIGURE 4 5′ exonuclease chemistry for real-time PCR applications (reprinted with permission of Elsevier from reference 134).

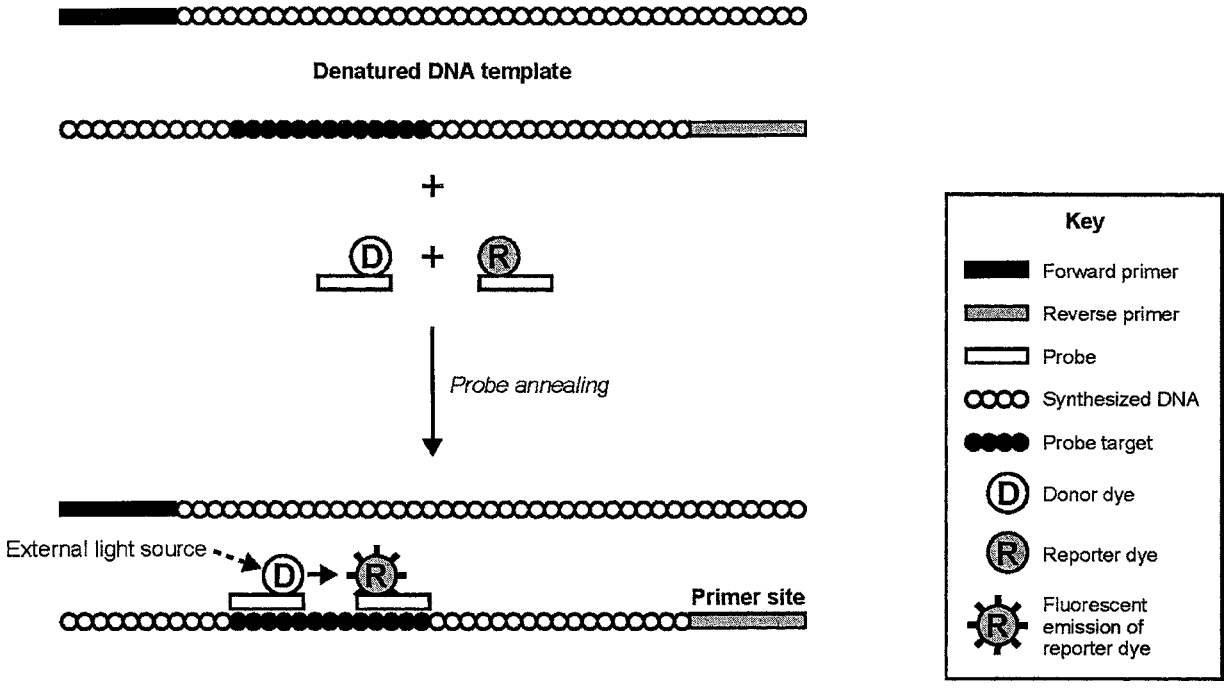

FIGURE 5 Dual hybridization probes for real-time PCR applications (reprinted with permission of Elsevier from reference 134).

reporter dye, resulting in an increase in the peak fluorescent emission. The increase in fluorescent emission indicates that specific PCR product has been made, and the intensity of fluorescence is related to the amount of the product (46). The specificity is increased because a signal is generated only when the primer and probe are bound to the same template strand.

The use of dual hybridization probes is another approach to real-time PCR (65). This method uses two specially designed sequence-specific oligonucleotide probes (Fig. 5). These hybridization probes are designed to hybridize within 1 to 5 nucleotides apart on the product molecule. The 3′ end of the anchor probe is labeled with a donor dye, and the 5′ end of the reporter probe is labeled with an acceptor dye. The 3′ end of the reporter probe is phosphorylated to prevent extension during PCR. The donor dye is excited by an external light source, and instead of emitting light, it transfers its energy to the acceptor dye by FRET. The excited acceptor dye emits light at a longer wavelength than the unbound donor dye, and the intensity of the acceptor dye light emission is proportional to the amount of PCR product.

Real-time detection and quantitation of amplification products can also be accomplished with molecular beacons (126). Molecular beacons are hairpin-shaped oligonucleotide probes with an internally quenched fluorophore whose fluorescence is restored when the probes bind to a target nucleic acid (Fig. 6). The probes are designed in such a way that the loop portion of each probe molecule is complementary to the target sequence. The stem is formed by the annealing of complementary arm sequences on the ends of the probe. A fluorescent dye is attached to one end of one arm, and a quenching molecule is attached to the end of the other arm. The stem keeps the fluorophore and quencher in close proximity such that no light emission occurs. When the probe encounters a target molecule, it forms a hybrid that is longer and more stable than the stem and undergoes a conformational change that forces the stem apart, causing the fluorophore and the quencher to move away from each other, restoring the fluorescence.

Scorpion probes combine a PCR primer with a molecular beacon (124, 131). Intramolecular hybridization of the loop structure to a downstream portion of the amplification product separates the reporter and quencher dyes. The hybridization kinetics of Scorpion probes are generally faster than those of molecular beacons because the primer and probe are located on the same molecule.

Dark quencher probes are also used in real-time PCR applications (Nanogen, Bothell, Wash.). Dark quencher probes contain a fluorophore on the 5′ end and a nonfluorescent

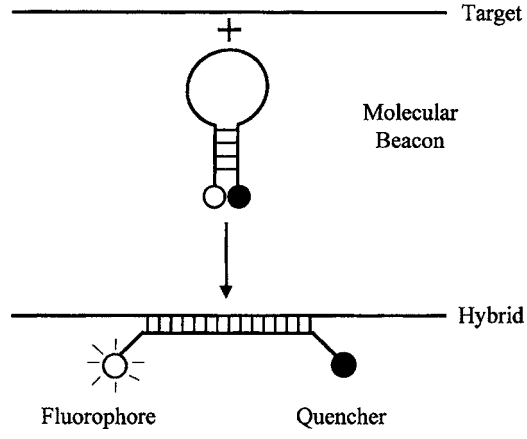

FIGURE 6 Molecular beacon probes for real-time amplification applications (reprinted with permission of Elsevier from reference 134).

quencher molecule on the 3′ end (62). The fluorescence is quenched when the probe is a random coil and emitted when the probe anneals to the target sequence. Unlike fluorogenic 5′ nuclease probes, these probes are not degraded by the DNA polymerase during target amplification. Since the dark quencher is not fluorescent, it does not contribute to the background signal. This trait has the advantage of improving the signal-to-noise ratio for the detection system, which may improve sensitivity. These probes also incorporate a hybridization-stabilizing compound, known as a minor groove binder. It is a small, crescent-shaped molecule that is covalently linked to the 3′ end of the probe that spans about 3 to 4 nucleotides and snugly fits into the minor groove of DNA, where it forms hydrogen bonds with the template. Minor groove binders will increase the T_m of the probe. The minor groove binder allows for the use of shorter probes because of the increased T_ms and enables improved T_m leveling, which increases the specificity of the detection reaction.

Real-time PCR methods decrease the time required to perform nucleic acid assays because there are no post-PCR processing steps. Also, since amplification and detection occur in the same closed tube, these methods eliminate the postamplification manipulations that can lead to laboratory contamination with the amplicon. In addition, real-time PCR methods lend themselves well to quantitative applications because analysis is performed early in the log phase of product accumulation and, as a result, is less prone to error resulting from differences in sample-to-sample amplification efficiency.

Transcription-Based Amplification Methods

Nucleic acid sequence-based amplification (NASBA) and transcription-mediated amplification (TMA) are both isothermal RNA amplification methods modeled after retroviral replication (22, 39, 63). The methods are similar in that the RNA target is reverse transcribed into cDNA and then RNA copies are synthesized with an RNA polymerase. NASBA uses avian myeloblastosis virus RT, RNase H, and T7 bacteriophage RNA polymerase, whereas TMA uses an RT enzyme with endogenous RNase H activity and T7 RNA polymerase.

Amplification involves the synthesis of cDNA from the RNA target with a primer containing the T7 RNA polymerase promoter sequence (Fig. 7). The RNase H then degrades the initial strand of target RNA in the RNA-cDNA hybrid. The second primer then binds to the cDNA and is extended by the DNA polymerase activity of the RT, resulting in the formation of double-stranded DNA containing the T7 RNA polymerase promoter. The RNA polymerase then generates multiple copies of single-stranded, antisense RNA. These RNA product molecules reenter the cycle, with subsequent formation of more double-stranded cDNA molecules that can serve as templates for more RNA synthesis. A 10^9-fold amplification of the target RNA can be achieved in less than 2 h by this method.

The single-stranded RNA products of TMA in the Gen-Probe tests are detected by modification of the hybridization protection assay. Oligonucleotide probes are labeled with modified acridinium esters with either fast or slow chemiluminescence kinetics so that signals from two hybridization reactions can be analyzed simultaneously in the same tube. The NASBA products in the bioMérieux (Durham, N.C.) tests are detected by hybridization with probes labeled with tris(2,2′-bispyridine)ruthenium and electrochemiluminescence. NASBA has also been used with molecular beacons to create a homogeneous, kinetic amplification system similar to real-time PCR (68).

Transcription-based amplification systems have several strengths, including no requirement for a thermal cycler, rapid kinetics, and a single-stranded RNA product that does not require denaturation prior to detection. Also, single-tube clinical assays and a labile RNA product may help minimize contamination risks. Limitations include the poor performance with DNA targets and concerns about the stability of complex multienzyme systems. Gen-Probe has developed TMA-based assays for detection of *Mycobacterium tuberculosis, C. trachomatis, N. gonorrhoeae,* HCV, and HIV-1. NASBA-based kits (bioMérieux) for the detection and quantitation of HIV-1 RNA and CMV RNA transcripts and detection of enterovirus and respiratory syncytial virus RNA are commercially available. A basic NASBA kit is also available for the development of other applications defined by the user.

Strand Displacement Amplification

Strand displacement amplification (SDA) is an isothermal template amplification technique that can be used to detect trace amounts of DNA or RNA of a particular sequence. SDA, as it was first described, was a conceptually straightforward amplification process with some technical limitations (128). Since its initial description, however, it has evolved into a highly versatile tool that is technically simple to perform but conceptually complex. SDA is the intellectual property of Becton Dickinson and Company, Sparks, Md.

In its current iteration, SDA occurs in two discrete phases, target generation and exponential target amplification (70). Both are illustrated in Fig. 8. In the target generation phase, a double-stranded DNA target is denatured and hybridized to two different primer pairs, designated as bumper and amplification primers. The amplification primers include the single-stranded restriction endonuclease enzyme sequence for BsoB1 located at the 5′ end of the target binding sequence. The bumper primers are shorter and anneal to the target DNA just upstream of the region to be amplified. In the presence of BsoB1, an exonuclease-free DNA polymerase, and a dNTP mixture consisting of dUTP, dATP, dGTP, and thiolated dCTP (C_s), simultaneous extension products of both the bumper and amplification primers are generated. This process displaces the amplification primer products, which are available for hybridization with the opposite-strand products with the opposite-strand bumper and amplification primers.

The simultaneous extension of opposite-strand primers produces strands complementary to the product formed by extension of the first amplification primer with C_s incorporated into the BsoB1 cleavage site. This product enters the exponential target amplification phase of the reaction. The BsoB1 enzyme recognizes the double-stranded site, but because one strand contains C_s, it is nicked rather than cleaved by the enzyme. The DNA polymerase then binds to the nicked site and begins synthesis of a new strand while simultaneously displacing the downstream strand. This step re-creates the double-stranded species with the hemimodified restriction endonuclease recognition sequence, and the iterative nicking and displacement process repeats. The displaced strands are capable of binding to opposite-strand primers, which produces exponential amplification of the target sequences.

These single-stranded products also bind to detector probes for real-time detection. The detector probes are single-stranded DNA molecules with fluorescein and rhodamine labels. The region between the labels includes a stem-loop structure. The loop contains the recognition site for the BsoB1 enzyme. The target-specific sequences are located 3′ of

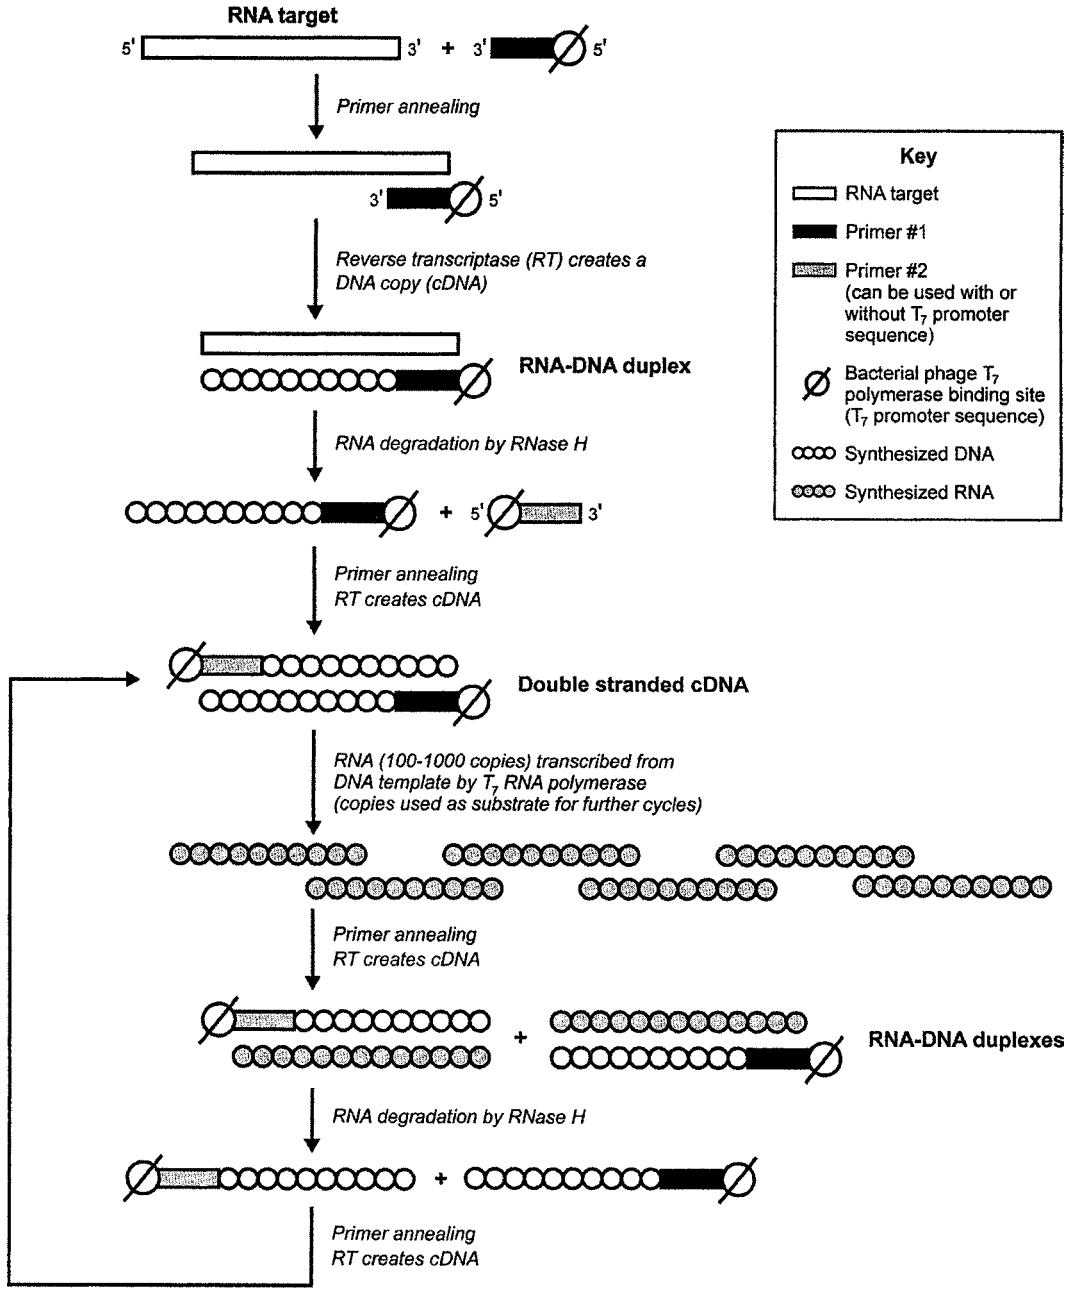

FIGURE 7 Transcription-based target amplification. NASBA and TMA are examples of transcription-based amplification systems (reprinted with permission of Elsevier from reference 134).

the rhodamine label. In the absence of a specific target, the stem-loop structure is maintained with the fluorescein and rhodamine labels in close proximity. The net effect is that very little emission for the fluorescein is detected after excitation. After SDA, the probe is converted to a double-stranded species, which is cleaved by BsoB1. The cleavage causes physical separation of the fluorescein and rhodamine labels, which results in an increase in emission from the flourescein label.

The diagnostic applications of SDA include the direct detection of *M. tuberculosis, C. trachomatis,* and *N. gonorrhoeae* in clinical specimens. SDA has a reported sensitivity high enough to detect as few as 10 to 50 copies of a target molecule (128). By using a primer set designed to amplify a repetitive sequence with 10 copies in the *M. tuberculosis* genome, the assay is sensitive enough to detect 1 to 5 genome copies from the bacterium. Recently, SDA has been adapted to quantitate RNA by adding an RT step (RT-SDA). In this case, a primer hybridizes to the target RNA and an RT synthesizes a cDNA molecule. This cDNA can then serve as a template for primer incorporation and strand displacement. The products of this strand displacement then feed into the amplification scheme described above. RT-SDA has been used for the determination of HIV viral load (88).

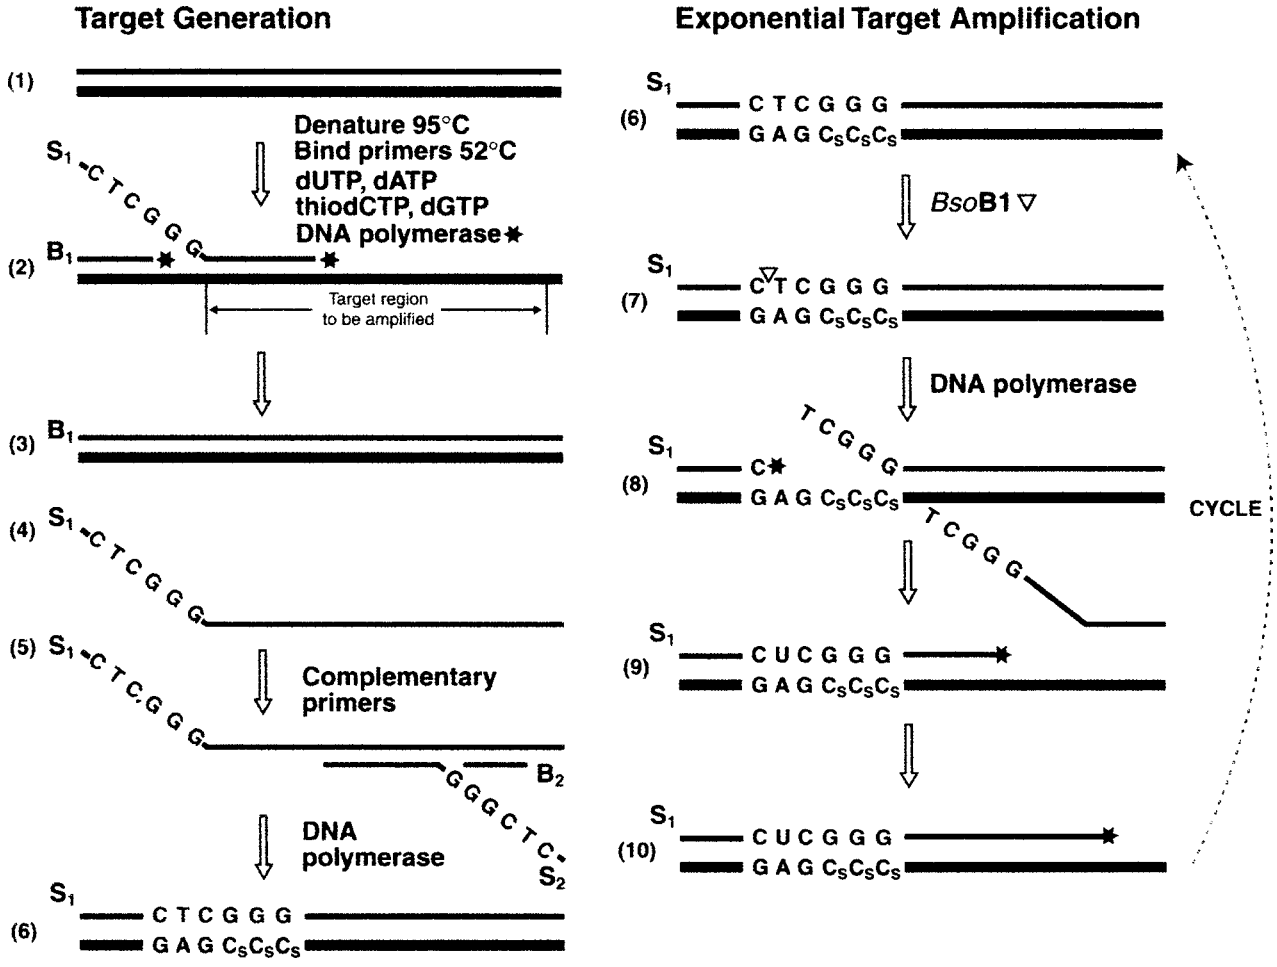

FIGURE 8 Strand displacement target amplification. The process is shown for only one strand of a double-stranded DNA target, but amplification occurs on both strands simultaneously. B_1 and B_2, bumper primers; S_1 and S_2, amplification primers. (Modified from reference 70.)

The main advantage of SDA is that it is an isothermal process that, unlike PCR, can be performed at a single temperature after initial target denaturation. This eliminates the need for expensive thermal cyclers. Furthermore, samples can be subjected to SDA in a single tube, with amplification times varying from 30 min to 2 h. The main disadvantage of SDA lies in the fact that, unlike those at which PCR is performed, the relatively low temperature at which SDA is carried out (52.5°C) can result in nonspecific primer hybridization to sequences found in complex mixtures such as genomic DNA. Hence, when the target is in low abundance compared to background DNA, nonspecific amplification products can swamp the system, decreasing the sensitivity of the technique. However, the use of organic solvents to increase stringency at low temperatures and the recent introduction of more thermostable polymerases capable of strand displacement have alleviated much of this problem.

PROBE AMPLIFICATION TECHNIQUES

Probe amplification methods differ from target amplification methods in that the amplification products contain only a sequence present in the initial probes. Ligase chain reaction (136), cycling probe technology (31), and cleavase-invader technology (73) are all examples of probe amplification methods for which diagnostic applications have been developed. However, diagnostic tests based on ligase chain reaction and cycling probe technology are no longer available in the United States.

Cleavase-Invader Technology

Invader assays (Third Wave Technologies, Madison, Wis.) are based on a probe amplification method that relies upon the specific recognition and cleavage of particular DNA structures by cleavase, a member of the FEN-1 family of DNA polymerases. These polymerases will cleave the 5′ single-stranded flap of a branched base-paired duplex. This enzymatic activity likely plays an essential role in the elimination of the complex nucleic acid structures that arise during DNA replication and repair. Since these structures may occur anywhere in a replicating genome, the enzyme recognizes the molecular structure of the substrate without regard to the sequence of the nucleic acids making up the DNA complex (69).

In the invader assays, two primers are designed which hybridize to the target sequence in an overlapping fashion

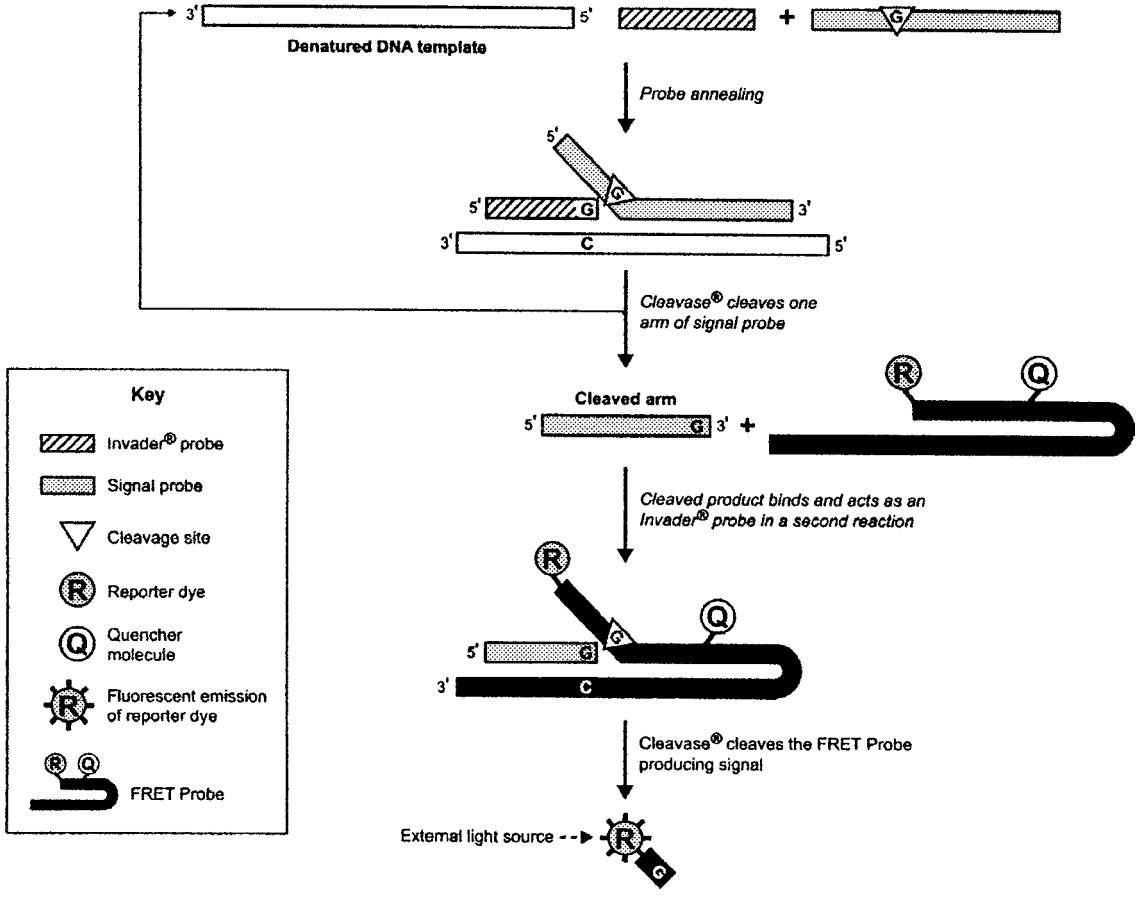

FIGURE 9 Cleavase-invader probe-based amplification (reprinted with permission of Elsevier from reference 134).

(Fig. 9). Under the proper annealing conditions, the probe oligonucleotide binds to the target sequence. The invader oligonucleotide is designed such that it hybridizes upstream of the probe with a region of overlap between the 3′ end of the invader and the 5′ end of the probe. Cleavase cleaves the 5′ end of the probe and releases it. It is in this way that the target sequence acts as a scaffold upon which the proper DNA structure can form. Since the DNA structure necessary to serve as a cleavase substrate will occur only in the presence of the target sequence, the generation of cleavage products indicates the presence of the target. Use of a thermostable cleavase enzyme allows reactions to be run at temperatures high enough for a primer exchange equilibrium to exist. This allows multiple cleavase products to form off of a single target molecule.

Various methods can be used to detect the cleavage products. Third Wave Technologies uses FRET probes and a second invasive cleavage reaction to detect the target-specific products. Invader technology can be used for genotyping, detection of mutations, and viral load testing. An ASR for HCV genotyping is currently available from Third Wave Technologies. ASRs are described in detail in the "Regulatory and Reimbursement Issues" section of this chapter.

The invader assay has several inherent advantages. Because the overlap in the invader probe need be only 1 bp, this technology can easily be adapted to detect point mutations of interest by designing the overlap region to encompass the mutation to be detected (74). The detection of these point mutations would not require postreaction restriction digestion, since the primers would be differentially cleaved on the basis of the presence or the absence of the mutation in question. This feature could be exploited to track mutations in pathogens associated with drug resistance or virulence. In addition, unlike amplification techniques such as PCR, SDA, and TMA, in which the target sequence itself is amplified, the invader assay does not increase the amount of the target sequence. As a consequence, invader assays are less prone to problems of false-positive results due to amplicon cross contamination.

POSTAMPLIFICATION DETECTION AND ANALYSIS

Gel Analysis

Visualization of amplification products in agarose gels after electrophoresis and ethidium bromide staining was the earliest detection method. After gel electrophoresis, DNA is often transferred onto a nitrocellulose or nylon membrane and hybridized to a specific probe to increase both the sensitivity and the specificity of detection. Membranes with bound radiolabeled probes are placed in proximity to X-ray film, and the hybrids are visualized as dark bands. Enzyme-labeled probes can be visualized through either light or color production after the addition of the appropriate chemiluminescent or

chromogenic substrates. Many of these nonisotopic approaches are at least as sensitive as isotopic methods and are faster. In addition, the enzyme-labeled probes are more stable. Although gel electrophoresis and blotting remain important research tools, these techniques are being replaced by faster and simpler methods in the clinical laboratory.

Single-strand conformation polymorphism (SSCP) analysis and restriction fragment length polymorphism (RFLP) analysis have been used to ascertain information about the base compositions of the amplification products visualized in a gel. In SSCP analysis, the PCR product is denatured and then subjected to electrophoresis in a nondenaturing gel (92). Variations in the physical conformations of the PCR products are related to the base compositions and are detected by differential gel migration. This technique has successfully been used to detect mutations causing rifampin resistance in *M. tuberculosis* (120).

RFLP analysis uses restriction endonucleases to cleave amplification products at specific recognition sites. The fragments are separated by electrophoresis, and the resulting banding pattern provides information about the nucleic acid sequence. When coupled with a hybridization reaction, RFLP analysis can also provide information about the location and number of loci homologous to the probe. Both SSCP analysis and RFLP analysis of short products have largely been replaced by direct DNA sequencing as this technology has improved and the costs have decreased.

Colorimetric Microtiter Plate Systems

Colorimetric microtiter plate (CMP) systems are convenient alternatives to traditional gel and blotting techniques for detection of amplified products. In these systems, the amplified product is captured in microtiter plate wells by specific oligonucleotide probes coating the plastic surface. Bound product is detected by a color change that takes place after addition of an enzyme conjugate and the appropriate substrate. These systems resemble enzyme immunoassays and use microtiter plate washers and readers commonly found in clinical laboratories. CMP systems are more practical and faster than the traditional membrane hybridization techniques described above.

Several variations of CMP systems are commercially available. In one popular approach, biotinylated primers are used to amplify the target, and the biotin-containing PCR product is denatured and added to the microtiter well. After hybridization with a capture probe, the bound product is detected with a streptavidin-enzyme conjugate and a chromogenic substrate (71). Enzyme-conjugated antibodies directed against double-stranded DNA have also been used to detect PCR products in CMP systems (75). Another approach uses digoxigenin-dUTP to label the PCR product and enzyme-conjugated antidigoxigenin antibodies to detect the captured product (98).

Allele-Specific Hybridization

Line probe assays are manufactured by Innogenetics (Ghent, Belgium) for genotyping of HCV and HBV, identification of mycobacteria, and analysis for drug resistance mutations in HIV-1, HBV, *M. tuberculosis,* and *Helicobacter pylori* (105, 117, 118). The HCV line probe assays are distributed by Bayer. In these assays, a series of probes with poly(T) tails are attached to nitrocellulose strips. Biotin-labeled PCR product is then hybridized to the immobilized probes on the strip. The labeled PCR product hybridizes only to the probes that give a perfect sequence match under the stringent hybridization conditions used. After hybridization, streptavidin labeled with alkaline phosphatase is added and binds to the biotinylated hybrids. Incubation with a chromogen results in a purple precipitate. The pattern of hybridization provides information about the nucleic acid sequence of the amplicon. This method is capable of detecting single-nucleotide polymorphisms.

Direct Sequencing

The combination of PCR and dideoxynucleotide chain termination methods can be used to determine DNA sequences in clinical samples (52). The use of fluorescent dye terminator chemistry and laser scanning in a polyacrylamide gel electrophoresis format has been the standard in electrophoretic separation technology. However, the recent application of capillary electrophoresis techniques to the separation of PCR and dideoxy chain termination products has streamlined the sequencing process by eliminating some of the labor-intensive steps, which makes the technology a better fit for diagnostic applications (30). The Clinical and Laboratory Standards Institute (CLSI) has recently developed guidelines for nucleic acid sequencing in clinical laboratories (19, 85).

CLIP (a coupled amplification and sequencing method) uses oligonucleotide primers labeled with different fluorescent dyes, standard dideoxynucleotide termination reagents, and PCR to produce extension products that end with a chain-terminating nucleotide. The nucleic acid sequence is deduced from the electrophoretic mobilities of the different extension products from a set of four reactions, each product containing a different chain-terminating nucleotide. A unique feature of CLIP sequencing is that one reaction produces sequence information for both nucleic acid strands. CLIP sequencing serves as the basis for commercially available assays for HIV-1 drug resistance and HCV genotyping (Bayer).

The ViroSeq HIV-1 genotyping assays (Celera Diagnostics, Alameda, Calif.; distributed by Abbott Molecular Diagnostics, Des Plains, Ill.) also use dideoxy chain-terminating sequencing, but each dideoxynucleotide is labeled with a different fluorescent dye. Each reaction mixture contains one primer but all four uniquely labeled dideoxynucleotides. Separation of the terminated PCR products is done by capillary electrophoresis.

Although direct sequencing of PCR products by electrophoresis is a powerful research tool, its routine use in the clinical laboratory depends upon the development of high-throughput systems with integrated databases and data analysis software. Such systems are available for HIV-1 and HCV genotyping and for identification of bacteria and fungi by rRNA gene sequence analysis.

Pyrosequencing (Biotage, Uppsala, Sweden) represents an alternative approach to conventional sequencing and is useful for genotyping and short-read-length sequencing (26). Pyrosequencing is based on the luminometric detection of pyrophosphate that is generated during DNA synthesis.

A sequencing primer is hybridized to a single-stranded PCR amplicon and incubated with the enzymes DNA polymerase, ATP sulfurylase, luciferase, and apyrase and the substrates adenosine 5′ phosphosulfate and luciferin. The first of four dNTPs is added to the reaction mixture. DNA polymerase catalyzes the incorporation of the dNTP into the DNA strand. Each incorporation event is accompanied by release of pyrophosphate (PP_i) in a quantity equimolar to the amount of incorporated nucleotide. The ATP sulfurylase quantitatively converts PP_i to ATP in the presence of adenosine 5′ phosphosulfate. This ATP drives the luciferase-mediated conversion of luciferin to oxyluciferin that generates light in amounts that are proportional to the amount of ATP. The light produced in the reaction is detected by a charge-coupled device camera.

A program is produced in which the height of each peak is proportional to the number of nucleotides incorporated. Apyrase, a nucleotide-degrading enzyme, continuously degrades ATP and unincorporated dNTPs. This degradation switches off the light and regenerates the reaction solution. The next dNTP is added, and the process is repeated.

Pyrosequencing has been used in microbiology to detect drug resistance mutations and to identify and type bacteria, viruses, and fungi (2, 37, 40, 91). Unlike conventional sequencing strategies, pyrosequencing provides reliable data for sequences adjacent to the sequencing primer termini. Pyrosequencing provides a simple-to-use and robust platform for short-read-length sequencing.

Hybridization Arrays

DNA hybridization arrays are produced by attaching or synthesizing hundreds or thousands of oligonucleotides on a solid support in precise patterns. A labeled amplification product is hybridized to the probes, and hybridization signals are mapped to various positions within the array. If the number of probes is sufficiently large, the sequence of the PCR product can be deduced from the pattern of hybridization. A number of manufacturers are developing DNA microarrays and the instrumentation required to acquire and analyze the data. Hybridization arrays have a number of applications in microbiology, including microbial and host gene expression profiling and diagnostic sequencing. The CLSI has published a guideline for the use of diagnostic nucleic acid microarrays (18).

One of the most developed approaches brings together advances in synthetic nucleic acid chemistry with photolithography, a process used in the manufacture of semiconductors for the computer industry. This approach uses light to direct the synthesis of short oligonucleotides on a silica wafer (94). On a 15-mm-square chip, thousands of individual sites or features can be established. At each feature, specific oligonucleotides are assembled one nucleotide at a time by light-activated chemistry.

The DNA chip is incubated in a flow cell with DNA product that has been fragmented and labeled with a fluorophore. After hybridization, a scanning laser confocal microscope evaluates the surface fluorescence intensity of the chip. Automated scanning by the microscope takes only a few minutes to acquire an image of the entire surface of the chip, and computer software analyzes the fluorescent image and determines the nucleic acid sequence of the PCR product. A DNA chip based on this technology for the detection of HIV-1 drug resistance mutations is commercially available (Affymetrix, Santa Clara, Calif.).

Another method of producing DNA hybridization arrays involves the precise micropipetting of premade double-stranded DNA probes (typically 200 to 2,000 bp in length) onto glass slides with a robotic device (110). These arrays are not suitable for mutation detection due to the size and density of the arrayed DNA probes but have facilitated gene expression profiling. DNA arrays of this type can be used to determine the activation states (mRNA levels) of thousands of genes simultaneously. Gene expression profiling of pathogens by use of arrays may provide new insights into pathogenic mechanisms and help identify new therapeutic and vaccine targets.

Nanogen (San Diego, Calif.) has developed a bioelectronic chip with 100 individually addressable electrodes. The silicon chip is manufactured by using the same type of photolithographic and deposition techniques used in the microelectronics industry. The technology uses electrical fields to move biological samples through the chip and direct the samples to the electrodes. Cheng and colleagues (13) used a microelectrode array to separate *E. coli* cells from a whole-blood sample and then to lyse the isolated *E. coli* cells on the chip. The lysate was then transferred to another bioelectronic chip for an electronically enhanced hybridization assay developed previously (114). The development of fully integrated analytical systems that function as a laboratory, the so-called "lab on a chip," is the ultimate goal of microchip designers.

DNA microarrays and bioelectronics hold much promise for molecular diagnostics. However, the current technology has several limitations, including the complexity of fabricating the microarrays, limited availability, and high test cost.

QUANTITATIVE METHODS

Many of the methods discussed above can be used to quantify the amount of RNA or DNA in a clinical sample. The most commonly used methods include PCR and RT-PCR, transcription-based amplification, bDNA assays, and hybrid capture. The principle of quantitative molecular methods is that there is a linear relationship between the quantity of the input template and the amount of the product or signal generated. Competitive PCR (cPCR) is a reliable and robust method that is commonly used in commercial and laboratory-developed assays. The basic concept behind cPCR is the coamplification in the same reaction tube of target and calibrator templates with equal or similar lengths and with the same primer binding sequences. Since both templates are amplified with the same primer pair, identical thermodynamics and amplification efficiencies are ensured. The amount of the calibrator must be known, and after amplification, products from both templates must be distinguishable from each other. Different types of calibrators have been used in cPCR, but in general those calibrators similar in size and base composition to the target work most effectively. RNA competitors should be used in quantitative RT-PCRs to address the problem of variable RT efficiency. This competitive amplification approach has also been used effectively with transcription-based amplification methods using RNA targets and RNA calibrators.

For cPCR, the concentration of the target template in the clinical sample can be determined by a simple calculation. The yield of the PCR product is described by the equation $Y = I(1 + e)^n$, where Y is the quantity of the PCR product, I is the quantity of the template at the beginning of the reaction, e is the efficiency of the reaction, and n is the number of cycles. In cPCR, this equation is written for both templates, as follows: competitor, $Y_c = I_c(1 + e)^n$; target, $Y_t = I_t(1 + e)^n$. Since e and n are the same for both the competitor and the target, the relative product ratio Y_c/Y_t directly depends on the initial concentration ratio I_c/I_t and the function $Y_c/Y_t = I_c/I_t$ is linear.

An alternative method of quantification is to run multiple concentrations of the calibrator in parallel with the reaction mixtures containing the target molecules. The signal generated from these external calibrators is used to generate a calibration curve, and the amount of the target in the original specimen is calculated based on comparison to the curve. The use of external calibration with the target amplification methods offers the advantage that the calibrators do not compete with the target for assay components. However, since the final amount of the amplified product depends on exponential amplification of the initial quantity of the template, minor differences in amplification efficiency may lead to very large and unpredictable differences in the final product yield (16). The

sample-to-sample differences may depend on sample preparation, nucleic acid purification procedures, the presence of inhibitors, and thermal cycler performance. For these reasons, simple quantitation of the amplified product and the use of external standard reference curves may not provide reliable quantitation of the template initially present in the sample.

Real-time amplification and detection methods are particularly well suited for quantification of nucleic acid because the amount of the fluorescent signal generated is proportional to the concentration of the target DNA or RNA in the original sample. Real-time PCR and transcription-based amplification methods are the most commonly used quantitative methods. For real-time PCR, the fluorescent signal is measured during the exponential phase of amplification, which is where the amplification plot crosses the threshold (Fig. 3). This is in contrast to standard PCR methods that measure the end point signal. There are advantages to measuring the fluorescent signal during the exponential phase of amplification; the reaction components are not limiting, and the assay is less sensitive to the effects of inhibitors. As a result, real-time PCR assays are more reproducible than standard PCR assays. Both internal and external calibrators can be used with real-time assays, but the improved precision of real-time assays allows more reliable results to be obtained with an external calibration curve than would be obtained with standard PCR. When external calibrators are used, a calibration curve is generated by plotting the $\log_{10}$ concentration of the external calibrator versus the C_T and this plot is used to calculate the concentration of nucleic acid in the sample. The concentration of nucleic acid in the sample is inversely related to the C_T: the higher the concentration of the nucleic acid, the lower the C_T (49). In general, quantitative real-time PCR assays are not more sensitive than standard PCR assays; however, they have a much broader linear range, typically 6 to 7 orders of magnitude.

The CLSI has published guidelines for quantitative molecular methods for infectious diseases that address the development and application of quantitative PCR assays and other nucleic acid amplification methods (84).

AUTOMATION AND INSTRUMENTATION

Molecular assays consist of three major steps: specimen processing, nucleic acid amplification, and product detection. Sample processing is usually the most labor-intensive step and has represented the biggest challenge for manufacturers of automated test systems. However, in the past several years there have been considerable advances in this area with the availability of both semiautomated and fully automated systems. Automation of the nucleic acid extraction process offers laboratories several advantages, including ease of use, limited handling of the sample, improved reproducibility, reduced opportunity for cross contamination, and for some systems, postelution functions such as adding samples into the master mix. These advantages need to be weighed against the costs of automated systems, the inflexibility of batch size, and the large sizes of many of the automated instruments. The systems vary in the types of nucleic acid extraction methods that they provide and include total nucleic acid, DNA-only, and RNA-only protocols. Other features of automated extraction systems to consider are the availability of protocols for various specimen types and volumes, variable elution volumes, the availability of target-specific and/or generic target extraction methods, and specimen throughput. The available automated systems range from fully automated high-throughput systems such as the MagNA Pure system (Roche) and *m*2000 generic extractor (Abbott) to those designed for a small number of specimens with random access capabilities, such as BioRobot EZ1 (Qiagen).

There are a few automated systems available for the conventional amplification methods, such the COBAS system (Roche) for PCR and the System 340 platform for bDNA assays (Bayer). Considerable advances in automation have been made with the availability of real-time amplification and detection systems.

Several instruments are commercially available for real-time PCR testing. These instruments vary as to speed, capacity of samples per test run, reaction volume, optics, and support for different fluorescence probe types. The time required for analysis depends to a great extent on the time required for thermocycling, and the speed of thermocycling depends on how quickly the instrument can change temperature over time. For example, some instruments can change the temperature at 20°C per s, permitting instrument analysis of up to 32 samples in as little as 30 min. Capacity may offset thermocycling speed. Although a higher-capacity instrument may have a longer thermocycling time than a lower-capacity instrument, potentially more samples may be analyzed by the high-capacity instrument in a specific time period than by the low-capacity instrument.

The reaction mixture volume assayed may also vary from one system to another. If target nucleic acid is present in extremely small amounts in a sample, an instrument that permits higher-volume analysis may be preferred.

Real-time PCR instruments utilize a variety of optics for fluorescence detection. A tungsten source lamp for excitation and selectable filters for excitation and emission wavelength detection are used in a number of instruments. Light-emitting diodes or laser excitation devices coupled with emission wavelength detection may also be used. The new real-time PCR instruments allow up to five different fluorogenic dyes to be used simultaneously in one reaction. Until recently, real-time PCR instruments were designed for research applications. The ABI Prism series of sequence detection systems (Celera), LightCycler (Roche), and SmartCycler (Cepheid, Sunnyvale, Calif.) are examples of research instruments that find widespread use in molecular diagnostics laboratories. The COBAS TaqMan analyzer (Roche) and the *m*2000 system (Abbott) are the first real-time instruments designed specifically for use in clinical laboratories (5).

Many manufacturers are coupling automated nucleic acid extraction instruments with amplification and detection systems to create high-throughput, fully automated nucleic acid analyzers. The TIGRIS system (Gen-Probe) (77), the AmpliPrep-COBAS TaqMan system (Roche), and the *m*2000 system (Abbott) are examples of fully automated and integrated systems designed to perform sample processing, nucleic acid amplification, and product detection. The TIGRIS system was developed for screening the blood supply for HCV and HIV RNA and can process up to 500 nucleic acid detection tests in 8 h. The GeneXpert system (Cepheid) represents the other end of the automation spectrum in which a single sample is added to a disposable fluidic cartridge that fully automates and integrates sample preparation, amplification, and real-time detection. The instrument is a random access design, raising the possibility of on-demand molecular testing.

PROTEOMICS

The term proteome was coined in 1994 to describe the set of proteins encoded by the genome (132). Proteomics, the study of the proteome, has come to encompass the identification,

characterization, and quantification of the complete set of proteins expressed by the entire genome in the lifetime of a given cell, tissue, or organism. Development of vaccines, therapeutics, and diagnostics directed at a particular infectious disease commonly requires analysis of organisms at the protein level. Genome level analysis of an organism, as valuable as that has been, is incomplete because only a fraction of the genome is translated into mRNA. Similarly, analysis of an organism at the mRNA level (transcriptome) may also be misleading because proteins translated from mRNA can undergo posttranslational modifications.

Two-dimensional gel electrophoresis and mass spectrometry are the tools used to define an organism's proteomic signature. Comparison of the proteomic signature of a reference state to a proteomic signature derived under experimental conditions or a disease state can reveal important information about the biology of the pathogen and the host's immune response to it (11, 54, 56, 127). Proteomic approaches have been used successfully to identify diagnostic markers for gastric disease caused by *Helicobacter pylori* (41), Lyme disease (55), severe acute respiratory disease (101), and tuberculosis (4).

The same approaches that are used to find biomarkers can also be used to develop rapid, sensitive, and high-throughput multimarker assays. The premise is to first establish composite fingerprint profiles for both disease and nondisease states and then use the composite profiles to make a diagnosis with an unknown patient sample. The development of chip-based protein differential display systems will facilitate the development of diagnostics based on protein expression analysis (33).

CURRENT APPLICATIONS

Molecular methods have created new opportunities for the clinical microbiology laboratory to impact patient care in the areas of initial diagnosis, disease prognosis, and monitoring of response to therapy. Over time the methods have become more automated, the cost of testing has decreased, and clinical utility has been proven for the diagnosis and management of a variety of infectious diseases. As a result, molecular testing is now routinely performed in many clinical microbiology laboratories and clinical applications will continue to expand in the future.

Initial Diagnosis

With the development of molecular methods, the clinical microbiology laboratory is no longer reliant solely on the traditional culture methods for detection of pathogens in clinical specimens. Culture-based methods have long been the gold standard for infectious disease diagnosis, but for several diseases, nucleic acid-based tests have replaced culture as the gold standard. Hepatitis C infection, enteroviral meningitis, pertussis, herpes simplex virus (HSV) encephalitis, and genital infections due to *C. trachomatis* are some examples of infectious diseases in which nucleic acid-based tests are the new gold standards for diagnosis. This technology has been used to best advantage in situations in which traditional methods are slow, insensitive, expensive, or not available. These techniques work particularly well with fragile or fastidious microorganisms that may die in transit or be overgrown by contaminating flora when cultured. *N. gonorrhoea*e is an example in which the nucleic acid can be detected under circumstances in which the organism cannot be cultured. The use of improper collection media, inappropriate transport conditions, or delays in transport can reduce the viability of the pathogen but may leave the nucleic acid still detectable. It is beyond the scope of this chapter to review all of the possible applications or to provide a compendium of methods for detection of various pathogens. The reader is directed to another excellent resource for this information (96).

Opportunities to actually replace culture for bacterial pathogens in routine practice are limited by the need to isolate the organisms for antibiotic susceptibility testing. In those applications in which culture has actually been replaced by nucleic acid testing, the pathogens are of predictable susceptibilities and, consequently, routine susceptibility testing is not performed, or the genetics of resistance are well defined and simple to detect, such as methicillin resistance in *S. aureus*.

Molecular methods have had the biggest impact in clinical virology in which the molecular approaches are often faster, more sensitive, and more cost-effective than the traditional methods. The diagnoses of enteroviral meningitis, HSV encephalitis, and CMV infections in immunocompromised patients are examples of clinically relevant and cost-effective applications of nucleic acid-based tests. There are greater opportunities to replace the conventional methods in virology than in bacteriology because the culture-based methods are costly and antiviral susceptibility testing is not routinely performed. In those situations in which antiviral susceptibility testing is required, such as identification of ganciclovir-resistant CMV, it may also be more amenable to molecular approaches. A limitation of molecular tests for viral diagnostics is the clinical need for simultaneous identification of multiple pathogens, for example, respiratory viruses. Multiplex PCR can be difficult to optimize, so detection of common respiratory pathogens may require multiple tests.

Perhaps the greatest impact of molecular methods has been in the discovery of previously unrecognized or uncultivable pathogens. During the past 15 years, a number of infectious agents were first identified directly from clinical material by using molecular methods**.** HCV, the principal etiologic agent of what was once known as non-A, non-B hepatitis, was discovered in 1989 through the application of molecular cloning techniques by investigators from the Centers for Disease Control and the Chiron Corporation (15). Cloning and analysis of the HCV genome led to production of viral antigens that now serve as the basis of the specific serological tests used to screen the blood supply and to diagnose hepatitis C. To date, HCV has resisted all attempts at sustained in vitro propagation. As a result, RT-PCR is used to detect, quantitate, and genotype HCV in infected individuals.

Tropheryma whippelii, the causative agent of Whipple's disease, is another example of an uncultivable microorganism which was initially identified by molecular methods (100). It was discovered by the use of broad-range PCR, in which primers are directed against conserved sequences in the bacterial 16S rRNA gene. Sequence analysis of the PCR product and comparison with known 16S rRNA gene sequences were used to characterize the organism and establish its disease association. This approach provides a new paradigm for discovery of unrecognized pathogens that is of value in other diseases with features that suggest an infectious etiology.

Recently, molecular methods were used to rapidly identify the etiologic agent of severe acute respiratory syndrome as a coronavirus (60, 95). Within a few months of the recognized outbreak, the virus was identified and sequenced and the molecular assays were developed that played an essential role in diagnosing the infection and defining the epidemiology of the infection.

Identification of Bacteria and Fungi by Nucleic Acid Sequencing

Nucleotide sequence analysis of the 16S bacterial rRNA gene has expanded our knowledge of the phylogenetic relationships among bacteria and is the new standard for bacterial identification. rRNA contains several functionally different regions, with some regions having highly conserved and others having highly varied nucleic acid sequences (133). The sequence of the 16S rRNA gene is a stable genotypic signature that can be used to identify an organism at a genus or species level. The 16S gene sequence can be determined rapidly and provides objective results independent of phenotypic characteristics. As discussed in the preceding section, it can also be used to characterize previously unrecognized species. A similar approach that targets the nuclear large subunit of the rRNA gene can be used for the identification of fungi (61). This gene is universally found in all fungi and contains sufficient variation to identify most fungi accurately to the species level.

The DNA sequencing approach to microbial identification involves extraction of the nucleic acids, amplification of the target sequence by PCR, sequence determination, and a computer software-aided search of an appropriate sequence database. The major limitations of this approach to microbial identification include the high cost of automated nucleic acid sequencers, the lack of appropriate analysis software, and limited databases.

Applied Biosystems (Foster City, Calif.) has developed ribosomal gene sequencing kits for bacteria and fungi. A sequence from an unknown bacterium is compared with either full or partial 16S rRNA sequences from over 1,000 type strains by using the MicroSeq analysis software (119). The software analysis provides percent base pair differences between the unknown bacterium and the 20 most closely related bacteria, alignment tools to show differences between the related sequences, and phylogenetic tree tools to verify that the unknown bacterium actually clusters with the 20 closest bacteria in the database. The MicroSeq fungal identification system is similar to the bacterial identification system but targets D2 large-subunit rRNA (42, 43). Continued improvements in automation, refinements of analysis software, and decreases in cost should lead to more widespread use of nucleic acid sequence-based approaches to microbial identification.

Disease Prognosis

Molecular techniques have created opportunities for the laboratory to provide important information that may predict disease progression. Probably the best example is HIV-1 viral load as a predictor of progression to AIDS and death in infected individuals. This predictive value was first demonstrated in 1996 as part of a multicenter AIDS cohort study (79). The investigators showed that the risk of progression to AIDS and death was directly related to the magnitude of the viral load in plasma at study entry. The viral load in plasma was a better predictor of disease progression than the number of $CD4^+$ lymphocytes. Subsequent studies have confirmed that baseline viral load critically influences disease progression.

Subtyping of certain viruses by molecular methods may also have prognostic value. Subtyping of respiratory syncytial viruses may provide information about the severity of infection in hospitalized infants, with those infected with group A viruses having poorer outcomes (130). HPV causes dysplasia, intraepithelial neoplasia, and carcinoma of the cervix in women. HPV types 16 and 18 are associated with a high risk of progression to neoplasia, and types 6 and 11 are associated with a low risk of progression (99). The clinical utility of molecular testing for high-risk HPV DNA has been established for managing women with the cervical cytologic diagnosis of atypical squamous cells of undetermined significance. Women with this condition can be referred for colposcopy based on the detection of high-risk HPV DNA (113). HPV DNA testing was recently approved by the Food and Drug Administration (FDA) for use as an adjunct to cytology for cervical cancer screening in women aged 30 years or more (135).

CMV viral load testing has recently been shown to be useful for deciding when to initiate preemptive therapy in organ transplant recipients and distinguishing active disease from asymptomatic infection. Qualitative CMV DNA PCR assays have been unable to distinguish patients with asymptomatic CMV infection from those with active CMV disease (36, 89). Recently, studies have shown that the level of CMV DNA can predict the development of active CMV disease. With the availability of standardized commercial assays, it is possible to establish viral load cutoffs for predicting the development of CMV disease and initiating preemptive therapy (1, 51). It is likely that quantitative assays will be useful in distinguishing disease from infection with other herpesviruses such as Epstein-Barr virus and human herpesvirus type 6.

Response to Therapy

Molecular methods have been developed to detect the genes responsible for resistance to single antibiotics or classes of antibiotics in bacteria and in many cases are superior to the phenotypic, growth-based methods. The detection of methicillin resistance in staphylococci, vancomycin resistance in enterococci, and rifampin resistance in *M. tuberculosis* provide examples of where molecular methods are used to supplement the growth-based methods (123). However, it is difficult to imagine, given our current state of knowledge of the molecular genetics of antimicrobial resistance and the technological limitations, that a genotypic approach to routine antimicrobial susceptibility testing of bacteria could rival the phenotypic methods in terms of information content and cost.

Molecular techniques are playing an increasing role in predicting and monitoring patient response to antiviral therapy. The laboratory may have a role in predicting response to therapy by detecting specific drug resistance mutations, determining viral load, and genotyping. Both viral load and genotype are independent predictors of response to combination therapy with pegylated interferon and ribavirin in chronic HCV infections (32, 78). Those patients with high pretreatment viral loads of >2 million copies/ml or with genotype 1 infections have poor sustained response rates. Both of these virological parameters are used in conjunction with other factors to determine the duration of therapy (83).

Quantitative tests for HIV-1 RNA are the standard of practice for guiding clinicians in initiating, monitoring, and changing antiretroviral therapy. Several commercially available HIV-1 viral load assays have been FDA approved, and guidelines for their use in clinical practice have been published (107). Viral load assays have also been used in monitoring response to therapy in patients chronically infected with HBV and HCV (32, 47, 67). In organ transplant recipients, the persistence of CMV viral load after several weeks of antiviral therapy is associated with the development of resistant virus (10).

LABORATORY PRACTICE

The unparalleled analytical sensitivity of nucleic acid amplification techniques coupled with their susceptibility to cross

contamination presents unique challenges to the routine application of these techniques in the clinical laboratory. There are special concerns in the areas of specimen processing, workflow, quality assurance, and interpretation of test results. Additional information can be found in the CLSI documents MM3-A2, *Molecular Diagnostic Methods for Infectious Diseases; Approved Guideline,* 2nd ed. (20), and MM13-A, *Collection, Transport, Preparation, and Storage of Specimens and Samples for Molecular Methods; Approved Guideline* (17).

Specimen Collection, Transport, and Processing

Proper collection, transport, and processing of clinical specimens are essential to ensure reliable results from molecular assays. Nucleic acid integrity must be maintained throughout these processes. Important issues to consider in specimen collection are the timing of specimen collection in relationship to disease state and the proper specimen type. Other factors that come into play include the use of the proper anticoagulant, transport and storage temperatures, and time to processing of the specimen. HIV-1 viral load testing is an example in which the proper conditions for specimen collection, transport, and processing have been well described and has provided insight into the importance of these factors. For HIV-1 viral load testing, the plasma needs to be separated from the cells within 6 h of collection to minimize degradation of RNA. Once the plasma has been separated, it can be stored at 4°C for several days, but −70°C is recommended for long-term storage (107). Most types of specimens are best stored at −20 to −70°C prior to processing.

Molecular methods have several advantages over conventional culture with regard to specimen collection. It may be easier to maintain the integrity of nucleic acid than the viability of an organism. Molecular tests for the detection of *C. trachomatis* and *N. gonorrhoeae* are an example in which DNA is stable on dry cervical swabs for a week at room temperature or refrigeration temperatures, which is in stark contrast to the conditions required to maintain organism viability for culture. Nucleic acid persists in specimens after initiation of treatment (35, 66), thus allowing detection of a pathogen even though the organism can no longer be cultured. Also, due to the increased sensitivity of molecular assays, it may be possible to test a smaller volume of specimen or use a specimen that is collected using a less invasive method.

The major goals of specimen processing are to release nucleic acid from the organism, maintain the integrity of the nucleic acid, render the sample noninfectious, remove inhibiting substances, and in some instances concentrate the specimen. These processes need to be balanced with minimizing manipulation of the specimen. Complex specimen processing methods are time-consuming and may lead to the loss of target nucleic acid or result in contamination between specimens. Care must be taken to avoid carrying over inhibitory substances, such as phenol or alcohol, from the nucleic acid isolation step to the amplification reaction.

There are several general methods for nucleic acid extraction. Different methods may be used depending on whether the desire is to purify RNA or DNA or both. Another factor to consider when deciding on a nucleic acid extraction method is the type of pathogen sought. Some pathogens, such as viruses, can be very easy to lyse, and mycobacteria, staphylococci, and fungi can be very difficult to lyse. Enzyme digestion or harsh lysis conditions may be required to disrupt the cell walls of these organisms.

DNA isolation methods often use detergents to solubilize the cell wall or membranes, a proteolytic enzyme, such as proteinase K, to digest proteins, and EDTA to chelate divalent cations needed for nuclease activity (7, 38). The lysate can be used directly in amplification assays, or additional steps may follow to purify the nucleic acid. These additional steps remove proteins and traces of organic solvents and concentrate the specimen. In order to successfully use a crude lysate, the target DNA must be present in a relatively high concentration and there must be minimal inhibitors of amplification in the sample. If these criteria are not met, additional purification steps should be used.

Another commonly used method of nucleic acid isolation involves disruption of cells or organisms with the chaotropic agent guanidinium thiocyanate and a detergent (14). After a short incubation, the nucleic acid can be precipitated with isopropanol. Guanidinium thiocyanate denatures proteins and is also a strong inhibitor of ribonucleases, making it a very useful method of RNA isolation, although it is also used for purification of DNA. The Boom extraction method is also based on the lysing and nuclease-inactivating properties of guanidinium thiocyanate but utilizes the acid-binding properties of silica or glass particles to purify nucleic acid (8). Over the past several years, various manufacturers have developed commercially available reagents using one of these basic methods or a modification of these methods. Many of these methods rely on the use of spin column technology, are easy to use, and provide a rapid, reproducible method for purification of nucleic acid from a wide variety of clinical specimens. In recent years, further advances have been made with the introduction of magnetic silica particles which are coupled with instruments providing various degrees of automation, thus further simplifying nucleic acid extraction and purification. These reagents tend to be expensive, but the additional cost can be offset by labor savings.

Tissue samples need to be disrupted prior to the nucleic acid extraction process. This can be accomplished by cutting the tissue into small pieces or mechanically homogenizing the tissue prior to proceeding with one of the above-described extraction methods. Preserved tissue specimens require removal of the paraffin with solvents and slicing into fine sections prior to processing.

Removing inhibitors of amplification is a key function of the nucleic acid extraction process. Simple methods of nucleic acid extraction that involve boiling of the specimen have been used for relatively acellular specimens such as cerebrospinal fluid (CSF). Though the boiling method is fast and easy, there are problems with inhibitors of amplification in CSF that are not inactivated by boiling (80). The inhibition rate can be reduced to <1% by using a silica-based extraction method. Similarly, crude lysates of urine and cervical swab specimens are commonly used for the detection of *C. trachomatis* and *N. gonorrhoeae*. Specimens containing amplification inhibitors have been reported to range from 1 to 5% for urine to as much as 20% for cervical swabs (104). Common inhibitory substances include hemoglobin, crystals, β-human chorionic gonadotropin, and nitrates. Blood samples are used commonly for detection and/or quantification of a variety of viral pathogens including HIV-1, HCV, and CMV. HIV-1 viral load testing is an example in which the effects of different anticoagulants have been well studied. HIV-1 viral RNA is most stable when collected in EDTA, and heparin has been shown to be inhibitory to amplification and should be avoided (6, 53). In addition, very small volumes of whole blood (1%) can be inhibitory to *Taq* DNA polymerase (48). Other compounds such as acidic polysaccharides, which are components of glycoproteins present in sputum and cervical specimens and bile salts found in stool,

can also inhibit polymerase (34). With the recognition of such a wide array of inhibitors of amplification and the availability of simple, reliable, semiautomated and automated nucleic acid extraction methods, the use of crude lysates for testing becomes more difficult to justify. Regardless of the nucleic acid extraction method employed, the laboratory should monitor inhibition rates for different specimen types and nucleic acid extraction methods (see "Quality Control and Assurance").

Contamination Control

Several types of contamination can occur with molecular testing: cross contamination of specimens during the nucleic acid extraction step, contamination of specimens with positive control material, and carryover contamination of amplified products. Contamination with amplified products can occur with DNA or RNA target amplification and with probe amplification methods. It does not occur with signal amplification assays since no nucleic acid molecules are synthesized with these methods. Cross contamination that occurs during specimen processing or handling of positive control material can occur with all amplification methods. The approach to the control of contamination due to amplified products has changed dramatically with the widespread use of real-time amplification and detection methods. Since the reaction tube is not opened after amplification, there is minimal risk of contamination from the amplified product. Many laboratories using real-time methods continue to use a variety of good laboratory practices to control for contamination, but the focus is on minimizing cross contamination between specimens rather than contamination from the amplified product. Refer to CLSI document MM3-P2, *Molecular Diagnostic Methods for Infectious Diseases; Proposed Guideline,* 2nd ed. (20), for a detailed description of good laboratory practices to minimize contamination.

Clinical microbiologists have long been concerned about minimizing contamination between samples with microorganisms during specimen processing. Molecular methods have raised the level of concern considerably, and for good reason, as current methods can detect a few molecules. The previously undetected low levels of contamination that occurred in processing specimens for routine culture can lead to false-positive results in molecular assays. Prevention of contamination due to target DNA is best done by careful handling of specimens to avoid splashing, opening only one specimen tube at a time, pulse-spinning tubes prior to opening, using screw-top tubes rather than snap-cap tubes to minimize aerosolization, bleaching work surfaces, and using plugged pipette tips. Some of these approaches can be difficult for high-volume laboratories, which is why automated extraction systems can be very useful. Care must be taken with these systems to ensure that there is no cross contamination during the automated process. This is often done by alternating negative and high-titer specimens in a checkerboard arrangement and monitoring for carryover of sample into the negative specimens. These experiments should be designed with an understanding of the concentration of the organism in the clinical specimen. For example, the concentration of HSV in CSF from patients with meningitis is quite low compared to the concentration of BK virus in the urine of a patient with nephropathy.

Preventing contamination of the laboratory with DNA from a clinical specimen or positive control material is very important, because eliminating contamination with target DNA once it occurs can be very difficult. This is why care should be taken to use a positive control at the lowest concentration that consistently amplifies. The enzymatic and photochemical inactivation methods used to control carryover contamination of amplified products are not effective in preventing contamination with target DNA.

Enzymatic inactivation of amplified product can be accomplished with uracil-*N*-glycosylase (UNG), a DNA repair enzyme found in a variety of bacterial species. During the PCR, dTTP is replaced with dUTP so that dUTP is incorporated into the newly synthesized DNA products. This allows for a distinction between starting template DNA and amplified products; only newly synthesized PCR products will contain deoxyuracil. If UTP-containing amplification products are present as contaminants, the addition of UNG to the reaction mixture will result in the cleavage of deoxyuracil residues, thus destroying the contaminating DNA (72). The use of UNG increases the amount of carryover DNA needed to contaminate the reaction mixture by several orders of magnitude (93). When UNG is used, it is important to keep the annealing temperature above 55°C so that the UNG remains inactive, thus avoiding degradation of newly synthesized product. For the same reason, after completion of amplification, the reaction mixture should be held at 72°C (125). UNG can be inactivated at 94°C, but prolonged inactivation at 94°C may also affect the activity of the polymerase enzyme. UNG will not remove uracil from RNA molecules and is therefore ineffective in controlling contamination in RNA amplification assays, such as TMA and NASBA.

When UTP and UNG are used, the PCR reaction conditions should be reoptimized as the magnesium requirement may increase. The efficiency of amplification may be reduced when UTP is substituted for TTP. This can be overcome by adding a mixture of dUTP and dTTP into the master mix. The efficiency of inactivation using UNG depends on the size of the amplified product and its G+C content. Inactivation may not be effective with amplified products of fewer than 100 bp, as maximum UNG efficiency requires the DNA molecule to be 150 bp (28).

Quality Control and Assurance

Verification and validation are terms that are often used interchangeably; however, they are very different processes. Verification is the process by which assay performance is determined; parameters such as sensitivity, specificity, positive and negative predictive value, and accuracy are established. The verification of an assay is completed before the assay is used for patient testing. Validation is the ongoing process of proving that the assay is performing as expected and achieves the intended results.

The verification of an assay includes analytical verification and clinical verification. The analytical verification provides information on the performance characteristics of the assay, and the clinical verification determines the clinical utility of the assay. Determining the clinical utility of a molecular assay can be difficult when the molecular assay is more sensitive than the gold standard. This situation was seen with the commercial assays designed to detect *C. trachomatis* in genital specimens. Molecular assays proved to be much more sensitive than the gold standard method of culture. An insensitive gold standard can make a molecular assay appear to have a falsely low specificity. In this situation, an expanded gold standard can be used. For *C. trachomatis,* this included direct fluorescent-antibody testing and/or another molecular method (35, 66, 109). There are additional challenges in determining the clinical utility of molecular assays that detect rare pathogens. These assays are usually laboratory developed, and any given medical center may see very few cases of

the disease, making clinical verification difficult. Moreover, standards and control material can be difficult to obtain for rare pathogens. Several companies now provide control material for the more common molecular assays such as those for *C. trachomatis*, *N. gonorrhoeae*, HIV-1, HCV, and CMV.

A positive control is designed to ensure that the test can consistently detect a concentration of target nucleic acid at or near the limit of detection of the assay. The positive control should be at the lowest concentration that can be reproducibly amplified. A positive control that is significantly greater than the cutoff of the assay may not detect small decreases in amplification efficiency. In addition, large amounts of target DNA can increase problems with contamination in the laboratory. Depending on the availability of material, the positive control may be purified nucleic acid or lysed or intact organisms. An extraction control tests the ability of the nucleic acid extraction or purification method to successfully free nucleic acid from the organism. The extraction control, which should be intact organisms, can also serve as a positive control if it is used at the appropriate concentration.

Monitoring for the presence of inhibitors in a specimen is important, particularly for complex specimens such as blood or sputum. Several methods can be used to control for inhibition. A commonly used method is to amplify two aliquots of a clinical specimen, one directly and the second spiked with an aliquot of positive control DNA. For a specimen to be considered negative for the target analyte, testing results for the direct specimen must be negative and those for the spiked specimen must be positive. If an inhibitor of amplification was present, the spiked specimen would be negative. The concentration of positive control used for the spike must be near the limit of detection of the assay to ensure that low-level inhibition of amplification is detected.

Another approach to monitoring for inhibition of amplification is adding an internal control to the clinical specimen prior to nucleic acid extraction. As discussed in "Quantitative Methods," the internal control molecule may be designed with the same primer binding sites as the target molecule but modified in some manner so as to allow detection separate from the target based on size or sequence. An internal control is an effective way to monitor for inhibition, but it may decrease the sensitivity of the assay due to competition for assay components. Amplification of a human housekeeping gene such as that for β-globin may also be used as an internal control, but the gene should not be present in vast excess of the target molecule or inhibition of amplification of the target molecule can occur without evidence of inhibition of the housekeeping gene. Inhibition controls should be included in assays that use a new specimen extraction method or specimen type. However, a cost-effective approach is to discontinue these controls once the inhibition rate is determined to be less than 1 to 2%.

Under certain conditions, there may be a need to determine if there is adequate nucleic acid in a specimen, for example, when using paraffin-embedded tissue or when evaluating the quality of a specimen. In these situations, amplification of housekeeping genes can be used to determine if the specimen contains human DNA. The absence of amplifiable human DNA from the specimen raises concern about whether the specimen quality is adequate.

Negative controls should be included in all assays and processed in a manner similar to the processing of the clinical specimens. The negative control should be taken through all steps of the assay, including the nucleic acid extraction process. However, no amplification in the negative control does not ensure that there is not contamination in the run, as contamination is often low level and sporadic. Including multiple negative controls in the run may provide additional assurance that there is no contamination, but this approach may be cost prohibitive. Ideally, the negative control should be a clinical specimen that does not contain the analyte of interest. These types of controls may be difficult to obtain, so water or buffer is often substituted.

Currently, the College of American Pathologists is the only Centers for Medicare and Medicaid Services-approved proficiency program for molecular testing for infectious diseases. The College of American Pathologists provides proficiency testing for many common pathogens for which routine testing is done in the clinical laboratory. The Quality Control for Molecular Diagnostics proficiency program, which is jointly sponsored by the European Society for Clinical Virology and the European Society for Clinical Microbiology and Infectious Diseases (Glasgow, Scotland, United Kingdom), also provides testing for a variety of pathogens. The Centers for Disease Control and Prevention also offer a model performance evaluation program for HIV-1 twice per year. When formal external proficiency testing programs are not available, laboratories may split sample testing with other laboratories, split samples between a new method and an established laboratory-developed method, or clinically validate the test result by clinical diagnosis. When exchanging specimens between laboratories for proficiency testing, it is important that both laboratories use the same method, particularly for quantitative methods, as viral load values will differ among the various assays.

Reporting and Interpretation of Results

The interpretation of molecular assays requires a basic understanding of the strengths and limitations of these technologies. There are unique problems in interpreting molecular testing results that are not routinely encountered with traditional microbiologic assays, such as culture and serology. Some of the problems that may occur in interpreting molecular assays include recognizing false-positive results, distinguishing viable from nonviable organisms, and correlating nucleic acid detection with the presence of disease.

For interpretation of a positive test result, the issues that need to be considered are assay specificity and contamination. The specificities of most molecular assays are established by the primers and probes used during amplification and detection steps; if they cross-react with other pathogens, then false-positive results are possible. For example, primers designed to detect *Mycobacterium pneumoniae* from respiratory specimens must not cross-react with organisms that are part of normal oral flora or other common respiratory pathogens, such as *Streptococcus pneumoniae*. Although uncommon, problems with primer specificity do occur; the primers designed to amplify the 5′ untranslated region of enteroviruses have been reported to cross-react with rhinoviruses (106). This would not be a problem for testing of CSF specimens but would preclude using the assay on respiratory specimens. Problems with primer specificity have also been reported for a commercially available PCR assay designed to detect *N. gonorrhoeae*. The primers used in this assay cross-react with *Neisseria subflava*, a nonpathogenic organism found in the oropharynx (29). False-positive results can also be due to contamination, which may occur during specimen processing or as a result of carryover contamination of previously amplified products.

The interpretation of a negative result requires consideration of assay sensitivity, specimen quality, nucleic acid extraction efficacy, and amplification efficiency. Problems with any of these factors can lead to a false-negative result,

which is why measures to control for each of these parameters should be included in assays whenever feasible. Another source of false-positive results is sequence variation, which may prevent binding of either primers or probes. To minimize this problem, one should perform a thorough search of known sequences before designing the assay and occasionally reexamine the available databases after the assay is put into clinical use.

Molecular assays detect pathogen nucleic acid but cannot determine whether that nucleic acid is found in a viable or nonviable organism. Pathogen nucleic acid can be detected for long periods of time after appropriate treatment is initiated. For example, *C. trachomatis* DNA can be found in the urine of patients for up to 3 weeks after completion of a course of therapy (35). Similar results have been reported for the detection of HSV DNA in the CSF of patients with encephalitis. DNA can persist for 2 weeks or longer after the initiation of acyclovir therapy (64). Due to the persistence of pathogen DNA after initiation of therapy, qualitative molecular assays should not be used to monitor response to therapy. One notable exception is the use of a qualitative HCV RNA RT-PCR assay to monitor the response to therapy with pegylated interferon and ribavirin. In this instance, the absence of detectable viral RNA from plasma is used to define treatment response (32).

The detection of pathogen nucleic acid does not ensure that the organism is the cause of disease. The organism may be present as part of the normal flora, as a colonizer of a particular area, or as a cause of infection. Distinguishing between colonization and infection may be more difficult when molecular techniques that are more sensitive than culture are used. Organisms present in very low concentrations, which may have gone undetected by routine culture methods, may be detected by using molecular techniques.

Distinguishing colonization from infection is easier when testing a specimen from a normally sterile site such as CSF or blood; however, this factor alone does not ensure that the organism is a true pathogen. This distinction is a concern with the detection of herpesviruses, which cause lifelong latent infections. An important example of distinguishing these two states is monitoring transplant recipients for CMV disease using molecular methods. Initial studies used very sensitive qualitative PCR assays (36, 87), and it was clear that CMV DNA could be detected in the blood of patients that never went on to develop symptomatic disease.

Reporting the results of a qualitative molecular assay is usually straightforward; results are often reported as DNA detected or not detected. Several key parameters that may also be reported are the limit of detection of the assay, data pertaining to the rate of inhibition for a given sample type, the gene target, and the amplification method used for testing. Reporting results from quantitative assays is more complex and requires consideration of several parameters including dynamic range, units, and precision. Results of quantitative assays can be expressed as copies, weight (nanograms or picograms), or international units of the target nucleic acid in a defined volume, such as milliliters of plasma or blood, grams of tissue, or number of leukocytes. When the results of quantitative assays are reported, the precision of the assays needs to be considered. For the currently available HIV-1 viral load assays, the assay and biological variability are approximately 0.5 $\log_{10}$ (107). Therefore, changes in viral load must exceed 0.5 $\log_{10}$ (threefold) in order to represent a biologically significant change in viral replication. For these assays, values should be reported as $\log_{10}$ rather than integers to avoid the overinterpretation of small changes in viral load. Quantitative assays have a defined linear or dynamic range. Values below the lower limit of quantification should be reported as less than the lower limit of the linear range, rather than as negative. Values above the upper limit of quantification should be reported as greater than the upper limit of the linear range. For values above the limit of detection but below the limit of quantitation, results may be reported as detectable, less than the lower limit of the linear range. For example, if the lower limit of quantitation of an HIV-1 viral load assay is 400 copies/ml, a value of 250 copies/ml could be reported as detectable, <400 copies/ml. Inclusion of the amplification method and specimen type in the report is particularly important for quantitative assays, as values from different assay types are not always comparable.

Regulatory and Reimbursement Issues

The medical needs for new molecular microbiology tests have exceeded the capacity of the diagnostic industry to provide FDA-cleared test kits to fill these needs. Table 1 lists the FDA-cleared nucleic acid-based tests for infectious diseases. Notably absent from the list are tests that have become a standard of care in a variety of diseases such as HSV encephalitis, enteroviral meningitis, and pertussis. Many laboratories have developed tests to fill these unmet needs. These laboratory-developed tests must be appropriately verified and validated as specified in the Centers for Medicare and Medicaid Services final rule for laboratory requirements, 42 CFR part 493 (88a). Such tests are eligible for reimbursement by Medicare and other payers if they are determined to be part of a standard of care or to be of proven clinical benefit.

Laboratory-developed tests often utilize a combination of reagents from different manufacturers, some of which are ASRs. ASRs are chemical substances, for example, antibodies or nucleic acid sequences, that are used in diagnostic tests to detect another specific substance in a specimen and are purchased from manufacturers under this label. ASRs do not include a protocol for use or information on analytical performance or clinical indication. The FDA requires a disclaimer on reports for laboratory-developed tests using ASRs, and it reads: "This test result was developed and its performance characteristics determined by [laboratory name]. It has not been cleared or approved by the U.S. Food and Drug Administration." This disclaimer was not intended to cover laboratory-developed tests not using ASRs or the off-label uses of FDA-cleared products.

A laboratory may want to include clarifying statements in the reports of results from laboratory-developed tests employing ASRs. These statements may point out that FDA clearance is not necessary for these tests and that they are used for clinical purposes. Additional information may include that the laboratory is certified under the Clinical Laboratory Improvement Amendments of 1988 to perform high-complexity testing and that pursuant to the requirements of the amendments the laboratory has established and verified the test's accuracy and precision.

Correct current procedural terminology (CPT) coding of molecular microbiology tests is essential to coverage and reimbursement by payers. In 1998, many analyte-specific codes for tests using direct probes, amplified probes, and amplified probes with quantification were established in the microbiology section of the CPT coding manual, and this list of available codes continues to expand (1a). Prior to 1998, molecular microbiology tests were billed using multiple-component CPT codes selected from the molecular pathology section of the manual. The introduction of analyte-specific codes has simplified the coding process and in many cases

TABLE 1 FDA-cleared or -approved molecular diagnostic tests for infectious diseases[a]

Test objective	Manufacturer (distributor)	Test name	Method[b]
C. trachomatis detection (single organism)	Digene Corp., Gaithersburg, Md.	HC2 CT ID	HC
	Gen-Probe, Inc., San Diego, Calif.	APTIMA CT assay	TMA
	Gen-Probe, Inc.	PACE 2 CT and PACE 2 CT probe competition assay	HPA
	Roche Diagnostics, Indianapolis, Ind.	AMPLICOR CT/NG test for *C. trachomatis*	PCR
	Roche Diagnostics	COBAS AMPLICOR CT/NG test for *C. trachomatis*	PCR
N. gonorrhoeae detection (single organism)	Digene Corp.	HC2 GC ID	HC
	Gen-Probe, Inc.	APTIMA GC assay	TMA
	Gen-Probe, Inc.	PACE 2 GC and PACE 2 GC probe competition assay	HPA
	Roche Diagnostics	AMPLICOR CT/NG test for *N. gonorrhoeae*	PCR
	Roche Diagnostics	COBAS AMPLICOR CT/NG test for *N. gonorrhoeae*	PCR
C. trachomatis and *N. gonorrhoeae* detection	Becton Dickinson and Company, Sparks, Md.	BD ProbeTec ET *C. trachomatis* and *N. gonorrhoeae* amplified DNA assay	SDA
	Digene Corp.	HC2 CT/GC combo test	HC
	Gen-Probe, Inc.	APTIMA combo 2 assay	TMA
	Gen-Probe, Inc.	PACE 2C CT/GC	HPA
	Roche Diagnostics	AMPLICOR CT/NG test	PCR
	Roche Diagnostics	COBAS AMPLICOR CT/NG test	PCR
Gardnerella spp. *Trichomonas vaginalis,* and *Candida* spp. detection	Becton Dickinson and Company	BD Affirm VPIII microbial identification test	Hybridization
Group A *Streptococcus* detection	Gen-Probe, Inc.	GASDirect	HPA
Group B *Streptococcus* detection	GeneOhm Sciences, Inc., San Diego, Calif. (Cepheid, Sunnyvale, Calif.)	IDI-Strep B assay	Real-time PCR
Legionella pneumophila detection	Becton Dickinson and Company	BD ProbeTec ET *Legionella pneumophila* amplified DNA assay	SDA
Methicillin-resistant *S. aureus detection*	GeneOhm Sciences, Inc. (Cepheid)	IDI-MRSA assay	Real-time PCR
M. tuberculosis detection	Gen-Probe, Inc.	AMPLIFIED *M. tuberculosis* direct test	TMA
	Roche Diagnostics	AMPLICOR *M. tuberculosis* test	PCR
Culture confirmation of *Mycobacterium* spp., various fungi, and other bacteria[c]	Gen-Probe, Inc	AccuProbe culture identification tests	HPA
CMV detection	Digene Corp.	HC1 CMV DNA test	HC
	bioMérieux, Inc., Durham, N.C.	CMV pp67 mRNA	NASBA
HCV detection	Gen-Probe, Inc. (Bayer HealthCare, Diagnostics Division, Tarrytown, N.Y.)	VERSANT HCV RNA	TMA
	Roche Diagnostics	AMPLICOR HCV test, version 2.0	RT-PCR
	Roche Diagnostics	COBAS AMPLICOR HCV test, version 2.0	RT-PCR
HCV quantitation	Bayer HealthCare, Diagnostics Division	VERSANT HCV RNA 3.0 bDNA assay	bDNA assay
HIV-1 drug resistance detection	Celera Diagnostics, Alameda, Calif. (Abbott Molecular Diagnostics, Des Plains, Ill.)	ViroSeq HIV-1 genotyping system	Sequencing
	Bayer HealthCare, Diagnostics Division	TruGene HIV-1 genotyping system	Sequencing

(Continued on next page)

TABLE 1 *(Continued)*

Test objective	Manufacturer (distributor)	Test name	Method[b]
HIV-1 quantitation	Bayer HealthCare, Diagnostics Division	VERSANT HIV-1 RNA 3.0 bDNA assay	bDNA assay
	bioMérieux, Inc.	NucliSens HIV-1 QT	NASBA
	Roche Diagnostics	AMPLICOR HIV-1 MONITOR test, version 1.5	RT-PCR
	Roche Diagnostics	COBAS AMPLICOR HIV-1 MONITOR test, version 1.5	RT-PCR
HBV, HCV, and HIV-1 screening for blood donations	Gen-Probe, Inc. (Chiron, Emeryville, Calif.)	Procleix HIV-1/HCV assay	TMA
	National Genetics Institute, Los Angeles, Calif.	UltraQual HCV RT-PCR assay	RT-PCR
	National Genetics Institute	UltraQual HIV-1 RT-PCR assay	RT-PCR
	Roche Diagnostics	COBAS AmpliScreen HBV test	PCR
	Roche Diagnostics	COBAS AmpliScreen HCV test, version 2.0	RT-PCR
	Roche Diagnostics	COBAS AmpliScreen HIV-1 test, version 1.5	RT-PCR
HPV detection	Digene Corp.	HC2 HR and LR	HC
	Digene Corp.	HC2 HPV HR	HC
	Digene Corp.	HC2 DNA with Pap	HC

[a] Information was current as of 15 August 2005. Modified from www.ampweb.org.
[b] HC, hybrid capture; HPA, hybridization protection assay.
[c] Mycobacteria include *M. avium*, *M. intracellulare*, the *M. avium* complex, *M. gordonae*, *M. kansasii*, and the *M. tuberculosis* complex. Fungi include *Blastomyces dermatitidis, Coccidioides immitis, Cryptococcus neoformans,* and *Histoplasma capsulatum*. Other bacteria include *Campylobacter* spp., *Enterococcus* spp., group A *Streptococcus*, group B *Streptococcus*, *Haemophilus influenzae, Listeria monocytogenes, N. gonorrhoeae, Streptococcus pneumoniae,* and *S. aureus*.

increased the reimbursement for molecular microbiology procedures, although there continues to be considerable regional variation in reimbursement rates for the codes. The analyte-specific codes cover all aspects of testing, including the interpretation of the test result, and the use of these specific codes precludes the use of the component codes.

Credentials

Staffing a molecular diagnostics laboratory with individuals who have an appropriate knowledge base and skill set remains a challenge. Until recently, molecular diagnostics was not part of the core curriculum in medical technology programs. However, the situation is changing, and the acquisition of credentials in this area is now available for medical technologists and technicians from the American Board of Bioanalysts, the National Credentialing Agency, and the American Society for Clinical Pathology. Laboratory directors may receive credentials in molecular diagnostics through the American Board of Bioanalysts (physicians and clinical laboratory scientists), the American Board of Clinical Chemistry (physicians and clinical laboratory scientists), and jointly through the American Boards of Pathology and Medical Genetics (physicians only).

FUTURE DIRECTIONS

Nucleic acid testing will continue to be one of the leading growth areas in laboratory medicine. The number of applications of this technology in diagnostic microbiology will continue to increase, and the technology will increasingly be incorporated into routine clinical microbiology laboratories as it becomes less technically complex and more accessible. More clinical and financial outcome data will be needed to justify the use of this expensive technology in an era of declining reimbursement and increased cost consciousness.

Despite its growth, molecular diagnostics largely remains a cottage industry, with the proliferation of tests developed by individual laboratories to satisfy new medical needs not met by the diagnostic test industry. As a result, one of the biggest concerns for the future is the development of effective proficiency testing programs that will help ensure that the results of these tests are reliable and reproducible among laboratories.

To a great extent, the future of molecular microbiology depends on automation. Many of the available tests are labor-intensive, with much of the labor devoted to tedious sample processing methods. Sample processing remains the greatest challenge to automation, but the recent development of fully automated systems for molecular diagnostics offers hope for the future. Perhaps the most exciting prospects for automation come from the biochip and microfluidics sectors. With the currently available technology, it is not difficult to imagine the development in the near future of a small chip that could automate several functions of the microbiology laboratory.

The use of multiplex nucleic acid-based assays to screen at-risk patients for panels of probable pathogens remains a goal for molecular microbiology. Success to date has been limited by technical difficulties, but the development of such assays is key to providing molecular tests with the same broad diagnostic range provided by culture and other conventional methods.

Advances in human genomics will be exploited in the future to develop tests for immunogenetic factors that may influence the risk of becoming infected with certain pathogens or the progression of disease. Human gene expression profiling with microarrays may be important in defining patterns of host gene expression associated with different pathogens or disease states. Better understanding of pathogen genomics, gene expression, and proteomics will lead to the discovery of new diagnostic and therapeutic targets.

Susceptibility Testing Instrumentation and Computerized Expert Systems for Data Analysis and Interpretation*

SANDRA S. RICHTER AND MARY JANE FERRARO

17

Commercial antimicrobial susceptibility testing (AST) systems were introduced into clinical microbiology laboratories during the 1980s and have been used in the majority of laboratories since the 1990s (46). Manual and semiautomated broth microdilution systems are utilized for small volumes of susceptibility testing, while larger laboratories often choose an automated broth microdilution system. Most AST systems also perform organism identification as described in chapter 15. Semiautomated systems available for the disk diffusion method are marketed primarily outside the United States. The AST systems include data management software that may be interfaced with a laboratory information system (LIS) and offer various levels of expert system analysis. Epidemiology and pharmacy software packages are also available.

The U.S. Food and Drug Administration (FDA) provides regulatory oversight for AST systems marketed in the United States. Susceptibility test systems are classified as class II medical devices (subject to general and special controls) and require premarket notification with a 510(k) submission for FDA clearance (30, 31). A 510(k) submission must demonstrate that a device is substantially equivalent to other devices marketed in the United States. The FDA recommends a multicenter comparison of an AST system to the Clinical and Laboratory Standards Institute (CLSI, formerly NCCLS) reference method (16, 17). The level of performance considered acceptable for each antimicrobial agent-organism combination is >89.9% categorical agreement (same susceptible, intermediate, or resistant classification), >89.9% essential agreement (MIC results within 1 dilution of the reference method), ≤1.5% very major errors (VME, false susceptibility based on the number of resistant organisms), and ≤3% major errors (ME, false resistance based on the number of susceptible isolates) (31). Any antimicrobial agent-organism combination not meeting these standards must be listed as a limitation in the package insert with a recommendation to use an alternative method. Limitation statements are also required if the evaluation did not include a sufficient number of resistant organisms, showed unacceptable (<95%) reproducibility, or showed an elevated "no growth" rate (>10%) for an organism group (31). The FDA allows reporting of AST results only if the antimicrobial agent has known clinical efficacy against the organism (31). Current information describing FDA regulations and a list of approved devices can be found online (http://www.fda.gov/cdrh/consumer/mda/index.html).

This chapter will focus primarily on commercial susceptibility testing systems currently available in the United States. The broth microdilution AST systems are manufactured by four companies: bioMerieux (Durham, N.C.; http://www.biomerieux-usa.com), Dade Behring, Inc. (Sacramento, Calif.; http://www.dadebehring.com), Becton Dickinson Diagnostics (Sparks, Md.; http://www.bd.com), and TREK Diagnostic Systems (Cleveland, Ohio; http://www.trekds.com). Only one disk diffusion system, manufactured by Giles Scientific (Santa Barbara, Calif.; http://www.biomic.com), has FDA clearance. Readers should be aware that susceptibility testing system components are constantly changing in response to new technology and problems that are discovered.

SEMIAUTOMATED INSTRUMENTATION FOR DISK DIFFUSION TESTING

The advantages of the disk diffusion method of susceptibility testing include simplicity, reliability, low cost, and a high degree of flexibility in the selection of agents tested (46). Semiautomated systems available for reading and interpreting disk diffusion inhibition zones are listed in Table 1. For all systems, agar plates are manually inserted into an instrument after incubation for image acquisition and measurement of the zone of inhibition. Despite advances in imaging technology, a visual review of plates for faint growth or pinpoint colonies within the zone is recommended to assess the need for manual adjustment of the diameter measurement. Data management software determines the categorical interpretation (susceptible, intermediate, or resistant) and may be interfaced with an LIS. Although linear regression may be used to generate an MIC from a zone measurement, the validity of this method for some antimicrobial agent-organism combinations has been questioned (93). Expert system analysis and epidemiology software are available for the systems. The primary advantages of these instruments are (i) less variability in zone measurement (in comparison to caliper readings by different technologists), (ii) reduced transcription errors,

*This chapter contains information presented in chapter 15 by Mary Jane Ferraro and James H. Jorgensen in the eighth edition of this Manual.

[b] These systems are not currently available in the United States.

(iii) labor savings, (iv) improved data management capabilities, and (v) expert review to ensure correct reporting of results that are consistent with known resistance phenotypes. In general, these instruments provide reproducible and accurate results. In evaluations of the systems, organisms with faint growth accounted for most discrepancies (33, 63, 66).

MANUAL BROTH MICRODILUTION SYSTEMS

The manual broth microdilution systems listed in Table 1 facilitate the visual reading and recording of MICs. The panels are frozen (Pasco system, TREK custom plates) or dehydrated microwell trays (MicroScan, Sensititre). Devices for rehydration and inoculation of dehydrated trays include the manual RENOK device (MicroScan), the microprocessor-controlled Sensititre Autoinoculator, and the Sensititre multichannel electronic pipette.

After off-line incubation, results are recorded on the Pasco Reader with a light pen and transferred to a data management system. The MicroScan data management system (LabPro) displays an image of the tray configuration for recording manual results directly on the computer. The Sensititre SensiTouch reader sequentially illuminates a liquid crystal display superimposed on the tray to guide the reading of endpoints that are recorded via a keypad and transferred to the data management system (SWIN, Sensititre Windows software) with expert analysis. The SWIN data management system is also available for recording of manual results without the SensiTouch reader.

Most manufacturers offer standard gram-positive, gram-negative, *Streptococcus pneumoniae*, and extended-spectrum β-lactamase (ESBL) confirmatory panels. TREK Diagnostic Systems also offers FDA-cleared yeast panels (Sensititre YeastOne) and "research use only" Sensititre panels for mycobacteria (rapid and slow growers) and anaerobes that can be read manually or on the SensiTouch.

SEMIAUTOMATED BROTH MICRODILUTION SYSTEMS

The semiautomated broth microdilution systems listed in Table 1 utilize automated devices to read endpoints after overnight off-line incubation. The results are transferred to a data management system that may include expert system analysis using the same software available for the automated systems. The Sensititre AutoReader and miniAPI read susceptibility and identification tests, while the MicroScan AutoSCAN-4 reads only susceptibility results from overnight panels. Further information regarding MicroScan and Sensititre panels is presented in the section on automated systems.

AUTOMATED BROTH MICRODILUTION SYSTEMS

Automated AST systems do not require further manual intervention to obtain results after placement of the test panel in an instrument where incubation and reading of endpoints occur. An overview of the automated systems currently available in the United States is presented in Table 2. The VITEK 1, VITEK 2, MicroScan WalkAway, and Phoenix systems provide AST results after short-term incubation (<16 h); the currently available Sensititre ARIS panels and some MicroScan WalkAway panels require overnight incubation. Manufacturers should be consulted regarding the current antimicrobial agents available for each system.

VITEK 1

The first VITEK instrument developed for the provision of rapid MIC results was introduced in the 1980s. The identification of common gram-positive and gram-negative bacteria may be determined simultaneously by running a separate ID card. The AST panels are thin plastic 45-well cards with one to five concentrations of 15 to 19 antimicrobial agents. After manual preparation of the inoculum, cards are placed in a vacuum module for card inoculation. Cards are then manually lifted to a sealing device and placed in a carousel within the incubator-reader unit. A robotic system moves cards to a photometer every 15 min for turbidimetric measurement of growth. Linear regression analysis is used to determine algorithm-derived MICs that are reported in 4 to 16 h. The system includes a computer with monitor and printer, an expert system, and a data management system (DataTrac) to archive test data and generate reports.

TABLE 2 Overview of automated broth microdilution susceptibility testing instrumentation[a]

Manufacturer	System	Panel capacity	Panels	Types of panels (no.)	Instrument features	Software
Becton Dickinson	BD Phoenix	100	Two-sided polystyrene tray: 85-well AST/ 51-well ID	Gram pos (2), gram neg (8), *S. pneumoniae* (1)	AST panels available as MIC +/− ID substrates. Turbidimetric and redox indicator readings every 20 min up to 16 h. Full-range MICs.	BDXpert, BD EpiCenter
bioMerieux	VITEK 1	32, 60, 120, 240, 480	45-Well cards	Gram pos (6), gram neg (36)	Turbidimetric reading every 15 min. MICs derived from 1–5 antimicrobial agent dilutions.	DataTrac, Expert System, Stellara
	VITEK 2 VITEK 2 XL	60 120	64-Well cards	Gram pos (2), gram neg (9), *S. pneumoniae* (1)	Most automated system with reduced time for initial setup. Also automated AST dilution and filling/ sealing of cards. Turbidimetric readings every 15 min. MICs derived from 1–6 antimicrobial agent dilutions.	DataTrac, AES, Stellara
	VITEK 2 Compact	30 or 60	Same as VITEK 2	Same as VITEK 2	Less automated, more affordable than VITEK 2. Windows-based DMS and expert system has improved visual aesthetics.	Observa, AES, Stellara
Dade Behring	MicroScan WalkAway SI	40 or 96	Standard 96-microwell trays	Overnight (23), *S. pneumoniae* (1) Rapid (7), Synergies Plus (6)	Panels available as full-range MIC or breakpoint. Combo panels include ID substrates. MIC readings: ON, turbidimetric; "read when ready," colorimetric; rapid panels (4.5–15 h), fluorometric.	LabPro, LabPro Alert, PharmLink
TREK	Sensititre ARIS 2x	64	Standard 96-microwell trays	Gram pos (4), gram neg (6), *S. pneumoniae* (1)	Fluorometric readings after ON incubation of full-range MIC trays. Nonfermenter, *Haemophilus*/ *S. pneumoniae*, custom MIC panels also available.	SWIN

[a] Abbreviations: DMS, data management system; ID, identification; neg, negative; ON, overnight; pos, positive.

VITEK 2

The VITEK 2 received FDA clearance in 2000 and is the most automated AST instrument currently available. The cards are slightly thicker than VITEK 1 cards, with 64 wells that contain one to six concentrations of 9 to 20 antimicrobial agents. An identification card for common gram-positive or gram-negative bacteria may be run simultaneously with each AST card. The Smart Carrier Station includes a bar code scanner and base unit with microprocessor that holds a cassette with a capacity of 15 cards. A memory chip on the cassette allows the transfer of scanned information to the reader-incubator unit. The workflow for large laboratories can be optimized by placement of Smart Carrier Stations at multiple locations. After placement of a cassette into the VITEK 2 loading station, it is automatically moved through stations for bar code reading, AST dilution preparation, card inoculation, and card sealing. The transport system then places cards on a carousel with a 60-card capacity for incubation. The VITEK 2XL instrument has a capacity of 120 cards. Each card is moved to an optic station every 15 min for measurement of light transmittance that is proportional to growth. The Advanced Expert System (AES) is discussed in a later section.

The VITEK 2 Compact was introduced in 2005 for smaller labs and uses the same cards as the VITEK 2 system. The instrument is available in two sizes that accommodate 30 or 60 cards. The VITEK 2 Compact is less automated and more affordable than the VITEK 2. The initial inoculum and dilution preparation is manual, but a bar code reader replaces the hand labeling required with VITEK 1. Cards are initially placed into the vacuum unit (on the left side of the instrument) for filling followed by manual transfer to the right side of the instrument for automated sealing and transfer to the incubator-reader unit. The VITEK 2 Compact data management system (Observa) is PC Windows-based with better visual aesthetics and a more layered presentation of the same expert system (AES) analysis originally offered with the VITEK 2. Observa software may be used for preparing epidemiologic reports with data from VITEK 2 Compact and the manufacturer's blood culture instrument, BacT/ALERT. Observa software is expected to become available for VITEK 2 in 2006.

All of the VITEK systems connect to Stellara, a new system component launched in 2005 utilizing wireless technology to allow Health Insurance Portability and Accountability Act-compliant real-time communication of lab results to pharmacists and clinicians. The results are compared to patient records, allowing clinicians to be notified via a personal digital assistant of inappropriate antimicrobial therapy with suggested changes. Other lab results (chemistry or hematology) may also be reported with Stellara.

MicroScan WalkAway

The MicroScan WalkAway system was developed in the late 1980s and until recently offered two major types of AST panels: conventional panels read turbidimetrically after overnight incubation and rapid panels read fluorometrically after 4.5 to 15 h of incubation. These panels, all conventional 96-well microdilution trays, include (i) MIC panels (a broad range of antimicrobial agent dilutions); (ii) MIC combo panels (some wells used for identification); and (iii) breakpoint combo panels (identification with a limited range of antimicrobial agent dilutions for a categorical result of susceptible, intermediate, or resistant). A third type of MicroScan panel, Synergies plus, became available in 2005. Synergies plus combines three methods in one panel: "read-when-ready" AST results available as quickly as 4.5 h (colorimetric reading), overnight results for drugs requiring longer incubation (turbidimetric reading), and identification (fluorometric results within 2.5 h). Synergies plus gram-negative panels contain 19 to 25 antimicrobial agents; FDA clearance for the gram-positive panel is pending.

The WalkAway system includes an incubator-reader unit, a personal computer with an LIS interface, and a printer. "Prompt" is available for preparation of the inoculum for overnight panels without measurement of turbidity and is stable for 4 h. A manual device (RENOK) rehydrates and inoculates panels. The humidified incubator-reader unit has a bar code scanner, rotating carousel, and robotics to position panels under a central photometer or fluorometer for readings. An updated data management system, LabPro, interprets results, generates patient reports, and archives data to allow production of user-defined reports (antibiograms, trend analysis, and epidemiology reports). Since 2002, the data management system may be coupled with an expert system (LabPro Alert) that incorporates >100 rules that may be customized. Two instrument sizes accommodate 40 or 96 panels. A new SI version of the WalkAway instrument available since 1999 has eliminated the need for manual addition of identification reagents; older instruments may be upgraded to SI capability.

BD Phoenix

The BD Phoenix System was launched in Europe in 2001 and the United States in 2004. The instrument holds up to 100 test panels. The panels are polystyrene trays containing 136 wells divided into a 51-well identification (ID) side and an 85-well AST side with 16 to 22 antimicrobial agents. After preparation of the AST inoculum, a drop of redox indicator is added. The suspension is manually poured into the AST side of the panel, sealed with a plastic cap, and bar coded prior to placement on the instrument. The instrument reads panels every 20 min using both the colorimetric change in the redox indicator and turbidity to determine organism growth. Growth (metabolic activity) causes the redox indicator to change from an oxidized (blue) state to a reduced (pink) form. A full range of antimicrobial agent concentrations and a "growth" or "no growth" reading for each well allow the system to provide direct rather than calculated MICs.

The BDXpert system applies rules based on CLSI guidelines to analyze AST results. AST results will not be reported for an organism-antimicrobial agent combination if clinical efficacy is unknown, there are no approved MIC interpretive criteria, or the organism has intrinsic resistance. The BD EpiCenter is data management software for analyzing epidemiologic trends and generating reports using information from multiple BD instruments (Phoenix, BACTEC blood culture, and MGIT 960 systems). Features of BD EpiCenter include an LIS interface, reporting of inferred results for antimicrobial agents not on panels, and the capability to apply BDXpert system analysis to manual off-line AST results.

Sensititre ARIS 2x

The Sensititre ARIS (Automated Reading and Incubation System) was introduced in the United States in 1992 and provides overnight AST results (13, 14). The latest ARIS 2x version with hardware and software upgrades was released in 2004. The ARIS 2x instrument fits on the Sensititre

AutoReader and holds up to 64 plates (standard 96-microwell trays) available as MIC panels or separate identification plates. Plates are rehydrated and inoculated with the Sensititre AutoInoculator or a handheld multichannel electronic pipette before placement in the instrument's carousel. An internal bar code scanner identifies the plate type to assign the appropriate time of incubation. After 16 to 24 h of incubation, each AST plate is transported to the AutoReader for fluorometric reading of endpoints. The data management software (SWIN) provides expert analysis of results.

ADVANTAGES OF AUTOMATED SYSTEMS

Advantages of automated AST systems include labor savings, reproducibility, data management with expert system analysis, and the opportunity to generate results more rapidly. A workflow and performance evaluation of the VITEK 2 and Phoenix systems reported a longer mean setup time per isolate for Phoenix (3 min) than for VITEK 2 (1.5 min) but more monthly maintenance time for VITEK 2 (63.2 min) than for Phoenix (21.2 min) (24). The mean time to generate AST results for *Enterobacteriaceae* isolates was higher for Phoenix (11.7 ± 2.6 h) than for VITEK 2 (7.5 ± 1.3 h) (24). Ligozzi et al. reported that the time required for VITEK 2 AST for gram-positive cocci was 6 to 17 h, with 90% of results available as follows: 8 h, *S. aureus;* 11 h, coagulase-negative staphylococci (CoNS); 9 h, enterococci; 7 h, *Streptococcus agalactiae;* 9 h, *S. pneumoniae* (56). The average times required for AST results in a Phoenix study were as follows: for *Enterococcus* spp., 5.5 h; for *Staphylococcus* spp., 7 h; for *Enterobacteriaceae*, 6.5 h; and for nonfermenting gram-negative bacilli, 12 h (T. Wiles, D. Turner, W. B. Brasso, J. Hong, and J. Reuben, Abstr. 99th Gen. Meet. Am. Soc. Microbiol., abstr. C-94, p. 123, 1999). There are limited data showing financial and clinical benefits in association with the rapid provision of AST results. Doern et al. reported lower mortality rates and cost savings (fewer diagnostic tests and days in intensive care) associated with the rapid reporting of AST results (22). Barenfanger et al. also demonstrated reduced lengths of stay and cost savings for patients with rapid reporting of AST results that were attributed to earlier adjustments in antimicrobial therapy (2). Effective communication of the results to clinicians and pharmacists is essential to realizing the potential benefits of rapid testing. Communication may be enhanced by software packages that interface with medication records and alert clinicians or pharmacists when adjustments in antimicrobial therapy are needed.

DISADVANTAGES OF AUTOMATED SYSTEMS

Disadvantages of automated systems include a higher cost for equipment and consumables than manual methods, predetermined antimicrobial panels, an inability to test all clinically relevant organisms, and problems with detection of some resistance phenotypes (47). Reports of AST performance for detecting problematic resistance phenotypes are discussed below. The current performance of a system may not be accurately reflected by studies utilizing panels and software that are no longer available. A higher error rate should be accepted for evaluations using challenge strains with difficult to detect phenotypes than for studies that test populations of isolates usually encountered in the clinical laboratory.

Vancomycin Resistance in Enterococci

Problems with the detection of low-level vancomycin resistance *(vanB* and *vanC)* among enterococci by automated systems have been demonstrated in multiple studies (72, 89). The change from a 30-well to a 45-well VITEK 1 card in 1999 increased the testing of vancomycin from 3 wells to 4 wells and improved sensitivity for *vanB* isolates (26, 41, 67). A VITEK 2 evaluation reported difficulty detecting only *vanC2 (Enterococcus casseliflavus)* strains (94). Other VITEK 2 and Phoenix studies have demonstrated accurate detection of vancomycin-resistant enterococci, but rigorous studies comparing systems are lacking (27, 32). MicroScan overnight panel studies reported detection of all isolates except those containing *vanC,* which are difficult to detect for all AST systems since their MICs (4 to 16 μg/ml) span susceptible and intermediate categories (15, 19).

HLAR in *Enterococcus* spp.

The detection of high-level aminoglycoside resistance (HLAR) in enterococci by overnight and short-incubation AST systems has been improved by changes in growth medium and extended incubation (95, 98). Initial problems detecting high-level streptomycin resistance (HLSR) in MicroScan overnight panels appear to have been resolved after a broth reformulation, since two subsequent studies have demonstrated detection of HLAR that compared favorably to that obtained with reference and molecular methods (15, 65). A study reporting a higher VME rate for MicroScan detection of HLSR (19) may not have performed the recommended read at 48 h for isolates that appear streptomycin susceptible after overnight incubation; in one study that read improved detection of HLSR by 6.2% (15). Separate VITEK 2 and Phoenix evaluations testing different strains reported VME rates of 0 to 5.2% and ME rates of 0.9 to 7.3% for the detection of high-level streptomycin or gentamicin resistance (27, 32).

Oxacillin Resistance in Staphylococci

Most of the studies discussed below used *mec*A PCR as the "gold standard" when evaluating the accuracy of a system for detection of oxacillin resistance in staphylococci. Multiple studies have demonstrated excellent sensitivity and specificity of automated systems for detecting methicillin-resistant *Staphylococcus aureus* (MRSA) (27, 56, 73, 100). However, an evaluation focusing on low-level MRSA isolates reported problems detecting heterogeneous MRSA strains that are often undetected by routine oxacillin testing (29). After assessing the detection of heterogeneous oxacillin-resistant strains among *S. aureus* challenge organisms by eight methods including VITEK 1, MicroScan conventional, and MicroScan rapid panels, Swenson et al. concluded that no phenotypic system was totally reliable and suggested using several methods (86).

For the detection of oxacillin resistance among CoNS, VITEK 1, VITEK 2, and Phoenix evaluations have demonstrated excellent sensitivities (95.7 to 99.4%) with lower specificities (64.9 to 95.5%) (27, 37–39, 56, 61, 62, 80, 99). Isolates with false-resistant results often have MICs of 0.5 to 2 μg/ml that would have been considered susceptible under previous CLSI CoNS oxacillin breakpoints, which were lowered to ≤0.25 μg/ml in 1999 (38). Some of the major errors involved *Staphylococcus lugdunensis* isolates with oxacillin MICs now considered susceptible based on the CLSI 2005 decision to apply *S. aureus* breakpoints (≤2 μg/ml) to this species of CoNS (37, 38).

The lower CoNS oxacillin breakpoint is most accurate for detecting *mecA* carriage in *Staphylococcus hominis*, *Staphylococcus haemolyticus,* and *Staphylococcus epidermidis* isolates but may overcall oxacillin resistance for other CoNS species (40, 62, 69, 99). Current CLSI guidelines promote *mecA* or PBP 2a assays as the most accurate means of detecting oxacillin resistance and suggest the use of these assays for testing CoNS isolates (not *S. epidermidis*) with oxacillin MICs of 0.5 to 2 μg/ml causing serious infections (18).

Reduced Glycopeptide Susceptibility in Staphylococci

The inability of automated AST systems or disk diffusion to reliably detect vancomycin-intermediate and vancomycin-resistant *S. aureus* (11, 70, 90, 91) led to the current CLSI recommendation to supplement those methods with a 6-μg/ml vancomycin agar screening plate incubated 24 h (18). AST system detection of CoNS with reduced glycopeptide susceptibility is also unreliable (20, 70). Any staphylococcal isolate with a reproducible vancomycin MIC ≥4 μg/ml requires confirmation at a reference laboratory (18, 70).

Inducible Clindamycin Resistance

Routine testing of macrolide-resistant staphylococci and nonpneumococcal streptococci to detect inducible clindamycin resistance by use of a disk approximation test is recommended by CLSI (18). The inoculum purity plates from an automated broth AST system may be used for the induction test and should replace the practice of reporting all macrolide-resistant staphylococci or streptococci as resistant to clindamycin (49). An investigation of *S. aureus* isolates with VITEK 1 erythromycin-intermediate results showed that all were resistant by broth microdilution (87). VITEK 2 and Phoenix revealed accurate results (erythromycin resistant) for 96 to 100% of the isolates (87). Disk diffusion testing found that 95% of the isolates had inducible clindamycin resistance, but expert rules did not override the clindamycin-susceptible results for any of the systems (87). Use of the disk approximation test in nonpneumococcal streptococci is supported by the inability of VITEK 1 and VITEK 2 to accurately detect macrolide resistance phenotypes among group B streptococci (88).

Pneumococcal Resistance

The VITEK 2 *S. pneumoniae* panel represents the first commercial method for rapid AST of pneumococci. Initial testing of the VITEK 2 *S. pneumoniae* panel demonstrated provision of reliable results in a mean time of 8.1 h, with most errors classified as minor (35, 45). VITEK 2 detected 86.7% of 60 gatifloxacin-resistant and 95.6% of 23 moxifloxacin-resistant pneumococci without any major errors (48). A Phoenix pneumococcal panel recently received FDA approval. Overnight *S. pneumoniae* trays are available from MicroScan and Sensititre, with accurate results reported for antimicrobial agents other than trimethoprim-sulfamethoxazole (TMP/SMX), for which the discrepancies were attributed to trailing endpoints (36).

ESBL-Producing *Enterobacteriaceae*

Confirmatory ESBL tests that typically measure the inhibitory effect of clavulanate on ceftazidime and cefotaxime are available for all of the automated systems listed in Table 2. The first automated ESBL test was available for VITEK 1 and demonstrated reliable performance (99.5% sensitivity and 100% specificity) for organisms that are the most common ESBL producers *(Escherichia coli, Klebsiella oxytoca,* and *Klebsiella pneumoniae)* (75). A comparative evaluation of ESBL detection among multiresistant *E. coli* and *Klebsiella* spp., using three AST systems, revealed sensitivities of 83% (VITEK 1), 74% (VITEK 2), and 92% (Phoenix) with specificities of 82 to 85% (55). Evaluations of a single AST system (VITEK 2 or Phoenix) have reported sensitivities of 95.8 to 100% and specificities of 96.2 to 99.3% for ESBL detection (78, 79, 81). A recent evaluation of VITEK 1 and MicroScan ESBL confirmation tests reported sensitivities of 99 and 100%, respectively, and a specificity of 98% for both systems (58). The MicroScan ESBL confirmation overnight panels accurately detected ESBL-positive strains of *Proteus mirabilis, E. coli,* and *Klebsiella* spp. (53, 85). False-positive ESBL results for K1-hyperproducing *K. oxytoca* isolates have been reported for MicroScan (85) and Phoenix systems (78, 84).

Pseudomonas Resistance

Automated commercial AST systems are contraindicated for testing isolates of *Pseudomonas aeruginosa* from cystic fibrosis patients due to high VME rates and poor correlation with reference methods attributed to slow growth and mucoid strains (10). Problems with false-intermediate and false-resistant results for cefepime-susceptible *P. aeruginosa* isolates tested on VITEK 1 and MicroScan WalkAway systems have been reported (7). Problems with the VITEK 1 system overcalling *P. aeruginosa* resistance to piperacillin, ticarcillin-clavulanic acid, and cefepime led to software adjustments; a subsequent study reported acceptable piperacillin results, but elevated VME and ME rates for ticarcillin-clavulanic acid and increased minor errors with cefepime (12). Susceptibility testing of *P. aeruginosa* isolates by use of VITEK 2 identified only a small number of agents with categorical agreement <90% (cefepime, cefotaxime, and gentamicin) that were predominantly minor errors (50). A Phoenix study reported low categorical agreement for *P. aeruginosa* isolates primarily due to minor and major errors with β-lactams (23).

Other Gram-Negative Resistance

An assessment of ciprofloxacin resistance detection using a challenge set of *Enterobacteriaceae* isolates revealed elevated error rates for both MicroScan WalkAway and VITEK 1 systems (83). In evaluations testing different collections of gram-negative isolates with a single system (VITEK 2 or Phoenix), antimicrobial agents with low essential or categorical agreement reported by at least one study were aztreonam, cefotaxime, ceftazidime, cefepime, imipenem, piperacillin, piperacillin-tazobactam, ciprofloxacin, and TMP/SMX (25, 57, 81).

Outbreaks reported in New York City of infections by ESBL-positive *K. pneumoniae* organisms that also possess the carbapenem-hydrolyzing β-lactamase KPC-2 are cause for concern (9). A surveillance study identified three clinical labs that each failed to detect an ESBL/KPC-positive isolate with MicroScan WalkAway or VITEK systems; thus, an alternative method to confirm carbapenem susceptibility in *Enterobacteriaceae* that are resistant to third-generation cephalosporins may become necessary (9).

More common is the problem of false resistance when determining carbapenem susceptibility. The CDC could confirm only 8.9% of 123 *Enterobacteriaceae* and 74.2% of 325 *P. aeruginosa* isolates initially reported as imipenem nonsusceptible by 44 U.S. hospital laboratories during 1996–99 (82). Most isolates had been tested locally using VITEK or MicroScan, but retesting at CDC using the systems showed

minimal errors except for a 20% ME rate for VITEK 1 testing of imipenem against *P. aeruginosa* (82). The lack of a clear explanation for this overdetection of carbapenem resistance (82) emphasizes the need for confirmation of any unusual AST results. Testing of five *K. pneumoniae* VIM-1-producing challenge isolates by using VITEK 2, Phoenix, and MicroScan Autoscan-4 resulted in false carbapenem resistance determinations by VITEK 2 and Phoenix (34). Tsakris et al. reported a problem with VITEK 1 overcalling imipenem resistance for *Acinetobacter baumannii* isolates in Greece (92). Antimicrobial agent deterioration in test panels (96) and technical errors are factors that may contribute to the overdetection of carbapenem resistance by AST systems (82, 92). Results of false resistance obtained by VITEK 1 for *P. aeruginosa* and *Enterobacteriaceae* have been attributed to heavy inoculum density—particularly for agents active against the cell wall (piperacillin, mezlocillin, aztreonam, ticarcillin, ticarcillin-clavulanic acid, ampicillin-sulbactam, and imipenem) (21, 43).

COMPUTERIZED EXPERT SYSTEMS

Expert systems to assist in the critical review of AST results are available for all commercial susceptibility systems currently marketed in the United States. Expert systems can enhance workflow by identifying the subset of results that require human expert attention and may also improve the quality of AST results reported from smaller labs that may lack a human expert (77). By continuous monitoring, the algorithms allow more rapid recognition of incorrect results and more uniform reporting. However, the software must be frequently updated to reflect the emergence of new resistance and changes in reporting guidelines recommended by national organizations such as CLSI. Users must be aware of what rules and comments are activated in their system and work closely with manufacturer-provided specialists to customize the expert system for their laboratory. Ideally an expert system will report actual MICs with categorical interpretation before and after recommended changes.

Most expert systems use a rules-based approach focusing on AST results for only one drug at a time without considering results for other agents tested simultaneously. The VITEK 2 AES differs from rules-based expert systems by performing an "interpretive reading" that compares the MICs for multiple agents to a large database of known resistance phenotypes and MIC distributions for different species (59). The rationale for interpretative reading with phenotype assignment is that a single mechanism typically mediates resistance to multiple agents (60). An evaluation of the VITEK 2 AES assignment of β-lactam phenotypes for *Enterobacteriaceae* and *P. aeruginosa* provides insight into the process of phenotype analysis (76). The VITEK 2 AES also deduces the susceptibility of an isolate to agents not tested and detects inconsistencies between organism identification and AST results (77).

Excellent concordance of VITEK 2 AES interpretive reading with resistance genotypes has been reported in multicenter studies (3, 59). When AES was compared to human expert analysis of VITEK 2 results for 259 consecutive clinical isolates in a university-based microbiology laboratory, there was disagreement for only 5 of the 65 isolates (7.7%) with AES corrections (77). A limitation that has been noted for the AES is an inability to interpret multiple inconsistent results as being caused by a single problem (8, 77).

CRITICAL REVIEW OF AST RESULTS

Regardless of whether a laboratory is using a commercial expert system, it is important to be aware of unusual "resistant" (Table 3) and "susceptible" (Table 4) results that require verification of the organism's identification and repeat of the susceptibility test by the same or a different method (18, 60). An example of an unprecedented phenotype that should prompt retesting is an *Enterobacteriaceae* or *P. aeruginosa* isolate that appears more resistant to piperacillin-tazobactam than to piperacillin (51). There are a number of antimicrobial agents that may appear active in vitro but lack clinical efficacy (Table 5) and to which the organisms should be reported as resistant. The most recent CLSI M100 document should be consulted for current recommendations regarding agents to test for specific organisms, methodology, interpretive criteria, results that may be inferred without testing a specific agent, antimicrobial agents to report based on the site of infection, and unusual results requiring verification.

SELECTING AN AST SYSTEM

Factors to consider when selecting an AST system include cost, performance, workflow, data management capabilities, and manufacturer technical support (44, 64). Performance may be assessed by comparing dilutions of FDA-cleared antimicrobial agents and limitations (antimicrobial agent/organisms listed in package inserts that require an alternative method) of panels from different manufacturers.

TABLE 3 Resistance phenotypes that are rare or have not been detected

Organism	Antimicrobial agent(s) to which resistance requires verification
Gram positive	
Enterococcus faecalis	Linezolid, daptomycin, ampicillin
Enterococcus faecium	Linezolid, daptomycin, quinupristin-dalfopristin
S. pneumoniae	Vancomycin, linezolid, fluoroquinolone
Viridans group streptococci	Vancomycin, linezolid, daptomycin
Beta-hemolytic streptococci	Vancomycin, linezolid, daptomycin, ampicillin, penicillin, cephalosporins
Coagulase-negative staphylococci	Vancomycin, linezolid, daptomycin, quinupristin-dalfopristin
S. aureus	Vancomycin, linezolid, daptomycin, quinupristin-dalfopristin
Gram negative	
Enterobacteriaceae (all)	Carbapenem
Neisseria gonorrhoeae, N. meningitidis	Extended-spectrum cephalosporin
Haemophilus influenzae	Third-generation cephalosporin, aztreonam, carbapenem, fluoroquinolone

TABLE 4 Gram-negative organisms with expected resistance to commonly tested antimicrobial agents

Organism	Agent(s) to which organism is usually resistant
Enterobacteriaceae	
Citrobacter, Enterobacter, Klebsiella, Morganella, Proteus penneri, Proteus vulgaris, Providencia, Serratia, Yersinia	Ampicillin
Citrobacter freundii, Enterobacter, Morganella, Proteus penneri, Proteus vulgaris, Providencia, Serratia, Yersinia	Cefazolin, cephalothin
Klebsiella	Ticarcillin
C. freundii, Enterobacter, Serratia	Cefoxitin, cefotetan
C. freundii, Enterobacter, Proteus vulgaris, Serratia	Cefuroxime
Citrobacter, Enterobacter, Serratia	Amoxicillin-clavulanic acid, ampicillin-sulbactam
Non-*Enterobacteriaceae*	
Acinetobacter, Burkholderia cepacia, Pseudomonas aeruginosa, Stenotrophomonas maltophilia	Ampicillin, 1st- and 2nd-generation cephalosporins
Burkholderia cepacia, Stenotrophomonas maltophilia	Aminoglycosides
Stenotrophomonas maltophilia	Carbapenems
P. aeruginosa	Trimethoprim-sulfamethoxazole

TABLE 5 Antimicrobial agents that may appear active in vitro but lack clinical efficacy

Organism	Antimicrobial agents to which the organisms should be reported as resistant
Oxacillin-resistant staphylococci	All β-lactam agents including β-lactam/β-lactamase inhibitor combinations, cephems, and carbapenems
Enterococcus spp.	Aminoglycosides (other than high-level), cephalosporins, clindamycin, trimethoprim-sulfamethoxazole
ESBL-producing *E. coli, Klebsiella* spp., and *Proteus mirabilis*	Aztreonam, cephalosporins (except cephamycins), penicillins
Listeria spp.	Cephalosporins
Salmonella and *Shigella* spp.	Aminoglycosides, 1st- and 2nd-generation cephalosporins
Yersinia pestis	All β-lactam agents

Current users of systems should be consulted, and publications in peer-reviewed journals should be reviewed. Manufacturers should be asked if problems reported for particular antimicrobial agent-organism combinations have been resolved and what is under development. Extensive exhibits at the annual American Society for Microbiology general meeting provide demonstrations of systems and a convenient venue for interaction with manufacturer representatives. Poster presentations at national meetings may provide new information and the opportunity to interact with recent users of systems.

Another method of assessing the performance of AST systems is participation in proficiency testing surveys such as that of the College of American Pathology (42, 68), whose final critiques of susceptibility testing challenges provide information regarding AST methods used and problem antimicrobial agent-organism combinations with high error rates.

An AST system's ability to perform identification is also important because expert rules are linked to organism identity. Additional information regarding the selection of an AST system and laboratory verification of performance as required by the Clinical Laboratory Improvement Amendments of 1988 (28) is in the *Clinical Microbiology Procedures Handbook* (64).

SUMMARY

AST systems provide accurate and reproducible results for many antimicrobial agent-organism combinations. Expert analysis may improve workflow as well as the quality of reported results. The labor savings attributed to automated AST systems is particularly important for laboratories in regions with current or projected technologist shortages. In addition, the provision of more rapid AST results with a short incubation system may improve patient care and lower health care costs. Future advances in AST system development will likely increase their clinical impact with the incorporation of real-time PCR growth detection (71) or gene arrays for common resistance determinants that dramatically shorten the time required for results.

Immunoassays for the Diagnosis of Infectious Diseases*

A. BETTS CARPENTER

18

Immunoassays are laboratory tests that employ antibodies as analytical reagents (8, 22, 24, 29, 30, 48). They have become increasingly used in the diagnosis of infectious diseases either as a primary means of diagnosis or as a confirmation of culture results. Overall immunoassays are specific, sensitive, and relatively inexpensive. They are used in all parts of the clinical laboratory. Due to the high specificity of the antigen-antibody reaction and the ease of use, immunoassays are leading the way for an increasing number of laboratory tests that are available at the patient bedside (point-of-care testing), in doctors' offices, and even in at-home testing. This chapter summarizes the variety of different assays available and their particular application in the field of infectious disease. The discussion emphasizes general assay design with important caveats relevant to test interpretation and development. Relevant examples are given as they relate to testing for particular infectious disease agents; however, for in-depth discussions, the reader is directed to the particular chapters on the specific agents.

HISTORY OF DEVELOPMENT OF IMMUNOASSAYS

Immunoassays have changed significantly over time with improvements in the types of antibodies and antigens available as well as improved detection systems (8, 22, 24, 27, 30, 48). With immunoassays, any analyte can be measured if an antibody can be raised to it or an antigenic form is available. The first immunoassays available measured milligram to microgram quantities of antibodies and relied primarily upon precipitation reactions between antigen and antibody. In the 1960s, the advent of radioimmunoassay (RIA) heralded techniques with greater sensitivity and greatly expanded the repertoire of analytes available for testing. By use of RIA, previously undetectable analytes were now easily available for testing in the clinical laboratory. The discovery of monoclonal antibodies led to assays with greater specificities and further expanded the repertoire of analytes available for measurement. Concerns about utilization of radioactivity and the desire for greater sensitivities led to the development of chemiluminescence (CL) immunoassays and use of the avidin-biotin detection system. Increasing automation of laboratory testing has expanded into the area of immunoassays, with many tests requiring only limited technologist input. As immunoassays have evolved, there has been increased utilization of various solid-phase matrices for adherence of either antigens or antibodies. Initially polypropylene test tubes were used. This has evolved to microtiter plates, and with the increased use of automated systems, smaller solid phases such as tiny disks or spheres are being increasingly used. Thus, immunoassays have significantly advanced in both the level of sensitivity detected and the breadth of their utilization, so they are now some of the most popular and most widely used of all laboratory tests.

DEFINITION OF TERMS

The array of terms used for immunoassays can be a confusing alphabet soup. This chapter discusses some widely used conventions in terminology; however, the reader may find some references in which the terms are used differently. Overall, most assays utilize the term "immuno" coupled with a second term which describes the type of assay or label used. For example, immunoprecipitation is an immunoassay utilizing a precipitation reaction. RIA is an immunoassay that utilizes radioactivity as the label. The term enzyme immunoassay (EIA) is a more general term that can be applied to any immunoassay which uses an enzyme label, although often EIA is used to refer to reagent-limited competitive type assays. The term enzyme-linked immunosorbent assay (ELISA) can also be used as a general term for any assay utilizing an enzyme label; however, it is most often used to refer to assays in which the antigen or antibody is adsorbed to a solid-phase matrix, often then employing a second enzyme labeled antibody, the so-called "sandwich" assay format. Immunometric is an additional term used and generally refers to any reagent excess assay. For the purposes of this chapter, the term EIA is used to refer to any assay using an enzyme, while ELISA refers only to solid-phase "sandwich"-type assays.

GENERAL CONCEPTS OF ASSAY DESIGN

There are a number of ways to characterize immunoassays. One useful classification scheme looks at the amount of label and reagent available (18). There are three major

*This chapter contains information presented in chapter 16 by Niel T. Constantine and Dolores P. Lana in the eighth edition of this Manual.

groups of immunoassays: label free, reagent excess, and reagent limited. The assays which are label free rely upon the ability of antigen and antibodies to bind and form a detectable agglutination or precipitation. There are many classic agglutination assays used in the diagnosis of infectious disease such as the Widal test for typhoid fever. The reagent excess methods require an excess of labeled antigen or antibody, use either one or two sites, and include immunoblotting and solid-phase ELISA. These are commonly employed immunoassays in microbiology today. Reagent-limited assays are competitive-based tests and employ a limited amount of either antigen or antibody and either require separation or are separation free. These include classic RIA and EIA and are less often used in diagnosis of infectious disease.

Another commonly used classification scheme looks at immunoassays as either heterogeneous (solid phase) or homogeneous (free-solution assays) (8, 24). Heterogeneous assays are ones in which the bound and free components must be separated, whereas homogeneous assays do not require a separation step. In addition, heterogeneous assays involve some type of solid phase to which the immunoreactants are attached. Homogeneous assays generally are free-solution methods. While this is a useful and commonly employed classification scheme, there are assays that do not strictly fit into this classification scheme. For example, agglutination assays and particle-enhanced light-scattering methods are considered homogeneous assays; however, the antibody is bound to a solid phase, and there is no required separation of the bound from the free components.

ASSAY INTERPRETATION

When choosing an assay for the laboratory and in-patient diagnosis, it is critical to understand the concepts of sensitivity, specificity, and predictive values (48). Sensitivity is the proportion of individuals *with* a disease that are correctly identified with a particular test. Sensitivity defines the true positives (TP), which are the number of patients with disease detected by the assay. Conversely, false negatives (FN) are the patients with disease who are not detected by the test. The formula for sensitivity is as follows: Sensitivity = $[TP/(TP + FN)] \times 100$. Specificity is the proportion of those *without* the disease that are correctly classified. Conversely, specificity is a measure of the true negatives (TN), which are the number of patients without disease not detected by the assay. False positives (FP) are the proportion of patients without disease who test positive. The formula for specificity is as follows: Specificity = $[TN/(TN + FP)] \times 100$. With a highly sensitive test, the majority of diseased individuals are picked up, and thus the number of false-negative results is very low. In contrast, with a highly specific test, the majority of individuals without the disease test negative, so the number of false-positive results is very low. When an assay is developed, the diagnostic cutoffs can be modified to alter both the sensitivity and the specificity. For example, if one moves the cutoff to a lower level, the assay sensitivity is increased with a resulting decrease in specificity. The optimal balance of these two components must be evaluated for each laboratory test and depends on multiple factors such as the utility of the test and the prevalence of the disease in the population.

The probability of having the disease, given the results of a test, is called the predictive value of the test. Positive predictive value (PPV) determines the percentage of patients with positive results who are diseased: PPV = $[TP/(TP + FP)] \times 100$; the negative predictive value (NPV) calculates the percentage of patients with negative test results who do not have the disease: NPV = $[TN/(TN + FN)] \times 100$. The predictive value of a test combines the prevalence of disease in a particular population with the sensitivity and specificity. Positive and negative predictive values are important because they assess the ability of a test to predict the presence or absence of disease in a patient from a particular population. In this context, the disease prevalence is a critical component. Prevalence is the proportion of the population with the disease in question. If a disease state has a low prevalence in the target population, a positive result will most likely be a false-positive result, whereas the opposite is true in a high prevalence population. A potential use of a high negative predictive value is that a negative test can exclude disease. In addition to the values discussed above, there are a variety of other statistical methods that can be used to evaluate laboratory tests such as odds ratio, receiver-operator curve analysis, and likelihood ratios, among others. It is beyond the scope of this chapter to discuss these, and the reader is referred to other sources for a more complete discussion (43).

SCREENING VERSUS DIAGNOSTIC ASSAYS

An important component of assay design is based upon the ultimate use of the test, i.e., whether it will be used as a screening or diagnostic test (37, 45). Screening tests are designed to pick up disease in asymptomatic individuals who may have early disease or precursors of disease, whereas diagnostic tests are performed for persons with specific indications of possible disease. However, the screening procedure itself does not diagnose the illness; those individuals with a positive result from the screening test need further evaluation with additional diagnostic tests. If the individual has a previous positive screening test, the diagnostic test acts as a confirmatory test. The ideal screening test should be both highly specific and sensitive; however, this may be difficult to achieve. As there is such a variety of screening tests available, there is not a particular sensitivity target value which is suggested; nevertheless, the sensitivity should be as high as possible without sacrificing specificity. It is not advisable to use a test with low specificity as a screening test, since many people without the disease will screen positive and potentially receive unnecessary diagnostic procedures. Moreover, for an effective screening test, the prevalence of disease in the population should be high; for if the prevalence of the disease is low, then a positive test will most likely be a false positive, leading to further unnecessary testing. Other considerations in regard to screening tests include weighing the cost of the test versus the impact of early detection. Overall, good screening tests should be easy to perform, inexpensive, and performed in high disease prevalence populations. In addition, early detection of disease should have a measurable impact on patient outcomes.

SEROLOGICAL ASSAYS

Traditionally, serological assays referred to the use of serum or plasma samples for the detection of antibodies to a variety of antigens. This concept has been broadened to refer to a variety of patient samples such as cerebrospinal fluid, urine, and other body fluids. In addition, it refers to the detection of both antibodies and antigen. There are a variety of clinical scenarios in which serological assessment is

the test of choice. For the identification of organisms for which culture is difficult or requires prolonged incubation, the determination of antibody titers or antigen detection can often give a quick answer. Although molecular techniques have sometimes supplanted serology in these situations, often cost issues make serology a more viable technique. There are frequent clinical situations where it is unnecessary to perform a culture if an antigen test is positive. One of the most common situations is the diagnosis of group A beta-hemolytic streptococcal throat infection. A rapid immunoassay for the detection of the group A streptococcal antigen is performed. If this is positive, then treatment can be instituted. Only when this quick test is negative is it necessary to perform a culture.

Basic Immunologic Reactions

In order to facilitate understanding of antibody titers, a brief review of basic immunologic reactions is provided (1, 2). Upon initial exposure to an infectious disease (primary antibody response), there are four phases in the subsequent response: an initial lag (or window) phase, when there is no antibody detected; a log phase, when the antibody titer increases in a logarithmic fashion; a plateau phase, in which the amount of antibody stabilizes; and a decline phase, during which the antibody is cleared or catabolized. The actual time course and ultimate maximum antibody titer depend on the antigen and the host. In the primary response, the initial antibody response is the production of immunoglobulin M (IgM), which usually appears after 10 days. The period after initial exposure, but before antibody is produced or is at sufficient levels to be detected, is called the "window period." This can vary, depending on the infectious agent, from as short as 10 days to as long as 6 months. IgG antibody production usually begins 10 days after exposure but is much less than the IgM response. As the IgM antibody level decreases, the IgG level increases, so that usually by the end of the first month, only IgG antibody is detectable. If there is a repeat infection with the same infectious agent, the kinetics of the response are different, with a lag phase of only 1 to 3 days, and IgG antibody is the primary isotype produced. In the months following antigen exposure, the IgG level reaches a plateau, and the antibody may remain detectable for life, even if there is no further exposure to the antigen. B lymphocytes utilize membrane-bound antibodies to recognize a wide array of antigens. In the case of infectious disease agents, the antigens are often expressed on the microbial surfaces. The particular parts of the expressed antigens that are bound by antibodies are referred to as epitopes; the strength of the binding of one epitope to one antibody is called the affinity. Upon repeated infection with a microbe, there is an increase in the strength of the antigen-antibody binding, a phenomenon called affinity maturation. However, depending upon the immunoglobulin molecule present, there are more than one antigen binding sites on each immunoglobulin (IgG, 2 sites; polymerized IgA, 4 sites; IgM, 10 sites); therefore, the total strength of the antigen-antibody binding is much greater than the affinity of a single interaction. This is called the avidity. Just as with affinity maturation, there is an increase in avidity with additional exposure to an antigen. Upon initial exposure to an antigen, the avidity of the IgG is low; upon secondary exposure, there is an increase in IgG avidity. Although there is exquisite specificity in the antigen-antibody reaction, there can be a spectrum of antibodies produced in response to a particular antigen; they can have differing affinities and avidities with a particular antigen and thus can be responsible for cross-reactions. Recognizing cross-reacting antibodies can be critical to assay specificity. Often, initial screening assays are set up with crude antigen preparations in which false-positive reactions can occur. Secondary confirmatory or diagnostic assays utilize purified and more expensive antigen preparations which confer greater specificity. Recognition of cross-reactivity is critical in tests used in infectious disease, because often organisms within the same genus and species share multiple antigenic determinants, making cross-reactivity a common problem. Although assays are designed to obviate these problems, laboratorians and clinicians should just be cognizant of the potential for cross-reactions.

Caveats in Serologic Interpretation

In general, a positive IgG titer means only that an individual has been exposed to a particular infectious agent and thus is "immune." For each infectious agent, the laboratory result is usually set up so that a positive result is the minimum amount of IgG antibody present which makes the individual "immune." For purposes of this discussion, the term "immune" is used; however, this does not necessarily mean that the level of antibody is protective against reinfection. The actual amount of antigen-specific antibody present in the serum of a particular individual is host determined and is controlled by immune-response genes which are products of the human histocompatibility system. The level of the IgG titer from a single serum sample to a particular infectious agent may not be used to determine if the infection is recent or remote. For example, person A may be a high responder to certain antigens and a low responder to others. Therefore, if a high titer of IgG is obtained for an individual, it may be tempting to think that this may represent a more recent exposure; however, this may indicate only that the individual is a high responder to that particular antigen. Therefore, a positive IgG titer establishes only that the individual has been exposed to a particular agent at some time in the past and has detectable IgG. In addition, the nature of the antigen is important, as some antigens are more effective than others in stimulating the immune system. Moreover, the ability of the immune system to respond to antigens can be affected by a variety of factors, such as age. For example, the very young may be unable to respond to certain types of antigens (e.g., carbohydrates) (1, 2).

Using serologic methods, there are several ways to determine if the infection is recent. The most useful and frequently used method is assessment of IgM antibody to a particular infectious disease agent. In general, a positive IgM titer to a particular organism is evidence of an active (i.e., recently acquired) infection with that agent. However, there are several considerations to keep in mind in the interpretation of this test. First of all, a positive IgM titer does not always mean that the infection is recent. There have been reports of persistent elevations of IgM antibody for a year or more. This has been seen with multiple organisms, including cytomegalovirus, *Mycoplasma pneumoniae,* hepatitis A virus, and *Toxoplasma gondii,* among others (9, 33, 45). Conversely, a negative IgM titer does not exclude a recent exposure. The amount of IgM may have been small and resolved quickly; thus, it was not detected at the time of the assay. The second way to establish a primary infection is to determine acute- and convalescent-phase titers. This requires drawing two sets of antibody titers: one set early in the exposure to the infectious agent and a second set 2 to 3 weeks later. Evidence of an acute infection can be confirmed if there is a fourfold increase in antibody titer between the first and second titers.

While this can sometimes provide information on the pathogenesis of a disease state, it requires at least 2 to 3 weeks for definitive results, thus obviating its use for early clinical management. Also, a false-negative reaction is not uncommon due to the fact that it requires drawing the specimen at a point low enough on the log part of the antibody response curve to obtain the required fourfold increase in antibody titer. Therefore, the lack of a fourfold increase does not rule out a primary infection.

At present, many assays report results as absorbance values or international units, making it problematic to apply the concept of a fourfold increase in titer. While it is possible to develop an approximate equivalency between titers and absorbance values, this has to be individually developed for each assay. One method to do this involves collecting multiple pairs of acute- and convalescent-phase sera to use as reference sera. They must demonstrate a fourfold increase in titer on traditional assays. They are then run on the EIA for the agent in question, and reference ranges are reported in optical density units. Assuming that the EIA provides distinctly different absorbance ranges to adequately separate acute- and convalescent-phase sera, pairs of test sera can then be run on the EIA, and the values can be compared to the reference ranges. While this can theoretically provide an adequate way to evaluate acute- and convalescent-phase titers by using the newer assay formats, it can have multiple problems. First of all, establishment of the reference range has to be performed separately on assays for each infectious agent, which can be expensive and time-consuming. Secondly, the lab has to have multiple sets of positive acute- and convalescent-phase paired sera for each organism tested, which can be quite difficult to obtain. In addition, depending on the EIA used and the range of the standard curve, titer values may not be easily converted into equivalent and meaningful absorbance values. Considering the cost and difficulties associated with this type of analysis, it is not generally recommended. Instead, it is preferable to test for the presence of an acute infection by using an IgM assay or an IgG avidity test (see below) or to directly test for the organism by using one of the increasingly available molecular techniques.

An additional test to perform, which can address some of the concerns with IgM testing and acute- and convalescent-phase titers, is an IgG avidity test (28, 33, 39). IgG antibodies produced early in infection have a low avidity, but a much greater avidity is seen with a secondary exposure. Using an avidity assay, in conjunction with the assessment of IgG and IgM antibody levels to a pathogen, can provide a much clearer indication of acute infection. Avidity tests are performed with a modification of the standard IgG EIA, in which IgG antibodies are exposed to a dissociating agent (usually high concentrations of urea). The serum IgG avidity is estimated by comparing the treated sample with one untreated. While this test can be quite useful, there are several caveats with its use. First of all, low avidity does not always mean that the infection is recent because low avidity antibodies can persist for months to years. In addition, there can be quality control issues in this testing with variability in test results related to the type of assay plates used, the antigens employed, and the type of dissociating agent used. This test has special utility in testing for some of the pathogens associated with pre- and perinatal infections (toxoplasmosis, rubella, and cytomegalovirus) (28, 33). For example, one algorithm suggested for prenatal toxoplasmosis testing follows all positive IgG antibody assays with an avidity test. If the avidity test is high, an acute infection is ruled out; however, if the avidity test is low, an IgM test is then performed. If the IgM test is positive, then a recent IgM infection is highly suspected. However, considering the implications for pregnancy, the FDA recommends that sera with positive IgM results obtained at a nonreference laboratory should then be sent to a toxoplasma reference laboratory for confirmatory testing.

SPECIFIC IMMUNOASSAYS

The spectrum of immunologic assays is discussed in detail in the following sections. Table 1 lists selected assays in order of relative sensitivities and provides approximate levels of detection.

Precipitation Reactions

When soluble antigens and antibodies are in equimolar concentrations, they bind and form insoluble antigen-antibody complexes which form a visible precipitate (24, 29). There are a number of laboratory tests available that utilize this reaction. Immunodiffusion is the simplest of the precipitation assays and involves putting the immune reactants in an inert semisolid material and then viewing the visible precipitation line. There are several variants of immunodiffusion. Radial immunodiffusion is designed to provide protein quantitation, whereas double immunodiffusion (Ouchterlony analysis) allows characterization of the relationship between different antigens. Overall, immunodiffusion reactions are simple to perform, easy to evaluate, and inexpensive and can be adapted to a variety of health care settings. The drawbacks include low sensitivity, as the level of detection is microgram quantities of antibody or antigen; requirements for relatively large amounts of antigens and antibody; and long assay times. Immunodiffusion is also routinely used for determination of antibody titers to a variety of agents, most commonly antifungal antibodies *(Coccidioides, Aspergillus, Histoplasma,* and *Entamoeba histolytica)*.

Agglutination Reactions

Agglutination reactions require a particulate antigen and its antibody with the resultant visible clumping as evidence of a positive reaction (21, 24, 29, 30). A test involving the particulate antigen which agglutinates the antibody present in the patient sample is termed a direct agglutination assay. To enhance the visibility of the agglutination reaction, an indirect assay format can be used, in which the antigen is coupled with a variety of particles that serve as an inert matrix. Various materials which have been employed include gelatin, latex, erythrocytes, polypeptides, and silicates. In addition, soluble antigen can be detected in a patient sample by absorption of a specific antibody to a particle; this is termed

TABLE 1 Sensitivity of immunoassays (34, 41)

Technique	Approximate sensitivity (per ml)
Precipitation, tube	100 mg
Immunodiffusion	1–3 mg
Agglutination	1 mg
Hemagglutination, passive	15–30 mg
Complement fixation	0.001 mg
Particle immunoassay	30–50 ng
EIA	<1 ng

reverse agglutination. Due to the large IgM molecule with its pentameric structure, IgM antibodies are several hundred times more efficient at agglutination than IgG and thus give more consistent and stable agglutination reactions. If the immune response involves primarily IgG antibody, the reaction may require some type of chemical enhancement or an antiglobulin reagent. Flocculation assays are another variant of agglutination assays, in which the particles are suspended. The most frequently used assays are the Venereal Disease Research Laboratory and rapid plasma reagin tests for syphilis.

Many agglutination assays, called hemagglutination assays, employ red blood cells (RBC) and use either a direct or an indirect assay format. Direct agglutination of RBC is commonly used in the blood bank for ABO typing. For infectious disease diagnosis, one of the most frequently ordered direct hemagglutination assays is the monospot test. This test detects the presence of a heterophile antibody which is produced in infectious mononucleosis and happens to spontaneously agglutinate equine RBC. The indirect hemagglutination assay is a commonly used format in which antigen is adsorbed to RBC, thus testing for the presence of specific antibody in the patient serum. Alternatively, the assay can be modified to test for antigen, in which case it is called reverse agglutination assay. For infectious disease testing, hemagglutination (especially indirect) is a popular assay format, as it is sensitive and simple to perform and does not require sophisticated equipment. For these reasons, it has been used in many third world countries for testing of a variety of infectious disease agents such as human immunodeficency virus (HIV), hepatitis virus (A, B, and C), and *Treponema pallidum.* There is a unique type of hemagglutination assay format used primarily in viral serology called hemagglutination inhibition. It is most commonly used for detection and quantitation of antiinfluenza antibodies. It is based on the principle that some viruses have surface proteins that will agglutinate RBC, so the assay uses the ability of antiviral antibodies in the patient sample to inhibit the spontaneous agglutination of the test RBC. The titer of antiviral antibodies is reported as the last dilution of the patient serum still able to inhibit the agglutination reaction.

Specialized types of agglutination assays that require optical counting are called particle immunoassays (8, 15, 16, 26). They involve primarily the measurement of scattered light which occurs upon the antigen-antibody reaction, and this is measured by either turbidimetry or nephelometry. They can be used for testing a wide range of proteins and analytes. Particle immunoassays are 3 orders of magnitude more sensitive than standard agglutination. One additional assay is the particle-counting immunoassay, which is used for quantitating haptens, antigens, and antibody. It is also available in a fully automated immunoassay format. In this assay, optical cell counting is employed, and there is an assessment of the decrease in agglutination following the immunoreaction. These assays are sensitive to a level of nanograms per milliliter. The patient sample is mixed with latex beads coated with antibody. As the antigen-antibody reaction occurs, the antigen particles are no longer dispersed in the solution; therefore, the antigen concentration is inversely proportional to the amount of antigen particles remaining in solution. Antibody can also be quantitated in this assay. The use of a particle-counting immunoassay has been reported for quantitation of hepatitis B virus surface antigen, along with quantitation of antibodies to hepatitis C virus, *T. pallidum,* and *T. gondii* (15, 16, 20).

Overall, basic agglutination assays are easy to perform and inexpensive and can be done in a variety of clinical settings such as the doctor's office, the emergency room, and the hospital bedside and in the field. They are performed either on a card, in tubes, or in microtiter plates. Often they provide only qualitative results, although an antibody or antigen titer can be obtained through serial dilutions of the sample. Direct assays continue to be performed for rare pathogens such as *Francisella* and *Brucella.* They utilize an inactivated source of the whole organism mixed with the patient sera. Although agglutination assays suffer from both limited sensitivity and limited specificity, they continue to be utilized because they are easy to perform and relatively inexpensive. If a more quantitative assay is needed, the assay can be adapted to light-scattering equipment such as a nephelometer to provide more quantitative and sensitive results. Overall the major drawback to direct agglutination assays is their limited sensitivity. They detect only to a level of microgram to milligram quantities of analytes per ml. However, greater sensitivities can be achieved with many of the variants of direct agglutination. For example, microtiter passive hemagglutination assays for infectious agents can achieve a sensitivity equivalent to that of a conventional EIA. The more sensitive hemagglutination assays for measuring antigen can measure as low as 15 to 30 μg/ml. If an agglutination assay is read visually, it is reported as a titer value. While these are fairly sensitive assays, titer values are always plus or minus one tube dilution, so that a titer of 16 could actually represent a titer of either 8 or 32. With latex-enhanced nephelometry or turbidimetry, sensitivity ranges in the area of 30 to 50 ng/ml.

There are several problems that can affect both sensitivity and specificity. The first problem affecting sensitivity is called the prozone effect (8, 24, 29). This refers to a lack of agglutination due to an excessive amount of antibodies in the patient sample. The high concentration of antibody inhibits agglutination, giving a false-negative result. This can be easily overcome by simply diluting the sample. In regard to specificity, the major concern is false-positive reactions from IgM rheumatoid factor (RF) (8, 11, 24, 29, 32). This occurs most commonly in assays in which the latex beads are coated with IgG antibody. This has been commonly reported for the latex agglutination test for cryptococcal antigen (24, 46). IgM RF, which is specific for the Fc portion of the IgG molecule, binds and gives a false-positive reaction. RF has also been reported to bind to other serum proteins nonspecifically, also giving a false-positive reaction. It is crucial that the clinician notify the laboratory if the patient has a known RF. There are several measures that could be taken. First of all, if a false-positive reaction is suspected, the sample result can be compared to the reaction using control particles coated with normal IgG. If this indicates that there is a false-positive reaction, the sample can be treated with a reducing agent such as 2-mercaptoethanol or it can be treated with pronase. Both of these treatments have been shown to reduce the majority of false-positive reactions due to IgM RF. Alternatively, the sample could be pretreated with aggregated IgG to remove the IgM RF; however, this can result in loss of antigen or specific antibodies and give a false-negative result. Also, an alternate test method could be used for assessment of the ordered analyte. Most importantly, communication of pertinent clinical information to the laboratory is critical to ensure the most accurate diagnostic information.

CF Test

Another traditional immunoassay is the complement fixation (CF) test, which is based upon the interaction of immune complexes with complement (29). As antigen-antibody complexes form, the complement cascade is activated and complement components are "fixed" or consumed. Conversely, if there is no antigen-antibody complex formation, there will be no activation of the complement cascade. This two-step test is primarily used to determine the titer of antibodies to specific antigens. For example, to set up a CF test for anti-*Mycoplasma pneumoniae* antibodies, patient serum would be incubated with *M. pneumoniae* antigen and a defined quantity of guinea pig complement. If the patient sample contains *M. pneumoniae* antibody, immune complexes will form and fix the complement. RBC coated with antierythrocyte antibodies are then added to the tube. The final readout for the assay is the release of hemoglobin from any lysed RBC. If the patient sample is positive for *M. pneumoniae,* then there will be no complement remaining, so there will be no release of hemoglobulin. The opposite will occur if the patient sample is negative for anti-*M. pneumoniae* antibody. Although CF assays are relatively sensitive and inexpensive, they can be technically demanding and time-consuming. Therefore, many of these assays have been converted to ELISA formats. However, a number of laboratories still use them as a confirmatory test for the presence of antibodies to a variety of infectious agents such as *Coccidioides, Histoplasma capsulatum,* adenovirus, herpesvirus, influenza virus, *M. pneumoniae,* and rickettsias.

Neutralization Assays

Neutralization assays are traditional laboratory tests used to determine if an antibody which can neutralize the infectivity of a particular virus is present (29). The classic assay involves mixing patient serum antibody samples with virus and then using this mix to inoculate either a cell line or a preparation of peripheral blood mononuclear cells. The readout involves either the assessment of viral cytopathic effect in the cell line or some other measure of viral replication, such as that obtained by a classic immunoassay of viral protein. For example, in the case of HIV testing, one can perform a p24 antigen test or reverse transcriptase assay and look for lower values. Evidence of decreased viral replication confirms the presence of neutralizing antibody. Although these assays are relatively simple, they can be expensive and can take days to complete. In addition, they can be difficult to standardize, especially when comparing results from different laboratories. To decrease the assay length, the quantitation of viral products can be assessed using PCR; however, this technique can be expensive and also difficult to standardize between laboratories. A blocking ELISA can also be performed, in which viral antigen and serum are mixed, after which a standard ELISA for virus is performed and the decrease in the amount of antibody detected is assessed. An additional traditional neutralization assay is a reverse passive hemagglutination, as previously discussed. In the field of HIV vaccine development, there is interest in developing new and better assays for neutralization, since it is crucial in the assessment of vaccine efficacy to demonstrate that a putative virus can initiate antibody production to prevent infection (35).

IFAs

The immunofluorescence assay (IFA) uses a histochemical technique to detect either antigen or serum antibody, utilizing a fluorescent-compound-labeled detector antibody (24, 29, 30). There are two types of IFA, direct and indirect (Fig. 1). Direct assays are used to detect the presence of antigens in tissue or body fluids. For example, to detect the presence of influenza virus in a nasal wash specimen, it is applied to a slide, and then it is overlaid with a fluorescent-compound-labeled anti-influenza antibody. If there is influenza antigen present, there is emission of fluorescent light, which is evaluated with a fluorescent microscope. Indirect assays are two-step tests used primarily for the detection of antibodies in serum or a body fluid. The patient sample is applied to a slide containing the target antigen; this is allowed to incubate, and specific antibody in the patient sample forms immune complexes with the antigen present on the slide. Any unbound reagent is then washed away, and the slide is overlaid with a fluorescent-compound-labeled anti-immunoglobulin. Positive staining is the emission of fluorescent light. Overall, IFAs are useful tests that are relatively easy to perform and inexpensive. In addition, they allow the localization of the antibody to a specific antigen location in the tissue. For example, the IFA for antibody to Epstein-Barr virus early antigen allows visualization of a specific pattern of staining of the virus-infected cell line. The disadvantages of this assay are that it is relatively time-consuming and requires both the purchase of an expensive fluorescence microscope and the presence of trained and experienced personnel for interpretation.

EIAs

EIAs are taking on increasingly more prominent roles in laboratory medicine (7, 8, 22, 24, 30, 47, 48). They are found in all areas of the clinical laboratory, in physicians' offices, and in at-home testing and are being increasingly used in molecular pathology laboratories. EIAs have taken the place of the RIAs in many laboratories, as they offer comparable sensitivity without the problems of disposal and the short half-life associated with radioactive materials. They are also replacing a variety of other techniques in the laboratory such as immunofluorescence and agglutination because EIAs provide greater objectivity, the potential to automate, and the ability to process large numbers of samples with less hands-on technician time. As a single unit of enzyme label can amplify a reaction product manyfold, many EIAs are optimized for detection at the pico- or attomole level. EIAs can be broadly classified as either homogeneous or heterogeneous assays. In homogeneous assays, the enzyme activity is altered as part of the immunologic reaction itself. In these assays, there is no requirement to separate the bound from the free immunoreactants. Although this technique is especially suited for the measurement of drugs and haptens, homogeneous assays

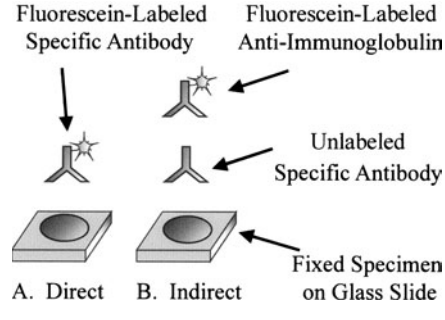

FIGURE 1 Direct and indirect immunofluorescence assays.

have not achieved widespread use in microbiology laboratories. In contrast, heterogeneous immunoassays are widely used in microbiology. In these assays, the enzyme activity of the labeled immunoreactant is not directly involved in the immunologic reaction itself.

The basic principle of the heterogeneous EIA is the use of an antibody or antigen conjugated with an enzyme which, upon reacting with its substrate, forms a measurable reaction product. Often a color reaction product is produced. The color change is monitored visually or with the use of a spectrophotometer to determine the proportionality between the amount of color and the amount of analyte present. An essential component of these assays is the separation of the bound enzyme-labeled component from the free labeled reagent. Assays can be competitive or noncompetitive and can be used to measure antigens or antibodies. The presence of all antibody isotypes can be quantitated depending on the specificity of the antibodies used. Whenever antibody or antigen is absorbed to the solid phase, the assay is referred to as an ELISA and also as a "sandwich" assay.

EIAs can be set up primarily as competitive or noncompetitive (7). Competitive assays most commonly measure antigens and are set up with either antibody or antigen on the solid phase. They are often termed "limited reagent" methods because the antigens and antibodies are used in measured and limited amounts. When the assay design uses specific antibody with which the solid phase is coated, the patient sample containing the putative antigen and the labeled antigen are added simultaneously and compete for binding to this matrix (Fig. 2). It is critical that the avidity of the antibody for both the labeled and unlabeled antigens be the same. In addition, a separate reaction is set up using enzyme-labeled antigen and buffer alone, which are added to the antibody-adsorbed solid phase. The substrate for the enzyme is added, and the color reaction is assessed. If the patient sample contains the antigen in question, it will effectively compete for binding to the solid phase, thus preventing any enzyme-labeled antigen from binding, thus giving no or minimal color. This reaction is compared to a reaction well to which buffer alone is substituted for the patient sample. The separation of the bound reactant from the free reactant is achieved through the washing steps. As is true with all competitive assays, the amount of labeled immunoreactant detected through the enzymatic reaction is inversely proportional to the amount of antigen present in the sample.

Antigens present in a patient sample can also be measured by using the coating of the solid phase with antigen. For this technique, the test sample containing the antigen in question is mixed with a limited amount of enzyme-labeled antibody. If the patient's sample contains the antigen, it will bind the labeled antigen, thus preventing this antibody from binding to the antigen with which the solid phase is coated. Following the washing step, the color reaction is developed and again, no color is seen if the sample contains the antigen. This technique can be modified by using unlabeled antibody in the first step and then adding a secondary enzyme-labeled anti-Ig.

Another variant of a competitive technique uses a two-step procedure. In the first step, test antigen is preincubated with its specific antibody. Any antigen-antibody complexes that have formed are removed during a wash step. Enzyme-labeled antigen (ag*) is then added to bind any remaining free antibody not bound by test antigen in the initial reaction. In the second step, beads coated with anti-immunoglobulin are added. These beads will bind any ag*-antibody complexes which formed in the previous step, and they can be quantitated in the pellet following centrifugation.

Compared to noncompetitive assays, competitive tests often provide greater specificity with less sensitivity; however, this is dependent on the affinity and purity of the immunological reagents and the design of the particular system. Competitive assays are ideal for measuring relatively small molecules which can be obtained in relative purity and in large enough amounts to be labeled with an enzyme. As they generally require small amounts of antibody, competitive assays are ideal for use in systems which have a limited amount of antibody available.

Noncompetitive ELISAs

The next major type of assay is the noncompetitive indirect solid-phase ELISA. This method is one of the most frequently employed immunoassays in the clinical laboratory. As with competitive assays, the two major variants involve using either antigen or antibody on the solid phase. When antigen is used for coating, specific antibodies in the sample bind to the solid phase and are detected with an enzyme-labeled anti-immunoglobulin secondary antibody (Fig. 3). Isotype-specific, enzyme-labeled anti-Ig antibodies can be used to determine the specific Ig class present. This type of assay is commonly used in the measurement of immune status to infectious agents and for autoantibody testing. A variety of solid-phase supports are used, including microtiter plates, nitrocellulose, and beads. One common variant, which uses nitrocellulose membranes, is the dot blot assay (12, 29, 40). In this system, the antigen or antibody is coupled to the membrane, and usually the reaction is assessed

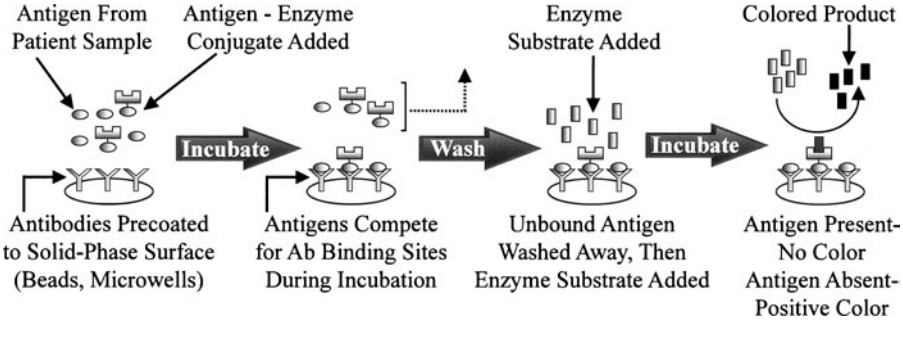

FIGURE 2 Competitive EIA.

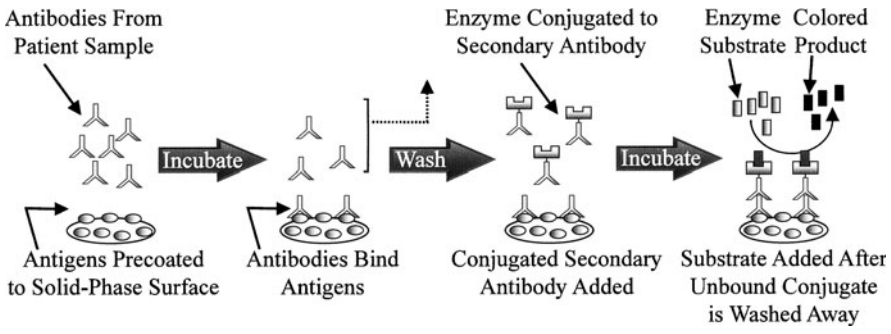

FIGURE 3 Noncompetitive indirect solid-phase ELISA.

visually by a colored reaction production, providing a qualitative assay. Many of the at-home testing kits (e.g., pregnancy kits) use a variant of this technique. This assay can be modified for increased sensitivity with such variants as can be made semiquantitative by using a densitometer for reading the color reaction.

When the antibody is coupled to the solid phase, these assays are often termed "capture" or "sandwich" assays, because the antigen in the sample is captured by an antibody-coated matrix. An enzyme-labeled secondary antibody directed to a different antigenic epitope is then added, completing the sandwich. There are numerous variations of this type of assay. The antigen captured can be an immunoglobulin, a viral protein, or any antigen that has at least two epitopes.

Noncompetitive ELISAs can also be modified by incorporating additional layers of immune reactants. This increases the sensitivity of the assay, but it also increases both the cost and time requirements. The most frequent application is the so-called avidin-biotin-peroxidase complex (ABC method) which can significantly improve the level of detectability. Biotinylated anti-Ig is generally used as the second antibody of the sandwich. This is then reacted with a preformed mixture of avidin and biotinylated peroxidase (ABC). The peroxidase can be developed with chemiluminescent reagents for increased sensitivity. Other variants include peroxidase anti-peroxidase methods and the incorporation of lectins as bridging molecules.

Microparticle Enzyme Immunoassay

The microparticle enzyme immunoassay is a variant of the ELISA that utilizes tiny beads (1-mm-diameter or less) that can be coupled with antibody or antigens (24, 28). The small size leads to a greater surface area for binding of antibody or antigen, which results in a decrease in reaction time. The particles act as the solid phase, but the reaction can be performed in suspension. These types of assays can be easily adapted to automated analyzers.

Analytical Interferences and Technical Issues

As in all laboratory tests, there are always factors that can affect test validity. Overall, immunoassays are affected more than routine chemistry and microbiology assays (6, 11, 22, 31, 32, 42, 47, 48). There are various clues that should alert one to the possibility of erroneous results. These include test results that are inconsistent with the clinical findings and/or an unexplained change in a test result from a previous assessment. These findings should prompt consideration of the possibility of technical issues or some type of test interference.

Plate Variability

There are several issues to consider with solid-phase microtiter plates that are often used for reagent excess sandwich-type ELISA (7, 47, 48). First, there can be variability between readings on adjacent wells of a microtiter plate. This variability is expressed as the well coefficient of variation, which should not be greater than 3 to 5% between wells. Secondly, there is the "edge effect," which refers to the variability between the readings on the outer wells of a microtiter plate and the readings on the inside wells. Although manufacturing variability in the plates must be evaluated as a possible cause, this occurs primarily due to differences in temperature between outer wells and interior ones. This can affect both the antigen-antibody and enzyme-substrate reactions. There are several ways to deal with the edge effect. One easy solution is to use smaller break-apart wells that can be placed in a larger plate. Simply being careful to protect the plate from exposure to light can also easily solve this problem. It is crucial that different plates from several manufacturers be screened for this effect when initially setting up an assay. In addition, when the lot of a plate is changed, the plates should be reevaluated to ensure that it is not necessary to modify any of the assay parameters.

Hook Effect

The hook effect refers to an unexpected fall in the amount of an analyte at the high end of the dose-response curve, resulting in a gross underestimation of the analyte (6, 11, 22, 31, 32, 42, 47, 48). This is particularly a problem in sandwich immunoassays with patient samples which contain an extremely high level of an analyte. The patient sample gives a low to moderately high result when using the standard assay dilution. However, upon further dilution of the sample, either the result is out-of-range high or, if it is diluted far enough, the sample gives an extremely elevated value. Therefore, if the laboratory ran the sample only at the routine dilution, a significant underestimation of the value would be reported.

The explanation for this phenomenon has not been completely established. Many investigators feel that it is caused by antigen excess, in which a majority of the antigen binding sites are filled, preventing completion of the sandwich. It has also been suggested to arise from low-affinity antibody, inadequate washing, and suboptimal concentrations of labeled antibody. Tests that are especially susceptible to problems with the hook effect include ones in which there may be samples with extremely high levels of the measured substance. These include IgE, human chorionic gonadotropin, tumor markers, ferritin, infectious antigens, and antibodies.

Numerous suggestions have been made regarding ways that laboratories can deal with the hook effect. One obvious strategy is to run all patient samples at 2 dilutions to screen for this problem. If the sample provides an answer with the first dilution, while the more dilute sample is out-of-range high, then the laboratory is alerted to the possibility of the hook effect. Although this is an effective approach, many laboratories are concerned about the time, cost, and labor involved in running 2 dilutions for every sample to avoid problems with only a small minority of patients. Thus, there are other strategies which can lessen the probability of the hook effect occurring.

First of all, always ensure that adequate washing is performed between all steps of the ELISA, especially between the steps following the addition of each antibody. Automatic plate washers are relatively inexpensive and can simplify this task. In addition, good communication with the kit manufacturers can also lessen the frequency of this problem. A number of companies have established the level at which the hook effect occurs and will readily share this information. Also, when completing new kit evaluations, testing specimens with high levels of the analyte is also crucial, as the frequency of the hook effect with different kits may be variable. Lastly, good communication with the clinician is also important; include discussion of the hook effect with a suggestion of notifying the laboratory when patients are expected to have very high levels of the analyte ordered.

Antibody Interference

There are a number of endogenous antibodies in patients' sera that may cause either positive or negative interferences in immunoassays (6, 11, 22, 31, 32, 42, 47, 48). There are multiple types of antibody interferences; they can be caused by antibodies binding to the actual analyte (e.g., antiviral antibodies), binding to components of the detection system (e.g., anti-alkaline phosphatase), and binding to reagent antibodies (e.g., anti-immunoglobulin antibodies). The last category is the most common and involves three types of antibodies. First, there are heterophile antibodies, which are weak antibodies to immunoglobulins from multiple species with no known or obvious identifiable immunogen. Secondly, RF can have a known effect on a variety of immunoassays and is most often found in patients with connective tissue diseases. Thirdly, there are various types of anti-animal antibodies; the most commonly reported are human anti-mouse antibodies (HAMA). Estimates of the prevalence of anti-mouse antibodies in normal sera vary greatly, from 0.5% to as high as 40%, depending on the sensitivity of the testing assay. There are both iatrogenic and noniatrogenic causes for the development of HAMA. In regard to iatrogenic causes, the culprit appears to be the increasing use of mouse monoclonal antibodies for therapeutic and imaging purposes. In regard to noniatrogenic causes, there are a number of suggested etiologies including environmental exposure to mice, maternal transfer across the placenta, passage of dietary antigens across the gut wall in inflammatory conditions, such as celiac disease, and association with a number of disease states, such as cardiomyopathy (25). While mouse anti-human antibodies can affect a variety of immunoassays, they are most often reported in two-site murine monoclonal antibody assays which often require only a small serum dilution. The presence of these antibodies can have a variable effect on immunoassays. If the analyte is present, they may cause either an over- or an underestimation. However, if the analyte is not present, a false-positive result may arise from the anti-mouse antibody cross-linking the two mouse monoclonal antibodies of the sandwich (the coating and conjugate antibodies). There have been a number of techniques advocated for decreasing the interference caused by heterophile antibodies and HAMA. These include heating the sample to 70°C, precipitating with polyethylene glycol, blocking with mouse IgG, and blocking with solid-phase anti-human IgG or mouse IgG. Caution should be observed in using heat treatment. The most popular method is the addition of nonimmune mouse immunoglobulin; however, the amount and source of the mouse serum may be crucial. Some studies with interfering anti-mouse antibodies demonstrated that the serum had to be from the same strain of mouse as the monoclonal antibody used in the assay. Therefore, it is recommended that a pool of mouse immunoglobulin from various strains be used to increase the probability of blocking as many patients' samples as possible. Most studies use approximately 10% mouse serum added to the reaction buffer; however, a few patient samples required a high concentration (>20%) of normal serum coupled with a long incubation time to correct the interference. To obviate problems with the majority of samples, laboratorians should consider routinely adding normal pooled heterologous sera to the dilution buffer of sandwich assays. In addition, special attention should be given to any sample for which the lab result is discordant with the clinical presentation, as this may represent a heterophile antibody resistant to the standard protocols.

Measurement of IgM

Quantitation of the IgM isotype of specific antibody poses special technical problems (7, 24, 28, 48). False positivity is common due to the presence of IgM RF in the patient sample. In addition, false negativity can occur from competitive inhibition of IgM binding in the presence of high levels of specific IgG. Previously, assays for IgM used a standard indirect solid-phase ELISA with the antigen immobilized and an IgM-specific secondary antibody. However, these assays were frought with the problems of false positivity and negativity. To obviate these problems, an IgM capture assay was developed (Fig. 4). In this procedure, a polyclonal anti-IgM antibody is bound to the solid phase. Upon incubation of the patient sample, all IgM is captured on the plate. The test antigen is then added, binding any specific IgM present on the plate. An enzyme-labeled secondary antibody is then added, and the reaction is completed. This assay obviates the problems with false-negative results due to competitive inhibition with IgM, as all the IgG in the patient sample is washed away in the first step. False-positive results, however, may still occur due to bound IgM RF reacting with either the IgG conjugate or binding any antigen-specific IgG in the sample. One way to avoid the problem with conjugate binding is to use $F(ab')_2$-conjugated capture antibodies. Alternatively, the assay can be modified to a direct technique by employing enzyme-labeled antigen in the second step, thus eliminating any Ig which could bind RF. Even with these modifications, problems can still occur with borderline and low positive IgM results. For this reason, all IgM-specific antibody results should be evaluated cautiously. As mentioned above, often running an IgG avidity assay can help in the evaluation of IgM results.

RIA

RIA was the original immunoassay technique and ushered in the area of improved and more sensitive immunoassays. Basically, all principles of assay design for EIA were based upon the experience gleaned from the RIA. Although RIA

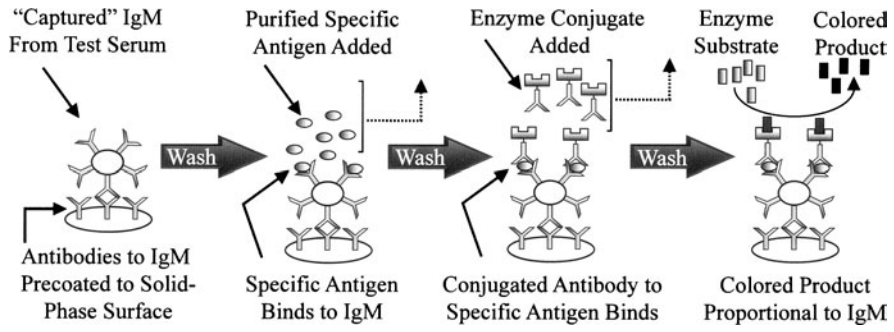

FIGURE 4 IgM capture assay.

is still a viable technique, it has largely been replaced by CL and EIA in most clinical laboratories. A variety of radioisotopes are utilized, most commonly ^{125}I, ^{3}H, and ^{14}C. Both CL and EIA offer more stable reagents and comparable to more sensitive detection limits, and they present no problems with hazardous waste disposal.

FIAs

The fluorescence immunoassay (FIA) uses fluorescence as the detection end point, and this method can be used in either homogeneous or heterogeneous assays (8, 24, 29). Fluorescence is the emission of photons of light as electrons go from an excited singlet state to the original ground state. The system requires a light source, excitation and emission filters, and a detection system utilizing photo multiplier tubes. A mercury lamp is the most frequently used light source, although xenon, halogen, and laser can also be used as excitation light. Fluorescein isothiocyanate and rhodamine are two of the most popular fluorochromes; however, there are a variety of other compounds used which have unique properties making them especially suited to a particular assay design.

There are numerous homogeneous assays which are performed in the liquid phase and do not require a separation of the bound from the free components. One popular homogeneous technique is the fluorescence polarization immunoassay. Some popular clinical analyzers utilize this methodology. This technique gives a measure of the bound/free ratio of the analyte without requiring a separation step. Polarization of light is measured by illuminating a sample with two polarizers in the same plane as the incident light and then at 90° to each other. The assay is based on an increase in light polarization which occurs when a fluorescent-tag antigen binds antibody and forms an immune complex. The labeled antigen is small and thus can rotate rapidly, causing depolarization of light. When the antigen-antibody complex forms, the increase in molecular weight causes a slower rotation and an increased emission of highly polarized light. This technique is primarily utilized for measurement of drugs and some hormones; however, it has utility for the detection of infectious disease. Its use has been described for the detection of antibodies to a variety of organisms such as gram-negative bacteria (*Brucella* spp. and *Salmonella* spp.) and equine infectious anemia virus (20, 44). There are a number of variants of both homogeneous and heterogeneous assays; however, it is beyond the scope of this chapter to discuss these and the reader is referred to other sources (24). FIAs have a number of advantages including high sensitivity and speed, and they are at least as sensitive as RIA. In addition, the reagents are stable and the assays are easily performed. For the fluorescence polarization immunoassay, one limitation is that the antigen used must be relatively small (i.e., with an MW no greater than 2,000) to allow a significant difference in the polarization when it forms an immune complex. Another important drawback in the use of fluorescent assays is the problem of autofluorescent compounds both in the patient sample and in the reaction mixture. This can be a significant problem in homogeneous assays where no washing steps occur and sample components are present during the entire assay. To circumvent this problem, samples can be treated with proteolytic enzymes, oxidizing agents, or denaturing reagents which will limit the amount of autofluorescence. In solid-phase assays, the majority of inferring substance will be washed away.

CL Immunoassays

The chemiluminescence (CL) immunoassay is a very popular technique which is widely utilized in many different assay formats (8, 24). Chemiluminescence is the emission of light which occurs when a substrate decays from an excited state to a ground state. In contrast to the fluorescence reaction which utilizes incident radiation for energy, chemiluminescence derives energy from the chemical reaction itself, which most often is an oxidation reaction. It is one of the most sensitive of all immunoassays, with detection limits down to the attomole (10^{18}) or zeptomole (10^{21}) level. CL substrates are used as the end point in both homogeneous and heterogeneous assays, in addition to their use in immunoblotting and multianalyte detection. Either chemiluminescence is used as a direct label on an antigen or antibody in a reaction which is catalyzed by adding a substrate, or a chemiluminescence compound is used as the substrate for an enzyme-labeled immunoreactant. The acridinium ester labels most commonly employed are derivatives of isoluminol and acridinium esters. The latter is a popular label which is the most sensitive and widely used. It can be conjugated to antigen and antibody by using standard techniques. Detection is relatively simple with the addition of sodium hydroxide and hydrogen peroxide. This reaction results in a flash of light which is read using a luminometer. In addition, the light signal can be captured on photographic film.

Western Blot and Immunoblot

Western blot and immunoblot are two solid-phase assays which combine the separation of proteins, using separation by denaturing gel electrophoresis followed by transfer to a filter (Fig. 5), and the determination of reactivity of the patient sera with the individually separated proteins, using a

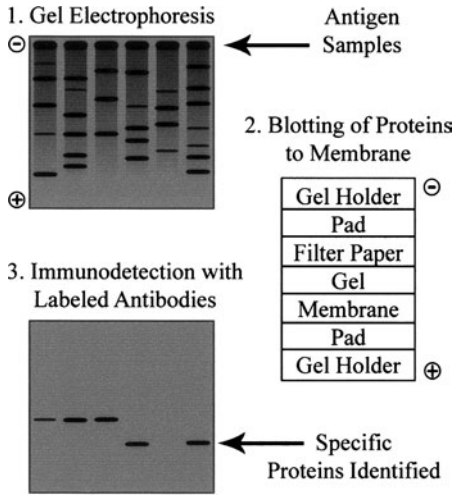

FIGURE 5 Western blot procedure.

typical sandwich-type ELISA. Immunoblotting utilizes a solid-support membrane filter containing antigens which are identified by a specific reaction with antibody. Most commonly, this technique is utilized for identifying the specific pattern of antibody to various infectious disease agents. One common application is for confirmation of antibody to HIV. Immunoblotting patterns can be read visually, using radiolabeled isotopes or using a CL substrate which is then developed on X-ray or photographic film or a charged-coupled device camera.

IPCR

The immuno-PCR (IPCR) is a novel technique that combines traditional ELISA with PCR (3, 4, 5, 11, 13, 27, 36). It uses antibodies labeled directly with nucleic acids (Fig. 6). It is an ultrasensitive technique which has been used for the detection of a variety of viruses. It has the advantage of being able to detect prion proteins where there is no nucleic acid present. In addition, it can detect viral proteins not associated with nucleic acids. This technique has been reported for ultrasensitive detection of a variety of infectious agents such as *Streptococcus,* HIV, and rotavirus, among others. In the case of rotavirus, it has been reported to detect as few as 100 viral particles/ml (versus 100,000 particles detected by ELISA). For detection of p24 HIV antigen, IPCR is a very sensitive test for determination of HIV type 1 viral load for p24 antigen. Although IPCR is a powerful technique, there can be technical issues when combining nucleic acids to proteins, and there can be problems with high assay backgrounds. An alternative approach which uses an indirect double-stranded DNA substrate for alkaline phosphatase has also been published (4). Overall, these highly sensitive methodologies represent the wave of the future, and there will be an increasing number of applications in infectious disease testing.

Rapid Immunoassays

The development of a multitude of rapid immunoassays has revolutionized diagnostic testing, for many tests that were previously available only in specialized or reference laboratories are now easily performed and can usually be completed in less than 30 min (10, 17, 29, 37, 38). There are a variety of formats utilized for these assays which can detect both antigens and antibodies along with products of nucleic acid amplification tests. One of the most popular formats is the lateral-flow immunoassay or immunochromatography. This has the advantage of being a one-step assay. One common format uses a chromatographic pad with three zones: sample application area, conjugate pad, and capture line (Fig. 7). The conjugate pad can use a variety of types of conjugates to generate a signal including colloidal gold, dye, or latex beads. The sample is applied to the sample pad and flows laterally by capillary action. Upon reaching the conjugate pad, if the analyte is present, it binds to the conjugate, forming an immune complex. The complex then continues to flow laterally along the pad by capillary action and is captured by the second antibody or antigen impregnated in the capture line. The presence of a colored line is a positive reaction. There is a positive control line also included in the test to make sure that the test was properly performed. There are variations to this assay format with systems which require no separate venipuncture, combining collection of fingerstick samples with testing in a one-step lateral-flow assay. Another frequently used type of rapid test is the dot blot immunoassay, which has been previously discussed. These rapid assay formats have been especially useful for HIV testing and have been used extensively in testing for HIV in underdeveloped countries. Overall, rapid assays are simple and easy to perform, can be used in field conditions, and can be performed by individuals with little training. While many are not as sensitive as conventional EIAs, there are reports of some with sensitivities approaching the traditional assays (10). Problems with rapid assays include the facts that they cannot be automated, that interpretation can be subjective, and that performance by individuals with no formal laboratory training can result in erroneous results. However, considering their overall advantages and low cost, their use will continue and be expanded as more analytes are adapted to this type of testing.

Automated Technologies

With the expansion of EIAs available, the immunoassay market of automated analyzers and the repertoire of tests available have exploded. Recently, 36 immunoassay analyzers that can run a wide spectrum of tests important in infectious disease testing were profiled (14). The machines run the gamut of serological assays (both antigen and antibody determinations) for infectious disease including HIV infection, hepatitis (A, B, and C), *T. gondii* infection, cytomegalovirus infection, rubella, and *Chlamydia trachomatis* infection, among others. Many of the systems listed are walk-away machines, requiring only limited technologist input. There are also robotic systems available which are cost-effective for even moderate-size hospital laboratories. For detailed information about each analyzer, the complete table can be downloaded from the Internet (http://www.cap.org).

An exciting new area is the development of multiplex immunoassay systems (19, 23). These are laboratory instruments which combine several technologies and allow rapid and simultaneous tests of multiple analytes in a single sample. There are many different assay designs which combine an array of technologies including CL, FIA, flow cytometry, and molecular diagnostics (PCR and use of oligonucleotides and nanoparticles). As these assays provide rapid results and can be performed with very small sample sizes, they have wide applicability to epidemiological studies and vaccine trials. These assays are also especially suited to the assessment of multiple biological agents in a variety of samples.

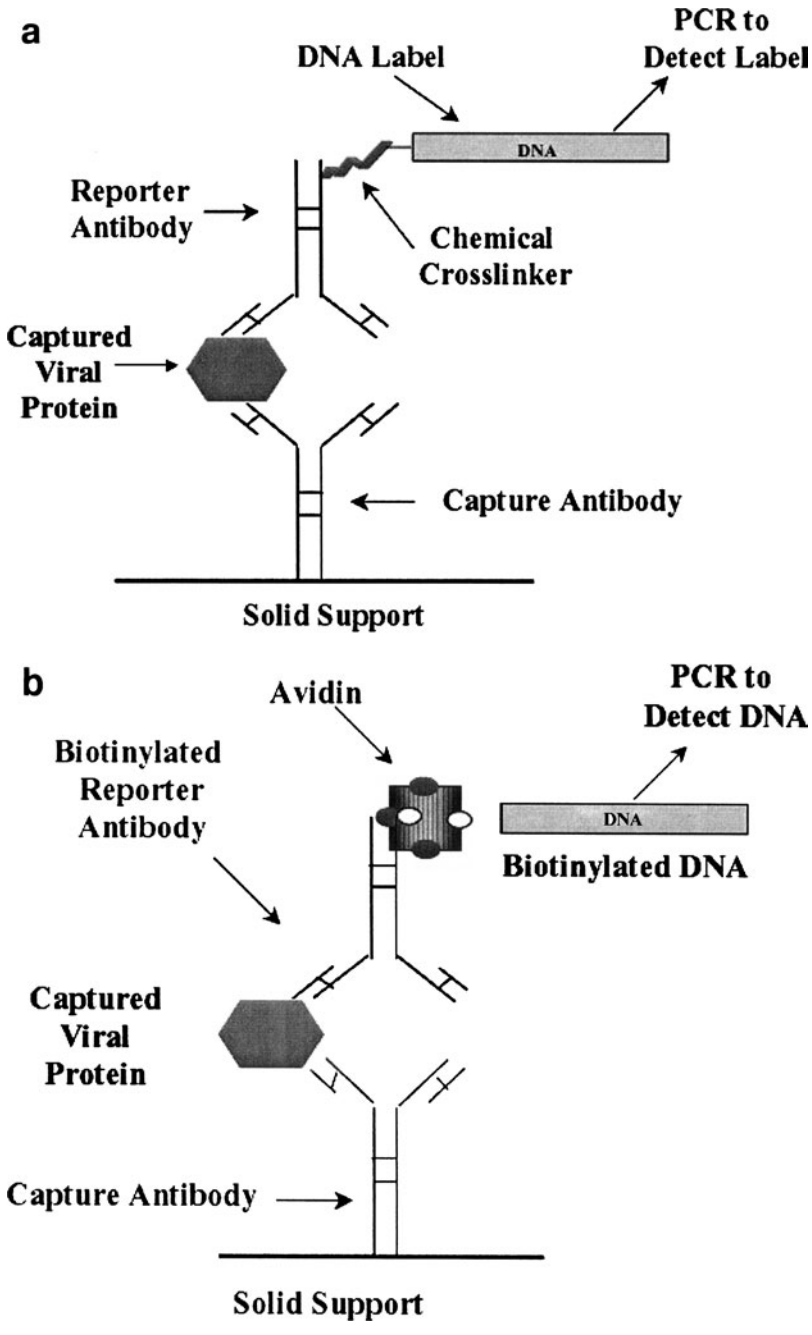

FIGURE 6 Principle of immuno-PCR. (a) DNA directly conjugated to reporter antibody; (b) DNA conjugated via an avidin-biotin reaction.

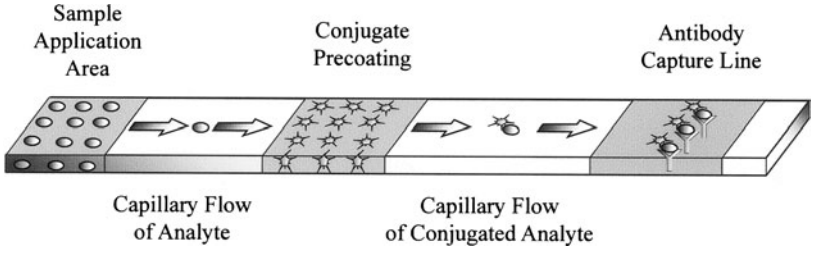

FIGURE 7 Lateral-flow immunoassay.

With this advent of extensive tests easily performed by automated systems, the potential for both improper test utilization and incorrect interpretation of results will increase. This results in even greater pressure on laboratorians and infectious disease specialists to provide information to both their colleagues and patients about the proper use and interpretation of laboratory tests for diagnosis of infectious disease agents.

Special recognition goes to Ryan Morrison, Ph.D., for his expertise and creativity in preparing the figures for this chapter.

PETER A. R. VANDAMME

19

Taxonomy is written by taxonomists for taxonomists; in this form the subject is so dull that few, if any, non-taxonomists are tempted to read it and presumably even fewer try their hand at it. It is the most subjective branch of any biological discipline, and in many ways is more of an art than a science.

With these words, S. T. Cowan introduced a sparkling essay on the sense and nonsense in bacterial taxonomy in 1971 (18). His contributions to the practice of bacterial taxonomy, written in the 1960s and 1970s (15–18), should be read by everyone interested in this field. Taxonomy is generally considered a synonym of systematics and is traditionally divided into classification (the orderly arrangement of organisms into taxonomic groups on the basis of similarity), nomenclature (the labeling of the units), and identification (the process of determining whether an unknown belongs to one of the units defined) (16). During the past decade, it became generally accepted that bacterial classification should reflect as much as possible the natural relationships between bacteria, which are considered the phylogenetic relationships as encoded in highly conserved macromolecules such as 16S or 23S rRNA genes (68, 132). Nowadays, whole-genome comparisons offer new and exciting opportunities for the study of these natural relationships.

It is nevertheless true that every classification is artificial and that boundaries are made by humans. However, classification serves very practical purposes, i.e., the recognition of organisms that were encountered previously and the categorization of new ones into a logical and tractable system. In this era of whole-genome sequence analysis, it is more than ever obvious that the genomes of microbes undergo change, sometimes considerably. Although the extent of lateral gene transfer is controversial, it does not alter our need to identify organisms, particularly in the context of epidemiological studies and surveillance, as identification bears a tremendous amount of accompanying information. Science indeed has a way of making itself useful, and the useful application of classification is identification (15).

CLASSIFICATION OF BACTERIA

The process of species delineation in bacterial systematics underwent drastic modifications as the species concept evolved in parallel with technical progress. Early classification systems used mainly morphological and biochemical criteria to delineate the species of bacteria. This type of classification was monothetic, as it was based on a unique set of characteristics necessary and sufficient to delineate groups. This early classification concept was replaced by theories of so-called natural concepts, which were the phenetic and phylogenetic classifications (36). In the former, relationships between bacteria were based on the overall similarity of both phenotypic and genotypic characteristics. Phenetic classifications demonstrate the relationships between organisms as they exist, without reference to ancestry or evolution. In phylogenetic classifications, relationships are described by ancestry, not according to their present properties.

Special-purpose and general-purpose classification systems are the main categories of classification systems. Special-purpose classification systems are objectively determined and do not fit a preconceived idea. For instance, the separation between the very closely related species *Escherichia coli* and *Shigella dysenteriae* or between *Bordetella pertussis* and *Bordetella bronchiseptica* does not conform to the general ideas of present-day species delineation (see below) but fits primarily a practical and historical purpose (36). Yet, nowadays, most taxonomists favor a general-purpose classification system that is stable, objective, and predictive and that can be applied to all bacteria. The classifications obtained with a general-purpose classification system do not fit a single purpose but attempt to reflect the natural diversity among bacteria. The best way to generate such general-purpose classifications is by combining the strengths of both phenetic and phylogenetic studies, a practice now often referred to as polyphasic taxonomy (118).

Criteria for Species Delineation

The criteria used to delineate species have developed in parallel with technology. The early classifications were based on morphology and biochemical data. When evaluated by means of our present views, many of these early phenotype-based classifications generated extremely heterogeneous assemblages of bacteria. Individual species were characterized by a common set of phenotypic characters and differed from other species in one or a few characters which were considered important. The introduction of computer technology allowed comparison of large sets of characteristics for large numbers of strains, forming the basis for phenetic taxonomy (96, 98). Such numerical analyses of phenotypic characters

yielded superior classifications in terms of objectivity and stability. Gradually, chemotaxonomic and genotypic methods were introduced into classification systems. Numerous different chemical compounds were extracted from bacterial cells, and their suitability for use in the classification of bacteria and the definition of species has been analyzed.

In 1987, the Ad Hoc Committee on Reconciliation of Approaches to Bacterial Systematics (125) stated that taxonomy should be determined phylogenetically and that the complete genome sequence should therefore be the standard for species delineation. In present-day practice, whole-genome DNA-DNA hybridization analysis approaches the sequence standard and represents the best applicable procedure. A bacterial species was therefore defined as a group of strains, including the type strain, that share 70% or greater DNA-DNA relatedness with a ΔT_m of 5°C or less (T_m is the melting temperature of the hybrid, as determined by stepwise denaturation; ΔT_m is the difference in T_m [in degrees Celsius] between the homologous hybrid and the heterologous hybrid formed under standard conditions [135]). This species definition was based on a large amount of empirical data including both DNA-DNA hybridization data and other characteristics. The designated type strain of a species serves as the name bearer of the species and as the reference specimen (104). It was also recommended that phenotypic and chemotaxonomic features should agree with this definition. Preferentially, several simple and straightforward tests should endorse the species delineation based on DNA-DNA hybridization values. Groups of strains which were delineated by means of DNA-DNA hybridization studies as distinct species but which could not be distinguished by phenotypic characteristics should not be named. The term "genomovar" was subsequently introduced for such phenotypically similar genomic species (110); however, this term may be somewhat misleading, as these taxa are given an infraspecific rank, whereas by definition they are to be considered species that cannot be reliably differentiated by phenotypic tests.

The level of DNA-DNA hybridization thus plays a key role in our present species concept as defined by Wayne et al. (125). Although that seems to suggest that the species definition has become less vague, the practice of DNA-DNA hybridization is very complex (see below).

The Polyphasic Species Concept

A wide variety of cellular components have been used to study relationships between bacteria and to design classifications. The information present at the DNA level has been analyzed by estimations of the DNA base composition and the genome size, whole-genome DNA-DNA hybridization, restriction enzyme analysis, and, increasingly more, by direct sequence analysis of various genes. rRNA fractions have been studied intensively, particularly because they serve as phylogenetic markers (68). Various chemical compounds including fatty acids, mycolic acids, polar lipids, polysaccharides, sugars, polyamines, and respiratory quinones, as well as, again, a tremendous number of expressed features (data derived from, e.g., morphologic, serologic, and enzymologic studies), were all used to characterize bacteria. Several of these approaches have been applied to taxonomic analyses of virtually all bacteria. Others, such as amino acid sequencing, were performed with a limited number of organisms because they are laborious, time-consuming, or technically demanding or because they were relevant only for a particular group.

The term "polyphasic taxonomy" was coined by Colwell (12) in 1970 and described the integration of all available genotypic, phenotypic, and phylogenetic information into a consensus type of general-purpose classification. It departs from the assumption that the overall biological diversity cannot be encoded in a single molecule and that the variability of characters is group dependent. Therefore, it integrates several generally accepted ideas for the classification and reclassification of bacteria. Polyphasic taxonomy is phylogeny based and uses sequence analysis and signature features of rRNA for the deduction of a phylogenetic framework for the classification of bacteria (43, 118, 121). Several other macromolecules such as the beta subunit of ATPase, elongation factor Tu, chaperonin, various ribosomal proteins, RNA polymerases, and tRNAs (43, 68) have similar potential. The next step in the process of classification is the delineation of individual species—and other taxa—within these phylogenetic branches. Despite its drawbacks, DNA-DNA hybridization forms the cornerstone of species delineation. However, the threshold value for species delineation should be allowed considerable variation. This polyphasic approach is pragmatic; for instance, *B. pertussis, Bordetella parapertussis,* and *B. bronchiseptica,* which share DNA-DNA hybridization levels of over 80%, are considered three distinct species because they differ in many phenotypic and chemotaxonomic aspects (114). In other genera which are phenotypically more homogeneous, such as *Acidovorax* (131), species are defined as groups of strains that have DNA-DNA hybridization levels of at least 40%. It is essential that the boundaries of species demarcation be flexible in order to achieve a classification scheme that facilitates identification.

The application of numerous other types of analyses of genotypic, chemotaxonomic, and phenotypic characteristics of bacteria to the delineation of bacteria at various hierarchical levels represents the third component of polyphasic taxonomy (118). The goal is to collect as much information as possible and to evaluate all results in relation to each other in order to draw useful conclusions. An additional advantage is that, once the taxonomic resolution of these approaches has been established for a particular group of bacteria through the analysis of a set of taxonomically well-characterized strains, they may be used as alternative tools to classify new isolates at different taxonomic levels. A typical example is the application of one-dimensional whole-cell protein electrophoresis to replace DNA-DNA hybridization experiments for identification to the species level of *Helicobacter* species (117). It should be noted that the resolution of these alternative methods is often group dependent. For instance, cellular fatty acid analysis is useful for the accurate identification of strains of many bacterial species to the species level. In certain bacterial groups, however, the cellular fatty acid profile may be indicative of the genus or a group of phylogenetically related genera but not of a particular species within one of these genera (118). Within the group of the gram-negative nonfermenting bacteria, this is nicely illustrated by the characteristic fatty acid profiles of members of the genera *Chryseobacterium, Empedobacter, Ornithobacterium,* and *Riemerella* (the last two genera are of veterinary interest), which are characterized by extremely high percentages (80 to 90% of the total fatty acid content) of saturated branched-chain fatty acids in the *iso* and *anteiso* configurations (119, 120).

The contours of a polyphasic bacterial species are obviously less clear than the ones defined by Wayne et al.

(125), and this lack of a rigid definition has been contested as it allows too many interpretations (135). Polyphasic classification is empirical and contains elements from both phenetic and phylogenetic classifications. There are no strict rules or guidelines, and the approach integrates any significant information on the organisms, resulting in a consensus type of classification. Its main weakness is indeed that it relies on common sense to draw its conclusions. The bacterial species appears as a group of isolates in which a steady generation of genetic diversity resulted in clones characterized by a certain degree of phenotypic consistency, by a significant degree of DNA-DNA hybridization, and by a high level of 16S rRNA sequence similarity (118).

Obviously, the species is the most important and, at the same time, the central element of bacterial taxonomy. There are at present no rules for the delineation of higher hierarchical ranks such as genus, family, and order. Although there is an expectation that at the generic level taxa should be supported by phenotypic descriptions (76), in practice higher ranks are mostly delineated on the basis of 16S rRNA sequence comparison and stability analyses of the clusters that are obtained. Undoubtedly, the latter has weakened the emphasis on phenotypic descriptions of taxa (135). In polyphasic taxonomy, attempts are made to endorse these phylogeny-driven demarcations by other data. An example is the subdivision of the former genus *Campylobacter* into the revised genus *Campylobacter* and the novel genera *Arcobacter* and *Helicobacter* (38, 116). Although this subdivision was mainly phylogeny based, it was supported by differences in respiratory quinone components and ultrastructural properties.

A New Species Concept?

In 2002, a new Ad Hoc Committee for the reevaluation of the species definition in bacteriology made various recommendations regarding the species definition in light of developments in methodologies available to systematists (99). As stated by the Ad Hoc Committee, the introduction of innovative methods is providing new opportunities for prokaryotic systematics. One of the particularly interesting developments includes the analysis of complete genome sequences. There is a growing interest in using these genome sequence data to assess evolutionary relationships among prokaryotic species. It has become clear that, in addition to nucleotide substitutions, other genetic forces such as gene loss, gene duplication, horizontal (or lateral) gene transfer, and chromosomal rearrangements shape the genome and that considerable fractions of the genome of any particular strain may be unique to that strain (9, 59). With an increasing number of species for which multiple whole-genome sequences are available, a range of novel approaches for assessing taxonomic relationships within and between closely related species become available. These novel approaches include analysis of gene content and gene order, comparative sequence analysis of conserved and other macromolecules or of complete genomes, presence-absence analyses, nucleotide signature composition analyses, and even metabolic pathway reaction content analyses (reviewed in reference 9). Despite the documented enormous strain-to-strain variation in genome content, these novel taxonomic analytical tools generally substantiate that bacterial species delineated by DNA-DNA hybridization experiments and ordered in a phylogenetic backbone through comparative 16S rRNA sequence analysis represent coherent biological entities, although, in terms of population genetics, they still encompass considerable ecological and genetic heterogeneity (10).

Studies by Konstantinidis and Tiedje (59) revealed the average nucleotide identity of the shared genes between two strains to be a robust means to compare genetic relatedness among strains and that average nucleotide identity values of approximately 94% corresponded to the traditional 70% DNA-DNA reassociation standard of the current species definition. At the 94% average nucleotide identity cutoff, current species included only moderately homogeneous strains, apparently as a result of the strains having evolved in different ecological settings. A large fraction of the differences in gene content within species was associated with bacteriophage and transposase elements, revealing an important role of these elements during bacterial speciation. These findings were consistent with a definition for species that would include a more homogeneous set of strains than that provided by the current definition and one that considers the ecology of the strains in addition to their evolutionary distance (10).

Multilocus sequence analysis (MLSA) is another novel approach that holds great promise. In contrast to multilocus sequence typing, a specific tool designed for molecular epidemiology and for defining strains within named species, whereby similarities and differences are usually measured as differences in allelic profiles, MLSA aims to amplify and sequence gene fragments of strains representing different species within and between genera. Gene sequences are subsequently studied by traditional software used for phylogenetic analyses. Examples of such studies have recently been published for two groups of *Burkholderia* species, i.e., *Burkholderia mallei, Burkholderia pseudomallei,* and *Burkholderia thailandensis* (34) and the *Burkholderia cepacia* complex (2), and for *Yersinia* species (61). Especially for depicting relationships within and between closely related species, this approach promises a resolution superior to the traditional 16S rRNA gene sequence analysis. The deduced phylogenetic trees not only provide a phylogenetic backbone but also reveal intraspecies relationships at a level where comparative 16S rRNA sequence analysis is no longer discriminatory. It is for instance noteworthy that the DNA-DNA hybridization results which demonstrated that *Yersinia pestis* and *Yersinia pseudotuberculosis* on the one hand and *B. mallei* and *B. pseudomallei* on the other hand represented a single species each were mirrored in the MLSA trees where *Y. pestis* clusters among *Y. pseudotuberculosis* strains and *B. mallei* clusters among *B. pseudomallei* strains. Two studies of complete genomes have suggested a universal set of protein-coding genes that may be useful for such an MLSA-based approach to microbial taxonomy (91, 138).

Major Groups of Bacteria

The tree of life based on comparative small subunit rRNA studies comprises three lines of descent that are nowadays referred to as the domains *Bacteria, Archaea*, and *Eucarya* (132). The *Bacteria* have been grouped into 23 phyla, which are further subdivided into 28 classes (62). Three phyla, the *Proteobacteria,* the *Firmicutes* (gram-positive organisms with low G+C contents, including *Bacillus, Clostridium, Staphylococcus, Mycoplasma,* and the classical lactic acid bacteria such as *Enterococcus, Streptococcus,* and *Lactobacillus*), and the *Actinobacteria* (gram-positive organisms with high G+C contents, including *Bifidobacterium, Mycobacterium,* and *Corynebacterium*), comprise the large majority of the clinically relevant species. The *Bacteroidetes* (*Bacteroides,* flavobacteria,

and sphingobacteria), the *Spirochaetes* (spirochetes and leptospiras), and the *Chlamydiae* (chlamydias) represent some of the other phyla. A detailed overview is given by Krieg and Garrity (62) and Ludwig and Klenk (66) in their introductory chapters to the second edition of *Bergey's Manual of Systematic Bacteriology.* That edition is structured in an order based on the topology of the 16S rRNA phylogenetic tree.

The largest phylum by far is the *Proteobacteria,* which contains five main clusters (classes) of genera that are referred to with the Greek letters alpha, beta, gamma, delta, and epsilon (102). The *Proteobacteria* comprise the majority of the known gram-negative bacteria of medical, industrial, and agricultural significance. This phylum includes *Brucella, Ehrlichia*, and *Rickettsia (Alphaproteobacteria); Burkholderia*, *Bordetella,* and *Neisseria (Betaproteobacteria); Aeromonas, Legionella,* and *Vibrio* and the family *Enterobacteriaceae (Gammaproteobacteria)*; and *Campylobacter* and *Helicobacter (Epsilonproteobacteria)*. The *Deltaproteobacteria* comprise a variety of mainly sulfate-reducing bacteria that have little clinical relevance.

Unculturable Bacteria

The classification and nomenclature of unculturable bacteria that are only minimally characterized by morphological characteristics or by differences in a molecular sequence (77) are outstanding challenges in bacterial classification. The members of the International Committee on Systematic Bacteriology have agreed to recognize a category that formally classifies incompletely described prokaryotes (78). This action was useful and timely because of the increasing involvement of sequencing technology in the characterization of prokaryotes that are difficult to cultivate. *Candidatus* is considered a taxonomic status for uncultured "candidate" species for which relatedness has been determined (for instance, for which phylogenetic relatedness has been determined by amplification and sequence analysis of prokaryotic RNA genes by use of universal prokaryotic primers) and authenticity has been verified by in situ probing or a similar technique for cell identification. In addition, it is also mandatory that information concerning phenotypic, metabolic, or physiological features be made available. The latter data may serve as a starting point for further investigation and eventual description and naming. A detailed list of items for inclusion in the codified record of a *Candidatus* taxon is provided elsewhere (78). With the increasing application of molecular methods to the assessment of the diversity of prokaryotic populations in nature and to the study of complex symbioses, it was anticipated that numerous *Candidatus* organisms would be recorded (78). There are several caveats. Information derived from 16S rRNA gene sequence analysis may not be sufficient to ensure that the uncultured organism represents a novel species (see below). Also, 16S rRNA gene sequences are not available for all known bacteria for comparison. Alternatively, morphological characteristics, for example, may not be sufficiently reliable to conclude that uncultured cells represent a novel organism (118).

CLASSIFICATION METHODS

In principle, all genotypic, phenotypic, and phylogenetic information can be used to classify bacteria. Genotypic information is derived from the nucleic acids (DNA and RNA) present in the cell, whereas phenotypic information is derived from proteins and their functions, different chemotaxonomic markers, and a wide range of other expressed features.

When working one's way through lists of methods, it is of primary interest to understand at which level these methods carry information and to realize their technical complexity, i.e., the amount of time and work required to analyze a certain number of isolates. The list of methods given below is not meant to be complete or to describe all of their aspects. It comprises the major categories of taxonomic techniques required to study bacteria at different taxonomic levels and roughly describes general concepts and applications of those techniques, as well as some other considerations. Detailed descriptions of such methods can be found in handbooks such as those by Goodfellow and O'Donnell (36) or Priest and Austin (89).

Genotypic Methods

DNA-DNA Hybridization Studies

At present, DNA-DNA hybridization is acknowledged as the reference method to establish relationships within and between species. Different DNA-DNA hybridization procedures have been described: the hydroxyapatite method (4), the optical renaturation method (20), and the S1 nuclease method (19, 41) have mostly been used. These classical techniques, however, need considerable amounts of DNA and are time-consuming. New quick methods that consume less DNA have been described (6, 24, 51) and have partially replaced the classical methodologies.

Many DNA-DNA hybridization protocols have been described, and it is often not clear if hybridizations were performed under optimal, stringent, or suboptimal conditions. The stringency of the reaction is determined by the salt and formamide concentration and by the temperature and the mol percent G+C contents of the DNAs used. DNA-DNA hybridizations are often performed under standard conditions that are not necessarily optimal or stringent for all bacterial DNAs. As a standard, optimal conditions for hybridizations should be preferred because the optimal temperature curve for hybridization is rather broad (about 5°C) (118).

Obviously, quantitative comparisons of DNA hybridization values generated with different techniques should be handled with caution. When different methodologies are used, it is safer to distinguish categories of DNA-DNA relatedness, such as "high DNA-DNA relatedness" (denoting relationships between strains of a single species), "low but significant DNA-DNA relatedness" (comprising the significant hybridization levels below the cutoff for a separate species; the depth of this range depends primarily on the technique used), and finally, "non-significant DNA-DNA relatedness" (denoting that the degree of DNA hybridization is too low to be measured by the method used).

rRNA Similarity Studies

It is now generally accepted that rRNA is the best target for studying phylogenetic relationships because it is present in all bacteria, it is functionally constant, and it is composed of highly conserved as well as more variable domains (43, 62, 66, 93, 100, 132). The components of the ribosome (rRNA and ribosomal proteins) have been the subjects of phylogenetic studies for several decades. The gradual development of molecular techniques enabled microbiologists to focus on the comparative study of the rRNA molecules, and direct sequencing of parts of, or nearly entire, 16S or 23S rRNA molecules by the PCR technique with a selection

of appropriate primers has become common practice. These sequences provide a phylogenetic framework that serves as the backbone for modern microbial taxonomy (62, 66). The larger the conserved elements examined, the more information they bear and the more reliable the conclusions become. International databases comprising published and unpublished partial or complete sequences have been constructed (82, 121). The presence of universal sequence motifs in the bacterial rRNA genes allowed taxonomists to classify unculturable organisms and to perform phylogenetic identifications and in situ detection of individual cells without cultivation (1).

More recently, however, it has been found that rRNA sequence analysis is no longer exclusively used to determine relationships between genera, families, and other higher ranks but often replaces DNA-DNA hybridization studies for the delineation of species in taxonomic practice. In many cases, such application of rRNA similarity data is not appropriate. In 1992, Fox et al. (28) reported that 16S rRNA sequence identity is not always sufficient to guarantee species identity. Indeed, three phenotypically similar *Bacillus* strains exhibited more than 99.5% rRNA sequence similarity, while DNA-DNA hybridization experiments indicated that they belonged to two distinct species. Stackebrandt and Goebel (100) reported on the place for 16S rRNA gene sequence analysis and DNA-DNA reassociation in the present species definition in bacteriology. Their extensive literature review revealed that organisms sharing more than 97% rRNA similarity may or may not belong to a single species and that the resolution of 16S rRNA sequence analysis for determination of the degree of relatedness between closely related organisms is generally low. There is obviously no threshold value of 16S rRNA similarity for species recognition (100). However, they reported that organisms with less than 97% 16S rRNA sequence similarity do not give a DNA-DNA reassociation level of more than 60%, no matter which DNA-DNA hybridization method is used. In fact, rRNA sequence analysis seemed to rightfully replace DNA-DNA hybridization studies as part of the description of new species, provided that the rRNA similarity level was below 97% and provided that rRNA sequence data for all relevant taxa were available for comparison. However, more recent studies extended the observations on intraspecies 16S rRNA divergence considerably, as differences in 16S rRNA gene sequence of up to 4.5% were reported among strains of several species belonging to the *Epsilonproteobacteria* (46, 117).

Clearly, one should be prudent in drawing conclusions based on analysis of a single sequence. In 1995, Clayton and colleagues (8) presented a detailed comparison of duplicate rRNA sequences present in the GenBank database with remarkable results. Unexpectedly high levels of intraspecies variation (within and between strains) of 16S rRNA sequences were found. The variability was thought to represent interoperon variation within a single strain, strain-to-strain variation within a species, misidentification of strains, sequencing error, or other laboratory errors. Critical selection and the use of sequences from databases are required. More recently, studies by Jaspers and Overmann (53) and Gonzales-Escalona et al. (35) provided new examples of diversity among 16S rRNA genes within single organisms and sequence identity in bacteria with highly divergent genomes and ecophysiologies. Alternatively, numerous other macromolecules have been examined for their potential as microbiological clocks. Among others, various ribosomal proteins (81), the beta subunit of ATPase (66, 67), elongation factor Tu (66, 67), chaperonin (123), RNA polymerases (58, 140), and manganese-dependent superoxide dismutase (29) were shown to be valuable molecular chronometers in bacterial systematics. These alternative macromolecules should be universally distributed among bacteria, they should not be transmitted horizontally, and their molecular evolution rate should be comparable to, or somewhat higher than, that of 16S rRNA, which would render them more suitable for differentiation of closely related organisms (for example, see reference 29).

Other Applications of rRNA in Taxonomy

The interesting taxonomic properties of rRNA or rRNA gene molecules have been exploited in several alternative ways (5, 40, 44, 48, 128). An rRNA operon typically consists of the following components (5′ to 3′): 16S, spacer, 23S, spacer, and 5S rRNA sequences. Amplification of part of this operon by means of PCR assays, followed by digestion of the amplicon by means of restriction enzymes and the electrophoretic separation of the resulting array of DNA fragments, is referred to as amplified rRNA restriction analysis or rRNA restriction fragment length polymorphism analysis (44). Depending on the target selected, the banding pattern is useful for species level discrimination (for target sequences that are highly conserved) or for strain typing (for target sequences that are variable). The technique has most of the advantages inherent in the rRNA approach; in addition, it is clearly less expensive and more rapid than direct sequence analysis and large numbers of strains can easily be examined. This not only renders the method a useful screening tool but also provides a better view on the intraspecies variability of the rRNA operon.

Another rRNA-based approach for the identification and classification of bacteria is ribotyping (3, 40). By this procedure, genomic DNA is digested with a restriction enzyme (or with a set of restriction enzymes). The digest is separated by electrophoresis, and the bands are transferred to a membrane and hybridized with a labeled rRNA probe. This probe may be based on 16S rRNA, 23S rRNA, or both, with or without the spacer region, or on a conserved fragment of one of the rRNA genes. Although designed and mostly used to determine interstrain relationships (40), a fully automated procedure for identification of bacteria to the species level is commercially available (RiboPrinter; Dupont Qualicon Inc., Wilmington, Del.).

Finally, terminal restriction fragment length polymorphism analysis of 16S rRNA genes has been used in several studies for the characterization of microbial diversity in natural specimens and for identification of the members therein (65, 90). The technique employs a PCR assay in which one of the two primers used is fluorescently labeled at the 5′ end and is used to amplify a selected region of bacterial genes encoding 16S rRNA from total community DNA. The PCR product is digested with restriction enzymes, and the fluorescently labeled terminal restriction fragment is precisely measured by using an automated DNA sequencer. Computer-simulated analysis of terminal restriction fragment length polymorphisms for 1,002 bacterial sequences showed that with proper selection of PCR primers and restriction enzymes, 686 sequences could be PCR amplified and classified into 233 unique terminal restriction fragment lengths or "ribotypes" (65).

Other Genotypic Methods for Bacterial Classification

A range of different genotypic techniques has been used to characterize bacteria at various taxonomic levels. The molar percentage of guanosine plus cytosine (the DNA base ratio

or percent G+C value) is one of the classical genotypic characteristics and is part of the standard description of bacterial taxa. Generally, the range observed within a species should not be more than 3%, and within a genus it should not be more than 10% (101). It varies between 24 and 76% in the bacterial world.

During the past decade, a tremendous number of molecular diagnostic methods, most of which are PCR based, have been developed. Most of these generate arrays of DNA fragments that are separated and detected in various ways, and appropriate software has been developed for pattern recognition and analysis and for database construction.

One of these DNA fingerprinting methods, amplified-fragment length polymorphism (AFLP) analysis (136), was shown to be very useful for the classification of strains at the species and genus levels. The basic principle of AFLP is restriction fragment length polymorphism analysis, modified by using a PCR-mediated amplification to select particular DNA fragments from the pool of restriction fragments. AFLP analysis screens for AFLPs by selective amplification of restriction fragments. The restriction is performed with two restriction enzymes, which yield DNA fragments with two different types of sticky ends that are randomly combined. To these ends, short oligonucleotides (adapters) are ligated to form templates for the PCR. The selective amplification reaction is performed by using two different primers that contain the same sequence as the adapters but whose sequences are extended to include one or more selective bases next to the restriction site of the primer. Only those fragments that completely match the primer sequence are amplified. The amplification process results in an array of about 30 to 40 DNA fragments, some of which are group specific, while others are strain specific (52).

PCR-based typing methods that use random or repetitive elements as primers have been applied to strain characterization of a wide variety of bacteria (47, 70, 112, 127, 128). In several of these studies, species-specific DNA fragments or patterns have been generated (e.g., for species belonging to the genera *Campylobacter*, *Capnocytophaga*, *Enterococcus,* and *Naegleria* [21, 31]). These specific DNA fragments may be useful as probes to rapidly screen and identify other isolates. Although primarily applied for infraspecies strain comparisons, these techniques are useful in classification as well.

Phenotypic Methods

Phenotypic methods comprise all those that are not directed toward DNA or RNA and therefore also include the chemical or chemotaxonomic techniques. As the introduction of chemotaxonomy is generally considered one of the essential milestones in the development of modern bacterial classification, it is often treated as a separate unit in taxonomic reviews. The classical phenotypic tests traditionally constituted the basis for the formal description of bacterial species, subspecies, genera, and families. While genotypic data are used to allocate taxa on a phylogenetic tree and to draw the major borderlines in classification systems, phenotypic consistency is required to generate useful classification systems and may therefore influence the depth of a hierarchical line (118, 125). The paucity or variability of phenotypic characteristics for certain bacterial groups regularly causes problems in describing or differentiating taxa. For such bacteria, alternative chemotaxonomic or genotypic methods are often required to reliably characterize strains.

The classical phenotypic characteristics of bacteria comprise morphological, physiological, and biochemical features. Individually, many of these characteristics were shown to be poor parameters for genetic relatedness, yet as a whole, they provide descriptive information for the recognition of taxa. The morphology of a bacterium comprises both cellular (shape; the presence of an endospore, flagella, and inclusion bodies; and Gram staining characteristics) and colonial (color, dimensions, and form) characteristics. The physiological and biochemical features comprise data on growth at different temperatures; growth in the presence of different pH values, salt concentrations, or atmospheric conditions; and growth in the presence of various substances such as antimicrobial agents and data on the presence or activities of various enzymes, utilization of compounds, etc. Very often, highly standardized procedures are required to obtain reproducible results within and between laboratories (for examples, see references 83 and 84).

In taxonomic practice, phenotypic characterization became compromised and sometimes more of a burden than a useful taxonomic activity. Frequently, phenotypic data are compared with literature data, which were obtained using other conditions or methods. The need for continued phenotypic characterization at every taxonomic level not only to delineate taxa and appreciate their phenotypic coherence but also to evaluate their physiological and ecological functions cannot be denied. A minimal phenotypic description is not only the identity card of a taxon but also a key to its biology. Although accepted as necessary, differential phenotypic characters are often hard to find with a reasonable amount of effort and time.

Numerical Analysis

Phenotypic data were the first to be analyzed by means of computer-assisted numerical comparison. In the 1950s, numerical taxonomy arose in parallel with the development of computers (96, 98) and allowed comparison of large numbers of phenotypic traits for large numbers of strains. Data matrices showing the degree of similarity between each pair of strains and cluster analyses resulting in dendrograms revealed a general picture of the phenotypic consistency of a particular group of strains. As such large numbers of characteristics reflect a considerable amount of genotypic information, it soon became evident that numerical analysis of large numbers of phenotypic characteristics was indeed taxonomically relevant.

Semiautomated Systems

A large number of miniaturized semiautomated phenotypic test systems are commercially available and partially replace classical phenotypic analyses. These microtest galleries can be used for both classification and identification (see chapter 15). It should be noted that the outcomes of a particular test obtained with a commercial system and by a classical procedure may be different. This, however, may occur with two classical procedures of the same test as well.

Chemical Methods

The term "chemotaxonomy" refers to the application of analytical methods to the collection of information on various chemical constituents of the cell to classify bacteria. As for the other phenotypic and genotypic techniques, some of the chemotaxonomic methods have been widely applied on vast numbers of bacteria, whereas others were so specific that their application was restricted to particular taxa. Similarly, a high degree of automation was introduced

with the development of novel technologies such as matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF [MS]) or Fourier transform infrared (FTIR) spectroscopy.

Apart from the chemical markers discussed in more detail below, a range of other chemical markers have been examined in bacterial classification. They include cytochromes, polyamines, pigments, particular enzymes, sterols, and hopanoids (37, 107). Very often, analytical difficulties have been the main restrictions to their wide-scale application.

Cellular Fatty Acid Analysis

Over 300 fatty acids and related compounds are present in bacterial cells. Polar lipids are the constituents of the lipid bilayer of bacterial membranes and have been frequently studied for classification and identification purposes. Other types of lipids, such as sphingophospholipids, occur in only a restricted number of taxa and were shown to have taxonomic value within these groups (54). Fatty acids are the major constituents of lipids and lipopolysaccharides and have been used extensively for taxonomic purposes. Variabilities in chain lengths, double-bond positions, and substituent groups are very useful for the characterization of bacterial taxa (105). Mostly, the total cellular fatty acid fraction is extracted, but particular fractions, such as the polar lipids, have also been analyzed.

The cellular fatty acid methyl ester composition is a stable parameter, provided highly standardized culture conditions are used. The methylated fatty acids are typically separated by gas-liquid chromatography, and both the occurrence and the relative amounts of methylated fatty acids characterize bacterial fatty acid profiles.

Cellular fatty acid analysis offers many advantages over other phenotype-based identification systems; however, it has several limitations as well. First, the result of the analysis is culture dependent. Strains must be grown under identical conditions so that their fatty acid compositions can be compared. Although the conditions recommended by the manufacturer allow cultivation of a large number of bacteria, different sets of conditions and databases are used for different groups of bacteria (e.g., the aerobic bacteria, anaerobic bacteria, and mycobacteria). In addition, the level of resolution is organism dependent. Many bacteria may be adequately characterized and identified at the species level by means of their cellular fatty acid profile. However, others are not, and often species of the same genus or even different genera have highly similar fatty acid compositions. Whole-cell fatty acid analysis is widely used both in taxonomic studies and in identification analyses. The applications and restraints of the technique were extensively discussed and documented by Welch (126). In the framework of polyphasic taxonomy, cellular fatty acid analysis is often very useful as a rapid and fairly inexpensive screening method. The method allows the comparison and clustering of large numbers of strains with a minimal effort and yields descriptive information to characterize the organisms.

MALDI-TOF (MS)

The first reports involving the use of MALDI-TOF (MS) were published in the late 1980s, and its application increased exponentially during the past 15 years. The two main research areas are the field of proteomics, where it is used as an instrument to identify proteins, and the detection of biomarkers of several diseases including cancer, Alzheimer's disease, arthritis, and allergy (72, 137). In MALDI-TOF (MS), the sample is mixed with a matrix that is chosen such that it specifically absorbs a laser beam. The resulting high-energy impact is followed by the formation of ions that are extracted through an electric field and that are subsequently focused and detected as an m/z (mass/charge) spectrum. The potential to desorb high-molecular-weight thermolabile molecules, the extremely high precision and sensitivity, and the large mass range (1 to 300 kDa) indicate that MALDI-TOF (MS) is a promising tool for the study of biomolecules in complex biological samples. The simplicity and speed of analysis represent part of its strength. Sample processing is potentially restricted to adding matrix to a bacterial sample, and all measurements can be performed within a few minutes. The whole process can be highly automatized. These features make the approach particularly attractive to research laboratories that routinely deal with the analysis and identification of large numbers of bacterial isolates. In microbiology, MALDI-TOF (MS) has been used to distinguish antimicrobial-resistant isolates from susceptible ones and to differentiate strains within a single species, thus highlighting its potential as a tool for strain quality control and identity check (57, 111). The most challenging diagnostic problem, i.e., the differentiation of closely related species through the analysis of an appropriate number of reference strains of multiple closely related species, is gradually being explored (23, 57, 103, 111).

Surface enhanced laser desorption ionization (SELDI) is distinguished from MALDI in its use of an active sample probe—the ProteinChip array—which has an adsorptive surface that allows bacterial lysates to be subjected directly, without prior treatments, to on-chip sample preparation steps, such as selective washing and desalting. This procedure minimizes sample losses, while speeding up and simplifying sample preparation, compared to the standard methods normally employed prior to the use of MALDI. Furthermore, the active capture of the proteins by the ProteinChip array ensures nondiscriminatory binding of target proteins, which in turn improves the reproducibility and allows both peak mass-to-charge (m/z) ratios and intensity to be used in sample characterization. SELDI-TOF-MS was used by Lundquist et al. (69) to discriminate between the four subspecies of *Francisella tularensis*.

FTIR Spectroscopy

FTIR spectroscopy is used for the identification of substances in chemical analyses. In general, the wave number, the reciprocal of the wavelength, is used as the physical unit. FTIR spectroscopy involves the observation of vibrations of molecules that are excited by an infrared beam. Molecules are able to absorb the energy of distinct light quanta and start a rocking or rotation movement. The FTIR spectrum uses only vibrations that lead to a change in the dipole moment. An infrared spectrum represents a fingerprint which is characteristic for any chemical substance. The composition of biological material and thus of its FTIR spectrum is exceedingly complex, representing a characteristic fingerprint. Naumann and coworkers suggested identifying microorganisms by FTIR spectroscopy (79). In principle, a reference spectrum library is assembled based on well-characterized strains and species. The FTIR spectrum of any unidentified isolate is then measured under the same conditions as those used for the reference spectra and is compared to spectra in the reference spectrum library. The application of FTIR spectroscopy has been reported for a limited number of strains of some species of the genera *Lactobacillus*, *Actinomyces*, *Listeria*, *Streptococcus*, and *Clostridium* (63). More extensive studies have been

published for yeasts (63, 130) and coryneform bacteria (80); these organisms display a certain degree of overlapping distribution of different taxonomical markers, leading to a limited differentiation capacity of nongenotypical identification methods. The easy handling, rapid identification (within 25 h starting from a single colony), satisfactory differentiation capacity, and low cost have shown FTIR technology to be superior to routine methods for the identification of coryneform bacteria and related taxa.

Whole-Cell Protein Analysis

The comparison of whole-cell protein patterns obtained by a highly standardized procedure, sodium dodecyl sulfate polyacrylamide gel electrophoresis, has proved to be extremely reliable for comparison and grouping of large numbers of closely related strains, and numerous studies document the application of this procedure in taxonomic studies (14, 56, 88). Bacterial strains cultivated under highly standardized conditions have characteristic protein compositions that can be separated and visualized by electrophoretic techniques. Mostly, a high similarity in whole-cell protein content is an indication of extensive DNA-DNA hybridization (14, 56, 88). Therefore, an obvious advantage of this technique is that, once the correlation between percentage similarity in whole-cell protein composition and DNA-DNA relatedness for a particular group has been established, it can replace DNA-DNA hybridization experiments. Provided highly standardized conditions are used throughout the procedures of cultivation and electrophoresis, computer-assisted numerical comparisons of protein patterns are feasible, and databases can be created for identification purposes. This allows comparison of large numbers of strains and grouping of the strains in clusters of closely related strains (14, 56, 88). For some bacteria, numerical analysis is strongly hindered by the presence of distorted protein profiles or hypervariable (often immunogenic) dense protein bands. In these cases, visual comparison is essential to interpret the similarity of protein patterns.

Cell Wall Composition

The distinction between gram-negative and gram-positive types of bacteria is still one of the characteristics that is first analyzed in order to guide subsequent characterization and identification steps. The determination of the cell wall composition has traditionally been important for gram-positive bacteria. The peptidoglycan type of cell wall of gram-negative bacteria is rather uniform and provides little information. The cell walls of gram-positive bacteria, in contrast, contain various peptidoglycan types which may be genus or species specific (92, 105). The most valuable information is derived from the type and composition of the peptide cross-link between adjacent chains in the polymer network. A variable that received little attention is the degree of N and O acetylation of the amino sugars of the glycan chain. The analytical procedure is time-consuming, although a rapid screening method has been proposed. Membrane-bound teichoic acid is present in all gram-positive species, but cell wall-bound teichoic acid is present in only some gram-positive species. Teichoic acids can easily be extracted and purified and can be analyzed by gas-liquid chromatography (25).

Isoprenoid Quinones

Isoprenoid quinones occur in the cytoplasmic membranes of most prokaryotes and play important roles in electron transport, oxidative phosphorylation, and, possibly, active transport (11, 105). Two major structural groups, the naphthoquinones and the benzoquinones, are distinguished. The former can be further subdivided into two main types, the phylloquinones, which occur less commonly in bacteria, and the menaquinones. The large variability of the side chains (e.g., differences in length, saturation, and hydrogenation) can be used to characterize bacteria at different taxonomic levels (11).

IDENTIFICATION

Identification is part of taxonomy. It is the process whereby an organism is recognized as belonging to a known taxon (species, genus) and designated accordingly. It relies on a comparison of the characters of an unknown with those of established units in order to name it appropriately. This implies that identification depends on adequate characterization.

Identification Strategy

In routine diagnostic laboratories, the majority of isolates are identified using classical biochemical tests and a combination of intuition and stepwise analysis of results that are obtained. However, if an organism is not readily identified in a minimal amount of time and at minimal expense, it often remains unidentified. Such strains must be identified without a clue to their phylogenetic affiliation. Comparison of (nearly) entire 16S rRNA gene sequences is arguably one of the most powerful tools for establishment of the phylogenetic neighborhood of an unknown organism, and commercial identification systems based on analysis of rRNA gene sequences have become available (e.g., MicroSeq 500 and 16S rDNA Bacterial Sequencing Kit [Perkin-Elmer Applied Biosystems, Foster City, Calif.]). A fraction of the 5′-terminal region of the 16S rRNA gene (positions 60 to 110 of the *Escherichia coli* numbering system) is one of the most informative or discriminating regions for closely related organisms (66). Similar variable regions (flanked by highly conserved regions) occur in the 23S rRNA gene (113). A review by Clarridge recently covered this topic in detail (7) but struggled with the rRNA sequence similarity level as a limit for species delineation. As outlined above, use of the DNA-DNA hybridization level as a threshold for species delineation is more than just a mere "proposal" (7) and is now supported by a range of whole-genome-based analyses. Comparison of 16S rRNA gene sequences will lead to correct identification to the species level in many bacterial genera, but it is equally true that many taxonomic studies have revealed that comparative rRNA sequence analysis is often not sensitive enough to identify strains to the species level. There is clearly a lack of knowledge not only of the strain-to-strain variation within a species but also of the interoperon variation within a single strain. Therefore, concluding that an unidentified isolate belongs to a particular species because it shares a high percentage of its 16S rRNA gene sequence with particular species or concluding that it represents a novel species because it occupies a unique position in the phylogenetic tree or because it shares only 97% of its 16S rRNA sequence with its closest neighbor is premature in the absence of appropriate complementary data. This is even more true for partial sequence data, as partial rRNA gene sequences carry only limited information of the molecule and different parts of the gene may carry information for different taxonomic levels (66, 68). Nevertheless, erroneous claims that 16S rRNA gene sequencing represents the general "gold

standard" for identification of new isolates appear regularly in medical (and other) microbiological literature (27).

Alternative Approaches

As part of identification strategies, dichotomous keys based on morphological and biochemical characteristics have only partly been replaced by other methods. As described above, taxonomic analyses provided an impressive array of alternative techniques derived from analytical biochemistry and molecular biology for examination of numerous cellular compounds (36, 37, 89). Each of these parameters is useful for characterization and hence identification of bacteria. Databases of rRNA sequences, whole-cell fatty acid components, ribotyping profiles, MALDI-TOF mass spectra and FTIR spectra, or miniaturized series of phenotypic characteristics are available (see above and chapter 15) and allow identification of many isolates. Yet, the success of these databases also depends on the exactness of the methods and how carefully the individual entries have been delineated. The classification of new or unusual isolates will, however, often require a polyphasic approach, whereby an unknown is allocated to a certain phylogenetic neighborhood (typically by using 16S rRNA gene sequence analysis), followed by a comparison of characteristics of the unknown with those of its closest phylogenetic neighbors by using appropriate taxonomic tools in order to assign it a particular species rank.

Molecular Diagnostics

The information content of the rRNA cistrons and other genomic information have been used in several alternative ways for the identification of bacteria by the development of a range of DNA or RNA probes and amplification assays. Although the overall rRNA sequence similarity may be very high, the presence of variable regions in 16S or 23S RNA genes can provide the basis for specific and sensitive targets for identification purposes (for examples, see references 68, 94, and 113). During the last 20 years, DNA technology has emerged, and the tools of molecular biology are now used for the detection, characterization, and identification of bacteria. The first applications were labeled probes intended to hybridize with specific nucleic acid fragments. Later, in vitro nucleic acid amplification procedures were developed. It was thought that this enzymatic duplication and amplification of specific nucleic acid sequences would gradually replace culture-based approaches. However, it became rapidly clear that the molecular diagnostic approach has its own difficulties in terms of sensitivity, specificity, turn-around time, and cost. As a consequence, its application was restricted to the solution of these problems in cases in which it is superior to the conventional approach (50). Molecular diagnostic techniques are indicated for the detection of organisms that cannot be grown in vitro, for which current culture techniques are too insensitive, or that require sophisticated media or cell cultures and/or prolonged incubation times.

The basic principle of any molecular diagnostic test is the detection of a specific nucleic acid sequence by hybridization to a complementary sequence of DNA or RNA, a probe, followed by detection of the hybrid (68). There are two types of molecular diagnostic techniques: those in which the hybrids are not amplified prior to detection and those in which they are. With the probe technology not involving amplification, the probes used for the detection of complementary nucleic acid sequences are labeled with enzymes, chemiluminiscent moieties, radioisotopes, or antigenic substrates (49). This technology was first applied in the field of infectious diseases for the detection of enterotoxigenic *E. coli* in stool samples by DNA hybridization after growth on MacConkey agar plates (74). This application illustrated the major advantage of the technology: in a mixture of pathogenic and nonpathogenic bacteria belonging to the same species, present in the same specimen, and difficult to distinguish by traditional culture and identification techniques, the former bacteria were easily detected and identified (49).

Alternatively, any DNA fragment can be copied by using a DNA polymerase, provided that some sequence data are known for the design of appropriate primers. In vitro DNA replication was made possible in 1959 when Kornberg (60) discovered DNA polymerase I, but only in 1986 did Mullis and coworkers (75) introduce the idea of PCR, i.e., reiteration of the process of DNA polymerization, leading to an exponential increase of the nucleic acid. Alternative nucleic acid amplification techniques have been developed by using different enzymes and strategies, but they are all based on reiterative reactions. In most of these the target nucleic acid is amplified; in some the probe is multiplied (13, 33, 42, 64, 124). The advantages of these amplification systems are obvious: they can be highly specific and rapid, and they have very high sensitivities. However, there are many practical problems as well (chapter 16; see also references 49 and 50).

Immunological Techniques

Immunoassays are procedures which measure antigen or antibody levels to determine whether patients are infected or are immunologically responding to infection or immunization. Two general approaches are distinguished: testing for specific microbial antigens and testing for specific microbial antigen-specific antibodies. These immunological techniques are described in detail in chapter 18. An important advantage of immunoassay tests is that they provide information even when culture and Gram staining results are negative for patients who received antimicrobial therapy.

Conclusion

At present, the scientifically and economically ideal identification technique remains beyond reach. Cowan's (15) intuitive approach (which is used when the identity of the unknown is anticipated) and the stepwise method (which involves the use of dichotomous keys) suffice for numerous isolates and require only simple, rapid, and cheap biochemical tests. Cowan's views are easily adapted to modern methodology. If this first-line approach fails, alternative procedures are required and available. At present, complete 16S rRNA gene sequence analysis is the most straightforward and obvious choice to establish a rough identity of an isolate, although in the present species concept with DNA-DNA hybridization levels as the cornerstones, it often fails to differentiate closely related species. Much of its superiority is based on its capacity to reveal the phylogenetic neighborhood of the organism studied, which is information not provided by any of the other current identification protocols. This information will direct the additional analyses required for final identification to the species level.

NOMENCLATURE

Valid Publication of Bacterial Names

The *International Code of Nomenclature of Bacteria* (97) includes rules on how to name bacteria at different taxonomic ranks. The aim of nomenclature is to ensure that

an organism is tagged with a unique name that carries valuable information. Prior to 1980, a proposal of a new bacterial taxon could be validly published in any microbiological book or journal, and the authors of the relevant sections of the successive editions of *Bergey's Manual of Determinative Bacteriology* had to attempt to give a complete list of the members of any particular genus or group of genera. The unavailability of type strains and the fact that microbiologists from different disciplines were not always familiar with one another's work caused great difficulty. All too often a worker would discover several years later that "his" or "her" organism had in fact been described earlier under a different name.

To overcome such problems and others, 1 January 1980 was chosen as a new starting date for bacterial nomenclature. At that time, Approved Lists of Bacterial Names were published on behalf of the Judicial Commission of the International Committee on Systematic Bacteriology (95). Only those names included on these lists had standing in bacterial nomenclature, and names of taxa were to be included only if they were adequately described and if a type strain was available. From then onward, all new names were validly published only in the *International Journal of Systematic Bacteriology* (now the *International Journal of Systematic and Evolutionary Microbiology*). Names could effectively be published in other journals and then validated subsequently by announcement in Validation Lists in the *International Journal of Systematic and Evolutionary Microbiology*. A number of organisms were involuntarily omitted from the Approved Lists and were revived later (for instance, see reference 72). After 1980 several updates of these lists were published in the form of Validation Lists, and in 1989, an update of all names validly published between 1 January 1980 and 1 January 1989 was published by Moore and Moore (73). Nowadays, complete overviews of validly published names can easily be obtained through Internet sites such as http://www.bacterio.cict.fr/ or http://www.dsmz.de/bactnom/genera1.htm. Proposals of new taxa can continue to be made in any journal, but their names are only validated the moment that they are included in one of the Validation Lists, published regularly in the *International Journal of Systematic and Evolutionary Microbiology*. In case different names for the same organism are validly published, nomenclatural priority goes to the name that was validated first. As a result of this practice, all validly named species in any particular group can easily be traced and reference strains are available.

Why Do Names Change?

There are more important causes for the modification of bacterial names than the occasional detection of synonymy. As described above, our present view on bacterial classification is phylogeny based. With the advent of rRNA-DNA hybridization and, subsequently, the various rRNA gene sequencing methods, taxonomists had a new framework in which they could revise classification schemes. The classical—and extreme—example is the revision of the taxonomy and nomenclature of the genus *Pseudomonas,* which has been proceeding painstakingly slowly during the past 3 decades. The most important reason for this slow progress is that, through the work of De Vos and De Ley (22), it became clear not only that the genus *Pseudomonas* consisted of five major species clusters (87) but also that these clusters formed a polyphyletic part of a major group of bacteria now known as the *Proteobacteria.* Revision of the taxonomy of the pseudomonads had to consider the relationships of the various subbranches toward their numerous respective neighbors (55).

The modification of our view on classification is by far the most important reason for name changes. However, various forms of poor taxonomic practice also invoke a lot of changes, and hence irritation. As observed long ago (18), nomenclature often is "the generator of heat, bad temper and ill-will among taxonomists and every kind of microbiologists." The classification (and identification) of *Helicobacter* species represents a fine example of the difficulties encountered in our present-day view on taxonomy. Although this view is often challenged, it is the level of DNA-DNA hybridization and not the level of 16S rRNA gene sequence similarity that is the most critical parameter for species delineation. Relatively few laboratories have the experience required to perform DNA-DNA hybridization experiments in a highly standardized way. Yet, because of the tremendous clinical relevance of these bacteria, numerous investigators study all sorts of *Helicobacter*-like organisms from human and animal hosts. The biodiversity within *Helicobacter* is very high, and there is a need for many DNA-DNA hybridization data to delineate the species. Regrettably, helicobacters mostly are fastidious organisms, and many are difficult (and some nearly impossible) to culture in vitro; in addition, the preparation of sufficient DNA for the hybridization experiments is a hardy, if not impossible, task. In practice, new species have often been described on the basis of 16S rRNA gene sequence data and a limited number of differential phenotypic characteristics. A recent study that involved various taxonomic approaches, including DNA-DNA hybridization experiments, demonstrated that comparison of nearly complete 16S rRNA gene sequences combined with minimal biochemical characterization does not provide conclusive evidence for identification to the species level and may prove highly misleading (117).

Another example is the ongoing revision of the classification and nomenclature of group II pseudomonads. In 1992, Yabuuchi et al. (133) reclassified several rRNA group II pseudomonads as *Burkholderia* species. However, in this study only some of the rRNA group II pseudomonads were examined and the conclusions were based on data for only a limited set of strains. As a consequence, several additional rounds of name changes were required to reclassify the remaining rRNA group II pseudomonads as *Burkholderia* species (32, 109, 134, 139). This group of bacteria also serves as an example to illustrate other causes for name changes: the lack of criteria for genus delineation (two of the *Burkholderia* species *[B. solanacearum* and *B. pickettii]* were again reclassified into the new genus *Ralstonia* [32, 134], and some of the *Ralstonia* species were then further reclassified into the novel genus *Wautersia* [122]) and the intrinsically inadequate description of species that comprise only a single isolate. The lack of precise guidelines for genus level delineation was discussed recently by Young (135), who argued strongly that phenotypic coherence at the genus level should have priority over phylogenetic information.

The *Ralstonia* example also illustrates a tedious problem raised by Clarridge (7), namely, the challenges in the nomenclature for organisms named before their correct taxonomy was revealed by 16S rRNA gene sequence comparisons. Shortly after the reclassification of several *Ralstonia* species into the novel genus *Wautersia* (122), Vandamme and Coenye (115) reported that *Wautersia eutropha,* the type species of the genus *Wautersia,* is a junior

synonym of *Cupriavidus necator,* the type (and only) species of the genus *Cupriavidus,* which was validly named in 1987, i.e., long before 16S rRNA gene sequence studies were performed routinely (71). The only possible consequence—if one does not decide to bend the rules each time they turn out to be inconvenient—was to replace the name *Wautersia* by *Cupriavidus* and to consider all species of the genus *Wautersia* species of the genus *Cupriavidus*. While renaming and subsequent further renaming of bacterial species cause confusion and—not the least—irritation in the wider microbiological community, adhering to the rules of nomenclature is essential for establishing a truly systematic taxonomy.

The so-called "one strain taxa" (species or genera that are proposed on the basis of data for only one strain) have probably caused more problems than they have solved, and this is definitely the case in the context of diagnostic microbiology. It is not possible to estimate the variability of the phenotype in the case of a species with one strain or in the case of a genus with one species and one strain, for which many recent examples exist. The question of whether such strains can be validly named has been the subject of many debates. There are different views, each with advantages and disadvantages. In diagnostic microbiology, it is well known that a species is characterized by a certain degree of variability. This variability can be measured by both phenotypic and genotypic criteria and may be revealed by simple biochemical testing or sophisticated genomic fingerprinting techniques. In the absence of sufficient strains for quantitation of the range of divergence within a species, it will be difficult or impossible to identify new isolates of this organism without DNA-DNA hybridization experiments. A classification based on results obtained with a single strain cannot be stable. Indeed, the detection of a second strain will inevitably necessitate revision of the original species description.

Clearly, some of the instances of nomenclatural modifications described above could have been avoided, and that is the main reason why they jeopardize the credibility of taxonomists in the microbiology community. As a concluding remark, it should be mentioned that there is no "undo" function in bacterial nomenclature. A name that was validly published remains valid regardless of the number of modifications it undergoes thereafter. For instance, the changes of the name *Pseudomonas maltophilia* to *Xanthomonas maltophilia* (106) and finally to *Stenotrophomonas maltophilia* (85) or the changes of the name *Pseudomonas acidovorans* to *Comamonas acidovorans* (108) and finally to *Delftia acidovorans* (129) may be reasonable to some taxonomists, but the changes, particularly the most recent, have been refuted by many clinical microbiologists. As these six names were all proposed according to the rules of bacterial nomenclature, they were all validated, and the use of each of them is correct and valid. Use of the original *Pseudomonas* names could imply that the user disagrees with the phylogenetic rationale for present-day genus level classification. Use of the names *X. maltophilia* or *C. acidovorans* may simply indicate that one disagrees with the most recent modification, whether the reason is scientific or practical, or it may be a simple statement of discord with successive and excessive name changes.

CONCLUSION

A much broader range of taxonomic studies of bacteria has gradually replaced the former reliance upon morphological, physiological, and biochemical characterization. This polyphasic taxonomy takes into account all available phenotypic and genotypic information and integrates it in a consensus type of classification, framed in a general phylogeny derived from 16S rRNA gene sequence analysis. The bacterial species appears as a group of isolates which originated from a common ancestor population in which a steady generation of genetic diversity resulted in clones that had different degrees of recombination and that were characterized by a certain degree of phenotypic consistency, a significant degree of DNA-DNA hybridization, and a high degree of 16S rRNA gene sequence similarity (118).

The majority of bacteria in routine diagnostic laboratories will continue to be identified by classical methods, as these methods are adequate, cheap, readily available, and easy to handle. In the case of new or atypical isolates, or for many research groups in which, for example, bacteria are isolated from new sources, a straightforward means of identification of microorganisms by a single method is often not possible, and several methods are needed. The most direct approach is first to allocate such isolates in the phylogenetic framework and then to determine the finer relationships by means of an appropriate approach, which may be polyphasic. This tendency of identification to become polyphasic is an unavoidable reality.

In some cases, the consensus classification is a compromise that contains a minimum of contradictions. It is thought that the more parameters that become available in the future, the more polyphasic classification will gain stability. Although the idea is purely speculative at present, insight into the vast amount of data that are potentially available could be the basis for a perfectly reliable and stable classification system. However, already with our present data, it is sometimes unclear if it makes sense to order bacteria into a classification system. Undoubtedly, there is a huge amount of biodiversity, which can be handled in a practical manner only if it is arrayed in an ordered structure, artificial or not, with appropriate terms for communication.

Our present view on classification reflects the best science of this time. The same was true in the past, when only data from morphological and biochemical analyses were available. The main perspective in bacterial taxonomy is that technological progress will dominate and drastically influence methodology, as it always has. More data will become available, more bacteria will be detected (whether they can be cultivated or not), there will be more automation, and bioinformatics will have to address the combination and linking of databases. Most important, the increasing access to whole-genome sequences will generate proposals for novel species concepts. These future concepts may be based on whole-genome sequences, on a shared core of genes, on a certain type of genes such as housekeeping or informational genes (26, 45), or on a well-balanced selection of genes included in an MLSA type of analysis (9, 30). It will be a formidable challenge to translate such information into classification and identification schemes and to evaluate classifications that have been carefully designed.

Specimen Collection, Transport, and Processing: Bacteriology*

RICHARD B. THOMSON, JR.

20

The use of specimens for bacteriological analysis requires that specific clinical material be collected, stabilized, and transported according to exacting specifications to ensure valid results. Poor specimen quality contributes to misdiagnosis and inappropriate antimicrobial therapy. Communication between the laboratory representative and clinician is essential to the proper selection of bacteriology tests and interpretation of their results. Laboratory personnel are responsible for monitoring and educating those collecting and transporting specimens. The use of professional journals is an excellent approach to the continuing education of all who work in and use the laboratory. Laboratories are required by accrediting agencies to provide specimen collection and transport manuals. A useful alternative to printed manuals is an electronic version available over a local area network (13, 100).

Specimens for bacteriological culture should be collected as soon as possible after the onset of disease and before the initiation of antimicrobial therapy. A second specimen may be necessary because of poor specimen quality or inadequate transport conditions that affected the first specimen, but is otherwise rarely required for diagnosis of an acute infectious disease. Exceptions include the collection of multiple blood specimens for culture and those obtained for the detection of fastidious or unusual pathogens not originally suspected.

SELECTION AND COLLECTION OF SPECIMENS

Material for bacteriological testing should be collected from a site representative of the active disease process. Sites of an inflammatory process and free of contaminating flora are optimal. In practice, most specimen collection sites are contaminated with various quantities of commensal bacteria. As examples, urethral floras contaminate urine collected by micturition, skin floras contaminate blood collected by percutaneous venipuncture, vaginal and cervical floras contaminate endometrial specimens collected through the endocervix, skin and environmental floras contaminate cutaneous fistulas and deep wounds that are open to skin or mucous membrane surfaces, floras in the external ear canal contaminate middle ear fluid following rupture of the tympanic membrane, floras in the nasopharynx and nasal passages contaminate specimens from the nasal sinuses, and the floras in the upper respiratory tract contaminate sputum and other lower respiratory tract specimens. Table 1 lists common diseases with appropriate and inappropriate clinical specimens (11, 224). General specimen selection and collection guidelines include the following (122).

1. Select the proper anatomic site from which to collect the specimen.
2. Avoid contamination with indigenous flora. Growth and reporting of normal flora can be mistaken by the physician or caregiver as the cause of the infectious process. In addition, the flora can overgrow and obscure the true etiology.
3. Surface disinfection followed by aspiration and biopsy of tissue are appropriate methods for specimen collection when anaerobic bacteria are suspected (Table 2). Collection with a swab is not recommended because of the relatively small amount of specimen sampled, difficulty of actually obtaining anaerobes on the swab, aeration of swabs, and the ease with which the swab can be contaminated with adjacent members of the normal flora. Unless they are in a completely airtight container, specimens for anaerobic culture should be stored at room, not refrigeration, temperature, since oxygen diffuses into cold specimens more readily.
4. Collect sufficient volume of material to enable all test requests to be performed satisfactorily. Insufficient material may yield false-negative results.
5. Label each specimen with the patient's name and identification number, source of specimen, date and time of collection, and initials of the collector.
6. Use a specimen container designed to promote survival of pathogenic bacteria, eliminate leakage of specimen, and allow safe handling during transport and processing. Do not transport specimens in syringes.

Specific specimen collection guidelines are summarized in Table 3.

TRANSPORT OF SPECIMENS

Specimens for bacterial culture should be transported to the laboratory immediately. Excessive delay or exposure to temperature extremes compromises results and must be avoided.

* This chapter contains information presented in chapter 20 by Richard B. Thomson, Jr., and J. Michael Miller in the eighth edition of this Manual.

TABLE 1 Selection of common clinical specimens for bacterial culture[a]

Anatomic site	Clinical specimen(s)	
	Appropriate	Inappropriate
Lower respiratory tract	Freshly expectorated mucus and inflammatory cells (pus), sputum	Saliva, oropharyngeal secretions, sinus drainage from nasopharynx
Sinus	Secretions collected by direct sinus aspiration, or washes, curettage, and biopsy material collected during endoscopy	Nasal or nasopharyngeal swab, nasopharyngeal secretions, sputum, and saliva
Urinary tract	Midstream urine, urine collected by "straight" catheterization, urine collected by suprapubic aspiration, urine collected during cystoscopy or other surgical procedure	Urine from Foley catheter collection bag, "bagged" urine from infants
Superficial wound	Aspirations of pus or local irrigation fluid (nonbacteriostatic saline), swab of purulence originating from beneath the dermis	Swab of surface material or specimen contaminated with surface material, irrigation with saline containing preservative
Deep wound	Purulence, necrosis, or tissue from deep subcutaneous site	Specimen contaminated with surface material
Gastrointestinal tract	Freshly passed stool, washes, or feces collected during endoscopy; rectal swab (in selected cases)	Rectal swab, specimen for bacterial culture if diarrhea developed after patient was in hospital for >3 days
Venous blood	Two or three blood specimens collected from separate venipunctures, before initiation of antibiotics, each containing approx 20 ml of blood for patients >90 lb (see Table 7 for pediatric volumes); antisepsis with iodine-containing compound or chlorhexidine	Clotted blood; one or more than three blood specimens collected within a 24-h period; vol of blood <20 ml per culture (i.e., per venipuncture); antisepsis with alcohol only (adults)

[a] Reprinted from reference 195 with permission.

TABLE 2 Suitability of various specimens for anaerobic culture

Acceptable material (method of collection)	Unacceptable material
Aspirate (by needle and syringe)	Bronchoalveolar lavage washing
Bartholin's gland inflammation/secretions	Cervical secretions
Blood (venipuncture)	Endotracheal secretions (aspirate)
Bone marrow (aspirate)	Lochia secretions
Bronchoscopic secretions (protected specimen brush)	Nasopharyngeal swab
Culdocentesis fluid (aspirate)	Perineal swab
Fallopian tube fluid or tissue (aspirate/biopsy)	Prostatic or seminal fluid
IUD, for *Actinomyces* spp.	Sinus washings or swabs
Nasal sinus (aspirate)	Sputum (expectorated or induced)
Placenta tissue (via cesarean delivery)	Stool or rectal swab samples
Stool, for C. *difficile*	Tracheostomy secretions
Surgical site (aspirate, tissue)	Urethral secretions
Transtracheal aspirate	Urine (voided or from catheter)
Urine (suprapubic aspirate)	Vaginal or vulvar secretions (swab)

TABLE 3 Bacteriology collection, transport, and storage guidelines[a]

Specimen type (reference)	Collection guidelines	Transport device and/or minimum vol	Transport[b] time and temp	Storage time and temp	Replica limits	Comments
Abscess (17)						
General	Remove surface exudate by wiping with sterile saline or 70% alcohol.					Tissue or aspirate is always superior to a swab specimen. If swabs must be used (aerobic culture only), collect two, one for culture and one for Gram staining. Preserve swab material by placing in Stuart's or Amies medium.
Open	Aspirate if possible or pass a swab deep into the lesion to firmly sample the lesion's "fresh border."	Swab transport system	≤2 h, RT	≤24 h, RT	1/day/source	Samples of the base of the lesion and abscess wall are most productive.
Closed	Aspirate abscess material with needle and syringe. Aseptically transfer *all* material into anaerobic transport device.	Anaerobic transport system, ≥1 ml	≤2 h, RT	≤24 h, RT	1/day/source	Contamination with surface material will introduce colonizing bacteria not involved in the infectious process. Do not use syringe for transport.
Bite wound	See Abscess					Do not culture animal bite wounds ≤12 h old (agents are usually not recovered) unless signs of infection are present.
Blood (15, 160)	Disinfect culture bottle; apply 70% isopropyl alcohol or phenolic disinfectant to rubber stoppers and wait 1 min. Palpate vein before disinfection of venipuncture site. Disinfection of venipuncture site: 1. Cleanse site with 70% alcohol. 2. Swab concentrically, starting at the center, with tincture of iodine or chlorhexidine. 3. Allow the disinfectant to dry. 4. *Do not palpate vein at this point without sterile glove.*	Blood culture bottles for bacteria; adult, 20 ml/set (higher vol most productive); infant and child, 1–20 ml/set depending on wt of patient (see Table 7)	≤2 h, RT	≤2 h, RT or per instructions	3 sets in 24 h	Acute febrile episode: 2 sets[c] from separate sites, all within 10 min (before antimicrobials) Nonacute disease, antimicrobials will not be started or changed immediately: 2 or 3 sets from separate sites, all within 24 h at intervals no closer than 3 h (before antimicrobials) Endocarditis, acute: 3 sets from 3 separate sites, within 1–2 h, before antimicrobials if possible Fever of unknown origin: 2 or 3 sets from separate sites ≥1 h apart during 24-h period. If negative at 24–48 h, obtain 2 or 3 more sets. Some data indicate that an additional aerobic or fungal bottle is more productive than the anaerobic bottle.

(Continued on next page)

TABLE 3 Bacteriology collection, transport, and storage guidelines[a] *(Continued)*

Specimen type (reference)	Collection guidelines	Transport device and/or minimum vol	Transport[b] time and temp	Storage time and temp	Replica limits	Comments
	5. Collect blood. 6. After venipuncture, remove iodine from the skin with alcohol.					Pediatric: collect immediately; rarely necessary to document ccontinuous bacteremia with hours between cultures.
Bone marrow aspirate	Prepare puncture site as for surgical incision.	Inoculate blood culture bottle or a 1.5-ml lysis centrifugation tube.	≤24 h, RT, if in culture bottle or tube	≤24 h, RT	1/day	Small volumes of bone marrow may be inoculated directly onto culture media. Routine bacterial culture of bone marrow is rarely useful.
Burn	Clean and debride the burn.	Tissue is placed into a sterile screw-cap container; aspirate or swab exudates; transport in sterile container or swab transport system	≤24 h, RT	≤24 h, RT	1/day/source	A 3- to 4-mm punch biopsy specimen is optimum when quantitative cultures are ordered. Process for aerobic culture only. Quantitative culture may or may not be valuable. Cultures of surface samples of burns may be misleading.
Catheter i.v. (109)	1. Cleanse the skin around the catheter site with alcohol. 2. Aseptically remove catheter and clip 5 cm of distal tip directly into a sterile tube. Some elect to culture the 5-cm intracutaneous portion to evaluate for soft tissue infection. 3. Transport immediately to microbiology laboratory to prevent drying.	Sterile screw-cap tube or cup	≤15 min, RT	≤2 h, 4°C	None	Acceptable i.v. catheters for semiquantitative culture (Maki method): central, CVP, Hickman, Broviac, peripheral, arterial, umbilical, hyperalimentation, Swan-Ganz
Foley	Do *not* culture, since growth represents distal urethral flora.					Not acceptable for culture.
Cellulitis, aspirate from area of (17)	1. Cleanse site by wiping with sterile saline or 70% alcohol.	Sterile tube (syringe transport not recommended)	≤15 min, RT	≤24 h, RT	None	Yield of potential pathogens in minority of specimens cultured

	2. Aspirate the area of maximum inflammation (commonly the center rather than the leading edge) with a needle and syringe. Irrigation with a small amount of sterile saline may be necessary. 3. Aspirate saline into syringe and expel into sterile screw-cap tube.					
CSF	1. Disinfect site with iodine preparation. 2. Insert a needle with stylet at L3-L4, L4-L5, or L5-S1 interspace. 3. Upon reaching the subarachnoid space, remove the stylet and collect 1–2 ml of fluid into each of 3 leakproof tubes.	Sterile screw-cap tubes Minimum amt required: bacteria, ≥1 ml	Bacteria: never refrigerate; ≤15 min, RT	≤24 h, RT	None	Obtain blood for culture also. If only 1 tube of CSF is collected, it should be submitted to microbiology first; otherwise submit tube 2 to microbiology. Aspirate of brain abscess or a biopsy sample may be necessary to detect anaerobic bacteria or parasites.
Decubitus ulcer (17)	A swab is not the specimen of choice (see comments). 1. Cleanse surface with sterile saline. 2. If a biopsy sample is not available, aspirate inflammatory material from the base of the ulcer.	Sterile tube/container (aerobic) or anaerobic system (for tissue)	≤2 h, RT	≤24 h, RT	1/day/source	Since a swab specimen of a decubitus ulcer provides no clinical information, it should not be submitted. A tissue biopsy sample or needle aspirate is the specimen of choice.
Dental culture: gingival, periodontal, periapical, Vincent's stomatitis	1. Carefully cleanse gingival margin and supragingival tooth surface to remove saliva, debris, and plaque. 2. Using a periodontal scaler, carefully remove subgingival lesion material and transfer it to an anaerobic transport system. 3. Prepare smear for staining with specimen collected in the same fashion.	Anaerobic transport system	≤2 h, RT	≤24 h, RT	1/day	Periodontal lesions should be processed only by laboratories equipped to provide specialized techniques for the detection and enumeration of recognized pathogens.

(Continued on next page)

TABLE 3 Bacteriology collection, transport, and storage guidelines[a] *(Continued)*

Specimen type (reference)	Collection guidelines	Transport device and/or minimum vol	Transport[b] time and temp	Storage time and temp	Replica limits	Comments
Ear						
Inner (25)	Tympanocentesis reserved for complicated, recurrent, or chronic persistent otitis media 1. For intact eardrum, clean ear canal with soap solution and collect fluid via syringe aspiration technique (tympanocentesis). 2. For ruptured eardrum, collect fluid on flexible shaft swab via an auditory speculum (aerobic culture only).	Sterile tube, swab transport medium, or anaerobic system	≤2 h, RT	≤24 h, RT	1/day/source	Results of throat or nasopharyngeal swab cultures are not predictive of agents responsible for otitis media and should not be submitted for that purpose.
Outer (168)	1. Use moistened swab to remove any debris or crust from the ear canal. 2. Obtain a sample by firmly rotating swab in the outer canal.	Swab transport	≤2 h, RT	≤24 h, 4°C	1/day/source	For otitis externa, *vigorous* swabbing is required since surface swabbing may miss streptococcal cellulitis.
Eye						
Conjunctiva (4, 86)	1. Sample both eyes with separate swabs (premoistened with sterile saline) by rolling them over each conjunctiva. 2. Medium may be inoculated at time of collection. 3. Smear may be prepared at time of collection. Roll swab over 1- to 2-cm area of slide.	Direct culture inoculation: BAP and CHOC Laboratory inoculation: swab transport	Plates: ≤15 min, RT Swabs: ≤2 h, RT	≤24 h, RT	None	If possible, sample both conjunctivas, even if only one is infected, to determine indigenous microflora. The uninfected eye can serve as a control with which to compare the agents isolated from the infected eye. If cost prohibits this approach, rely on the Gram stain to assist in interpretation of culture.
Corneal scrapings (4, 86)	1. Specimen collected by ophthalmologist 2. Using sterile spatula, scrape ulcers or lesions, and inoculate scraping directly onto medium. 3. Prepare 2 smears by rubbing material from spatula onto 1- to 2-cm area of slide.	Direct culture inoculations: BHI with 10% sheep blood, CHOC, and inhibitory mold agar	≤15 min, RT	≤24 h, RT	None	If conjunctival specimen is collected, do so before anesthetic application, which may inhibit some bacteria. Corneal scrapings are obtained after anesthesia. Include fungal media.

Vitreous fluid aspirates	Prepare eye for needle aspiration of fluid.	Sterile screw-cap tube or direct inoculation of small amount of fluid onto media	≤15 min, RT	≤24 h, RT	1/day	Include fungal media. Anesthetics may be inhibitory to some etiologic agents.
Feces						
Routine culture (63)	Pass specimen directly into a clean, dry container. Transport to microbiology laboratory within 1 h of collection or transfer to Cary-Blair holding medium.	Clean, leakproof, widemouthed container or use Cary-Blair holding medium (>2 g)	Unpreserved: ≤1 h, RT Holding medium: ≤24 h, RT	≤24 h, 4°C ≤48 h, RT or 4°C	1/day	Do not perform routine stool cultures for patients whose length of hospital stay is >3 days and the admitting diagnosis was not gastroenteritis without consultation with physician. Tests for *C. difficile* should be considered for these patients. Swabs for routine pathogens are not recommended except for infants (see Rectal swabs).
C. difficile (84)	Pass liquid or soft stool directly into a clean, dry container. Soft stool is defined as stool assuming the shape of its container. Swab specimens are not recommended for toxin testing.	Sterile, leakproof, widemouthed container, >5 ml	≤1 h, RT; 1–24 h, 4°C; >24 h, −20°C or colder	2 days, 4°C, for culture; 3 days at 4°C or longer at −70°C for toxin test	1 or 2 specimens may be necessary to detect low toxin levels.	Patients should be passing ≥5 liquid or soft stools per 24 h. Testing of formed or hard stool is not recommended. Freezing at −20°C or above results in rapid loss of cytotoxin activity.
E. coli (O157:H7) and other Shiga toxin-producing serotypes (5, 50)	Pass liquid or bloody stool into a clean, dry container.	Sterile, leakproof, widemouthed container, or Cary-Blair holding medium (>2 g)	Unpreserved. ≤1 h, RT Swab transport system: ≤24 h, RT or 4°C	≤24 h, 4°C ≤24 h, RT	1/day	Bloody or liquid stools collected within 6 days of onset from patients with abdominal cramps have the highest yield. Shiga toxin assay for all EHEC serotypes is better than sorbitol MacConkey or chromogenic agar culture for O157:H7 only.
Leukocyte detection (68) (not recommended for use with patients who have acute infectious diarrhea)						This procedure should be discouraged because it provides results of little clinical value.

(Continued on next page)

TABLE 3 Bacteriology collection, transport, and storage guidelines[a] *(Continued)*

Specimen type (reference)	Collection guidelines	Transport device and/or minimum vol	Transport[b] time and temp	Storage time and temp	Replica limits	Comments
Rectal swab	1. Carefully insert a swab approx 1 in. beyond the anal sphincter. 2. Gently rotate the swab to sample the anal crypts. 3. Feces should be visible on the swab for detection of diarrheal pathogens.	Swab transport	≤2 h, RT	≤24 h, RT	1/day	Reserved for detecting *N. gonorrhoeae, Shigella, Campylobacter,* herpes simplex virus, and anal carriage of group B *Streptococcus* and other beta-hemolytic streptococci, or for patients unable to pass a specimen.
Fistula	See Abscess					
Fluids: abdominal, amniotic, ascites, bile, joint, paracentesis, pericardial, peritoneal, pleural, synovial, thoracentesis (17)	1. Disinfect overlying skin with iodine preparation. 2. Obtain specimen via percutaneous needle aspiration or surgery. 3. Always submit as much fluid as possible; *never* submit a swab dipped in fluid.	Anaerobic transport system, sterile screw-cap tube, or blood culture bottle for bacteria; transport immediately to laboratory Bacteria, >1 ml	≤15 min, RT	≤24 h, RT; pericardial fluid and fluids for fungal cultures, ≤24 h, 4°C	None	Amniotic and culdocentesis fluids should be transported in an anaerobic system and need not be centrifuged prior to Gram staining. Other fluids are best examined by Gram staining of a cytocentrifuged preparation. One aerobic blood culture bottle inoculated at bedside is highly recommended.
Gangrenous tissue	See Abscess					Discourage sampling of surface or superficial tissue. Tissue biopsy or aspirates should be collected.
Gastric						
Wash or lavage for mycobacteria (24)	Collect in early morning before patients eat and while they are still in bed. 1. Introduce a nasogastric tube to the stomach. 2. Perform lavage with 25–50 ml of chilled sterile, distilled water. 3. Recover sample and place in a leakproof, sterile container.	Sterile, leakproof container	≤15 min, RT, or neutralize within 1 h of collection	≤24 h, 4°C	1/day	The specimen must be processed promptly, since mycobacteria die rapidly in gastric washings. Neutralize with sodium bicarbonate when holding for > 1 h.
Biopsy for *H. pylori*	Collected by gastroenterologist during endoscopy.	Sterile tube with transport medium	<1 h, RT	≤24 h, 4°C	None	Culture may be needed for antimicrobial testing.
Genital, female						
Amniotic fluid (209)	Aspirate via amniocentesis, or collect during cesarean delivery.	Anaerobic transport system, ≥1 ml	≤2 h, RT	≤24 h, RT	None	Swabbing or aspiration of vaginal secretions is *not* acceptable because of the potential for contamination with commensal vaginal flora.

Bartholin gland secretions	1. Disinfect skin with iodine preparation. 2. Aspirate fluid from ducts.	Anaerobic transport system, ≥1 ml	≤2 h, RT	≤24 h, RT	1/day	
Cervical secretions (6)	1. Visualize the cervix using a speculum without lubricant. 2. Remove mucus and secretions from the cervical os with swab and discard the swab. 3. Firmly yet gently sample the endocervical canal with a new sterile swab.	Swab transport	≤2 h, RT	≤24 h, RT	1/day	See text for collection and transport need for *C. trachomatis* and *N. gonorrhoeae*.
Cul-de-sac fluid	Submit aspirate or fluid.	Anaerobic transport system, >1 ml	≤2 h, RT	≤24 h, RT	1/day	
Endometrial tissue and secretions	1. Collect transcervical aspirate via a telescoping catheter. 2. Transfer entire amount to anaerobic transport system.	Anaerobic transport system, ≥1 ml	≤2 h, RT	≤24 h, RT	1/day	
Products of conception	1. Submit a portion of tissue in a sterile container. 2. If obtained by cesarean delivery, immediately transfer to an anaerobic transport system.	Sterile tube or anaerobic transport system	≤2 h, RT	≤24 h, RT	1/day	Do not process lochia, culture of which may give misleading results.
Urethral secretions (6)	Collect at least 1 h after patient has urinated. 1. Remove old exudate from the urethral orifice. 2. Collect discharge material on a swab by massaging the urethra against the pubic symphysis through the vagina.	Swab transport	≤2 h, RT	≤24 h, RT	1/day	If no discharge can be obtained, wash the periurethral area with Betadine soap and rinse with water. Insert a small swab 2–4 cm into the urethra, rotate swab, and leave swab in place for at least 2 s to facilitate absorption.
Vaginal secretions (6)	1. Wipe away old secretions/discharge. 2. Obtain secretions from the mucosal membrane of the vaginal wall with a sterile swab or pipette. 3. If a smear is also needed, use a second swab.	Swab transport	≤2 h, RT	≤24 h, RT	1/day	For IUDs, place entire device into a sterile container and submit at RT. Gram stain, not culture, is recommended for diagnosis of BV.

(Continued on next page)

TABLE 3 Bacteriology collection, transport, and storage guidelines[a] *(Continued)*

Specimen type (reference)	Collection guidelines	Transport device and/or minimum vol	Transport[b] time and temp	Storage time and temp	Replica limits	Comments
Genital, female or male lesion	1. Clean with sterile saline and remove lesion's surface with a sterile scalped blade. 2. Allow transudate to accumulate. 3. While pressing the base of the lesion, *firmly* rub base with a sterile swab to collect fluid.	Swab transport	≤2 h, RT	≤24 h, RT	1/day	For dark-field examination to detect *T. pallidum*, touch a glass slide to the transudate, add coverslip, and transport immediately to the laboratory in a humidified chamber (petri dish with moist gauze). *T. pallidum* cannot be cultured on artificial media.
Genital, male						
Prostate	1. Cleanse urethral meatus with soap and water. 2. Massage prostate through rectum. 3. Collect fluid expressed from urethra on a sterile swab.	Swab transport or sterile tube for >1 ml of specimen	≤2 h, RT	≤24 h, RT	1/day	Pathogens in prostatic secretions may be identified by quantitative culture of urine before and after massage. Ejaculate may also be cultured.
Urethra	Insert a small swab 2–4 cm into the urethral lumen, rotate swab, and leave it in place for at least 2 s to facilitate absorption.	Swab transport	≤2 h, RT	≤24 h, RT	1/day	
Pilonidal cyst	See Abscess					
Respiratory, lower						
Bronchoalveolar lavage, brush or wash, endotracheal aspirate	1. Collect washing or aspirate in a sputum trap. 2. Place brush in sterile container with 1 ml of saline.	Sterile container, >1 ml	≤2 h, RT	≤24 h, 4°C	1/day	A total of 40–80 ml of fluid is needed for quantitative analysis. For quantitative analysis of brushings, place brush into 1.0 ml of saline.
Sputum, expectorated (10)	1. Collect specimen under the direct supervision of a nurse or physician. 2. Have patient rinse or gargle with water to remove excess oral flora. 3. Instruct patient to cough deeply to produce a lower respiratory specimen (not postnasal fluid). 4. Collect in a sterile container.	Sterile container, >1 ml Minimum amt: bacteria, >1 ml	≤2 h, RT	≤24 h, 4°C	1/day	For pediatric patients unable to produce a sputum specimen, a respiratory therapist should collect a specimen via suction. The best specimen from all patients should have ≤10 squamous cells/100× field (10× objective and 10× ocular).

Sputum, induced (10)	1. Have patient rinse mouth with water after brushing gums and tongue. 2. With the aid of a nebulizer, have patients inhale approx 25 ml of 3–10% sterile saline. 3. Collect in a sterile container.	Sterile container, >1 ml	≤2 h, RT	≤24 h, RT	1/day	Same as above for sputum, expectorated.
Respiratory, upper						
Oral	1. Remove oral secretions and debris from the surface of the lesion with a swab. Discard this swab. 2. Using a second swab, vigorously sample the lesion, avoiding any areas of normal tissue.	Swab transport	≤2 h, RT	≤24 h, RT	1/day	Discourage sampling of superficial tissue for bacterial evaluation. Tissue biopsy specimens or needle aspirates are the specimens of choice.
Nasal	1. Insert a swab, premoistened with sterile saline, approx 1–2 cm into the nares. 2. Rotate the swab against the nasal mucosa.	Swab transport	≤2 h, RT	≤24 h, RT	1/day	Anterior nose cultures are reserved for identifying staphylococcal carriers or for nasal lesions.
Nasopharynx (25)	1. Gently insert a small swab (e.g., calcium alginate) into the posterior nasopharynx via the nose. 2. Rotate swab slowly for 5 s to absorb secretions.	Direct medium inoculation at bedside or examination table, swab transport	Plates: ≤15 min, RT Swabs: ≤2 h, RT	≤24 h, RT	1/day	
Throat or pharynx	1. Depress tongue with a tongue depressor. 2. Sample the posterior pharynx, tonsils, and inflamed areas with a sterile swab.	Swab transport (dry swab with or without silica gel is good for *S. pyogenes* and *C. diphtheriae*)	≤2 h, RT	≤24 h, RT	1/day	Throat swab cultures are contraindicated for patients with epiglottitis. Swabs for *N. gonorrhoeae* should be placed in charcoal-containing transport medium and plated ≤12 h after collection. JEMBEC, Bio-Bags, and the GonoPak are better for transport at RT.
Tissue	Collected during surgery or cutaneous biopsy procedure	Anaerobic transport system or sterile, screw-cap container. Add several drops of sterile saline to keep small pieces of tissue moist.	≤15 min, RT	≤24 h, RT	None	Always submit as much tissue as possible. If excess tissue is available, save a portion of surgical tissue at −70°C in case further studies are needed. Never submit a swab that has been rubbed over the surface of a tissue. For quantitative study, a sample of 1 cm^3 is appropriate.

(Continued on next page)

TABLE 3 Bacteriology collection, transport, and storage guidelines[a] *(Continued)*

Specimen type (reference)	Collection guidelines	Transport device and/or minimum vol	Transport[b] time and temp	Storage time and temp	Replica limits	Comments
Urine						
Female, midstream (29)	1. While holding the labia apart, begin voiding. 2. After several milliliters has passed, collect a midstream portion without stopping the flow of urine. 3. The midstream portion is used for bacterial culture.	Sterile, widemouthed container, ≥1 ml, or urine transport tube with boric acid preservative	Unpreserved: ≤2 h, RT Preserved: ≤24 h, RT	≤24 h, 4°C	1/day	Chlamydial DNA detection in urine from women is less sensitive than in urine from men. Urine is toxic to cell lines and is therefore not the specimen of choice for chlamydial culture. Cleansing before voiding does not improve urine specimen quality; i.e., midstream urine samples are equivalent to clean-catch midstream urine samples.
Male, midstream (29)	1. While holding the foreskin retracted, begin voiding. 2. After several milliliters has passed, collect a midstream portion without stopping the flow of urine. 3. The midstream portion is used for culture.	Sterile, widemouthed container, ≥1 ml, or urine transport tube with boric acid preservative	Unpreserved: ≤2 h, RT	≤24 h, 4°C	1/day	First part of urine stream is used for probe and DNA amplification tests for *Chlamydia*. Collect urine for probe and DNA amplification tests at least 2 h after previous urination.
Straight catheter (29)	1. Thoroughly cleanse the urethral opening with soap and water. 2. Rinse area with wet gauze pads. 3. Aseptically, insert catheter into the bladder. 4. After allowing approx 15 ml to pass, collect urine to be submitted in a sterile container.	Sterile, leakproof container or urine transport tube with boric acid preservative	Unpreserved: ≤2 h, RT Preserved: ≤24 h, RT	≤24 h, 4°C	1/day	Catheterization may introduce urethral flora into the bladder and increase the risk of iatrogenic infection.
Indwelling catheter	1. Disinfect the catheter collection port with 70% alcohol. Clamp catheter below port and allow urine to collect in tubing for 10–20 min. 2. Use needle and syringe to aseptically collect 5 to 10 ml of urine. 3. Transfer to a sterile tube or container.	Sterile leakproof container or urine transport tube with boric acid preservative	Unpreserved: ≤2 h, RT Preserved: ≤24 h, RT	≤24 h, 4°C	1/day	Patients with indwelling catheters always have bacteria in their bladders. Do not collect urine from these patients unless they are symptomatic.
Wound	See Abscess					

[a] Abbreviations: AFB, acid-fast bacilli; BAP, blood agar plate; BHI, brain heart infusion; CHOC, chocolate agar; CVP, central venous pressure; i.v., intravenous; PVA, polyvinyl alcohol fixative; RT, room temperature.
[b] All specimen containers are to be transported in leakproof plastic bags having a separate compartment for the requisition.
[c] One set refers to one culture with both aerobic and anaerobic broths.

General specimen transport guidelines include the following (11, 122).

1. Specimens must be transported promptly to the laboratory. If transport will require more than 2 h, a special holding medium or refrigeration temperature is required (Table 3).

2. Do not store specimens for bacterial culture for more than 24 h even with appropriate holding medium or refrigeration temperature.

3. Optimal transport times of clinical specimens for bacteriological culture depend on the volume of material obtained. Small volumes of fluid (<1 ml) or tissue (<1 cm^3) should be submitted within 15 to 30 min to avoid evaporation, drying, and exposure to ambient conditions. Larger volumes and those specimens in holding medium may be stored as long as 24 h.

4. Bacteria that are especially sensitive to ambient conditions include *Shigella* spp., *Neisseria gonorrhoeae, Neisseria meningitidis, Haemophilus influenzae, Streptococcus pneumoniae,* and anaerobes. Reliable detection of these species requires immediate processing. Delays of up to 6 h result in minimal loss of CFU when transport media are used. Longer delays, even with the use of transport media, result in significant losses of organisms. For delays beyond 6 h, refrigeration improves recovery; however, specimens containing anaerobes should be stored at ambient temperatures (2, 42).

5. Transport of clinical specimens and infectious substances from one laboratory to another, regardless of the distance, requires strict attention to specimen packaging and labeling instructions. Materials for transport must be labeled properly, packaged, and protected during transport. Refer to the Centers for Disease Control and Prevention (CDC) website (http://www.phppo.cdc.gov/nltn/nphtcs/ps2005.aspx) for a complete description of packaging and shipping regulations mandated by the U.S. Department of Transportation.

Specific specimen transport guidelines are summarized in Table 3.

SPECIMENS FOR INFREQUENTLY ENCOUNTERED BACTERIA

Some bacteria cause infections that are infrequently encountered and require special transport conditions or holding medium. In many instances, these specimens will be shipped to reference laboratories; this necessitates relatively long transport times. Table 4 is a list of specimens and transport conditions for these bacteria (39).

PROCESSING OF SPECIMENS

Specimen processing includes detection of bacteria by staining and culturing, performing immunologic assays for microbial antigen, and the use of molecular techniques that identify specific nucleic acid sequences. The recommendations that follow are neither all-inclusive nor applicable to all laboratory settings (Table 5). Gram-stained smears are recommended whenever (i) rapid stain results are necessary for patient care, (ii) analysis of cellularity is used to determine adequacy of specimen, or (iii) results are needed to help interpret culture findings by the laboratory technologist. Anaerobic culture should be included only when ordered with an appropriate specimen source (Table 2) and when the specimen was transported in an oxygen-free container free of contamination with normal skin and mucosal anaerobic flora. Gram-stained smear and culture interpretation may require the intervention and opinion of a laboratory director trained in medical microbiology or pathology, and capable of reviewing clinical information with the patient's physician prior to report generation.

General Considerations

Safety

Refer to chapters 5, 8, and 9 for a complete description of safety issues.

Processing

Specimens for detection of bacteria by methods which include culture, staining, and antigen or nucleic acid detection must be processed in a timely manner. The lability of microorganisms, and their antigens and nucleic acids, mandates holding conditions and processing time limits. Improper handling prior to processing can result in death of pathogenic bacteria or overgrowth of contaminating bacteria. In addition, correct interpretations of culture results generally require a rough quantitation of bacterial densities in the clinical specimen. Allowing bacteria to multiply out of proportion to their original numbers may result in erroneous, sometimes detrimental, interpretations. General considerations for holding specimens and acceptable processing delays are summarized in Table 3 (122).

Processing at a Remote Site

Consolidation of laboratory services results in centralized microbiology laboratories located miles from the sites of specimen collection. Adhering to transport and processing time limits developed for laboratories located within or adjacent to the specimen collection site (e.g., hospital) is impossible for remote laboratories. The best approach to location of a core laboratory and the amount of local processing that should be performed can be determined on the basis of guidelines proposed by the Infectious Disease Society of America (149).

Specimen Labeling and Test Ordering Requirements

Upon arrival of specimens in the laboratory, the time and date of receipt should be recorded. Subsequently, the time of plating, which may differ substantially from the time of receipt, should be recorded. At the time of receipt, all specimens and requisitions should be carefully inspected. Specimens must be labeled and accompanied by a requisition reflecting the physician's order. Specimens are labeled with the patient's name and a description of the specimen source. The requisition must include the following information: patient name, age, sex, identifying number (such as social security number or unique registration/billing number), and location (hospital room, physician's office address, etc.); ordering physician's name; specimen source; date and time of collection; and test ordered. If the information is incomplete, laboratory personnel must call the collecting location and request the missing information. If a specimen is mislabeled or no patient name is provided, another specimen should be collected. Relabeling of a specimen is allowed only if the specimen cannot be recollected, such as tissue collected during a surgical procedure. Laboratory procedures must clearly state the exceptions that are allowed, the steps needed to verify and document exceptions, and the individuals responsible for relabeling. When relabeling has occurred, the course of events must be outlined in the laboratory report so the physician interpreting the results is aware of potential errors.

TABLE 4 Specimen management for infrequently encountered organisms[a]

Organism	Specimen(s) of choice	Transport issues	Comment
Bartonella sp. (cat scratch fever)	Blood, tissue, lymph node aspirate	1 wk at 4°C; indefinitely at −70°C	May see organisms in or on erythrocytes with Giemsa stain. Use Warthin-Starry silver stain for tissue. SPS is toxic.
Borrelia burgdorferi (Lyme disease)	Skin biopsy sample at lesion periphery, blood, CSF	Keep tissue moist and sterile; hand carry to laboratory if possible.	Consider PCR in addition to culture. Culture yield is low. Warthin-Starry silver stain for tissue. AO and Giemsa for blood and CSF.
Borrelia sp. (relapsing fever)	Blood smear (blood)	Hand carry to laboratory if possible.	Use direct wet mount in saline for dark-field microscopy. Stain with Wright's or Giemsa stain. Blood culture is unreliable.
Coxiella (Q fever),[b] *Rickettsia* (spotted fevers; typhus)	Serum, tissue (blood)	Blood and tissue are frozen at −70°C until shipped.	Refer isolation to reference laboratory. Serologic diagnosis is preferred.
Ehrlichia sp.	Blood smear, skin biopsy sample, blood (with heparin or EDTA anticoagulant), CSF, serum	Material for culture sent on ice; keep tissue moist and sterile; hold at 4–20°C until tested or at −70°C for shipment; transport on ice or frozen for PCR test.	Serologic diagnosis preferred. Fix smear in methanol. Tissue stained with FA or Gimenez stain. Refer isolation to reference laboratory. CSF for direct examination and PCR.
Francisella sp. (tularemia)[b]	Lymph node aspirate, scrapings, lesion biopsy sample, blood, sputum	Rapid transport to laboratory or freeze; ship on dry ice.	Send to reference laboratory. Serology helpful. Gram stain of tissue is not productive. IFA available. Culture effective 10% of the time.
Leptospira sp.	Serum, blood (citrate-containing anticoagulants should not be used), CSF (1st wk), urine (after 1st wk)	Blood, <1 h; urine, <1 h or dilute 1:10 in 1% bovine serum albumin and store at 4–20°C.	Serology most helpful. Acidic urine is detrimental. Dark-field microscopy and direct FA available. Warthin-Starry silver stain for tissue.
Streptobacillus sp. (rat-bite fever, Haverhill fever)	Blood, aspirates of joint fluid	High-vol bottle preferred	Do not refrigerate. Requires blood, serum, or ascitic fluid for growth. SPS is inhibitory. AO staining is helpful.

[a] Abbreviations: AO, acridine-orange; FA, fluorescent antibody; IFA, indirect fluorescent antibody.
[b] Laboratory safety hazard. Class II biological safety cabinet required. Also see chapter 9.

Laws governing specimen labeling can be reviewed at the Centers for Medicare and Medicaid Services website (http://www.hcfa.gov). Specimens from outpatient facilities require additional information for Medicare and Medicaid billing. Patient diagnosis, in the form of an ICD-9 code, is needed to confirm the need for a particular test. If a test is not deemed necessary for a specific diagnosis, the patient must sign an advanced beneficiary notice documenting that the test is not considered necessary and, if performed, the patient will be required to pay the test charge. Medicare and Medicaid compliance rules also can be reviewed at the Centers for Medicare and Medicaid Services website.

Specimen Rejection

In spite of acceptable labeling, some specimen collection sites, transport containers, or transport conditions render the specimen unacceptable for processing (164). Table 3 lists acceptable criteria for specimen management based on collection or transport conditions and times. When specimens fall outside these limits, new specimens should be collected whenever possible. In addition, specimens may be rejected because of the quality of specimen material collected rather than the conditions of transport (Table 6). Specimen quality is evaluated by examining the quantity and cellular composition. Although the quantity of many specimens is limited by the collection method or physical size of the infected area, some specimens, such as urine, stool, and sputum, are available in abundance. If another specimen can be collected easily with a larger volume, it is appropriate and necessary to request new or additional material. If the specimen volume must be limited, small volumes of liquid specimens can be extended by adding 1 to 2 ml of sterile saline or a

[b] Set up anaerobic culture upon request, if specimen is collected and transported appropriately. Call physician if appropriate specimen does not have request for anaerobic culture.

nutrient broth. It is important to add just enough liquid to provide specimen for all tests requested.

Examining the cellular composition of clinical material first requires a gross examination of the specimen. Infection gives rise to purulence (abundant polymorphonuclear cells), blood, necrosis, and mucus (mucous membrane specimens). In general, gross examination should identify yellow to tan purulence, red to rust-colored blood, clear and tenacious mucus, and brown to black discoloration of tissue denoting necrosis. Portions for smear and inoculation to culture media should be taken from these areas. It may be beneficial to ask the assistance of a surgical pathologist when choosing the best portion of excised tissue for examination (197). Ideally, microscopic examination of smears, using a 10× microscope objective, should demonstrate many polymorphonuclear cells and few or no squamous epithelial cells indicating the absence of cutaneous or mucocutaneous contamination with normal bacterial flora. Specimens in which tissue necrosis is present also may show elastin fibers in stained smears. Lower respiratory tract specimens are likely to show alveolar macrophages and Curschmann's spirals, indicating that secretions have originated from the distal airways. Curschmann's spirals are casts of bronchioles found in patients with chronic lung disease caused most commonly by asthma and cigarette smoking. Figures 1 and 2 illustrate elastin fibers and Curschmann's spirals, respectively. Although elastin fibers are present in noninfected surgical wounds and specimens from areas of tissue damage, they are also found in infected tissue where necrosis has occurred. Specimens determined to have gross bacterial contamination from normal flora, indicated by an abundance of squamous epithelial cells, should be rejected. Specimens are rejected by contacting the patient's caregiver, explaining the reason for rejection, and requesting a replacement specimen of acceptable quality. Timely notification and collection of a replacement are necessary, especially in instances where antimicrobial therapy has been initiated. Specimen rejection criteria should be reviewed by appropriate laboratory and medical staff representatives before becoming policy. Examples of acceptable and unacceptable specimens are listed in Table 6.

Culture Interpretation

Following examination of the stained smear and culture incubation, agar culture plates are interpreted for bacterial growth by attempting to differentiate potential pathogens, requiring identification and antimicrobial testing, from contamination by colonizing members of the normal bacterial flora. This is accomplished by examining the relative quantities of each isolate, correlating culture results with Gram-stained smear results, and recognizing usual contaminants and pathogens from respective specimen sites. In general, in cultures of specimens from sites likely to be contaminated (e.g., sputum, urine, and superficial wounds), potential pathogens should outnumber indigenous flora and should be seen in the direct Gram stain. In cultures of specimens from presumably sterile sites (e.g., cerebrospinal fluid [CSF], joint

TABLE 6 Screening specimens requested for routine bacterial culture to ensure quality[a]

Specimen (reference)	Screening method	Results of screen[b]	
		Acceptable	Unacceptable
Sputum (135)	Microscopic examination of Gram-stained smear	<10 SEC/average 10× field	>10 SEC/average 10× field
Endotracheal aspirate (129)	Microscopic examination of Gram-stained smear	<10 SEC/average 10× field and bacteria detected in at least 1 of 20 fields (100×)	>10 SEC/average 10× field and no bacteria detected in 20 fields (100×)
Bronchoalveolar lavage fluid (200)	Microscopic examination of Gram-stained smear	<1% of cells present are SEC	>1% of cells present are SEC
Urine (213)	Urinalysis, Gram stain of urine sediment	<3+ SEC on urinalysis. Positive LE[b] test result with >10 polymorphonuclear leukocytes/mm^3 from symptomatic patient (patients with asymptomatic bacteriuria may not have increased number of leukocytes)	≥3+ SEC on urinalysis or more than 3 potential pathogens by Gram stain implies gross contamination
Superficial wound (178)	Microscopic examination of Gram-stained smear	<2+ SEC, polymorphonuclear leukocytes present	>2+ SEC and no polymorphonuclear neutrophils
Stool for bacterial pathogens (127)	Location of patient? Duration of hospitalization?	Outpatient or inpatient for ≤3 days	In hospital >3 days, or diarrhea developed while in hospital
Other specimens	Screening methods unavailable or unproven

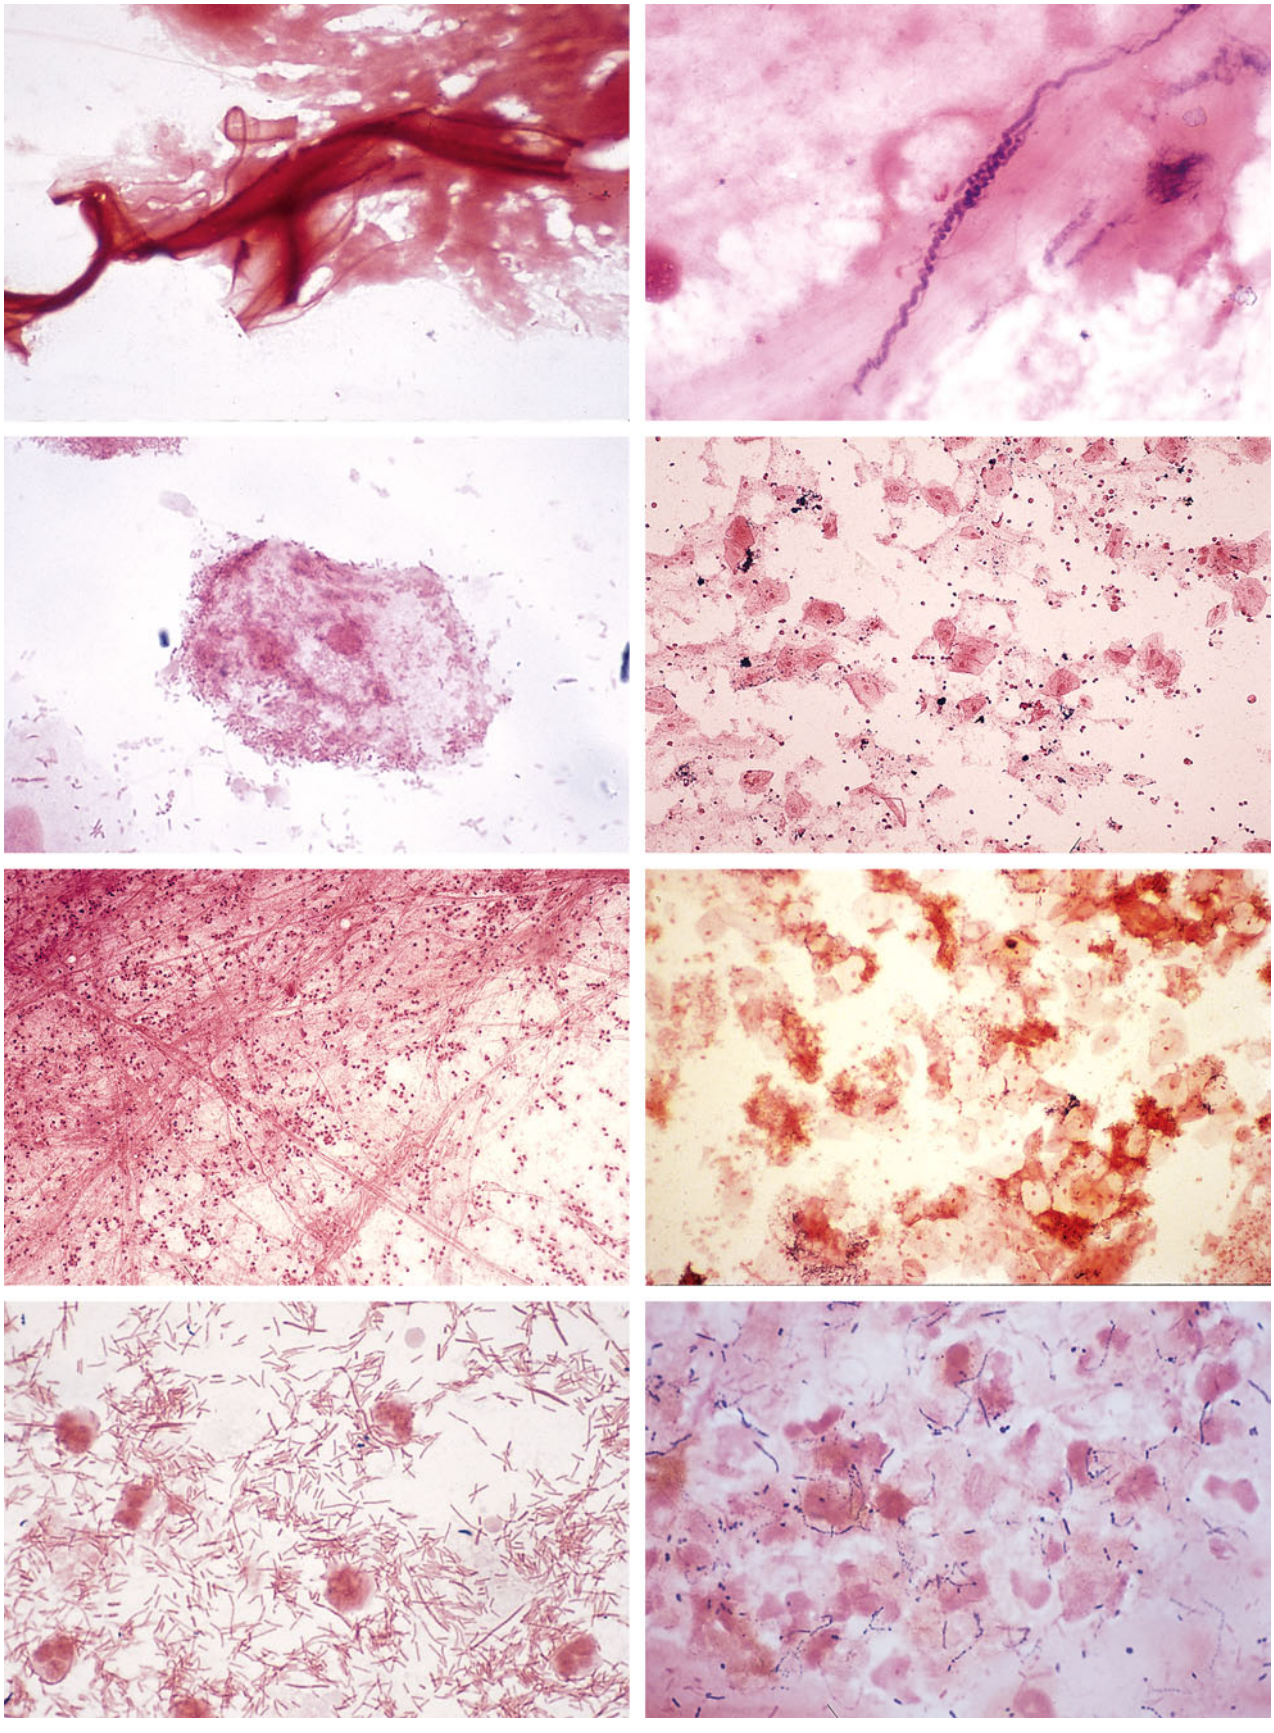
[b] LE, leukocyte esterase; SEC, squamous epithelial cells.



fluids, other body fluids, and deep tissue), potential pathogens occur in any quantity and may or may not be seen in the direct Gram-stained smear. Specific criteria for identifying potentially significant isolates and contaminating members of the normal flora are addressed in the following sections of this chapter. It is a useful policy to save the culture plates for 1 week, allowing physicians the opportunity to call to request further identification or antimicrobial testing when clinically indicated.

Critical Values in Microbiology

Many results in clinical microbiology can have an immediate impact on patient care. Although cultures require days to weeks to become positive, stained-smear results, results of antigen or nucleic acid detection, and culture results from presumably sterile specimen sources may contain information necessitating important changes in therapy or care. Examples of medical emergencies that require immediate notification of the patient's health care provider include a positive blood culture; positive CSF Gram stain or culture; group A streptococcus detected in a surgical wound specimen; Gram stain suggesting gas gangrene, necrotizing fasciitis, or other systemic toxemia; and positive blood smear for malaria. Examples of results that require notification of the physician or health care provider during a day shift, but not so immediate that calls are necessary during evening or overnight hours, include a positive acid-fast stain, new or unusual antimicrobial resistance, and the detection of highly significant or unusual microorganisms such as *Listeria, Legionella,* or *Brucella.* Most critical values are unique to individual medical centers and require laboratories to consult with medical staff representatives before compiling a call list for critical values (95, 108).

Blood and Intravascular Catheter Specimens

Blood is one of the most important specimens received by the laboratory for culture. In most cases, bacteria present in blood (bacteremia) indicate an infection that has spread from a primary site such as the lungs (pneumonia). Such a bacteremia is referred to as a secondary bacteremia. In the absence of an identifiable infected source, the bacteremia is referred to as a primary bacteremia. Primary bacteremia can also result from "silent," subclinical passage of bacteria from contaminated areas of the body, such as mucous membranes, into the blood. Consequences of a clinically apparent primary or secondary bacteremia are sepsis, septic shock, or severe sepsis. Sepsis implies a bacteremia with signs and symptoms, such as fever, chills, and tachycardia. Septic shock indicates the presence of hypotension with sepsis. Severe sepsis is characterized by septic shock with organ system failure and is associated with a 20 to 40% mortality rate (15).

A wide variety of bacteria are involved in bloodstream infections, the majority belonging to groups of bacteria, such as the streptococci/enterococci, staphylococci, or *Enterobacteriaceae,* that grow rapidly in culture (8, 220). It is important to recognize potential contaminants that grow, since treating contaminants as significant isolates is associated with unnecessary expense and dangers of antimicrobial misuse (12). Common contaminants include coagulase-negative staphylococci, corynebacteria, *Bacillus* spp., and propionibacteria. In general, single cultures positive for these bacteria represent contamination. Multiple, separate cultures growing one of these isolates are more likely to indicate a clinically significant bacteremia (90, 125, 219). Contamination is controlled by proper skin antisepsis before venipuncture. Iodine-containing antiseptics, including iodophors (iodine with a detergent) and tincture of iodine (iodine with alcohol, considered more effective than iodophors), or chlorhexidine is needed to reduce the number of viable bacteria at the venipuncture site (106, 124). Contamination rates of less than 3% are desired (172). Higher rates should be investigated and corrected by educational efforts (161).

Bacteremic patients fall into many patterns that determine specimen collection methods. Most patients are intermittently bacteremic, implying that bacteria are present in the blood for periods of time followed by nonbacteremic periods. Other patients who have intravascular sites of primary infection (such as endocarditis) are continuously bacteremic. All patients are likely to have very low quantities of bacteria in the blood, in spite of severe clinical symptoms. For these reasons, multiple blood cultures, each containing large volumes of blood, are required to detect bacteremia. As a rule for adults, two or three separate blood cultures, each inoculated with at least 20 ml of blood, are recommended per 24-h period (8, 219). Pediatric recommendations are similar, except for the volumes of blood recommended (8, 87). Adult and pediatric requirements for blood collection for culture are summarized in Tables 3 and 7.

It is best to collect blood directly into culture bottles during the venipuncture procedure, rather than into transport tubes that are sent to the laboratory for subsequent transfer of blood into the culture bottles. Collection directly into culture bottles enables bacteria to begin growing immediately, decreases the amount of anticoagulant to which bacteria are exposed, and decreases the chances of needlestick accidents for health care personnel. The anticoagulant used in all blood culture systems is sodium polyanethanolsulfonate (SPS) and is known to be inhibitory to meningococci, gonococci, *Peptostreptococcus anaerobius, Streptobacillus moniliformis,* and *Gardnerella vaginalis* (159). Although few practical methods are available to avoid exposure of these bacteria in blood to SPS, it is advisable to diminish the total amount of SPS used by avoiding transport tubes that also include SPS.

Culture of blood is the most sensitive method available for the detection of bacteremia. Semiautomated blood culture systems are present in nearly every clinical laboratory. Refer to chapter 15 for a complete discussion of manual and automated blood culture systems. Occasionally, direct staining of blood collected by venipuncture can provide rapid, nearly immediate, detection of bacteria in blood (157, 163). Gram staining a smear of peripheral blood or buffy coat layer may detect bacterial cells in the blood of patients with meningococcemia, *S. pneumoniae* infection, or overwhelming sepsis caused by other bacteria when the bacterial concentration in blood is very high (approaching 10,000 bacterial cells per ml of blood). In spite of published reports documenting the occasional use of direct staining of blood, the likelihood of results impacting patient management does not warrant use as a routine laboratory procedure.

Some bacteria, such as *Legionella* spp., mycobacteria, some *N. meningitidis* strains, and *N. gonorrhoeae,* fail to grow in routine commercial media and should be sought by using another method, such as lysis centrifugation. Other bacteria may require the addition of adsorbents to bind antimicrobials or inhibitory substances, or more specialized methods such as tissue culture. Prolonged incubation beyond the usual 5-day protocols for automated instruments is not necessary; however, blind subculture may be needed if the patient is receiving antimicrobials at the time of blood collection (7, 150).

Positive blood culture bottles are evaluated initially by examining a Gram-stained smear of the broth. The report should include a description of the bacterial morphology and the Gram reaction. If a presumptive identification of the microorganism can be made, it may be added to the report. For example, a blood culture Gram stain report might state "gram positive in clusters suggesting staphylococci." Specimens in positive blood culture bottles should be subcultured to media based on the organism seen in the Gram-stained smear. In addition, since 5 to 10% of all bacteremias

FIGURE 3 (row 2, left) Gram stain (×1,000) of vaginal secretions showing clue cells.

FIGURE 4 (row 2, right) Gram stain (×100) of unacceptable sputum specimen (grossly contaminated with oropharyngeal flora) showing >10 squamous epithelial cells per low-power field.

FIGURE 5 (row 3, left) Gram stain (×100) of acceptable sputum specimen showing <10 squamous epithelial cells per low-power field.

FIGURE 6 (row 3, right) Gram stain (×100) of urine showing 4+ squamous epithelial cells, indicating gross contamination with vaginal or periurethral secretions and bacteria.

FIGURE 7 (row 4, left) Gram stain (×1,000) of urine showing polymorphonuclear leukocytes and 4+ gram-negative bacilli.

FIGURE 8 (row 4, right) Gram stain (×1,000) of a wound showing polymorphonuclear leukocytes, mixed bacterial morphotypes suggesting aerobic and anaerobic bacteria, and both intra- and extracellular bacteria. This appearance suggests a mixed aerobic and anaerobic abscess or closed-space infection.

TABLE 7 Pediatric bacterial blood cultures: recommended blood volume[a]

Patient wt (lb)	Recommended blood vol per culture (ml)	Total blood vol for 2 cultures (ml)	Vol of blood equal to 1% of patient's total blood vol (ml)[b]
<19	1	2	2
18–30	3	6	6–10
30–60	5	10	10–20
60–90	10	20	20–30
90–120	15	30	30–40
>120	20	40	>40

[a] Data from reference 87.

[b] Blood volume calculated by assuming 85 ml/kg in newborns and 73 ml/kg in other patients. Two 20-ml blood specimens collected from an 80-kg adult (40 ml total) represent approximately 0.7% of the patient's total blood volume.

are polymicrobial (contain more than one bacterial type), the addition of a Columbia-colistin-nalidixic acid, or other agar medium inhibitory to gram-negative organisms, to cultures showing gram-negative bacilli in the Gram stain, or the addition of a MacConkey or related selective agar plate to cultures showing gram-positive bacteria, is recommended. Anaerobic media and culture conditions should be used if the morphology of the organism seen in the Gram-stained smear is suggestive of an anaerobic bacterium or if the organism is recovered from an anaerobic culture bottle only.

Special Considerations for Blood Cultures

Anaerobes

Anaerobes have always accounted for a relatively small percentage of organisms recovered from blood. Over the past several years, some investigators have noted a decline in bloodstream infections by anaerobes (134). However, this is not the case in all hospitals (30). Therefore, laboratories should review their own data when deciding whether to include an anaerobic culture bottle as part of the routine setup of blood specimens. Anaerobic media available for use with the automated systems appear to perform adequately. It is important to note that if the anaerobic component of a blood culture is dropped, the inoculum should be added to an additional aerobic bottle to ensure that the full volume of blood is cultured.

Lysis Centrifugation

The Isolator lysis centrifugation system (Wampole Laboratories, Cranbury, N.J.) is a commercially available manual blood culture method (219). The system consists of a tube containing anticoagulant (SPS), EDTA, and saponin. After the tube is filled with blood during phlebotomy, the contents are mixed and centrifuged, and the resulting pellet is inoculated onto agar media. The system effectively recovers aerobic and facultative bacteria and fungi. The Isolator system does not perform as well as other systems when recovering *S. pneumoniae,* other streptococci, *Pseudomonas aeruginosa,* or anaerobes (219). Advantages of the Isolator system are the ability to inoculate the pellet to specific agar media when attempting to detect unusual etiologies of bacteremia, such as those caused by *Legionella pneumophila, Franciscella tularensis,* and *Bartonella* spp., and to provide colony counts, reported as CFU per milliliter of blood (38, 219). Disadvantages of the system are the labor involved with initial processing and the potential for increased contamination that accompanies manipulation during processing (199).

Intravascular Catheter Tips

Culture of intravascular catheter tips is performed to determine the source of a bacteremia and should be performed only when concurrent blood cultures are obtained. Soft tissue infections around a catheter insertion site are cultured as a wound specimen using freshly expressed purulence that can be aspirated. The most common technique used to culture the intravascular portion of a catheter is the semiquantitative method, in which the 5-cm distal portion of the catheter is rolled across a blood agar plate four times (109). The catheter tip is discarded. Growth of more than 15 colonies is considered to be significant; i.e., it implicates the catheter tip as the likely source of a bacteremia if a similar isolate is detected in a blood culture.

Other techniques have been described for the identification of catheter-related infections. A meta-analysis of data was reported concerning the use of three types of catheter segment culture and three blood culture methods to determine the sensitivity and specificity of each method (182). The three catheter segment cultures included qualitative, semiquantitative (e.g., catheter roll method), and quantitative (dilutions to determine bacterial quantities used), while the three blood culture methods included qualitative catheter blood culture (reported as positive or negative), quantitative catheter blood culture, and paired quantitative catheter and peripheral venipuncture blood cultures. Based on this analysis, quantitative catheter segment culture was the most accurate method, with pooled sensitivity and specificity both >90%. The optimal method in all clinical settings for determining that an intravascular catheter is the source of a bacteremia has not been determined. Because the most serious manifestation of catheter infections is bacteremia, ordinary blood cultures may be the best way to determine which patients require therapy (158).

Sterile Body Fluid Specimens

CSF

CSF is collected for the diagnosis of meningitis (67). Bacterial meningitis can be divided into acute and chronic clinical presentations (196). Acute meningitis with onset of symptoms within the previous 24 h is usually caused by pyogenic bacteria. Specific etiologies are related to the age of the patient and whether the disease is community or nosocomially acquired. Chronic meningitis, with symptoms lasting at least 4 weeks, can have a wide variety of causes (Table 8). As with all clinical specimens, even those collected from a presumably sterile site, growth of contaminants occasionally does occur.

CSF is usually obtained by lumbar spinal puncture. Although bacterial staining and culture can be performed with as little as 0.5 ml of fluid, larger volumes are preferred since culture methods are more sensitive when low numbers of bacteria are concentrated by centrifugation before culture. A minimum of 5.0 ml and high-speed (3,000 × *g*) centrifugation are recommended for recovery of *Mycobacterium tuberculosis,* although the yield may still be low. Filtration through a 0.45-μm-pore-size filter results in better concentration of *M. tuberculosis* in CSF. Specimens should be transported to the laboratory immediately in a sterile container maintained at room temperature. All smears should be prepared by cytocentrifugation (176), and cultures should be inoculated with

TABLE 8 Usual etiologies of infectious disease syndromes

Disease	Etiologies
Central nervous system infection	
Acute meningitis, neutrophilic pleocytosis	*S. pneumoniae*
	N. meningitidis
	Listeria monocytogenes
	Streptococcus agalactiae
	H. influenzae
	S. aureus
	Gram-negative rods[a]
	Bacillus anthracis
Acute meningitis, CSF shunt related	Coagulase-negative staphylococci
	S. aureus
	Propionibacterium spp.
	Gram-negative enteric rods (e.g., *E. coli* and *Klebsiella* spp.)
	Gram-negative nonfermenting rods (e.g., *P. aeruginosa* and *Acinetobacter* spp.)
Chronic meningitis, predominantly lymphocytic pleocytosis	*Nocardia* species
	Brucella species
	L. interrogans
	M. tuberculosis
	T. pallidum
	Borrelia burgdorferi
Gastrointestinal tract infection	
Infectious diarrhea[b]	*Salmonella* serotypes
	Shigella spp.
	C. jejuni/coli
	Campylobacter spp. (other)
	EHEC serotypes
	C. difficile
	Vibrio spp.
	Aeromonas spp.
	P. shigelloides
	Y. enterocolitica
	E. coli toxigenic, invasive, and effacing strains
	Listeria monocytogenes (rare)
	Clostridium perfringens
	B. cereus
Ingestion of preformed toxin[c]	S. aureus
	B. cereus
	C. botulinum
Gastritis/gastric and duodenal ulcers	*H. pylori*
Genital tract infection	
Ulcers	*T. pallidum*
	H. ducreyi
	C. trachomatis (LGV)
	Klebsiella granulomatis
Urethritis	*N. gonorrhoeae*
	C. trachomatis
Vulvovaginitis	*N. gonorrhoeae* and *C. trachomatis* in prepubescent girls
BV	Overgrowth of vaginal flora with anaerobic bacteria
Cervicitis	*N. gonorrhoeae*
	C. trachomatis
Endometritis	*Enterobacteriaceae*
	Streptococci (groups A and B)
	Enterococci
	Mixed anaerobic genera
Salpingitis/oophoritis	*N. gonorrhoeae*
	C. trachomatis
	Mixed aerobic and anaerobic flora
Pelvic abscess	Mixed aerobic and anaerobic flora

(Continued on next page)

TABLE 8 Usual etiologies of infectious disease syndromes *(Continued)*

Disease	Etiologies
Epididymitis	*N. gonorrhoeae* *C. trachomatis* *Enterobacteriaceae* *P. aeruginosa* Various gram-positive cocci
Ocular infections	
Conjunctivitis	*S. pneumoniae* *S. aureus* *H. influenzae* *N. meningitidis* *N. gonorrhoeae* *C. trachomatis* (inclusion conjunctivitis) *C. trachomatis* (trachoma) Others[d]
Keratitis	*S. aureus* *S. pneumoniae* *P. aeruginosa* Enterococci *S. pyogenes* (group A) *Enterobacteriaceae* *Pasteurella multocida* Others[e]
Endophthalmitis	*S. aureus* *P. aeruginosa* *Propionibacterium acnes* *S. pneumoniae* *N. meningitidis*
Periorbital cellulitis	*S. aureus* *S. pyogenes* (group A) *S. pneumoniae* *H. influenzae* *Clostridium* spp.
Otitis	
Otitis externa	*S. aureus* *S. pyogenes* (group A) *P. aeruginosa* *Vibrio alginolyticus*
Otitis media	*S. pneumoniae* *H. influenzae* *Moraxella catarrhalis* *S. aureus* Rare pathogens Gram-negative rods Anaerobes
Respiratory tract infection	
Tracheitis, intubated patient	*Enterobacteriaceae* *S. aureus* *P. aeruginosa* Other nonfermenting gram-negative rods
Bronchitis, community acquired	*S. pneumoniae* *H. influenzae* (rarely, other *Haemophilus* species) *M. catarrhalis* *S. aureus* *C. pneumoniae* *M. pneumoniae* *B. pertussis* *S. pyogenes* (group A) Less commonly, same as hospital acquired

	L. pneumophila
	Other nonfermenting gram-negative rods
	Aspiration (anaerobes)
	Less commonly, same as community acquired
Lung abscess	*S. aureus*
	Klebsiella pneumoniae
	P. aeruginosa
	S. pyogenes (group A)
	Anaerobes (aspiration pneumonia)
	Nocardia species
Empyema	*S. pneumoniae*
	Anaerobes
	Viridans group streptococci, especially *Streptococcus anginosus* group
	S. aureus
	S. pyogenes (group A)
	Gram-negative rods
Urinary tract infection	
Prostatitis	*Enterobacteriaceae*
	P. aeruginosa
	Enterococci
Urethral syndrome	Same us cystitis, but in lower numbers
	C. trachomatis/N. gonorrhoeae
	Unknown—negative culture (about 15% of this disease group)
Cystitis	*Enterobacteriaceae*, especially *E. coli*
	Enterococci
	Staphylococcus saprophyticus (women of childbearing age)
	Nonfermenting gram-negative rods
	Corynebacterium urealyticum (patients with underlying urinary tract pathology)
Pyelonephritis	*Enterobacteriaceae*
	Enterococci
	Agents of bacteremia (descending infection), e.g., *S. aureus*

[a] Gram-negative rods, including *Enterobacteriaceae*, *P. aeruginosa,* and other nonfermenting gram-negative rods.
[b] Disease caused by ingestion of bacterium followed by tissue invasion, toxin production, or other pathogenic mechanism.
[c] Disease caused by ingestion of preformed toxin.
[d] *C. diphtheriae, M. tuberculosis, F. tularensis, T. pallidum, B. henselae* (cat scratch disease), *P. multocida, Bacillus thuringiensis,* and *M. lacunata*.
[e] *T. pallidum, N. gonorrhoeae, Moraxella* sp., *C. diphtheriae, Bacillus* spp., anaerobes, and nontuberculous mycobacteria.

0.5 ml of CSF or sediment resuspended in 0.5 ml of CSF following centrifugation (1,500 × *g* for 15 min) when >1 ml of fluid is received. Recently, PCR has emerged as a potentially useful test for the diagnosis of tuberculous meningitis (27).

Smears should be Gram stained, and the results should be reported to the physician immediately. Results should include a description and semiquantitative enumeration of polymorphonuclear inflammatory cells and bacterial morphology. If the results are suggestive of a bacterial group, this too can be communicated. Because of their low sensitivity and lack of effect on the care and management of patients, and because the cost of antigen testing is much higher than the cost of the Gram stain, direct antigen tests should be considered only when direct communication with the clinical service documents a specific need, such as prior antimicrobial therapy (67, 91, 118, 145, 187). Media are inoculated in accordance with recommendations in Table 5. Broth culture media are not necessary unless CSF is cultured from patients with a CSF shunt or external reservoir (119, 194).

Special Considerations for Sterile Body Fluid Specimens

Anaerobic Bacteria

Anaerobic culture of CSF is very rarely necessary and should be performed only when consultation with the clinical service provides evidence of risk factors for anaerobic etiology such as chronic otitis media with mastoiditis, chronic sinusitis, mixed aerobic-anaerobic soft tissue infection overlying the spine, or the possibility of anaerobic brain abscess, subdural empyema, or epidural abscess (74, 76). Even when a parameningeal abscess contains anaerobes, detection of anaerobes by culture of CSF is unlikely to be helpful, since diagnosis and management are based on microbiological evaluation of the abscess.

Leptospira spp.

Leptospires can be detected in CSF during the first 10 days of acute illness. CSF should be collected before initiation of antimicrobial therapy and while the patient is febrile. Direct detection of leptospires by dark-field examination of CSF has been used in the past but is no longer recommended. Culture should be performed using 1 or 2 drops of CSF inoculated into Ellinghausen-McCullough-Johnson-Harris medium. Cultures should be incubated at room temperature for up to 13 weeks (39) (see chapter 61).

Other Body Fluids

Specimens include pericardial, pleural, peritoneal, peritoneal dialysis, and synovial fluids. A volume of 1 to 5 ml is adequate for the isolation of most bacteria. Fluid submitted on a swab is not optimal. Educational efforts should address the habits of physicians and caregivers who use swabs rather than adding aspirated fluid to an appropriate transport tube. Specimens for anaerobic culture should be transported in an oxygen-free tube. Specimens for the diagnosis of peritonitis associated with chronic ambulatory peritoneal dialysis should include at least 10 ml of fluid (212). All body fluids should be inoculated directly into blood culture bottles in the laboratory or at bedside. For the latter, 0.5 ml should be left in a separate sterile tube for preparation of a smear (14). Body fluids that may clot during transport should be transported in tubes containing anticoagulant. Because heparin, sodium citrate, and EDTA are inhibitory to some bacteria, SPS-containing tubes are recommended. Physicians should be made aware that SPS is inhibitory also and affects the growth of *N. meningitidis, N. gonorrhoeae, P. anaerobius, S. moniliformis,* and *G. vaginalis* (160).

In the laboratory, volumes greater than 1.0 ml for culture should be centrifuged at 1,500 × *g* for 15 min. The supernatant is removed, leaving about 0.5 ml in which to resuspend the sediment. The resuspended sediment is used to inoculate culture media. Cytocentrifugation of 0.5 ml or less (depending on the turbidity of the specimen) should be used to prepare smears for Gram staining before centrifugation to concentrate for culture. Alternatively, smears can be prepared from the same sediment as used to inoculate media; however, this method is less sensitive than cytocentrifugation (176).

Solid media used for culture of body fluid specimens should include chocolate and blood agar, and selective agars for gram-positive and gram-negative organisms if mixed infections are expected (e.g., abdominal fluids from patients with appendicitis) (Table 5). The inoculation of aerobic blood culture bottles with excess fluid is suggested for pericardial, pleural, and synovial fluids, in addition to peritoneal fluids from chronic ambulatory peritoneal dialysis patients, to enhance detection of low numbers of bacteria that may be intracellular or inhibited by prior antimicrobial therapy (16). Cultures should be incubated at 35 to 37°C in the presence of 3 to 5% CO_2 for a minimum of 3 days before being discarded as negative. Blood culture bottles should be incubated for the usual 5- or 7-day protocol.

Some experts question the need to culture abdominal fluid or purulence from patients with intestinal tract perforation, since surgical drainage and broad-spectrum antimicrobials are effective in the majority of cases (137, 185). Complications occur in this clinical setting when microorganisms other than the expected *Enterobacteriaceae,* anaerobes, and enterococci are involved. Standard empirical therapy may not adequately treat *Staphylococcus aureus, P. aeruginosa, Candida* spp., or bacteria more resistant to antimicrobial agents than expected (66). A policy to refuse culture requests or limit identification of isolates that do grow to an arbitrary number (such as 3 or fewer) may not apply uniformly to all patients.

Ear Specimens

Two types of ear specimens are received most commonly by the laboratory, swab specimens for the diagnosis of otitis externa and middle ear fluid specimens for the diagnosis of otitis media (Table 5). Potential pathogens at these two sites differ (Table 8) (20, 25, 168). Since anaerobic bacteria may be involved in middle ear infections, anaerobic culture should be performed on properly collected and transported specimens when requested. Direct examination of Gram-stained smears of middle ear fluid is helpful and is recommended with all culture requests.

External ear specimens may be contaminated with normal flora from the skin or ear canal. Isolates of coagulase-negative staphylococci, diphtheroids, and viridans group streptococci may be listed as presumptive identifications without including results of antimicrobial testing. It is a useful policy to save the culture plates for 1 week, allowing physicians the opportunity to call to request further identification or antimicrobial testing when clinically indicated. Middle ear fluid is less likely to be contaminated. All isolates should be reported, and if requested, antimicrobial testing should be performed on strains with unpredictable susceptibility to antimicrobials.

Eye Specimens

Several types of specimens may be collected for the microbioloigcal analysis of eye infections, including conjunctival scrapings obtained with a swab or sterile spatula for the diagnosis of

conjunctivitis, corneal scrapings collected with a sterile spatula for the diagnosis of keratitis, vitreous fluid collected by aspiration for the diagnosis of endophthalmitis, and fluid material collected by aspiration or tissue biopsy for the diagnosis of periorbital cellulitis (223). Pathogenic bacteria potentially present in these anatomic sites are listed in Table 8. Because the volume of specimen collected from corneal scrapings and vitreous fluid aspiration is very small, direct inoculation of agar culture plates and preparation of smears in the clinic or at the bedside are recommended (223). A close working association is needed between the laboratory and ophthalmologist to ensure a supply of appropriate culture media, the correct technique for inoculation of media, and rapid transport of plates and smears to the laboratory. Media should be inoculated by rubbing the specimen onto a small area of the agar plates. Plates are placed directly into the incubator without cross-streaking by laboratory personnel. This allows the plate reader to detect more easily airborne contaminants that settle on the plate during inoculation procedures that occur outside controlled laboratory conditions.

Media needed for the detection of usual pathogens should include chocolate agar for fastidious bacteria (Table 5). Media for other microorganisms (fungi, viruses, mycobacteria, etc.) should be inoculated if deemed appropriate by the ophthalmologist and microbiologist, and specifically ordered. Incubation at 35 to 37°C in 3 to 5% CO_2 is necessary.

Special Considerations for Eye Specimens

Chlamydia trachomatis

Direct examination of conjunctival smears and detection of chamydial antigen in conjunctival scrapings are useful in the diagnosis of inclusion conjunctivitis or trachoma (45). Diagnosis of chlamydial infection is accomplished using direct fluorescent-antibody (DFA) staining with fluorescein-conjugated monoclonal antibodies or enzyme immunoassays (EIAs) (191). A less sensitive but readily available method is examination of Giemsa-stained conjunctival smears for intracytoplasmic, perinuclear inclusions within epithelial cells. Cell culture for the isolation of *C. trachomatis* is sensitive but more time-consuming and technically demanding than DFA or EIA. Conjunctival scrapings and secretions for culture should be transported in 2SP medium (sucrose phosphate or sucrose phosphate glutamate) with bovine serum and antimicrobials (usually gentamicin, vancomycin, and nystatin or amphotericin B). Swabs with wooden shafts should be avoided since constituents of the wood are toxic to chlamydiae. Specimens for culture should be refrigerated during short delays or stored at –70°C for delays longer than 48 h. Molecular probes and PCR methods are available for the detection of *C. trachomatis* but are not FDA approved at this time for eye specimens (71, 96).

Gastrointestinal Tract Specimens

Feces and, in some cases, rectal swab specimens are submitted to the microbiology laboratory to determine the etiologic agent of infectious diarrhea or food poisoning. Feces should be collected in a clean container with a tight lid and should not be contaminated with urine, barium, or toilet paper. Because intestinal pathogens can be killed by the metabolism of members of the fecal flora rapidly acidifying the specimen, specimens should be transferred to Cary-Blair transport medium soon after collection. Rectal swabs should be placed in a transport system containing an all-purpose medium such as Stuart's.

It should be standard practice in all laboratories to evaluate the appropriateness of stool culture requests. It is well established that hospitalized patients who did not enter the hospital with diarrhea are unlikely to develop enterocolitis caused by bacterial agents other than *Clostridium difficile* (68, 127). For this reason, stool for routine bacterial culture from patients who have been hospitalized for more than 3 days should not be processed without consultation and justification by the patient's physician or caregiver. Diarrhea that develops during hospitalization is likely to be caused by *C. difficile* or occur for noninfectious reasons (60). A simple policy of rejecting stool for routine bacterial culture from patients hospitalized for more than 3 days and offering *C. difficile* testing for nosocomial diarrhea is recommended. On the other hand, *C. difficile* colitis does occur as a community-acquired disease following hospital discharge or the use of outpatient antimicrobial therapy, and requests for diagnostic testing should not be rejected when ordered in the outpatient setting.

Fecal leukocyte examinations have been recommended for the differentiation of inflammatory diarrheas (fecal leukocyte positive) from secretory diarrheas (fecal leukocyte negative). Infectious, inflammatory diarrheas are caused by invasive bacteria, while secretory diarrheas result from toxin-producing bacteria, viruses, and protozoan pathogens (68, 170, 192). Unfortunately, fecal leukocyte morphology degrades in feces during transport and processing delays, making accurate recognition and quantitation difficult. This problem can be solved by using lactoferrin as a surrogate marker for fecal leukocytes (Leuko-Test; TechLab, Blacksburg, Va.), since lactoferrin is not degraded during normal transport and processing times. Lactoferrin-positive stool specimens are considered positive for fecal leukocytes. In addition, invasive pathogens may result in fecal leukocytes being intermittently present or unevenly distributed in stool specimens. Algorithms have been proposed depicting schemes for stool processing based on the use of a lactoferrin assay (63), but they are not commonly used or recommended for the diagnosis of acute, infectious diarrhea (68). The lactoferrin assay is used in the evaluation of patients with inflammatory bowel disease (52).

Usual gastrointestinal pathogens are listed in Table 8 (63). Inclusion of less frequently encountered pathogens should be considered when epidemiological factors suggest an increased likelihood. This may require periodic surveys of one's community to establish which pathogens are most common, especially when considering the addition of selective media or toxin assay for the routine detection of enterohemorrhagic *Escherichia coli* (EHEC), non-*jejuni/coli Campylobacter, Vibrio* spp., and *Yersinia enterocolitica.*

Selective and differential media are used to detect *Salmonella* and *Shigella* spp. (Table 5). These should include one that is differential but not selective for these pathogens, such as MacConkey agar, and one that is a mildly selective medium, such as Hektoen enteric or xylose-lysine desoxycholate agar. In some settings, a highly selective medium such as salmonella-shigella agar is also included. In addition, enrichment broth, such as gram-negative broth or Selenite-F broth, may increase detection of *Salmonella* and is recommended for testing sensitive populations such as food handlers. Subculture of gram-negative and Selenite-F broths to a mildly selective and differential medium after 6 to 8 h and 12 to 18 h of incubation, respectively, is necessary to prevent overgrowth of normal flora and decreased usefulness of the broth (116). All agar plates should be incubated in air at 35 to 37°C for 2 days before being reported as negative. The decision of whether to use a highly selective agar medium and an enrichment broth will vary from one laboratory to another.

Optimally, additional media are used for a trial period to determine their value, which is measured by the detection of strains not present on the two standard media. In settings where such a trial is not possible, the use of MacConkey, Hektoen enteric, or xylose-lysine desoxycholate agar and an enrichment broth is recommended (63).

Campylobacter jejuni and *Campylobacter coli* are detected with a medium such as campylobacter agar with 10% sheep blood and selective antimicrobial agents (Table 5). Media are incubated at 42°C in a microaerophilic atmosphere of nitrogen (85%), carbon dioxide (10%), and oxygen (5%) for up to 3 days. Special enrichment broths are available for the recovery of *Campylobacter;* however, their routine use does not increase the number of campylobacter-positive cultures significantly (1). Detection of other *Campylobacter* species may require media without antibiotics and 37°C incubation (33).

Special Considerations for Gastrointestinal Tract Specimens

Other Enteric Pathogens

A physician order for testing for *Vibrio* spp., *Y. enterocolitica, Aeromonas* spp., and *Plesiomonas shigelloides* may be needed in some geographic locations or epidemiological situations, since incidence is so low in most parts of the United States that the routine use of selective media is not justified. Media used for these enteric pathogens include thiosulfate citrate bile salts sucrose agar for vibrios, cefsulodin-Irgasan-novobiocin agar for *Y. enterocolitica,* and blood agar or selective blood agar to demonstrate hemolysis and provide a medium for oxidase testing for *Aeromonas* spp. and *P. shigelloides* (both oxidase positive) (63). All of these enteric pathogens grow on usual media, but detection is enhanced and simplified using specific selective media.

EHEC

The prevalence of EHEC varies in different parts of the United States and the rest of the world. It has been established that in addition to *E. coli* O157:H7, other serotypes are implicated as enterohemorrhagic strains. In fact, in the United States approximately 50% of Shiga toxin-producing strains, those capable of causing hemorrhagic colitis and hemolytic uremic syndrome, are not serotype O157:H7 (5, 50). For this reason, many laboratories have chosen to perform a Shiga toxin assay by EIA to detect all serotypes, rather than culture or antigen detection for O157:H7 strains only. Some Shiga toxin-producing strains may not harbor all the mechanisms needed to be fully pathogenic in humans. Strategies include testing all specimens year-round, testing all specimens only during summer months (when incidence is highest), testing only specimens containing gross blood, testing only when specifically ordered, testing only specimens from pediatric patients, or testing based on a combination of these factors (58). The best approach for a specific laboratory can be determined by a culture survey of all stool specimens during summer months. Alternatively, one can contact neighboring hospital laboratories or local health departments, which may be able to provide prevalence data. Laboratories should check with public health authorities to see if EHEC-containing stools need to be forwarded for serotyping of toxin-producing *E. coli* strains.

C. difficile

Approximately 15% of people who develop diarrhea following antimicrobial use have antibiotic-associated diarrhea caused by *C. difficile.* If use of the offending antimicrobial continues and disease remains undiagnosed and untreated, pathology may progress to more severe colitis, pseudomembranous colitis, and, possibly, death (9, 60). Nearly 100% of cases of pseudomembranous colitis are caused by *C. difficile.* Disease is caused by toxins (toxin A and toxin B) produced by *C. difficile.* The disease is diagnosed by detecting the organism or its toxins in stool, in conjunction with clinical criteria (84). Cell culture cytotoxicity assay for the detection of toxin B, EIA for the detection of toxin A or toxins A and B, latex agglutination or EIA for the detection of glutamate dehydrogenase (an antigen associated with *C. difficile* and occasionally other bacterial species), and culture of *C. difficile* from stool followed by toxin testing of the isolate are all methods used for diagnosis (9, 110). In practice, an EIA for toxin A or one that detects both toxins A and B is most practical since it requires minutes to hours to complete, compared to 24 to 48 h for the cell culture cytotoxicity assay or 2 to 4 days for culture and toxin testing of the isolate. A single specimen tested by EIA identifies 85 to 100% of specimens eventually proven to be toxin positive, whereas a single specimen tested by cell culture identifies nearly 100% of specimens eventually proven to be positive (110, 201). Testing of a second specimen, after a single negative EIA result, may be needed if symptoms persist and an alternative diagnosis has not been made (110), but testing a second specimen following a single cell culture negative result is not recommended (201).

Although *C. difficile*-associated gastrointestinal disease is most common in hospitalized patients, it can occur in any patient treated with antimicrobials, whether institutionalized or in the community. Testing should not be performed on formed stool (no diarrhea), or as a follow-up to therapy to confirm cure. Repeat testing is appropriate only if symptoms persist or recur (110). Symptoms in those successfully treated will resolve over a few days, in spite of the fact that patients may continue to carry *C. difficile* and even remain toxin positive for days or weeks (181). It is a faulty practice to require negative toxin or culture for *C. difficile* before allowing patients admission to long-term care facilities. Patients who do not have diarrhea and are not incontinent of stool are not an increased risk to other patients, even if carrying *C. difficile* and its toxins, when usual infection control measures are followed (9).

Rare and even fatal disease can be caused by toxin A-deficient strains (toxin B only produced), necessitating occasional use of a toxin A-plus-B immunoassay or cell culture. It is estimated that 2.4% of strains causing human disease are toxin A deficient (85). For epidemiological purposes, stool or rectal swabs placed in anaerobic transport medium may be cultured anaerobically to isolate *C. difficile.* The sample is inoculated to a selective medium such as cycloserine-cefoxitin-fructose agar and incubated anaerobically for 48 h (60).

Since 2002, outbreaks of severe *C. difficile* disease in North America and Europe have been reported. The strains involved are reported to be hyperproducers of toxins A and B. The putative cause is mutation of the regulator controlling production of both toxins. Peak average toxin levels were 16 to 32 times higher than normal in strains without regulator mutations (215). In addition, a third toxin, named the binary toxin, which is found in approximately 5% of all *C. difficile* strains, is reported to be present in nearly two-thirds of strains causing severe disease. Further investigation is needed to establish whether this newly detected toxin is an additional factor in the pathogenicity of *C. difficile* (3, 115).

S. aureus, Methicillin-Resistant *S. aureus* (MRSA), and *Bacillus cereus*

Stool specimens or gastric contents collected from persons with short-incubation food poisoning (2 to 6 h) can be

evaluated for *S. aureus* and *B. cereus*. In general, investigation is beneficial for general public health, rather than a sick individual who recovers quickly, and is best performed by public health laboratories rather than hospital clinical microbiology laboratories. Specimens should be examined by Gram stain, and, because both of these organisms may be present normally in food, quantitative cultures must be performed. A series of dilutions (10^{-1} to 10^{-5}) of the specimen are prepared in buffered gelatin diluent, and 0.1-ml samples of the undiluted specimen and each of the dilutions are plated onto colistin-nalidixic acid or phenylethyl alcohol blood agar. The presence of 10^5 CFU or more of *S. aureus* or *B. cereus* per g of specimen is of potential significance (22, 120).

S. aureus is a possible cause of antibiotic-associated diarrhea (18). The incidence is controversial but receiving more attention. Gram stain of smears of nonformed stool showing sheets of staphylococcal clusters in combination with appropriate clinical findings suggests the diagnosis.

MRSA may be a cause of nosocomial antibiotic-associated diarrhea (18). The overall incidence is unknown. Diagnosis consists of the detection of heavy growth of MRSA in combination with the detection of staphylococcal enterotoxin in stool. Greater recognition of this disease should confirm its significance and result in rapid diagnostic methods and appropriate treatment.

Clostridium botulinum

The clinical diagnosis of foodborne and infant botulism may be confirmed by detecting botulinal toxin, *C. botulinum,* or both in feces (121). Optimally, 25 to 50 g of stool, 15 to 20 ml of serum, and a sample of suspect food should be collected. Most clinical laboratories are not properly equipped to process specimens from persons with suspected botulism. In the United States, when a case of botulism is suspected, investigators at the CDC should be notified to ensure appropriate diagnosis, treatment, and investigation of the potential outbreak. Botulinal toxin could be used as a biological weapon (see chapter 9). Unexpected numbers of cases or unusual presentations should be investigated.

Helicobacter pylori

H. pylori is an important cause of gastritis and peptic ulcer disease (206). The organism can be observed in tissue sections by using hematoxylin and eosin, Giemsa, or Warthin-Starry silver staining. In addition, organisms can be visualized in touch preparations of dissected tissue stained with the Gram stain. The presence of *H. pylori* in stomach or small bowel lesions can be confirmed by culture, antigen detection, urease detection, or the detection of exhaled bacterial metabolite (*H. pylori* breath test) (101, 205, 206). Tissue biopsy specimens collected during endoscopy are used for culture and urease detection. Specimens for culture should be placed in transport medium (medium containing 20% glycerol, such as brucella broth, are best for transport and storage) and transported to the laboratory immediately, or refrigerated during delays (72). Lightly minced tissue is inoculated to freshly prepared blood agar and incubated in a humid, microaerophilic atmosphere (5 to 10% carbon dioxide, 80 to 90% nitrogen, and 5 to 10% oxygen) at 37°C for 7 days (Table 5). The addition of 5% hydrogen should improve the yield of *H. pylori.* Tissue for urease detection is placed as soon as possible into the detection system and processed as specified by the manufacturer. Stool for antigen detection should be collected and handled according to instructions included with the Premier Platinum HpSA test (Meridian Biosciences, Inc., Cincinnati, Ohio) (64, 205). In some clinical situations serologic testing for *H. pylori* antibody may be necessary. Serum should be collected and stored at refrigeration temperature for short periods (up to 1 week) or frozen at –70°C for longer periods (101).

Screening for VRE or Beta-Hemolytic Streptococci

Identifying Carriers of Vancomycin-Resistant Enterococci (VRE) for infection control purposes, detecting group B streptococci in pregnant patients, and detecting group A streptococci during investigations of outbreaks of necrotizing fasciitis or streptococcal toxic shock require collection of a rectal swab specimen. Carriers of VRE can be identified by culturing rectal swab or perirectal swab material (218). Specimens are inoculated to selective enrichment broth, such as Enterococcosel broth with 6 μg of vancomycin per ml, or agar media, such as colistin-nalidixic acid blood agar containing 6 μg of vancomycin per ml (see chapter 30). Carriers of group A streptococci can be identified by culturing rectal swab specimens on sheep blood agar or selective streptococcal agars used to identify patients with streptococcal pharyngitis. Carriers of group B streptococci are identified by culturing vaginal secretions and rectal swab material as discussed below (28).

Genital Tract Specimens

Genital tract specimens are sent to the microbiology laboratory to determine the etiology of various clinical syndromes, including vulvovaginitis, bacterial vaginosis (BV), genital ulcers, urethritis, cervicitis, endometritis, salpingitis, and ovarian abscess in females and urethritis, epididymitis, prostatitis, and genital ulcers in males. These diseases and their etiologies are listed in Table 8 (6).

Many specimens are contaminated with normal skin or mucous membrane flora. Pathogens such as *Haemophilus ducreyi, N. gonorrhoeae, Trichomonas vaginalis, Treponema pallidum,* and *C. trachomatis* are always significant. Other organisms, such as *S. aureus,* beta-hemolytic streptococci, *Enterobacteriaceae,* and anaerobes, are pathogenic only in certain clinical situations. The specimen source, relative quantity of potential pathogen compared to normal flora, and Gram stain interpretation help the technologist determine which isolates require identification and antimicrobial testing. At a minimum, isolates from presumably sterile specimens and pure or predominant potential pathogens from specimens likely to be contaminated with normal flora and containing polymorphonuclear neutrophils should be identified and reported. Mixtures of anaerobes do not require individual identification and listing in most cases. Laboratories should avoid isolating, identifying, and performing antimicrobial testing on every bacterial isolate from all specimens (6). In addition to the excessive cost of this approach, unnecessary reporting of bacterial species contributes to excessive treatment of patients. Exact protocols for workup and reporting may require discussion and mutual agreement with knowledgeable clinicians in each practice environment.

Special Considerations for Genital Tract Specimens

Detection of *N. gonorrhoeae* and *C. trachomatis*

Nucleic acid probe and amplification methods are commercially available for direct detection of *N. gonorrhoeae* and *C. trachomatis* in endocervical, urethral, and urine specimens. Users must pay close attention to the types of specimens approved for use with each kit. Specimens should be collected using the procedures and collection kits recommended by the manufacturer. In addition, false-positive

reactions have been reported with some kits, necessitating confirmation of positive results (208).

Although not as sensitive as molecular methods, both EIA and DFA tests are commercially available for the direct detection of *C. trachomatis* in endocervical, urethral, and, with some EIA kits, urine specimens (171). If these kits are used, collection and processing must follow instructions provided by the manufacturer. Cell culture for *C. trachomatis* is recommended for use with specimens not approved for molecular or EIA kits. These are likely to include eye, rectal, and abscess specimens collected during surgery. In addition, culture is the only acceptable diagnostic procedure in some jurisdictions for medical-legal cases.

Culture for *N. gonorrhoeae* is optimal when the specimen is directly inoculated to a selective medium, such as modified Thayer-Martin medium, and incubated immediately (48). Transport of inoculated media to the laboratory must be in an increased CO_2-containing environment. Swab specimens (cotton swabs should be avoided because they may be toxic) should be placed in a transport system containing Stuart's or Amies medium and delivered to the laboratory as quickly as possible. Specimens for *N. gonorrhoeae* culture should be held at refrigeration temperature during transport. As transport time increases, recovery by culture decreases. Specimens requiring more than 24 h for transport are unacceptable. Detection by nonculture methods is recommended in most settings where the additional cost of testing by molecular technique or immunoasssay is not prohibitive (204).

BV and Vaginitis

BV occurs when conditions result in overgrowth of usual vaginal flora with various anaerobic genera, including *Mobiluncus* and *Bacteroides* (184). Although not characterized by a polymorphonuclear response, BV results in an increase in vaginal secretions that are relatively alkaline (pH > 4.5) compared to normal, the usual predominant flora of lactobacilli being replaced by anaerobes, and the presence of aromatic amines which are detected by adding 10% potassium hydroxide and noting a pungent, fishy odor. In addition, excessive growth of a facultative bacterium called *G. vaginalis* generally coincides with BV. Although *G. vaginalis* commonly is a member of the normal vaginal flora, the presence of increased concentrations that adhere to vaginal squamous epithelial cells, called clue cells, is pathognomonic of BV. Clue cells are squamous epithelial cells peppered with anaerobic coccobacilli and *G. vaginalis* bacteria, frequently showing heavier adherence toward the periphery of the cell and appearing like a donut (Fig. 3). As a result of these characteristic changes, BV is diagnosed best without culture (140). Wet-mount or Gram-stained smears should be examined and interpreted according to Table 9. In summary, BV should be diagnosed by performing a "bedside" pH and KOH "whiff test" and a laboratory Gram stain.

Candida and *Trichomonas* infections of the vulvovaginal areas are inflammatory conditions referred to as vaginitis rather than vaginosis. *Candida* spp. and *T. vaginalis* can be detected using microscopic examination of a saline wet-mount preparation. Low-power examination (×10 to ×20) will detect budding yeasts and pseudohyphae of *Candida* spp. or motile trophozoites of *Trichomonas*. Cultures are much more sensitive than direct wet preparations. Alternatively, a combination probe assay (Affirm VPIII identification test; Becton Dickinson, Sparks, Md.) is commercially available for the simultaneous detection of *Candida* spp., *G. vaginalis,* and *T. vaginalis* in vaginal secretions (21). Specimens must be collected using procedures recommended by the manufacturer.

Screening for Group B Streptococcus

Group B streptococcus carriers are identified by culturing vaginal secretions and rectal swab material. Swabs of the vaginal introitus and anorectum are collected and inoculated into a single enrichment broth such as LIM broth. This broth is incubated at 35°C overnight and subcultured to a blood agar plate the following day (173). A rapid molecular assay is available for the detection of group B streptococcus colonization in pregnant women (35). The performance of this test allows for rapid intrapartum detection of group B streptococci.

Dark-Field Examination for *T. pallidum*

Dark-field examination of tissues, tissue exudates, and material collected from chancres can be used to confirm the diagnosis of syphilis. For dark-field microscopy, the specimen should be examined within 20 min of collection to ensure motility of treponemes and should not be exposed to temperature extremes during transport to a dark-field microscope. The test requires a microscope equipped with a dark-field condenser and experienced personnel who are able to recognize *T. pallidum* spirochetes based on the tightness and regularity of the spirals and on their characteristic corkscrew movement (98). A DFA stain can be used and is performed on air-dried smears. The stability of the smear during transport and the easily identified, fluorescing treponemes make the DFA an attractive alternative to dark-field microscopy (98). Unfortunately, reagents for the DFA test are not commercially or widely available; it may be performed at some public health laboratories.

H. ducreyi

If infection with *H. ducreyi* is suspected, material from the base of the ulcer is collected and held at room temperature until needed for processing (102). One swab is used to prepare a smear for Gram staining. The presence of many small, pleomorphic, gram-negative bacilli and coccobacilli arranged

TABLE 9 Diagnosis of BV using a Gram-stained smear of vaginal secretions, by the Vaginal Infection and Prematurity Study Group criteria[a]

Morphotype	Score for indicated no. of morphotypes seen per oil power field				
	None	≤1	1–5	5–30	>30
Lactobacillus	4	3	2	1	0
Gardnerella/Bacteroides spp.	0	1	2	3	4
Curved gram-variable rods (*Mobiluncus* spp.)	0	1	2	3	4

[a] Adapted from reference 140. Total score = *Lactobacillus* morphotypes + *Gardnerella/Bacteroides* morphotypes + *Mobiluncus* morphotypes. A score of 0 to 3 is considered normal, 4 to 6 is intermediate, and 7 to 10 indicates BV.

in chains and groups (school of fish) suggests *H. ducreyi* but is rarely seen (see chapter 41). Recovery of the organisms by culturing on an enriched medium such as GC agar containing 3 μg of vancomycin per ml, 1% hemoglobin, 5% fetal bovine serum, and 1% IsoVitaleX, or Mueller-Hinton agar with 5% horse blood, 1% IsoVitaleX, and 3 μg of vancomycin per ml, is necessary to confirm the diagnosis; culturing at 33°C yields better recovery than does culturing at 35°C (see chapter 41).

Actinomyces spp.

Actinomyces spp. may cause pelvic inflammatory disease in women who use intrauterine contraceptive devices (IUD) (104). An IUD submitted for culture should be placed in a sterile liquid medium (preferably reduced, such as thioglycolate) and vortexed, and the liquid medium should be used to inoculate aerobic and anaerobic culture media. Inflammatory debris and tissue attached to the IUD should be removed and cultured aerobically and anaerobically. *Actinomyces* spp. produce small knots of intertwined bacterial filaments called grains or granules, which may be 1 mm or more in diameter. These grains should be crushed on a slide for staining (Gram stain is acceptable) and transferred to media for culture. The presence of branching gram-positive filaments suggests *Actinomyces,* which characteristically occurs in mixed infections with other aerobic and anaerobic bacteria. Culture confirms the diagnosis.

Lower Respiratory Tract Specimens

Specimens from the lower respiratory tract are submitted to determine the etiology of airway disease (tracheitis and bronchitis), pneumonia, lung abscess, and empyema (10, 138, 179). Table 8 gives a list of lower respiratory tract diseases and their common etiologies. Usual specimens submitted consist of lower respiratory tract secretions and inflammation in the form of expectorated sputum, induced sputum, endotracheal tube aspirations (intubated patients), bronchial brushings, washes or alveolar lavage samples collected during bronchoscopy, and pleural fluid (198). Specimens should be delivered to the laboratory promptly and processed without delay (within 1 h of collection). If delays are unavoidable, the specimen should be refrigerated.

Usual pathogens detected in lower respiratory tract secretions are present in specimens containing acute inflammatory cells (polymorphonuclear leukocytes) and in quantities greater than contaminating respiratory flora. Frequently, pathogenic bacteria are present within the polymorphonuclear leukocytes. There are many ways to assess the quality of respiratory tract specimens. A simple screening method involves assessment of squamous epithelial cells only (128, 129, 135). Squamous epithelial cells are found in the oropharynx but not in the lower respiratory tract. Increased numbers (defined as >10 per 10× objective microscopic field) indicate gross contamination with oropharyngeal contents, which include usual oral bacterial flora (Fig. 4 and 5). Most bacterial lower respiratory tract disease is caused by inapparent aspiration of oropharyngeal contents. It follows that oropharyngeal floras include the bacteria that cause lower respiratory tract disease. Detection of a potential pathogen in a grossly contaminated specimen may represent contamination with oropharyngeal flora. The lack of usefulness of data from contaminated specimens has resulted in policies for screening and rejecting grossly contaminated respiratory tract specimens. Table 6 lists respiratory tract specimens and usual screening policies. Respiratory tract specimens for the detection of *Mycoplasma pneumoniae, Legionella* spp., dimorphic fungi, and *M. tuberculosis* should not be screened for adequacy. All specimens are considered acceptable for the detection of these microorganisms (34).

Once respiratory tract specimens have been deemed acceptable, Gram-stained smears should be examined further for inflammatory cells, bacteria, and other indicators of lower respiratory tract pathology, such as mucus, necrosis, intracellular bacteria, alveolar macrophages, and Curschmann's spirals (Fig. 2) (231). Tracheal and bronchial mucopurulence can be trapped behind an airway obstruction or within a lung abscess cavity or may pool in the bronchi or trachea, resulting in the death and disintegration of cells, reflected as necrosis and cell debris in stained smears. Intracellular bacteria can be differentiated from bacteria "lying" on top of polymorphonuclear leukocytes by their greater concentration within the phagocytic cell than in nearby extracellular areas. Phagocytosis is an active uptake process resulting in concentration of bacteria within the cell. Alveolar macrophages are identified by their vacuolated cytoplasm and round eccentric nucleus, which is difficult to see in Gram-stained smears. Alveolar macrophages and Curschmann's spirals indicate areas within the smear that originated within the alveoli and distal airways (Fig. 2). Occasionally elastin fibers are seen in respiratory tract specimens (Fig. 1).

Bacteria should be reported when detected in Gram-stained smears if they are potential pathogens. Bacteria not in sufficient quantity or not representative of morphotypes resembling potential pathogens should be lumped together and reported as normal respiratory flora. It is important to differentiate contaminating respiratory flora from respiratory flora causing aspiration pneumonia. Aspiration of relatively large amounts of oropharyngeal contents following loss of consciousness, paralysis of muscles involved with swallowing and breathing, or medical procedures such as intubation can result in infection of the airways with mixed respiratory flora leading to lung abscess and empyema (111). Gram stain of sputum from patients with aspiration pneumonia can be highly suggestive of the diagnosis. Stained smears show many polymorphonuclear leukocytes and many mixed respiratory flora morphotypes, especially those suggesting streptococci and anaerobes. Much of the flora is intracellular. Aspiration pneumonia can be detected in hospitalized patients and those admitted directly from the community (10, 138).

Cultures of respiratory tract material should include a medium selective for gram-negative organisms, such as MacConkey's agar, sheep blood agar, and chocolate agar for the detection of *Haemophilus* spp. (Table 5). Culture plates should be incubated at 35°C in 3 to 5% CO_2 for 48 h before being reported as negative. Cultures are interpreted by examining the relative numbers and types of bacteria that grow. Table 10 summarizes interpretative criteria used with respiratory tract specimens (200).

Special Considerations for Lower Respiratory Tract Specimens

Specimens Collected During Bronchoscopy

Bronchoalveolar lavage fluid and bronchial brush specimens from patients with suspected pneumonia should be cultured quantitatively to evaluate the significance of potential pathogens recovered (23). Bronchial brush specimens, which contain approximately 0.01 to 0.001 ml of secretions, should be placed in 1 ml of sterile nonbacteriostatic saline after collection. The specimen should be delivered to the laboratory immediately. In the laboratory, the specimen is agitated on a vortex mixer, a smear is prepared by cytocentrifugation for staining with the Gram stain, and 0.01 ml of specimen is

inoculated to appropriate media by using a pipette or calibrated loop. Colony counts of more than 1,000 CFU of potential pathogens per ml (corresponding to 10^6 CFU of original specimen per ml) appear to correlate with disease. Bronchoalveolar lavage results in collection of 50 ml or more of saline from a larger lung volume. In the laboratory, a smear is prepared by cytocentrifugation and Gram stained (155). The Gram stain report should include a comment about the presence of squamous epithelial cells and intracellular bacteria. Grossly contaminated fluid (>1% of all cells are squamous epithelial cells) may have falsely elevated counts of potential pathogens. Intracellular bacteria are more likely to be potential pathogens. A 0.01- or 0.001-ml aliquot of bronchoalveolar lavage fluid should be inoculated to agar media (Table 5). The recovery of <10,000 bacteria/ml suggests contamination. The recovery of >100,000 bacteria/ml suggests that the isolate is a potential pathogen. Detection of 10,000 to 100,000 bacteria per ml represents a "gray" zone (200). Counts of pathogens may be reduced by prior antimicrobial therapy or variations in "return" of lavage fluid during the bronchoscopy procedure (Table 10).

Legionella spp.

Legionella spp., especially *L. pneumophila,* are important causes of community- and hospital-acquired pneumonia (51). Legionellosis can be diagnosed by culture, DFA staining of smears of respiratory secretions, detection of antigens in urine, or serologic testing. Culture is preferred because, unlike other methods, it is not limited to detection of certain species or serotypes. Before culture, respiratory samples should be diluted 10-fold in a bacteriological broth, such as tryptic soy, or sterile water to dilute inhibitory substances that may be present in the specimen. Because legionellae grow slowly, optimal isolation from highly contaminated specimens, such as sputum, is achieved by decontaminating the specimens with acid before plating (214). The specimen is diluted 1:10 in KCl-HCl buffer (pH 2.2) and incubated for 4 min at room temperature. It is important not to incubate the specimen for longer than 4 min because legionellae may themselves be killed by acid exposure. Specimens are inoculated onto buffered charcoal yeast extract agar with and without antimicrobial agents (e.g., vancomycin, polymyxin B, and anisomycin). The cultures are incubated in humidfied air at 35°C for a minimum of 5 days. Using a dissecting microscope, small colonies with a ground-glass appearance, typical of *Legionella* spp., can be detected after 3 days of incubation.

M. pneumoniae

Mycoplasma pneumoniae is a common cause of pneumonia, referred to as primary atypical pneumonia. Because *M. pneumoniae* is fastidious and grows very slowly, a definitive diagnosis is often based on the results of serologic tests. When culture is required, the specimen of choice is a throat swab; however, sputum or other respiratory specimens are also acceptable. The specimen should be placed immediately into a transport medium containing protein, such as albumin, and penicillin to reduce the growth of contaminating bacteria. Specimens may be stored in the transport medium for up to 48 h at 4°C or frozen for longer periods at –70°C. PCR methods have been used successfully to detect *M. pneumoniae* directly in respiratory tract specimens. Molecular detection by PCR or a related technique may be the most sensitive method for the detection of *M. pneumoniae* (156).

Specimens from Patients with Cystic Fibrosis

Burkholderia cepacia is an important respiratory pathogen in persons with cystic fibrosis (31, 62). This organism grows well on routine media; however, selective media such as *B. cepacia* selective agar, *Pseudomonas cepacia* agar, and oxidative-fermentative-polymyxin B-bacitracin-lactose agar are useful for optimal recovery from respiratory secretions (79, 80). Comparative studies show *B. cepacia* selective agar to be superior (79) (also see chapter 49).

Chlamydia and *Chlamydophila* spp.

Chlamydiae are important causes of respiratory illnesses in children and adults (143). *C. trachomatis* can cause serious respiratory disease in newborn infants. *Chlamydophila pneumoniae*

TABLE 10 Interpretation of bacterial lower respiratory tract culture results[a]

Specimen	Likely to be significant	Not likely to be significant	Additional data suggesting that isolate is significant
Sputum—coughed or induced	Predominant potential pathogen in Gram stain and culture. Neutrophils abundant.	Potential pathogen not present in Gram stain and only 1–2+ growth in culture. Neutrophils not abundant in Gram stain.	Potential pathogen within neutrophils (intracellular bacteria)
Endotracheal tube aspirate (112)	Predominant potential pathogen in Gram stain and culture. Neutrophils abundant.	Potential pathogen only 1–2+ growth in culture. Neutrophils not abundant in Gram stain.	Potential pathogen in quantities $>10^6$ CFU/ml. Potential pathogen within neutrophils (intracellular bacteria)
Bronchoalveolar lavage fluid	Predominant potential pathogen seen in every 100× field of Gram stain. Quantitative culture detects $>10^5$ CFU of potential pathogen/ml.	Potential pathogen not seen in Gram stain. Quantitative culture detects $<10^4$ CFU of potential pathogen/ml.	Potential pathogen within neutrophils (intracellular bacteria)

[a] Reprinted from reference 195 with permission.

causes illness in all age groups, but most disease occurs in adolescents and young adults. *Chlamydophila psittaci* is primarily an animal pathogen but occasionally causes disease in humans exposed to sick animals. Lower respiratory tract secretions, in addition to nasopharyngeal washes, for the detection of chlamydiae are collected and transported to the laboratory immediately in a medium containing antimicrobial agents (e.g., gentamicin and nystatin). If delays in transport or processing occur, the specimen should be stored at 4°C for up to 48 h. Longer storage should be at –70°C or colder. Chlamydiae are detected by rapid cell culture techniques (shell vial) using McCoy cells for *C. trachomatis* and *C. psittaci* and HEp-2 cells for *C. pneumoniae*. As with *M. pneumoniae*, PCR may prove to be the most sensitive method for the detection of respiratory chlamydiae (156).

Nocardia Species

Respiratory specimens for the detection of *Nocardia* species should be transported to the laboratory as soon as they are collected. For short delays, storage at 4°C is acceptable. Direct examination of a Gram-stained smear containing a *Nocardia* species shows thin, beaded gram-positive branching filaments. The filaments are also partially acid fast when stained by the modified Kinyoun method. There are no media used routinely for the specific recovery of *Nocardia* spp. since they grow readily on many common media such as sheep blood and chocolate agar plates, Sabouraud agar for fungi, Lowenstein-Jensen medium for mycobacteria, and charcoal yeast extract agar for legionellae. Mycobacterial decontamination procedures reduce the recovery of *Nocardia*. Selective charcoal yeast extract agar is optimal for culture from contaminated specimens (210). Although *Nocardia* spp. are detected commonly following 1 week of incubation, cultures are incubated for a total of 3 weeks at 35°C.

Upper Respiratory Tract Specimens

Upper respiratory tract specimens include the external nares, nasopharynx, throat, oral ulcerations, and inflammatory material from the nasal sinuses. Although few serious diseases involve these areas, many pathogens colonize or persist in these sites while causing symptomatic infection in deeper, less accessible sites (147).

Throat specimens are collected to diagnose pharyngitis caused by *Streptococcus pyogenes*. Swab specimens should be placed in a standard transport carrier containing Amies or modified Stuart's medium. Refrigeration is preferred if transport requires more than a few hours. Many rapid direct tests for group A streptococci are commercially available, including EIA, optical immunoassay, and nucleic acid-based probe assays (59, 190). The reported sensitivities of EIAs and an optical immunoassay vary between 60 and 95% but can be as low as 31% (25, 217). The nucleic acid-based assay has a sensitivity of >90% (75, 78). When a rapid test is requested, two throat swabs should be collected. If only one swab is received, the culture plate should be inoculated first. Material remaining on the swab is used for the direct test. If the rapid test is positive, the second swab can be discarded, but if the rapid test is negative, the second swab must be used for culture to confirm the negative direct test. The nucleic acid-based probe test is considered sensitive and specific enough by many to obviate confirmatory culture (78). A position paper by representatives of the American Academy of Family Physicians, the American College of Physicians-American Society of Internal Medicine, and the CDC states that rapid tests do not require confirmatory culture when used with adult patients (32). This recommendation does not hold for specimens from children.

To culture group A streptococci, either sheep blood agar or selective blood agar may be used. Selective agar makes the organism easier to visualize by inhibiting accompanying flora but may delay the appearance of colonies of *S. pyogenes*. Cultures should be incubated for 48 h at 35°C in an environment of reduced oxygen achieved by incubating them anaerobically, in 5% CO_2, or in air with multiple "stabs" through the agar surface. Stabbing the agar surface with the inoculating loop pushes inoculum containing streptococci below the surface, where the oxygen concentration is reduced compared to ambient (25, 89). These culture conditions allow the recovery of group C and G streptococci, organisms which may cause pharyngitis but do not cause the serious sequelae associated with group A streptococci (203, 232).

Throat specimens also are used to identify patients infected with *N. gonorrhoeae*. For best results, the specimen should be inoculated immediately to a selective medium, such as modified Thayer-Martin agar. Cultures are incubated at 35°C in the presence of 5% CO_2 for 72 h.

The external nares can be cultured to identify carriers of *S. aureus* by using a single swab to collect secretions from both the left and right nares. The usual carrier systems used for swab transport containing Amies or Stuart's medium are acceptable. In the laboratory, the specimen can be inoculated to a sheep blood agar plate; however, use of selective media such as colistin-nalidixic acid agar, or a selective and differential medium such as BBL CHROMagar *Staph aureus* (BD Diagnostics, Sparks, Md.), BBL CHROMagar MRSA (BD Diagnostics), or mannitol salt agar is helpful in differentiating *S. aureus* or MRSA from other floras and useful when interpreting large numbers of specimens (53, 54, 57, 221). Published comparisons show the CHROMagar formulations to be superior (53, 54). Cultures should be incubated at 35°C for 2 days. Molecular testing by PCR for the detection of *S. aureus* in swabs from the external nares has been shown to be as sensitive as culture but much more rapid (142). A commercially available, FDA-approved molecular test (IDI-MRSA; Infectio Diagnostic, Inc., Sainte-Foy, Quebec, Canada) for the detection of MRSA in nasal swabs is also an option for those seeking a rapid test (216).

Nasopharyngeal secretions and cells are used to identify patients infected with *Bordetella* spp. and carriers of *N. meningitidis* (113). Specimens for the recovery of *Bordetella pertussis* and *Bordetella parapertussis* should be collected with a small-tipped Dacron swab. Cotton may be toxic to the organism. Swabs should be transported to the laboratory in special media. For delays of up to 24 h, Amies medium with charcoal can be used. If the transport time will exceed 24 h, Regan-Lowe transport medium should be used (82, 126). Culture, DFA staining, and PCR can be used for detection. PCR is the most sensitive method for detecting *B. pertussis* and *B. parapertussis* (Dacron swabs are preferred for PCR tests) (107). Culture is performed using Regan-Lowe charcoal agar containing 10% horse blood and cephalexin. Because a few strains of *B. pertussis* do not grow in the presence of cephalexin, the use of Regan-Lowe medium with and without cephalexin is recommended for optimal recovery (77, 183). Cultures are incubated at 35°C for 5 to 7 days in a humid atmosphere. The DFA test has a lower sensitivity and specificity than PCR for *Bordetella* but offers rapid results (107). Depending on the reagents used, either *B. pertussis* or *B. parapertussis* is detected.

Nasopharyngeal swab specimens are used to identify carriers of *N. meningitidis*. Transport in a swab container with Amies or Stuart's medium is acceptable. Specimens should be inoculated as quickly as possible to sheep blood or chocolate agar; however, selective agars for pathogenic *Neisseria*

spp., such as modified Thayer-Martin, are necessary if interference by normal flora is expected. Culture plates are incubated for 72 h in a humidified atmosphere at 35°C in the presence of 5% CO_2.

Vincent's angina is an oral infection characterized by pharyngitis, membranous exudate, fetid breath, and oral ulcerations. Sometimes referred to as fusospirochetal disease or necrotizing ulcerative gingivitis, it is caused by *Fusobacterium* spp., *Borrelia* spp., and other anaerobes. Diagnosis is made by direct examination of a smear of a swab specimen collected from the ulcerated lesions and stained with the Gram stain (147). The presence of many spirochetes, fusiform bacilli, and polymorphonuclear leukocytes is presumptive evidence of this disease. Culture is not helpful. It should be noted that canker sores do not have a microbial etiology and should not be cultured.

Inflammatory material from the nasal sinuses should be cultured to detect the etiologies of sinusitis. Nearly all cases of bacterial sinusitis follow a primary, upper respiratory tract viral infection. Bacteria are trapped in the sinus as a result of damage to the epithelial lining cells of the sinus and inflammation and swelling that narrows or closes the nasal ostium, preventing normal drainage (69). Specimens collected during endoscopic procedures by physicians specializing in otorhinolaryngology are optimal, since they are sampled directly from the infected sinus, avoiding contamination by normal flora in the nasal passages. Aspirates, washes, scrapings or debridements, and biopsy material should be kept moist and sent in a sterile container to the laboratory (69). Examination of Gram-stained smears can provide a rapid, presumptive identification of likely pathogens. Aerobic culture is needed in all cases; anaerobic transport and culture may be needed in cases of chronic sinisitis. Ventilator-associated sinusitis occurs in fewer than 10% of patients with nasotracheal intubation. Members of the nosocomial flora are implicated. Endoscopic inspection is needed to obtain acceptable specimen for culture (222).

Special Considerations for Upper Respiratory Tract Specimens

Arcanobacterium haemolyticum

A. haemolyticum can cause pharyngitis and peritonsillar abscess (88). The organism can be recovered on media used to detect *S. pyogenes*. Colonies of *A. haemolyticum* are beta-hemolytic and easily confused with those of beta-hemolytic streptococci. Rapid differentiation can be accomplished with the Gram stain. *A. haemolyticum* is a diphtheroid-shaped gram-positive rod (see chapter 34). Incubation of plates at 35°C for up to 72 h may be required for optimal detection.

Corynebacterium diphtheriae

Cultures of both throat and nasopharyngeal specimens are used in the diagnosis of diphtheria. When specimens are processed for culture without delay, no special transport medium or conditions are required. For transport to a reference laboratory, specimens should be sent dry in a container with desiccant (44). Alternatively, specimens collected on swabs may be placed in Stuart's or Amies medium for transport to the laboratory. Smears of specimens for *C. diphtheriae* can be stained with the Gram stain and examined for pleomorphic (diphtheroid morphology) gram-positive rods. In addition, smears can be stained with Loeffler's methylene blue stain and examined for pleomorphic, beaded rods with swollen (club-shaped) ends and reddish purple metachromatic granules. Bacteria with these characteristics are suggestive of but not specific for *C. diphtheriae*. Specimens should be inoculated to Loeffler's serum and potassium tellurite media for the recovery of *C. diphtheriae*. Cultures are incubated for 2 days at 35°C in 5% CO_2 before being reported as negative.

Epiglottitis

A throat swab specimen may be helpful in determining the etiology of epiglottitis, a rapidly progressing cellulitis of the epiglottis and adjacent structures with the potential for swollen tissues to cause airway obstruction. Epiglottitis is almost always caused by *H. influenzae* serotype b but occasionally by other bacteria such as *S. pneumoniae* and *S. pyogenes* (202). The specimen should be collected by a physician only in a setting where emergency intubation can be performed immediately to secure a patent airway. Specimens should be inoculated onto enriched medium, such as chocolate agar, and incubated at 35°C in an atmosphere of 5% CO_2 for 72 h. Nearly 100% of patients with epiglottitis caused by *H. influenzae* have a blood culture positive for the same bacterium.

Tissue Specimens

Tissue specimens are obtained during surgical procedures at significant risk and expense to the patient. Therefore, it is mandatory for the laboratory to receive sufficient specimen for both histopathologic and microbiological examination, bearing in mind that many microbiological tests and cultures may have been ordered. Histopathologic examination of the lesion serves to differentiate between infection and malignancy, and also to distinguish between acute and chronic infectious processes (227). Swabs provide too little specimen and should be discouraged and eliminated through educational efforts. For complete setup of routine, anaerobic, fungal, and acid-fast bacillus cultures and smears, one needs approximately 1 cm^3 of tissue.

Tissue should be transported in a sterile container that maintains moisture. To avoid drying, small pieces of tissue can be moistened with a few drops of sterile, nonbacteriostatic saline. Alternatively, very small pieces of tissue can be placed on a square of moistened sterile gauze. This serves to maintain moisture and allow easy identification by those receiving and processing the specimen. Tissue should be gently minced or ground during processing to release microorganisms and to provide equal specimen for all media and smears. This can be accomplished by cutting with a sterile scalpel, grinding with a mortar and pestle or tissue grinder, or using a stomacher (Seward Co., London, United Kingdom) or masticator (available from several suppliers) (180). The resulting homogenate is used to prepare smears for staining and to inoculate culture media. The Gram stain should be examined for the presence of polymorphonuclear leukocytes and bacteria. Grinding renders most cell morphology and tissue architecture difficult to recognize and often renders fungal hyphae nonviable. A small piece of intact tissue should be retained for inoculation into fungal media. Smears should be examined closely for intracellular bacteria, especially common with staphylococci and streptococci. For bacterial culture, processed tissue should be inoculated to enriched agar media. The use of a broth medium is controversial (128, 130). Anaerobic culture should be included when ordered and when tissue is transported in an oxygen-free environment. Large pieces of tissue, approximately 1 cm^3 or greater, maintain a reduced atmosphere in spite of brief aerobic transport. Oxygen-free transport may not be necessary in this circumstance, and the absence of anaerobic transport should not disqualify large pieces of tissue from anaerobic culture. Routine, aerobic cultures are incubated at 35°C in the presence of 5% CO_2 for 72 h.

Collecting and processing tissue offers an opportunity for exogenous contamination. Cultures growing small numbers of bacteria not commonly associated with infection, such as coagulase-negative staphylococci, corynebacteria, propionibacteria, and saprophytic *Neisseria* spp., may represent contamination rather than true "pathogens." In general, growth of these bacterial groups in broth culture only represents contamination (128, 130). One or two bacterial colonies growing on a single plate, of multiple plates inoculated, and not growing in broth culture, if used, generally represent contamination. Growth of one or two bacterial colonies on agar media not in the area of specimen inoculation or on streak lines in the second through fourth plate quadrants also is likely to represent contamination. In addition, it is assumed that bacteria considered contaminants were not detected in Gram-stained smears prepared from the original specimen. On the other hand, detection of the bacteria listed above as unlikely pathogens should always be reported when seen in the original Gram-stained smear, when present in quantities above a few colonies, and when detected on or in multiple media (41).

Special Circumstances for Tissue Specimens

Bone Marrow

Bone marrow aspirates can be submitted for culture in lysis centrifugation tubes (Isolator; Wampole Laboratories). The "pediatric" tube holds a maximum of 1.5 ml of specimen. One or more of the 1.5-ml tubes can be used. Aspirates may also be submitted in a sterile container containing anticoagulant. Sterile tubes with anticoagulant are less desirable since they use heparin, sodium citrate, or EDTA as anticoagulant, all of which are more inhibitory than SPS (49, 166). Although SPS inhibits meningococci, gonococci, *G. vaginalis,* anaerobic cocci, and *S. moniliformis,* these bacteria are unlikely to be detected in bone marrow aspirate specimens (159).

Although bone marrow aspirate cultures may be helpful in identifying disseminated fungal and mycobacterial diseases, they are unlikely to assist in the identification of usual bacterial diseases (211). Patients infected with human immunodeficiency virus may benefit from bone marrow culture when other specimen cultures have been unsuccessful (47). It is policy in some laboratories to consult with the ordering physician and suggest that routine bacterial culture is not necessary. In most cases, blood or other organ system culture is preferred for the identification of disseminated bacterial infections. Even if bone marrow culture is performed, direct Gram stain of bone marrow aspirates is not helpful and should not be a routine component of bacterial culture.

Lymph Nodes

Lymph node cultures from immunocompetent patients are positive only when there is a granuloma or acute inflammatory lesion, in which case etiologies detected are limited to mycobacteria and fungi. Bacterial culture of lymph nodes from immunocompetent patients may not be necessary without specific clinical or epidemiological findings, such as suspected tularemia *(F. tularensis)* (56).

Quantitative Tissue Culture

Tissue from traumatic wound or burn injury may be submitted for quantitative culture, with results of $\geq 10^3$ CFU/ml being used to predict the likelihood of the development of wound-related sepsis (117, 228). Limitations include the lack of reproducible results and the low predictive value compared to histologic examination of tissue. To perform a quantitative culture, a portion of the specimen is weighed and homogenized in saline. The saline suspension is used to prepare serial dilutions for culture. Detailed procedures for quantitative tissue culture are given elsewhere (230).

Bartonella

Bartonella henselae is the agent of cat scratch disease in healthy hosts and causes bacteremia, endocarditis, bacillary angiomatosis, and bacillary peliosis primarily in immunocompromised hosts. Optimal detection of the organism requires PCR (186). Culture is very difficult but can be attempted using Isolator tubes (Wampole Laboratories) and freshly prepared rabbit blood agar plates incubated in a moist environment for an extended period (19). Tissue culture may have a better yield than agar (see chapter 54). Lymph node tissue is macerated and inoculated into media directly. Because the detection of *B. henselae* is time-consuming and expensive, the diagnosis of cat scratch disease is most often made by clinical criteria and exclusion of other diseases. *B. henselae* can be observed in sections of fixed tissue stained with Warthin-Starry or Diederle's silver stain (94, 123).

Urinary Tract Specimens

Diseases of the urinary tract include prostatitis, urethral syndrome, cystitis, and pyelonephritis. Etiologies are summarized in Table 8. Urine, prostatic secretion, or urethral cells or secretion specimens are needed to diagnose these diseases. Urine can be collected by midstream collection, catheterization (straight/in-out or indwelling), cystoscopic collection, or suprapubic aspiration. Foley catheter tips should not be submitted or accepted for culture since they are always contaminated with urethral flora and quantitation is not possible. A first-voided morning urine is optimal, since in most cases bacteria have been sitting in the bladder multiplying for a number of hours. Clean-catch urine, implying cleansing of periurethral areas, has not been shown to improve the quality of urine culture and is not recommended (103, 154).

Urine specimens should be transported to the laboratory immediately and processed within 2 h of collection. If a delay occurs, specimens may be refrigerated for up to 24 h. Transport tubes containing boric acid are available to stabilize the bacterial population at room temperature for 24 h, if refrigeration is not available (99). Boric acid-preserved urines are acceptable for dipstick leukocyte esterase testing (229).

Urine culture is the most common test performed by most microbiology laboratories, and most urine cultures are negative; i.e., no specific potential pathogen is detected. Screening methods are available that attempt to rapidly separate those specimens containing significant counts of bacteria from negative specimens. In general, screening methods compare well with specimens containing 10^5 CFU of bacteria per ml or greater but perform poorly when colony counts are lower. Screening urine specimens by staining with the Gram stain is rapid and economical with regard to reagents but is labor-intensive and requires a trained technologist. The presence of 1 or 2 bacteria of similar morphotype, or more, in each oil immersion field (100× objective lens) correlates with a count of 100,000 or greater by culture (162, 226). Commercially available dipstick tests that detect leukocyte esterase (an enzyme produced by neutrophils) and nitrite (the result of bacterial nitrate reductase acting on nitrate in the urine) are rapid, inexpensive, and simple to perform, but their sensitivity is low in some patient populations (144, 153, 175). False-negative dipstick screening occurs because frequent voiding dilutes the concentration of leukocyte esterase and nitrite in urine, enterococci and other less common urinary tract pathogens do not produce nitrate reductase, and many patients with

asymptomatic bacteriuria do not have significant numbers of leukocytes in their urine. In spite of this, outpatient screening algorithms have been proposed that incorporate enzyme screening in a "reflexive" urine test; i.e., urinalysis is performed, and if positive for leukocyte esterase or nitrate reductase, a culture will be set up, and if negative, a culture will not be done (29). Such screening works best in symptomatic patients, diabetics, and women older than 60 years (144, 153, 175).

In addition to the Gram stain and dipstick tests for leukocyte esterase and nitrite, several urine screening systems have been marketed (151). Notable among these are the FiltraCheck-UTI and a semiautomated version called the Bac-T-Screen, the UTI screen Bacterial ATP Assay, and the Cellenium automated urine screening system (133, 141, 151, 152, 162, 188). Currently, all are no longer available or not actively marketed, and they are not discussed further here.

The standard for quantitative bacterial culture of urine is the inoculation of 0.01 or 0.001 ml of specimen using a calibrated plastic or wire loop to appropriate media, usually sheep blood and MacConkey agars. The loop is dipped vertically into the well-mixed urine, just far enough to cover the loop, and the loopful of urine is spread over the surface of the agar plate by streaking from top to bottom in a vertical line and again from top to bottom perpendicular to this line in a back-and-forth fashion. Prior to plate inoculation, it is necessary to ensure that a film of urine fills the loop with no bubbles to alter the calibrated volume. The inoculum of urine is spread over the entire agar surface to simplify counting of colonies after growth. Urine cultures are incubated at 35°C for 24 to 48 h. Although most urinary tract pathogens grow readily on usual agar media, slowly growing pathogens and those inhibited by the presence of antimicrobials in the patient specimen may not appear after overnight incubation (16 h). One approach uses the results of the leukocyte esterase and nitrite tests to determine which cultures get incubated for a full 48 h. Urine cultures that are negative after overnight incubation but had one or both positive enzyme tests are incubated for an additional day. Those that had negative enzyme tests are reported as "no growth" in the final report (26, 132).

Contamination of urine is detected in approximately 5 to 40% of cultures. Contamination is not reduced by the use of central processing areas, refrigeration, urine screening systems, specimen preservatives, or insulated specimen transport (207).

Agar paddles are available for urine culture in settings where inoculation and incubation of conventional agar plates are not convenient or possible (165). A standard film of urine is distributed over the agar-covered paddle, usually by dipping the paddle into a jar of urine. The paddle is then reinserted into its plastic container for incubation. Following incubation, the density of growth is estimated by comparison to photographs or drawings. A preliminary identification of gram positive or gram negative can be determined by colony color and morphology, and, when appropriate, the entire paddle can be forwarded to a reference laboratory for complete identification and antimicrobial testing of the isolate. Agar paddle culture of urine with approximate colony counts compares favorably with standard culture (165).

The urinary tract above the urethra is sterile in healthy humans, but the urethra is colonized normally with many different bacteria. Because of this, urine collected by midstream voiding techniques becomes contaminated during passage. Commensal bacteria are differentiated from potential pathogens by quantitative culture. Bacterial counts indicating "significant" bacteriuria (isolate is a likely pathogen) vary with the host and type of infection. Table 11 summarizes significant counts for common clinical situations (189).

TABLE 11 Interpretation of urine culture results[a]

Urine specimen and patient[b]	Likely to be significant[b]	Not likely to be significant[b]	Additional data suggesting that isolate is significant
Midstream, female with cystitis	$>10^2$ CFU of potential pathogen/ml, urine LE is positive	Quantity of potential pathogen ≤ quantity of contaminating flora.	
Midstream, female with pyelonephritis	$>10^5$ CFU of potential pathogen/ml, urine LE is positive	Quantity of potential pathogen ≤ quantity of contaminating flora.	Gram stain demonstrates potential pathogen in neutrophils and/or casts.
Midstream, asymptomatic bacteriuria	$>10^5$ CFU of potential pathogen/ml, LE is usually negative	$<10^5$ CFU of potential pathogen/ml; quantity of potential pathogen ≤ quantity of contaminating flora.	Confirm by repeating urine when clinically indicated.
Midstream, male with UTI	$>10^3$ CFU of potential pathogen/ml, urine LE is positive	$<10^3$ CFU of potential pathogen/ml; quantity of potential pathogen ≤ quantity of contaminating flora.	Gram stain demonstrates potential pathogen in neutrophils and/or casts.
Straight catheter, all patients	$>10^2$ CFU of potential pathogen/ml, urine LE positive for symptomatic patients	$<10^2$ CFU of potential pathogen/ml; urine LE is negative.	Gram stain demonstrates potential pathogen in neutrophils and/or casts.
Indwelling catheter, all patients	$>10^3$ CFU of potential pathogens/ml (multiple pathogens may be present)	Bacteriuria detected in asymptomatic patients; urine LE positive or negative.	No reason to culture unless patient is symptomatic.

[a] Reprinted from reference 195 with permission.
[b] LE, leukocyte esterase; UTI, urinary tract infection.

Severe urinary tract infection generally involves the kidneys (pyelonephritis) and results in bacteremia. Rapid diagnosis and administration of appropriate antimicrobial therapy are necessary. In this clinical setting, blood cultures are needed and a stat Gram stain of the urine can be useful. The Gram stain provides an immediate indication of the quality of the urine and a preliminary identification of the likely pathogen. Specimens containing high numbers of squamous epithelial cells are likely to be grossly contaminated with periurethral or vaginal flora and new specimens should be collected immediately, before antimicrobials inhibit growth of the true pathogen (Fig. 6) (195). Gram stain identification of a potential pathogen confirms that empirical therapy is correct or may suggest a change based on an unexpected pathogen, such as *S. aureus* (Fig. 7).

Special Considerations for Urinary Tract Specimens

Leptospires

Leptospira interrogans can be recovered from blood and CSF during the acute stages of disease and from urine after the first week of illness and for several months thereafter. Urine should be processed as soon as possible after collection, because the acidity of urine harms the organisms. If a delay in processing is expected, urine should be neutralized with sodium bicarbonate, centrifuged (1,500 × *g* for 30 min), and resuspended in buffered saline before being used to inoculate media (see chapter 61). Alternatively, the urine may be diluted 1:10 in 1% bovine serum albumin and stored at 5 to 20°C. Undiluted urine and urine diluted 1:10, 1:100, and 1:1,000 in sterile buffered saline should be inoculated to Ellinghausen-McCullough-Johnson-Harris or equivalent medium, with and without neomycin (39). Cultures should be incubated at 30°C for at least 13 weeks (Table 5).

Bacterial Antigen Testing

Bacterial antigen testing kits, for the purpose of diagnosing bacterial meningitis, include procedures for use with urine specimens. In general, these kits should not be used with urine specimens for the diagnosis of bacterial meningitis. In addition, the FDA issued a product alert specifically cautioning against the use of the group B streptococcus antigen kits with urine specimens because of the risk of both false-positive and false-negative results (55).

An EIA is commercially available for the detection of *L. pneumophila* serogroup 1 antigen in urine. The antigen may be detectable in urine for months following an infection. The assay has a sensitivity of 80% when performed on unconcentrated urine (70, 73). Sensitivity is increased when urine is concentrated. The drawback of this assay is that only disease caused by *L. pneumophila* serogroup 1 is detected. A new EIA has been evaluated that detects all *L. pneumophila* serogroup antigens in urine (40).

S. pneumoniae antigen can be detected in urine using a commercially available EIA (NOW *S. pneumoniae* urinary antigen test; Binax, Portland, Maine) (83, 131, 167). Although the sensitivity for detecting urine antigen is 80% for patients with positive blood cultures and 52% for patients with positive sputum cultures, the specificity is high. This test may prove to be useful in settings where culture is not available, but at present it should be used in addition to, not in place of, culture.

Wound and Abscess Specimens

Abscess specimens should be collected by aspiration. Small amounts of purulence or wounds with nothing to aspirate can be irrigated with sterile, nonbacteriostatic saline to facilitate aspiration. In addition, wounds can be sampled by dissecting a small portion of infected tissue. Purulent specimens and wound specimens characterized by ulceration or necrosis, but with little moisture, can be collected with a swab, but this is generally inferior to aspiration or biopsy. Swab specimens contain less material, are more likely to be contaminated with adjacent flora, and are not amenable to optimal anaerobic transport. When swabs are used for collection, two swabs should be used, one for culture and one for preparation of a smear. Deep lesions that communicate with the surface are most problematic. The cutaneous portion and sinus tract are contaminated with bacteria found at the surface. Surgical debridement and sampling are recommended. If surgery is not performed, effort should be made to aspirate a "pocket" of infected material that is not open to the surface. As a last option, fresh specimen should be expressed from deep within the wound. A swab used to collect specimen from the surface overlying the draining wound is not acceptable. This is of particular importance when evaluating diabetic foot ulcers or infected pressure sores (169). Only deep specimens collected by aspiration or during debridement offer useful culture information (17, 105).

Gram staining of wound and abscess specimens is very important. The Gram stain result provides rapid presumptive identification of etiology, it can be used to evaluate the quality of the specimen submitted, and it guides the workup of culture results. Examination of a Gram-stained smear reveals bacterial morphotypes, acute inflammatory cells (polymorphonuclear neutrophils), intracellular bacteria, cell necrosis, and elastin fibers resulting from tissue necrosis. The quality of the wound specimen can be evaluated by comparing the number of polymorphonuclear cells and squamous epithelial cells (Table 12) (178). Excess numbers of squamous epithelial cells suggest gross contamination with cutaneous flora. It is acceptable to limit workup of bacterial isolates when the specimen shows gross contamination. An example of a limited workup would be to list by Gram stain morphology the isolates encountered, with a comment explaining that the physician must call if a replacement specimen cannot be collected and further identification and antimicrobial testing are clinically warranted.

Special Circumstances for Wound and Abscess Specimens

Cellulitis

Specimens from patients with cellulitis but without abscess are very difficult to collect. Recommendations have been made to inject a small volume of sterile, nonbacteriostatic saline into the infected tissue. The few drops that one can aspirate back should be sent for Gram stain and culture. Under the best of conditions, these specimens are unlikely to be positive (65, 81). Blood cultures from patients with cellulitis also are unlikely to be positive (146). In spite of the shortcomings of microbiology testing for patients with cellulitis, seriously ill patients may require biopsy and all should have blood collected for culture.

Necrotizing Fasciitis and Gas Gangrene

Necrotizing fasciitis and gas gangrene (myonecrosis) are medical emergencies requiring immediate diagnosis and therapy that may include antimicrobials, surgical debridement, and the use of immune globulin and immune mediators to combat the fatal complications of severe septic shock (177, 193). Necrotizing fasciitis and gas gangrene are caused most commonly by toxin-producing *S. pyogenes,* other beta-hemolytic

TABLE 12 Screening wound specimens to ensure quality[a]

Quantity of cells per 10× (objective lens) microscopic field					
No. of neutrophils	Q-value for neutrophils	Q-value for squamous epithelial cells present in the following no.[b]:			
		0	1–9	10–24	≥25
		0	−1	−2	−3
0	0	(1)	0	0	0
1–9	+1	1	0	−1	−2
10–24	+2	+2	+1	0	−1
≥25	+3	+3	+2	+1	0

[a] Attach Q-values to squamous cell and neutrophil quantities. Add the two Q-values together. Specimens with positive Q-values (+1 to +3) are more likely to contain increased numbers of potential pathogens and decreased numbers of potential contaminants. Specimens with negative Q-values (or a Q-value of zero) are likely to be contaminated with local flora. Specimens with no squamous cells or neutrophils are scored as one (1), allowing samples from neutropenic patients or those with necrotic or serous secretions to be processed as acceptable.

[b] The first row of numbers in the table is the Q-value for squamous epithelial cells only. The following four rows are the Q-values for the sum of the neutrophils and squamous epithelial cells.

streptococci, *S. aureus*, *Clostridium* spp., and mixed aerobic and anaerobic bacteria (46). The diagnosis is made by clinical examination of the patient and is confirmed by Gram stain and culture. Gram-stained smears generally show proteinaceous fluid, necrotic cell debris, rare or few polymorphonuclear leukocytes (because of cell lysis), and the bacterial etiology. Culture should confirm the etiology and provide antimicrobial testing results where appropriate.

Anaerobic Abscess

Anaerobes characteristically produce purulent infections in areas adjacent to mucous membranes containing anaerobes from the normal flora. Specimens must be transported to the laboratory in sterile, oxygen-free containers (148). As reviewed above, aspirated fluid or excised tissue is the recommended specimen. Specimens should be stored at room temperature (not refrigerated) during transport and processing delays. Infections of the mouth and gums (and adjacent areas), aspiration pneumonia, empyema, intra-abdominal infections, deep tissue abscesses, infections of the female genital tract, infected pressure sores, and diabetic foot ulcers are caused generally by a mixture of aerobes and anaerobes. Because of the usual microscopic appearance of mixed aerobic-anaerobic abscesses, the Gram stain can rapidly identify these infectious processes (Fig. 8). The presence of many polymorphonuclear leukocytes, many bacteria with anaerobic morphotypes (thin gram-negative bacilli, thin and poorly staining gram-positive bacilli, and boxcar-shaped gram-positive bacilli suggesting *Clostridium* spp.), and many intracellular bacteria suggests the presence of a mixed aerobic-anaerobic infectious process. Culture can determine the exact etiologies, characteristically a mixture of aerobes and anaerobes. However, the identification of most anaerobic bacteria and their susceptibility results are not necessary for the management of mixed infections. Aerobic and facultative bacteria present need full identification and antimicrobial testing results for proper therapeutic selection.

Specimens for anaerobic culture should be processed as soon as possible after arrival in the laboratory. Usual media include an anaerobic blood agar plate (CDC blood agar or brucella blood agar), a medium that inhibits gram-positive and facultative gram-negative bacilli such as blood agar with kanamycin and vancomycin, a differential or selective medium such as *Bacteroides* bile-esculin, and a gram-positive selective medium such as colistin-nalidixic acid blood agar or phenylethyl alcohol blood agar (Table 5). Media should be incubated in an anaerobic environment immediately after inoculation. Incubation in anaerobic containers, such as GasPak jars (Becton Dickinson Microbiology Systems, Cockeysville, Md.), AnaeroPack (Mitsubishi Gas Chemical America, Inc., New York, N.Y.), or Bio-Bag Anaerobic Culture Set (Becton Dickinson Microbiology Systems), or in an anaerobic chamber is acceptable (36, 37). Anaerobes grow more slowly than aerobic or facultative bacteria, necessitating a full 48 h of incubation before colony size is large enough to interpret accurately. Negative anaerobic cultures should be held for 3 to 5 days before being reported as negative. Longer incubation is necessary for isolation of *Actinomyces* and some other fastidious anaerobes.

Autopsy Specimens

Microbiology testing as a component of the autopsy examination has been and continues to be controversial (114, 174, 225). Postmortem and agonal invasion of sterile tissues confuses the significance of positive culture results, prompting some to argue against microbiology testing. Others have found that postmortem examination continues to uncover a significant number of infectious diagnoses, whether in the community or university hospital setting, which were missed by modern high-technology medicine (97). In addition, an important portion of missed diagnoses represents treatable diseases (136). The value of autopsy microbiology is further enhanced by its use to identify emerging diseases, etiologies of biological warfare, community outbreaks, nosocomial infections, and antimicrobial resistance and to uncover the cause of death in organ transplant patients and others with immunocompromising conditions. Safety precautions designed to protect the pathologist and dissection assistants during autopsy procedures have been thoroughly reviewed (139).

To minimize contamination of postmortem specimens, the body should be moved to a refrigerated locker (4 to 6°C) as soon as possible after death. Limited movement of the body has been shown to decrease the incidence of false-positive postmortem cultures (43). Although it has been shown that cultures collected within 48 h of death from a refrigerated cadaver did not show an increase in false-positive results, tissue and fluid specimens, as a rule, should be taken

from refrigerated bodies within 15 h of death (93). This serves to diminish the likelihood of postmortem overgrowth of contaminants and improve detection of true pathogens.

Specimens should be obtained by sterilizing the surface of the organ with a hot spatula or iron surface until the surface is thoroughly dry (43). Body fluids, including blood, should be collected first. For blood collection, the wall of the heart and large vessel should be seared and a sterile needle (18 to 20 gauge) should be inserted. A 20-ml volume, or as close to 20 ml as possible, should be collected and injected directly into aerobic and anaerobic blood culture bottles. Blood culture results obtained before opening the chest cavity by percutaneous subxyphoid aspiration have been shown to have greater interpretive value (less contamination but detection of relevant organisms). Most conclude that postmortem blood cultures rarely provide information that is not already known. Solid viscera should be sampled by immediately cutting blocks of tissue from the center of the seared area. Samples should be submitted to microbiology with a requisition providing a full explanation of the studies needed. Postmortem cultures can be very useful for detecting pathogens that are not considered normal human flora, such as *M. tuberculosis*, *Brucella* spp., *B. pertussis*, some systemic fungi (*Histoplasma capsulatum*, *Coccidiodes immitis*, etc.), parasitic helminths, and agents of biological warfare. Tissue samples should be transported to the microbiology laboratory immediately in sterile tubes. The use of transport media and laboratory processing methods should follow recommendations for premortem specimens. An efficient way to avoid unnecessary workup of contaminating microorganisms is to issue a preliminary report to the pathologist who performed the autopsy listing organisms detected by colony or Gram stain morphology, such as "lactose-fermenting gram-negative rod" or "gram-positive cocci in clusters." This is accompanied with a notation that further identification and antimicrobial testing will not be performed unless there is consultation with the laboratory director or technologist conducting the culture investigation. Plates can be held for 1 week and discarded if no additional information is requested.

Specimens for the Detection of Agents of Biological Warfare

An excellent review of the potential agents of biological warfare and their management in the clinical microbiology laboratory can be found in Cumitech 33 and chapter 9 of this Manual (61, 92).

Reagents, Stains, and Media: Bacteriology

KIMBERLE C. CHAPIN AND TSAI-LING LAUDERDALE

21

REAGENTS

The reagents listed in this chapter include those in common use and a few highly specialized ones. For information on specific reagents not included here, refer to literature cited in the chapter in which the reagent is mentioned or the general references listed at the end of this chapter (11, 49). Reagents are listed in alphabetical order, with brief descriptions of their intended uses and ingredients. The test protocol is included where appropriate. A fresh 18- to 24-h pure broth culture or well-isolated colonies from nonselective medium are most often appropriate to use for testing. Many of these reagents and tests are available commercially either individually or incorporated into commercial identification systems. The reader should be aware that commercial preparations in which two reagents are already combined may not contain the traditional percentage of each reagent and may require adjustment of laboratory protocols. Mycobacterial mucolytic and decontamination preparations from a number of manufacturers are an example. Unless stated otherwise, the reagents listed in this section should be prepared by dissolving the reagent components in the stated liquid with a magnetic stirring bar. The standard sterilization technique of autoclaving at 121°C at 15 lb/in^2 for 15 min followed by a slow exhaust cycle should be used when needed. However, certain solutions, such as those containing antibiotics or carbohydrates, cannot be autoclaved because the supplements will be denatured. These solutions are sterilized by filtration through a 0.22-μm-pore-size filter. Additionally, certain reagents require different heat sterilization times. Instructions for reagents that require special preparation or sterilization protocols are included in the discussion of the reagent.

It is critical that distilled, deionized water be used in the preparation of all components. Removal of contaminating pyrogens and minerals from water used for culture reagents is imperative, especially for the success of cell culture systems.

Storage of prepared reagents in sterile, airtight, screw-cap containers is recommended. Some reagents require storage in dark containers, and some need to be stored refrigerated (2 to 8°C) instead of at room temperature. Special storage instructions are given when appropriate. Standard safety precautions should be taken when preparing the reagents. Follow the safety guidelines for the chemicals being used, in addition to the laboratory safety protocols. For reagents that are prepared in-house, proper quality control measures must be taken with appropriate positive and negative controls.

■ Acetoin (acetyl-methyl-carbinol)

See Voges-Proskauer (VP) test.

■ *N*-Acetyl-L-cysteine-sodium hydroxide (NALC-NaOH)

NALC is a mucolytic agent used for digestion, and NaOH is a decontamination agent used in the processing of specimens for mycobacteriology. Sodium citrate is included in the mixture to exert a stabilizing effect on the acetylcysteine.

4% NaOH, sterile	50 ml
2.9% Sodium citrate, sterile	50 ml
NALC powder	0.5 g

Mix well in a sterile container. Use within 24 h of preparation.

■ L-Alanine-7-amido-4-methycoumarin (Gram-Sure; Remel)

Gram-Sure is a reagent-impregnated disk with the fluorogenic compound L-alanine-7-amido-4-methycoumarin. This is a rapid disk test that is used as an adjunct to the Gram stain to distinguish between gram-negative and gram-positive aerobic rods or coccobacilli and is used most commonly with gram-positive organisms that may appear gram variable or gram negative, such as *Bacillus* or *Lactobacillus*. The mechanism of the test is dependent on the presence of aminopeptidase in the cell walls of gram-negative organisms, which will hydrolyze the reagent L-alanine-7-amido-4-methycoumarin in the disk from a nonfluorescent substrate to a blue fluorescent compound. A pure colony growth is inoculated into demineralized water and then inoculated onto the disk. The disk is incubated at room temperature for 5 to 10 min and then observed under long-wave UV light for blue fluorescence. Blue fluorescence is gram negative, and the absence of blue fluorescence is gram positive. Obligate anaerobes may fail to give expected results (50).

■ Bile solubility (10% sodium deoxycholate)

The bile solubility test is used as a presumptive identification test for *Streptococcus pneumoniae*. Sodium deoxycholate is a surface-active bile salt. It acts upon the cell wall of pneumococci, resulting in cell lysis. The test is performed

with alpha-hemolytic streptococcal colonies. Oxgall is a dehydrated bile that can be used, but sodium deoxycholate is preferred.

Sodium deoxycholate	1.0 g
Sterile distilled water	9.0 ml

The pH should be 7.0. Store refrigerated in a sterile dark bottle.

Tube method
Prepare a heavy suspension of the organism in 2 ml of buffered broth (pH 7.4) or physiological saline (pH 7.0). The pH of the solution should not be below 6.8. Divide the organism suspension into two tubes. To one tube add a few drops of the 10% sodium deoxycholate solution. To the other tube add the same amount of sterile physiological saline. Incubate at 35°C. If the organism is bile soluble, the tube containing the bile salt will lose its turbidity in 5 to 15 min and show an increase in viscosity concomitant with clearing.

Agar colony test
Put a couple of drops of sodium deoxycholate on the suspected colonies. Incubate the plate right side up for 30 min at 35°C. Pneumococcal colonies will be lysed, but viridans group streptococci will not.

■ Bovine albumin fraction V, 0.2%

The 0.2% bovine albumin solution is used to buffer specimens for mycobacterial culture following decontamination with NALC-NaOH.

Bovine albumin solution, 5%	40.0 ml
Sodium chloride	8.5 g
Distilled water	960.0 ml

Adjust to pH 6.8 ± 0.2 with 4% NaOH. Sterilize by filtration. Aliquot into sterile screw-cap tubes. Store refrigerated.

Following decontamination and concentration by centrifugation, the sedimented specimen is resuspended in 1 to 2 ml of sterile 0.2% bovine albumin fraction V. This suspension is then used to inoculate media and prepare microscopic smears.

■ Catalase

Hydrogen peroxide (H_2O_2) is used to determine if bacteria produce the enzyme catalase. H_2O_2 (3%) is commercially available. Superoxol is a 30% H_2O_2 that is used for identification of *Neisseria* spp. (see chapter 39), and a 15% concentration is often used for differentiation and identification of anaerobes.

Slide method
Transfer a test colony to a clean glass slide and add 1 drop of 3% H_2O_2. Development of bubbles is considered a positive result. Extreme care should be taken to avoid picking up any media from a blood-containing agar plate because catalase is present in erythrocytes and any carryover of blood cells can cause a false-positive reaction. Hydrogen peroxide solution for detection of catalase in anaerobes is typically 15%.

Tube method
Add 1.0 ml of 3% H_2O_2 to an overnight pure culture slant. (Do not use blood agar medium.) Observe for immediate bubbling.

■ Cetylpyridinium chloride-sodium chloride (CPC-NaCl)

CPC-NaCl is used for decontamination of transported sputum specimens for mycobacteriology culture.

CPC	1 g
Sodium chloride	2 g
Distilled water	100 ml

Mix and store in a sealed brown bottle at room temperature. If crystals form, the solution should be gently heated before use.

An equal amount of sputum and CPC-NaCl is mixed until the specimen is liquefied, and then the specimen can be shipped to the testing site. Specimens treated with CPC-NaCl must be cultured on egg-based media or else residual CPC will inhibit mycobacterial growth.

■ Coagulase

The coagulase test is used to detect free coagulase or bound coagulase (clumping factor) and differentiate coagulase-producing *Staphylococcus* from other *Staphylococcus* spp. Dehydrated rabbit plasma reagent with EDTA is commercially available. Rehydrate and perform the test according to the manufacturer's directions. While human plasma is preferred for detection of clumping factor with *Staphylococcus lugdunensis* and *Staphylococcus schleiferi*, it is not recommended for routine testing because it may contain antibodies against staphylococci.

Slide test
The slide test detects bound coagulase (clumping factor). Emulsify a heavy suspension of staphylococci in a small drop of water on a clean glass slide. If autoagglutination occurs, do not continue; instead, perform a tube test. Add 1 small drop of rabbit plasma reagent to the suspension. Mix with a continuous circular motion while observing for the formation of visible white clumps. Known positive and negative controls should be set up in parallel. Negative or delayed positive (20 to 60 s) results should be confirmed by the tube test.

Tube coagulase test
The tube coagulase test detects bound and free coagulase. Dispense 0.5 ml of rabbit plasma into a sterile tube. Inoculate a loopful of the test organism into the tube. Incubate the tube at 35°C for 4 h. Observe for clotting at intervals during the first 4 h because some staphylococci produce fibrolysin, which could lyse the clot. Do not shake or agitate the tube while checking for clotting. The formation of a clot is considered positive. The majority of coagulase-positive *Staphylococcus aureus* isolates will form a clot within 4 h. Incubate the tube at room temperature overnight if no visible clot is observed after 4 h. However, a clot may have formed and subsequently dissolved over the 24 h, so overnight incubation is not always specific. Some investigators have recommended incubation at 35°C.

■ Dyes and pH indicators

A variety of dyes and pH indicators are used in media and reagents. The most common are given in Table 1.

■ Efrotomycin

Efrotomycin is used to separate *Enterococcus casseliflavus* and *Enterococcus gallinarum* (resistant) from *Enterococcus faecium* (susceptible). Dissolve 100 mg of efrotomycin (Merck

TABLE 1 Dyes and pH indicators

Indicator	pH and color
Acid fuchsin (Andrade's)	5.0, pink
	8.0, pale yellow
Bromcresol green	3.8, yellow
	5.4, blue
Bromcresol purple	5.2, yellow
	6.8, purple
Bromphenol blue	3.0, yellow
	4.6, blue
Bromthymol blue	6.0, yellow
	7.6, dark blue
Chlorcresol green	4.0, yellow
	5.6, blue
Chlorphenol red	5.0, yellow
	6.6, red
Cresolphthalein	8.2, colorless
	9.8, red
m-Cresol purple	7.4, yellow
	9.0, purple
Cresol red	7.2, yellow
	8.8, red
Methyl red	4.4, red
	6.2, yellow
Neutral red	6.8, red
	8.0, yellow
Phenolphthalein	8.3, colorless
	10.0, red
Phenol red	6.8, yellow
	8.4, red
Resazurin	Oxidized: blue, nonfluorescent
	Reduced: red, fluorescent
Thymol blue	8.0, yellow
	9.6, blue
Triphenyl-tetrazolium chloride	Oxidized: colorless
	Reduced: red

Sharpe & Dohme) in 0.1 ml of dimethyl sulfoxide and dilute in 9.9 ml of sterile distilled water. Dispense 10 μl of this solution onto filter paper disks and dry in the dark at room temperature for 5 to 6 h. A heavy inoculum of bacteria is spread with a loop or swab over half of a Trypticase soy blood agar plate, the efrotomycin disk is then placed on the heavy inoculum, and the plate is incubated for 18 to 24 h at 35°C. Organisms with any growth inhibition are considered efrotomycin susceptible. The availability of this antibiotic may be limited. An alternative test is the 1-*O*-methyl-α-D-glucopyranoside test (see below).

■ Ehrlich reagent

See Indole test.

■ Ferric ammonium citrate, 1%

Hydrolysis of esculin to esculetin is detected when the product reacts with ferric ammonium citrate to form a brown or black complex.

Dissolve 1.0 g of ferric ammonium citrate in 100 ml of distilled water. Store in a dark bottle, refrigerated, for up to 1 year.

After esculin broth is inoculated with the test organism and incubated for 1 to 2 days, a few drops of ferric ammonium citrate are added. A brown-black color develops immediately in positive tests. This test can also be performed by incorporating an iron salt into esculin agar medium.

■ Ferric chloride reagent

Ferric chloride reagent is used in both the phenylalanine deaminase test and the sodium hippurate hydrolysis test.

Ferric chloride ($FeCl_3 \cdot 6H_2O$)	12 g
Hydrochloric acid, 2%	100 ml

Hydrochloric acid (2%) is prepared by adding 5.4 ml of concentrated hydrochloric acid (37%) to 94.6 ml of distilled water.

Test procedure. Adding 4 or 5 drops of ferric chloride reagent onto overnight growth on phenylalanine agar or broth performs the phenylalanine deaminase test. If phenylpyruvic acid has formed, a brown color develops in the medium (positive reaction). Ferric chloride reagent can also be added to inoculated broths (e.g., heart infusion broth or Todd-Hewitt broth) supplemented with hippurate. Hydrolysis of hippurate produces benzoic acid and glycine. An insoluble brown ferric benzoate precipitate will form in a positive hydrolysis reaction.

■ Fildes enrichment

Fildes enrichment is a source of growth factors used to supplement media for the isolation of fastidious organisms. Commercial preparations are available and include the following ingredients.

Pepsin	4.0 g
Sodium chloride	5.4 g
Sodium hydroxide	70.0 ml
Hydrochloride acid, concentrated	24.0 ml
Sheep blood	200 ml
Deionized water	600 ml

The pH should be 7.0 ± 0.2. Media should be supplemented to a final concentration of 5.0%.

■ Formate-fumarate

Supplementation of media with formate and fumarate has been used to characterize selected anaerobes (e.g., *Bacteroides ureolyticus*).

Sodium formate	3.0 g
Fumaric acid	3.0 g
Distilled water	50.0 ml

To adjust the pH, add 20 pellets of NaOH, stirring until the pellets are dissolved and the fumaric acid is in solution. Bring the final pH to 7.0 with 4 N NaOH. Sterilize by filtration. Store refrigerated for up to 6 months. Add 0.5 ml of this solution to 10 ml of thioglycolate broth. Anaerobic growth in supplemented broth is then compared with the growth in unsupplemented broth.

■ β-Galactosidase

See *o*-Nitrophenyl-β-D-galactopyranoside (ONPG).

■ β-Glucuronidase (see also β-Methylumbelliferyl-β-D-glucuronidase [MUG] test)

Detection of β-glucuronidase activity is useful for the rapid identification of *Escherichia coli,* members of the *Streptococcus*

anginosus group, and other bacteria. A solution of 0.1% (wt/vol) *p*-nitrophenyl-β-D-glucopyranoside (colorimetric substrate) in 0.067 M Sorensen phosphate buffer (pH 8.0) is prepared. Tubes containing 0.5 ml of the substrate solution are inoculated with a loopful of bacteria from an overnight culture. The tubes are incubated at 35°C and examined after 4 h for the appearance of a yellow color (liberated *p*-nitrophenol). The fluorometric substrate 4-methylumbelliferyl-β-D-glucuronide is commercially available and yields a fluorescent product when hydrolyzed by β-glucuronidase.

■ Glycine-buffered saline

Glycine-buffered saline (0.043 M glycine, 0.15 M NaCl [pH 9.0]) is used in some serological procedures and is also used as a transport medium for enteric organisms.

Glycine	3.23 g
NaCl	8.77 g
Distilled water	1,000 ml

■ Hemin solution, 5-mg/ml stock

Hemin solution is one of the additives in thioglycolate and *Brucella* base medium that makes them enriched for fastidious organisms. Dissolve 0.5 g of hemin in 10 ml of 1 N NaOH. Bring the volume up to 100 ml with distilled water (final concentration of stock solution, 5 mg/ml). Sterilize by autoclaving. Store refrigerated for up to 1 month. It is used at a final concentration of 5μg/ml of medium.

■ Hippurate test

The hippurate test measures the hydrolysis of sodium hippurate. Hippurate is hydrolyzed to benzoic acid and glycine by the enzyme hippurate hydrolase (hippuricase), which is produced by some bacteria, including group B streptococci (GBS), some *Listeria* spp., *Gardnerella vaginalis, Campylobacter jejuni,* and *Legionella pneumophila*. The procedure described here detects the presence of glycine with the ninhydrin reagent. Ferric chloride reagents can also be used (see above).

Test procedure. A 1% (wt/vol) solution of sodium hippurate is prepared in 0.067 M Sorensen phosphate buffer (pH 6.4). Tubes containing 0.5 ml of this solution are inoculated and incubated at 35°C for 2 h, after which 0.2 ml of the ninhydrin reagent is added. Development of a deep blue-purple color within 5 min is a positive reaction.

For *L. pneumophila,* inoculate a 0.5-ml aliquot of 1% sodium hippurate solution with a loopful of organism and incubate at 35°C in ambient air for 18 to 20 h. Add 0.2 ml of ninhydrin reagent, mix well, and incubate for an additional 10 min at 35°C. Observe for 20 min for blue-purple color development.

Ninhydrin reagent, 3.5%

Ninhydrin	3.5 g
Acetone	50 ml
1-Butanol	50 ml

Mix acetone and butanol in a sterile dark container. Add ninhydrin, mix, and store at room temperature.

■ Indole test

The indole test is used for the determination of the organism's ability to produce indole from deamination of tryptophan by tryptophanase. Both the Ehrlich and Kovàcs reagents should be stored refrigerated away from light. For the Ehrlich and Kovàcs reagents, dissolve the aldehyde in alcohol and then slowly add acid to the mixture.

Ehrlich reagent

Ethyl alcohol, 95%	95 ml
p-Dimethylaminobenzaldehyde	1 g
Hydrochloric acid, concentrated	20 ml

Test procedure. Indole is first extracted with xylene. Add 1 ml of xylene to a 48-h tryptone broth or other tryptophan-containing broth medium. Shake the tube vigorously for 20 s and let stand for 1 to 2 min to allow the xylene extract to come to the top of the broth. Gently add 0.5 ml of the Ehrlich reagent down the side of the tube. Do not shake the tube. A red ring at the interface of the medium and the reagent phase within 5 min represents a positive test. Ehrlich's reagent is preferred for organisms that produce small amounts of indole such as nonfermenters and anaerobes.

Kovàcs indole reagent

Pure amyl or isoamyl alcohol	150 ml
p-Dimethylaminobenzaldehyde	10 g
Hydrochloric acid, concentrated	50 ml

Test procedure. Add 5 drops of Kovàcs reagent to either 48-h-old 2% tryptone broth or an 18- to 24-h-old tryptophan broth culture. Do not shake the tube after the addition of reagent. A red color at the surface of the medium is a positive test.

Spot indole test

p-Dimethylaminocinnamaldehyde (DMACA)	200 mg
Hydrochloric acid, concentrated	2 ml
Distilled water	18 ml

Add the acid to the water, and let it cool before adding DMACA.

Test procedure. Moisten a piece of Whatman no. 3 paper with a couple drops of the reagent. Remove a well-isolated colony from an 18- to 24-h-old culture onto a blood agar plate with a sterile inoculating loop or a wooden stick and smear it onto the moistened filter paper. Observe for a blue to blue-green color within 2 min, which is a positive reaction. No color change or a pinkish tinge is considered negative. This test should be used only on colonies from media containing sufficient tryptophan and no glucose. Colonies from media containing dyes (e.g., MacConkey or eosin-methylene blue [EMB] agar) may cause misleading results and should not be used. Colonies from mixed cultures should not be used, as indole-positive colonies can cause indole-negative colonies to appear weakly positive.

■ LAP (leucine aminopeptidase or leucine arylamidase) test

The LAP test detects the presence of leucine aminopeptidase (LAP). The substrate leucine-α-naphthylamide is hydrolyzed by LAP to leucine and free α-naphthylamine. a-Naphthylamine reacts with DMACA to form a red color. The LAP test, along with pyrrolidonyl-α-naphthylamide (PYR) hydrolysis, is helpful in the presumptive characterization of catalase-negative, gram-positive cocci (streptococci, enterococci, and streptococcus-like organisms). Some commercial identification kits include an assay for this enzyme, and commercial rapid disk tests are also available.

■ Lysozyme solution

Lysozyme	50 mg
Hydrochloric acid, 0.01 N	50 ml

Mix and sterilize by filtration. Store refrigerated. It may be stored for only 1 week.

Test procedure. Add 5 ml of lysozyme solution to 95 ml of basal glycerol broth, dispense in 5-ml aliquots, and keep refrigerated. Growth of the test organism in the lysozyme-supplemented glycerol broth is compared with the growth in the unsupplemented glycerol broth.

■ Lysozyme test

The lysozyme test measures the ability of organisms, such as *Nocardia*, to grow in the presence of lysozyme.

Basal glycerol broth

Peptone	1.0 g
Beef extract	0.6 g
Glycerol	14.0 ml
Distilled water	200 ml

Mix well and autoclave to sterilize. Store refrigerated. It may be stored for up to 3 months.

■ McFarland standard

For different McFarland standards, mix the designated amounts of 1% anhydrous barium chloride ($BaCl_2$) and 1% (vol/vol) cold pure sulfuric acid (H_2SO_4) as shown in Table 2 in screw-cap tubes. Tightly seal the tubes. When the barium sulfate is shaken up well, the density in each tube corresponds approximately to the bacterial suspension listed in Table 2. Store the prepared standard tubes in the dark at room temperature. The absorbance of the 0.5 McFarland standard should be 0.08 to 0.10 at 625 nm using a spectrophotometer with a 1-cm light path. The standard should be checked regularly to make sure the density is still accurate.

■ 1-*o*-Methyl-α-D-glucopyranoside (MGP) (α-methyl-D-glucoside)

The MGP test is used to separate *E. casseliflavus* and *E. gallinarum* (positive) from *Enterococcus faecalis* and *E. faecium* (negative). Heart infusion broth is prepared with 1% MGP and 0.006% bromcresol purple indicator, distributed into 2-ml aliquots, and autoclaved for 10 min. The broth is inoculated with a drop of an overnight broth culture or several colonies from a blood agar plate and incubated for 1 day at 35°C. Prolonged incubation (for up to 7 days) may be necessary. Development of a yellow color indicates a positive reaction.

TABLE 2 McFarland standards protocol

Standard	Vol (ml)		Corresponding bacterial suspension (10^8 CFU/ml)
	1% $BaCl_2$	1% H_2SO_4	
0.5	0.05	9.95	1.5
1	0.1	9.9	3
2	0.2	9.8	6
3	0.3	9.7	9
4	0.4	9.6	12
5	0.5	9.5	15
6	0.6	9.4	18
7	0.7	9.3	21
8	0.8	9.2	24
9	0.9	9.1	27
10	1.0	9.0	30

■ Methylumbelliferyl-β-D-glucuronidase (MUG) test (see also β-Glucuronidase)

The MUG test is the fluorogenic assay for β-glucuronidase. The enzyme hydrolyzes the substrate 4-methylumbelliferyl-β-D-glucuronide to yield 4-methylumbelliferyl, which fluoresces blue under long-wave UV light. The test is normally used for the presumptive identification of *E. coli* and more recently for streptococcal strains. The colorimetric test method is described under β-Glucuronidase.

Dissolve 50 mg of 4-methylumbelliferyl-β-D-glucuronide in 10 ml of 0.05 M Sorensen phosphate buffer, pH 7.5. Dilute 1:16 of the stock 4-methylumbelliferyl-β-D-glucuronide and add 1.25 ml to a vial containing 50 sterile paper disks. Allow the disks to be thoroughly saturated until no liquid remains in the vial. Spread the saturated disks out and allow to dry completely. The disks can be stored in a dark bottle at −20°C for 1 year or at 4°C for 1 month.

Test procedure. Wet disk with 1 drop of sterile water. Apply the organism to the disk using a wooden stick or loop and then incubate the disk for up to 2 h at 35°C. Shine a long-wave UV light on the disk. A positive reaction is indicated by blue fluorescence. A negative reaction is indicated by the lack of fluorescence.

■ Middlebrook enrichment (oleic acid-albumin-dextrose-catalase [OADC] and albumin-dextrose-catalase [ADC])

The Middlebrook enrichment is added to various Middlebrook media. The OADC and enrichment contain oleic acid as a carbon source, and both supplements contain dextrose as a carbon source and bovine albumin fraction V and catalase as growth factors. WR 1339 Triton encourages cording in *Mycobacterium tuberculosis*. All the enrichments described below are prepared in 100 ml and added to 900 ml of preautoclaved medium that has been cooled to 50 to 55°C.

OADC enrichment

Bovine albumin fraction V	5.0 g
Dextrose	2.0 g
Sodium chloride	0.85 g
Oleic acid	0.05 g
Catalase	4.0 mg (0.004 g)

Add all components to distilled and deionized water and bring the volume to 100 ml. Mix thoroughly and filter sterilize.

OADC enrichment with WR 1339

Add 0.25 g of WR 1339 Triton to the above OADC ingredients. Prepare as described above.

ADC enrichment

Bovine albumin fraction V	5.0 g
Dextrose	2.0 g
Catalase	4.0 mg (0.004 g)

Add all components to distilled and deionized water and bring the volume to 100 ml. Mix thoroughly and filter sterilize.

■ Modified oxidase

The test is used for differentiation of *Micrococcus* and related organisms from most other aerobic gram-positive cocci. Six percent tetramethyl-*p*-phenylenediamine dihydrochloride (the same chemical used in Kovàcs oxidase reagent) dissolved in dimethyl sulfoxide is used as the reagent. Keep the reagent away from light. A loopful of colonies from blood agar plates is smeared onto filter paper, and the reagent is dropped onto the bacterial growth. Development of a blue to purple-blue color in 2 min indicates a positive reaction. Commercially prepared disks are available (26).

■ Nessler reagent

The Nessler reagent is used in the determination of acetamide hydrolysis by some gram-negative bacteria.

Nessler reagent

Solution A
Dissolve 1 g of mercuric chloride in 6 ml of distilled water. Add 2 or 3 drops of concentrated hydrochloric acid (HCl) to dissolve the sediment.

Solution B
Dissolve 2.5 g of potassium iodide in 6 ml of distilled water completely. Add to solution A.

Solution C
Dissolve 6 g of potassium hydroxide in 6 ml of distilled water completely. Add to the mixture of solutions A and B. Add 13 ml of distilled water. Mix well. Filter using a sintered-glass funnel before use and store in a dark bottle. Note: do not use a Nalgene filter. The Nessler reagent solution may decompose at room temperature after several weeks and should therefore be checked with each use.

Test procedure. Inoculate 1 ml of mineral-based broth medium (carbon assimilation medium) supplemented with 0.1% acetamide. After incubation for 24 h at 30°C, 1 drop of Nessler reagent is added. A positive reaction is indicated by a red-brown sediment due to the presence of ammonia from the action of acylamidase. Acetamide agar is available commercially.

■ Nitrate reduction

The nitrate reduction test is used to determine the ability of an organism to reduce nitrate to nitrite or free nitrogen gas.

Reagent A

N,*N*-Dimethyl-naphthylamine	0.6 ml
Acetic acid (5 N), 30%	100 ml

Reagent B

Sulfanilic acid	0.8 g
Acetic acid (5 N), 30%	100 ml

Store each reagent in a brown glass bottle in the refrigerator. Store away from light.

Test procedure. At the time of testing, mix equal portions of the reagents and then add 10 drops to the overnight growth from the nitrate broth culture. A positive reaction is indicated by the development of a red color within 1 to 2 min, which means that nitrate has been reduced to nitrite. Negative reactions are confirmed by adding a pinch (approximately 20 mg) of zinc dust with development of red color within 5 to 10 min, which indicates that nitrate has not been reduced by the organism. If the tube remains clear, nitrate has been reduced to free nitrogen gas, and a clear tube is considered a positive reaction.

■ *o*-Nitrophenyl-β-D-galactopyranoside (ONPG)

The ONPG test is used to determine the ability of an organism to ferment lactose. It is especially useful for identification of members of the family *Enterobacteriaceae*. ONPG-impregnated tablets can be purchased commercially. Commercially prepared reagents are recommended because it is tedious and difficult to prepare the reagent in-house.

■ Oxalic acid, 5%

Oxalic acid is used as a decontamination agent for specimens that contain *Pseudomonas* spp. when culturing for mycobacteria. The reagent is especially helpful when processing respiratory specimens from cystic fibrosis patients.

Oxalic acid	50 g
Distilled water	1,000 ml

Autoclave to sterilize and store at room temperature. The solution has an expiration date of 1 year.

■ Oxidase test

The oxidase test detects the presence of a cytochrome oxidase system. Production of a dark blue-purple color on either a filter paper strip or disk indicates a positive test. A number of reagents can be used for this test.

Kovàcs oxidase reagent:
1% tetramethyl-*p*-phenylenediamine dihydrochloride (in water)
Gordon and McLeod's reagent:
1% dimethyl-*p*-phenylenediamine dihydrochloride (in water)
Gaby and Hadley (indolphenol oxidase) reagents:
1% α-naphthol in 95% ethanol
1% *p*-aminodimethylaniline HCl

Kovàcs reagent is less toxic and more sensitive than the other reagents. Add a few drops of the reagent to a strip of filter paper (Whatman no. 2 or equivalent) and then smear a loopful of the organism on the paper using a platinum loop or wooden stick. A wire loop containing iron may give a false-positive reaction. The oxidase test should not be performed on colonies growing on medium containing a high concentration of glucose because the fermentation of glucose may inhibit oxidase activity. Only colonies from nonselective, nondifferential media should be used to detect oxidase. A positive reaction with the Kovàcs reagent develops within 10 to 15 s and is characterized by a dark purple-black color. If the Kovàcs solution becomes blue due to autoxidation, it should be discarded. The dimethyl compound in Gordon and McLeod's reagent is more stable than the tetramethyl compound (Kovàcs reagent). A positive reaction is characterized by a blue color and develops within 10 to 30 min.

■ Oxidase, modified.

See Modified oxidase test.

■ Phosphate-buffered saline (PBS)

10× stock solutions

1. 0.1 M NaH_2PO_4 (sodium phosphate, monobasic). Dissolve 13.9 g of NaH_2PO_4 in 1,000 ml of deionized water.
2. 0.1 M Na_2HPO_4 (sodium phosphate, dibasic). Dissolve 26.8 g of $Na_2HPO_4 \cdot 7H_2O$ in 1,000 ml of deionized water.
3. 8.5% NaCl (sodium chloride). Dissolve 85.0 g of NaCl in 1,000 ml of deionized water. Sterilize by autoclaving for 20 min or by filtration. Store refrigerated.

Working PBS

Prepare a solution of the desired pH by combining the 10× stocks.

0.1 M NaH_2PO_4	See Table 3
0.1 M Na_2HPO_4	See Table 3
8.5% NaCl	100 ml
Deionized water	to 1,000 ml

■ Polysorbate 80

See Tween 80.

■ Potassium chloride solution (0.2 M, pH 2.2)

Potassium chloride is used to treat respiratory specimens for the recovery of *Legionella.*

For 100 ml of potassium chloride, 0.2 M (pH 2.2), solution

Potassium chloride, 0.2 M (solution A): place 1.49 g of potassium chloride into a volumetric flask and dilute to 100 ml with deionized water

Hydrochloric acid, 0.2 M (solution B): add 1.67 ml of concentrated hydrochloric acid to 75 ml of deionized water in a volumetric flask and QS to 100 ml. Add 13.5 ml of solution B to 86.5 ml of solution A and mix.

Potassium hydroxide (0.1 N), used for neutralizing the specimen after mixing with potassium chloride solution: add 0.56 g of potassium hydroxide to a volumetric flask and dilute to 100 ml with deionized water.

TABLE 3 Preparation of pH-specific 0.1 M sodium phosphate buffer[a]

pH	Vol (ml)		pH	Vol (ml)	
	A	B		A	B
5.7	93.5	6.5	6.9	45.0	55.0
5.8	92.0	8.0	7.0	39.0	61.0
5.9	90.0	10.0	7.1	33.0	67.0
6.0	87.7	12.3	7.2	28.0	72.0
6.1	85.0	15.0	7.3	23.0	77.0
6.2	81.5	18.5	7.4	19.0	81.0
6.3	77.5	22.5	7.5	16.0	84.0
6.4	73.5	26.5	7.6	13.0	87.0
6.5	68.5	31.5	7.7	10.5	89.5
6.6	62.5	37.5	7.8	8.5	91.5
6.7	56.5	43.5	7.9	7.0	93.0
6.8	51.0	49.0	8.0	5.3	94.7

[a] A, 0.1 M NaH_2PO_4; B, 0.1 M Na_2HPO_4.

Test procedure. Approximately 0.5 ml of specimen is mixed thoroughly with 4.5 ml of the 0.2 M potassium chloride (pH 2.2) solution, and the mixture is allowed to stand for 15 min at room temperature. The mixture is then neutralized to pH 7.0 with 0.1 N KOH and is inoculated onto isolation media.

■ Pyrrolidonyl-α-naphthylamide (PYR) hydrolysis

PYR is hydrolyzed by organisms that possess the enzyme pyrrolidonyl arylamidase (56). The PYR test is used for rapid presumptive identification of group A alpha-hemolytic streptococci *(Streptococcus pyogenes)*, *Enterococcus* spp., and other gram-positive cocci that grow aerobically and form cells arranged in pairs and chains. A pure culture or isolated colony for testing is critical given the number of PYR-positive organisms with similar Gram stain morphology and hemolytic characteristics.

PYR substrate (L-pyrrolidonyl-α-naphthylamide)

Dissolve L-pyrrolidonyl-α-naphthylamide in methyl alcohol first and then dilute with sterile distilled water. Adjust pH to 5.7 to 6.0. It is used at 0.01% in broth or agar media and at 0.02% in filter paper strips.

PYR reagent (DMACA)

DMACA	200 mg
Hydrochloric acid, concentrated	2 ml
Distilled water	18 ml

Add the acid to the water, and let it cool before adding DMACA.

Tube method. Prepare PYR broth (Todd-Hewitt broth containing 0.01% PYR substrate). Autoclave to sterilize. Dispense 0.15 ml per tube. Emulsify colonies from a blood agar plate in the PYR broth to a turbidity of McFarland no. 2 standard (milky suspension). Incubate at 35°C for 2 h. Add 1 drop of the PYR reagent to each tube, with gentle shaking. Observe for development of a cherry red color after 2 min. Yellow, orange, or orange-pink color is considered negative.

Spot paper strip method. Cut Whatman no. 3 filter paper into strips. Saturate the strips with 0.02% PYR substrate. Dry at room temperature and store desiccated at 2 to 6°C. Prior to testing, moisten the strip with sterile distilled water. Using an inoculating loop or wooden stick, rub colonies onto strip. Incubate for 10 min at 35°C. Then add PYR reagent to the strip and observe for development of a red color change. Yellow, orange, or pink is considered negative. For both methods, a positive reaction is indicated by cherry red to dark purple-red color. A negative reaction is indicated by orange or yellow (no change) color. PYR media, disks, and strips are available commercially.

■ Saline

Saline is used as a diluent in a variety of procedures. Normal or physiological saline is 0.85%.

Sodium chloride	8.5 g
Distilled water	1,000 ml

Other concentrations (e.g., 0.45%) are also used.

■ Skim milk, 20%

Skim milk is used to stabilize bacterial suspensions, particularly those containing anaerobes, for freezing.

Skim milk powder	20 g
Distilled water	100 ml

After the skim milk is dissolved in the water, dispense 0.25 to 0.5 ml into 2-ml vials. Autoclave at 110°C for 10 min. The vials can be refrigerated for up to 6 months.

■ Sodium bicarbonate ($NaHCO_3$), 20 mg/ml

Sodium bicarbonate is added to thioglycolate broth to enrich it for the recovery of anaerobes. Dissolve 2 g of $NaHCO_3$ in 100 ml of distilled water. Filter sterilize and store refrigerated for up to 6 months. Add 0.5 ml to 10 ml of thioglycolate broth.

■ Sodium citrate (0.1 M), 2.9%

Sodium citrate, dihydrate	29.4 g
Distilled water	1,000 ml

Dissolve and autoclave. Store at room temperature. If a precipitate forms, discard and prepare a fresh solution.

■ Sodium hydroxide (1 N), 4%

Sodium hydroxide	40 g
Distilled water	1,000 ml

Dissolve and autoclave. Store at room temperature. If a precipitate forms, discard and prepare a fresh solution.

■ Sodium polyanetholesulfonate (SPS) disks

SPS disks are used to differentiate *Peptostreptococcus anaerobius* (which is inhibited by SPS) from other anaerobic cocci. Dissolve 5 g of SPS in 100 ml of distilled water, filter sterilize, and then dispense 2 μl onto 6-mm-diameter sterile filter paper disks. Allow the disks to dry at room temperature for 72 h. The dried disks are stable at room temperature for up to 6 months. A zone of inhibition of 12 mm indicates that the organism is susceptible.

■ Sorensen pH buffer solutions (M/15 phosphate buffer solutions)

Solution A
M/15 (0.067 M) sodium phosphate, dibasic. Dissolve 9.464 g of anhydrous Na_2HPO_4 in 1 liter of distilled water.

Solution B
M/15 (0.067 M) potassium phosphate, monobasic. Dissolve 9.073 g of anhydrous KH_2PO_4 in 1 liter of distilled water. Mix *x* ml of solution A and solution B as indicated in Table 4 for a buffer of the desired pH.

■ Tween 80 (polysorbate 80), 10%

Tween 80 (polysorbate 80)	10 ml
Distilled water	90 ml

Mix Tween 80 with water until dissolved. Autoclave at 121°C at 15 lb/in^2 for 10 min. Swirl the solution immediately after autoclaving and during cooling to resolubilize the Tween 80.

TABLE 4 Sorensen pH buffer solutions

pH	Vol (ml)	
	Solution A	Solution B
5.29	0.25	9.75
5.59	0.5	9.5
5.91	1.0	9.0
6.24	2.0	8.0
6.47	3.0	7.0
6.64	4.0	6.0
6.81	5.0	5.0
6.98	6.0	4.0
7.17	7.0	3.0
7.38	8.0	2.0
7.73	9.0	1.0
8.04	9.5	0.5

Store refrigerated. The solution can be used for 6 months. Add 0.5 ml of 10% Tween 80 to 10 ml of broth medium when it is used as a medium supplement.

■ Urease test

Rapid enzymatic test used for identification purposes for a number of organisms. The procedure for identifying *Haemophilus* spp. is described.

KH_2PO_4	0.1 g
K_2HPO_4	0.1 g
NaCl	0.5 g
Phenol red, 1:500	0.5 ml

Add all ingredients into 100 ml of distilled water. Adjust the pH to 7.0 with NaOH, and add 10.4 ml of a 20% (wt/vol) aqueous solution of urea. To make 1:500 phenol red, dissolve 0.2 g of phenol red in NaOH and add distilled water to 100 ml. Red color developing within 4 h after inoculation indicates urease activity.

■ Vitamin K_1, 10-mg/ml stock

Vitamin K_1 (3-phytylmenadione) is added to enrich media for the recovery of anaerobes. Mix 0.2 g of vitamin K_1 in 20 ml of 95% ethanol by aseptic technique. Vitamin K_1 is a viscous liquid, and it may be hard to measure the exact amount. Adjust the amount of 95% ethanol accordingly to obtain a 10-mg/ml stock. Store refrigerated in a sterile dark bottle. The stock solution can be further diluted in sterile distilled water to obtain a 1-mg/ml working solution, which can be stored refrigerated in a dark bottle for up to 30 days.

■ Voges-Proskauer (VP) test

The VP test is used to detect acetoin (acetyl-methylcarbinol), which is produced by certain microorganisms during growth in a buffered peptone-glucose broth (MR-VP broth). The VP test is commonly used to aid in the differentiation between genera (such as *E. coli* from the *Klebsiella* and *Enterobacter* groups) and other species of the *Enterobacteriaceae* family. The test can be used as a differential test for other organism groups (viridans group streptococci).

Reagent A: 5%-α-naphthol
Dissolve 5 g of α-naphthol in 100 ml of absolute ethanol. Store refrigerated in a brown glass bottle away from light.

Reagent B: 40% KOH
Dissolve 40 g of potassium hydroxide in 100 ml of distilled water.

Test procedure. Inoculate MR-VP broth and incubate until good growth is obtained. Add 0.6 ml of the α-naphthol solution and 0.2 ml of the 40% KOH to 2.5 ml of culture broth. Shake well after the addition of each reagent. A positive reaction, indicated by the formation of a pink-red product, occurs within 5 min. However, allow 15 min for color development before considering the test negative.

STAINS

Direct Examination of Specimens

The first step in the processing of most clinical material is microscopic examination of the specimen. Direct examination is a rapid, cost-effective diagnostic aid. Methods for direct examination are designed to reveal and enumerate microorganisms and eukaryotic cells. Visible microorganisms may denote the presumptive etiologic agent, guiding the laboratory in the selection of the appropriate isolation media and the physician in the selection of the appropriate empirical antibiotic therapy. The quality of the specimen and the measure of the inflammatory response can also be evaluated. In addition, the direct smear serves as a quality control indicator for attempts to isolate observed organisms (1, 27, 28, 33, 54, 55).

Smear Preparation

Smears may be made from clinical material, culture broths, or isolated colonies. These smears should be prepared on clean glass slides, since dirt and grease may interfere with adhesion of the sample to the slide and with the staining process. The best smears are prepared after thoughtful selection of those portions of the sample most likely to reveal the etiologic agent (e.g., a purulent portion of sputum). Smears should contain enough material for an adequate survey of the specimen but should not be overly thick because thick smears may peel or flake off the slide during staining procedures. Thick smears also make the timing of decolorization harder to judge. Smears from swabs should be prepared by rolling the swab over the slide. This method of application helps to preserve host cell morphology and microorganism cell arrangements. Tissue smears may be prepared either by touching freshly exposed cut surfaces directly onto a slide or by first using a tissue grinder or stomacher to homogenize the sample. However, tissue grinding may distort cellular morphology. Smears from aspirates or body fluids may be prepared in several different ways, depending upon the amount of material and equipment available. When the quantity of a liquid sample is limited, a single drop placed on a slide will suffice. If more sample is available, the material should be centrifuged (1,500 × *g* for 15 min) to concentrate any cells, and the sediment can then be used to prepare the smear. An additional option for the preparation of smears from liquid samples is the use of cytocentrifugation. The cytocentrifuge method uses specimen funnels that are mounted with a slide and filter card and placed in the centrifuge. During centrifugation, the filter card absorbs the supernatant, while cells and microorganisms are centrifuged through a hole in the filter paper strip and are deposited in a continuous layering fashion onto a 6-mm-diameter circular area of the slide. The method is sensitive for the detection of pathogens from sterile body fluids, particularly cerebrospinal fluid (CSF) and peritoneal fluids (10, 62). The method has also been used for detection of acid-fast organisms and *Pneumocystis jiroveci* from respiratory specimens (8, 29). The deposition of specimen in a discrete area and the ability to lyse erythrocytes during centrifugation are particularly advantageous characteristics that allow more rapid and enhanced resolution in a smear examination.

Samples are fixed to the slides with either heat or methanol. Methanol fixation is preferred since heating may produce artifacts, may create aerosols, and may not adhere the specimen adequately to the slide (51). Once dry, the fixed smear is ready for staining.

Smear Preparations and Staining Methods

The following staining methods and techniques are individual methods used most often in the clinical bacteriology laboratory. They are presented in the following categories: wet mounts and single-stain methods, differential, acid-fast, and fluorescent. The stain method and significant characteristics are described. The principles of stains used for all microorganisms are described in chapter 14. Readers are referred to chapters 81, 117, and 134 for those staining procedures most commonly performed in the specialties of virology, mycology, and parasitology, respectively, and to other specific references (6, 23, 39, 47, 51, 58, 66).

Wet Mounts and Single-Stain Methods

■ **Colloidal carbon wet mounts (India ink, nigrosin)**

See chapter 117.

■ **KOH with and without lactophenol cotton blue**

See chapter 117.

■ **Lugol's iodine**

See chapter 134.

■ **Methylene blue stain**

Methylene blue is a simple direct stain used for a variety of purposes. The stain reveals the morphology of fusiform bacteria and spirochetes from oral infections (Vincent's angina). It may also establish the intracellular location of microorganisms such as *Neisseria.* Methylene blue is the stain of choice for identification of the metachromatic granules of diphtheria; however, one should be careful about overstaining, because this will lessen the contrast between the bacteria and the granules. Methylene blue stains organisms or leukocytes a deep blue in a light gray background. *Corynebacterium diphtheriae* appears as a blue bacillus with prominent darker blue metachromatic granules.

Basic procedure
Fix the prepared slide in absolute methanol for 1 to 3 min or heat fix. Air dry the slide and then stain with 0.5 to 1.0% aqueous methylene blue for 30 to 60 s and up to 10 min for possible *C. diphtheriae* granules. Rinse in water, blot dry, and examine at ×100 to ×1,000 magnification.

■ **M'Fadyean stain**

The M'Fadyean stain is a modification of the methylene blue stain developed originally for detecting *Bacillus anthracis* in clinical specimens. The rectangular bacteria stain black-deep

blue in chains of two to a few cells. Virulent *B. anthracis* rods will be surrounded by a clearly demarcated zone giving the appearance of a reddish-pink capsule ("M'Fadyean reaction").

Basic procedure
As *B. anthracis* is suspected, safety precautions must be taken throughout the procedure. All materials, including spent staining washes, should be discarded into disinfectant effective against endospores or autoclaved. See chapter 7. The staining reagent is prepared by dissolving 0.05 mg of methylene blue solution per ml in 20 mM potassium phosphate adjusted to pH 7.3. After the prepared slide is air dried, it is fixed in absolute methanol for 2 to 3 min. The slide is then dried and a large drop of the methylene blue solution is placed on the slide for 1 min. Rinse the slide under water into a 10% hypochlorite solution, blot, and allow to dry. Examine at ×100 to ×1,000 magnification.

Differential Staining Methods

■ Gram staining

Gram staining is the single most useful test in the clinical microbiology laboratory. It is the differential staining procedure most commonly used for direct microscopic examination of specimens and bacterial colonies because it has a broad staining spectrum. First devised by Hans Christian Joachim Gram late in the 19th century, it has remained basically the same procedure and serves in dividing bacteria into two main groups: gram-positive organisms, which retain the primary crystal violet dye and which appear deep blue or purple, and gram-negative organisms, which can be decolorized, thereby losing the primary stain and subsequently taking up the counterstain safranin and appearing red or pink. The staining spectrum includes almost all bacteria, many fungi, and parasites such as *Trichomonas, Strongyloides,* and miscellaneous protozoan cysts. The significant exceptions include organisms such as *Treponema, Mycoplasma, Chlamydia,* and *Rickettsia,* which are too small to visualize by light microscopy or which lack a cell wall. Mycobacteria are generally not seen by Gram staining; however, in smears illustrating heavy infections, the organisms may give a beaded appearance that is somewhat similar to that of *Nocardia* spp. or may exhibit organism "ghosts" (27). Gram staining can also be used to differentiate epithelial and inflammatory cells, thus providing information about the state of infection and the quality of the specimen (34, 54, 55, 63).

The Gram reaction, morphology, and arrangement of the organisms give the physician clues to the preliminary identification and significance of the organisms. Problems with analysis of the Gram staining generally result from errors in preparation of the slide, such as a smear that is too thick, excessive heat fixing (which can distort organisms), improper decolorization, and inexperience. Overdecolorization results in an abundance of bacteria that appear to be gram negative, while underdecolorizing results in too many bacteria that appear to be gram positive. If a chain of cocci resembling streptococci (normally gram positive) and epithelial cells appears to be gram negative, the slide is overdecolorized. Slides stained by Atkins' Gram staining method are less sensitive to decolorization because the mordant is more effective in retaining crystal violet. This allows better visualization of gram-positive organisms, especially those very sensitive to decolorization such as *S. pneumoniae* and *Bacillus* spp. Atkins' method does not offer a significant advantage over the conventional Gram staining procedure in visualizing gram-negative organisms, and in fact, such visualization may be more difficult with some specimens, such as blood cultures.

Other variations of the Gram stain exist in which the counterstain components may be different, specifically for the purpose of enhancing the appearance of gram-negative organisms. An example is the use of basic carbol fuchsin instead of safranin for easier identification of gram-negative anaerobic organisms (Table 2).

Laboratorians should note that organisms may not always stain true to their cell wall. Anaerobic organisms, older cultures, and organisms that are exhibiting the effects of antibiotics may be especially difficult to interpret. Two methods that may help in the cell wall identification include a string test noted to help distinguish gram-negative anaerobes. Another test is a simple fluorogenic disk test, Gram-Sure (Remel), that helps to differentiate aerobic gram-negative organisms (fluoresce blue with long-wavelength UV light) and gram-positive organisms (no fluorescence). See the reagent section for a full description (50).

Laboratories should evaluate various Gram staining procedure and then institute one as the routine procedure. Two methods of Gram staining are presented here. The first method is the conventional Gram staining method used by most laboratories. The second is an altered Gram staining method devised by Atkins (3) in 1920 that uses gentian violet, a different mordant, and acetone as the decolorizing agent. Each of the staining components is readily available commercially from a number of manufacturers (see Appendix 1).

Basic procedure—conventional Gram staining
The prepared slide is fixed in 95% methanol for 2 min. After air drying, the slide is flooded with crystal violet (10 g of 90% dye in 500 ml of absolute methanol). After at least 15 s, the slide is washed with water and flooded with iodine (6 g of I_2 and 12 g of KI in 1,800 ml of H_2O). The slide is washed with water after 15 s, decolorized with acetone-alcohol (400 ml of acetone in 1,200 ml of 95% ethanol), washed immediately, and counterstained for at least 15 s with safranin (10 g of dye in 1,000 ml of H_2O). This slide is then washed, blotted dry, and examined at ×100 to ×1,000 magnification.

Basic procedure—Atkins' Gram staining
The primary stain is gentian violet (20 g of crystal violet is dissolved in 200 ml of 95% methanol, 8 g of ammonium oxalate is dissolved in 800 ml of distilled water, and the solutions are mixed together and filtered after 24 h). The mordant is Atkins' iodine (20 g of crystals is dissolved in 100 ml of 1 N NaOH; the mixture is then combined with 900 ml of distilled water and stored in a brown bottle at room temperature). Acetone is the decolorizer, and safranin is the counterstain. The staining procedure is the same as that used for conventional Gram staining. The two dyes and the mordant should each be allowed to remain on the slide for at least 15 s. More time has little effect. The most critical aspect of this stain is the amount of time that the decolorizer is used. Unfortunately, the amount of decolorizer is directly related to the thickness of the specimen on the slide. The old benchmark that the slide should continue to receive decolorizer until no more crystal violet is seen to be washing away is still true but is difficult to attain in practice.

■ Spore stain (Wirtz-Conklin)

The Wirtz-Conklin spore stain is a differential stain for detection of spores. Spore-forming bacteria and cell debris will appear pink-red with green-staining spores.

Basic procedure
After the prepared slide is air dried and heat fixed, it is flooded with 5 to 10% aqueous malachite green. Stain is left

on the slide for 45 min. Alternatively, the slide can be heated gently to steaming for 3 to 6 min. Heating to steaming enhances the uptake of the stain into the spores. The slide is then rinsed with tap water. Aqueous safranin (0.5%) is used as a counterstain for 30 s. Rinse in water, blot dry, and examine at ×400 to ×1,000 magnification.

■ Wayson stain

The Wayson stain is a modification of the methylene blue stain and is actually a mix of two stains. It has been used for screening CSF for bacteria and amoebae and for demonstrating bipolar staining and examining tissue specimens for *Yersinia pestis* (15). The advantage of this stain is that the contrast between organisms and proteinaceous background is good. Organisms stain dark blue, leukocytes stain light blue and purple, and the background is light blue. However, slides stained by this method cannot be restained with the Gram stain, and the tinctorial qualities of the stain deteriorate over time.

Basic procedure

The staining reagents are prepared by dissolving 0.2 g of basic fuchsin in 10 ml of 95% ethyl alcohol and 0.75 g of methylene blue in 10 ml of 95% ethyl alcohol. The two solutions are added together slowly into 200 ml of 5% phenol in distilled water. The stain is then filtered and stored in an opaque bottle at room temperature. After the prepared slide is air dried, it is fixed in methanol for 2 min and stained for 1 min. Rinse in water, blot dry, and examine at ×100 to ×1,000 magnification.

■ Gimenez stain

The Gimenez stain formula and full description are in chapter 68 and Table 2 in chapter 14. This differential stain is used for the visualization of *Rickettsia* and *Coxiella* from cell cultures and *L. pneumophila*. Carbol fuchsin is the primary stain and fast green and Malachite green are the counterstains, allowing greater contrast with the organisms and background for easier visualization of the organisms. The stain must be heated 48 h prior to use and filtered.

Acid-Fast Staining Methods

The cells of certain organisms contain long-chain (30- to 90-carbon) fatty acids (mycolic acids) that give them a coat impervious to crystal violet and other basic dyes. Heat or detergent must be used to allow penetration of the primary dye into the bacterium. Once the dye has been forced into the cell, it cannot be decolorized by the usual solvent process. The acid-fast stains are useful for identification of a specific group of bacteria (e.g., *Mycobacterium, Nocardia, Rhodococcus, Tsukamurella, Gordonia,* and *Legionella micdadei*) and the oocysts of *Cryptosporidium, Isospora, Sarcocystis*, and *Cyclospora*. The Ziehl-Neelsen (Z-N) stain is one of the original acid-fast stains described. A number of modifications of the Z-N staining procedure have been made to differentiate various acid-fast organisms as well as to simplify the staining process (7, 41, 48, 66).

■ Ziehl-Neelsen (Z-N)

Basic procedure

The prepared slide is heat fixed for 2 h at 70°C. The slide is then flooded with carbol fuchsin (0.3 g of basic fuchsin is dissolved in 10 ml of 95% ethanol, 5 ml of phenol, and 95 ml of water; the solution is filtered before use). Heat the slide slowly to steaming and maintain for 3 to 5 min at 60°C. After cooling, wash with water and decolorize the slide with acid-alcohol (97 ml of 95% ethanol in 3 ml of HCl). Wash and counterstain for 20 to 30 s with methylene blue (0.3 g of dye in 100 ml of H_2O). Wash, blot dry, and examine at ×400 to ×1,000 magnification. An acid-fast organism will stain red, and the background of cellular elements and other bacteria will be blue, the color of the counterstain.

■ Kinyoun stain (Kinyoun modification of Z-N stain)

The basic difference between the Z-N and Kinyoun stains is the replacement of heating with the use of a higher concentration of phenol in the primary stain. The primary stain consists of 4 g of basic fuchsin in 20 ml of 95% alcohol, 8 g of phenol, and 100 ml of distilled water. The Z-N and Kinyoun stains have the same sensitivity and specificity; however, the Kinyoun (cold) staining procedure is less time-consuming and is easier to perform.

■ Modified Kinyoun stain (modified acid-fast stain)

Another modification of the acid-fast staining procedure has been the use of a weaker decolorizing agent (0.5 to 1.0% sulfuric acid) in place of the 3% acid-alcohol. This particular stain helps differentiate those organisms known to be partially or weakly acid-fast, particularly *Nocardia, Rhodococcus, Tsukamurella, Gordonia,* and *Diezia.* These organisms do not stain well with the Z-N or Kinyoun stain.

The acid-fast stains are important clinically and are relatively simple to use. Definitive identification of an acid-fast organism from a clinical specimen cannot be made by staining alone, but certain clues may be helpful. Mycobacteria often appear as slender, slightly curved rods and may show darker granules that give the impression of beading. *M. tuberculosis* can appear as beaded rods arranged in parallel strands or "cords"; *Mycobacterium kansasii* may form long, often broad and banded cells; and *Mycobacterium avium* complex cells appear as short, uniformly staining coccobacilli. *Nocardia* spp. often branch and almost always show a speckled appearance.

Difficulty in interpretation can result from smears that are too thick or insufficiently decolorized, yielding an acid-fast artifact. As a quality control measure, a known acid-fast organism such as nonpathogenic *M. tuberculosis* HRV 37 and a non-acid-fast organism such as *Streptomyces* can be stained in parallel with the clinical specimen.

Factors such as age, exposure to drugs, and a particular acid-fast organism itself may vary the acid-fast presentation. For example, while *M. tuberculosis* is consistently acid fast (with the Z-N or Kinyoun stain), rapidly growing mycobacteria and *Nocardia* are not. Therefore, use of the modified Kinyoun stain may be necessary for these organisms (41, 48, 66). Other modifications used in tissue preparations, such as the Fite-Faraco stain and Pottz stain, may be preferred for unusual isolates such as *Mycobacterium leprae* (66).

Detection of small numbers of acid-fast organisms in clinical specimens is generally significant. However, the use of acid-fast stains for gastric aspirates in the interpretation of pulmonary disease in adults or for stool specimens from human immunodeficiency virus-positive patients in diagnosing *Mycobacterium avium-Mycobacterium intracellulare* infection yields very poor specificity (false-positive smears with saprophytic organisms) as well as poor sensitivity (65). In addition, patients receiving adequate therapy may still have positive smears without positive cultures for a number of weeks. Rarely, small numbers of acid-fast organisms in a smear

may represent transferred contamination or the use of reagents contaminated with nonviable saprophytic mycobacteria (e.g., *Mycobacterium gordonae*). All smear-positive but culture-negative specimens should be investigated carefully.

Fluorescent Staining Procedures

See chapter 13 for fluorochrome filter recommendations.

■ Acridine orange

Acridine orange is a fluorochrome that can be intercalated into nucleic acid in both the native and the denatured states (61). The staining procedure is rapid and is more sensitive than the Gram staining procedure in the detection of organisms in blood culture broths, CSF, and buffy coat preparations (34, 44, 45, 52). Acridine orange is also useful in a number of miscellaneous infections, such as *Acanthamoeba* infections, infectious keratitis, and *Helicobacter pylori* gastritis (31). Bacterial and fungal DNAs fluoresce orange under UV light, and mammalian DNA fluoresces green. Results for cellular specimens or heavily laden bacterial specimens may be difficult to interpret owing to excessive fluorescence, and some interobserver variability may be noted.

Basic procedure

After the prepared slide is air dried and fixed in methanol, it is flooded with the acridine orange solution (stock solution, 1 g of dye in 100 ml of H_2O; working solution, 0.5 ml of stock added to 5 ml of 0.2 M acetate buffer [pH 4.0]). After 2 min, rinse the slide with tap water, air dry, and examine with UV light at ×100 to ×1,000 magnification.

■ Auramine-rhodamine

Auramine and rhodamine are nonspecific fluorochromes that bind to mycolic acids and that are resistant to decolorization with acid-alcohol (28). Staining procedures with these fluorochromes are thus equivalent to the fuchsin-based acid-fast procedures. The stain has become commonplace in laboratories that routinely perform acid-fast examinations because it allows rapid screening of specimens and because the procedure is more sensitive than the traditional acid-fast procedures. Acid-fast organisms fluoresce orange-yellow in a black background. If the secondary stain is not used, the organisms will fluoresce a yellow-green color. Smears with suspicious organisms may be confirmed directly with a Kinyoun stain. However, a single organism or a small number of organisms may be difficult to confirm.

Basic procedure

The prepared slide is fixed at 65°C for at least 2 h. It is then stained for 15 min with the auramine-rhodamine solution (1.5 g of auramine O, 0.75 g of rhodamine B, 75 ml of glycerol, 10 ml of phenol, and 50 ml of H_2O) and rinsed with water, followed by decolorization for 2 to 3 min with 0.5% HCl in 70% ethanol. After being rinsed, the slide is counterstained with 0.5% potassium permanganate for 2 to 4 min. The slide is rinsed, dried, and examined under UV light at ×100 to ×400 magnification.

Antibody Staining Methods

See chapter 18 on immunoassays.

MEDIA

This section reviews the basic components necessary in media for the growth and identification of organisms isolated in the clinical microbiology laboratory, specifically bacteriology. Media for the major groups of microorganisms are listed alphabetically. Refer to chapter 14 for discussion of principles of different media. The specific intended use and significant components are provided for each medium. Because media may be purchased from a number of suppliers and minor formulation variations exist for each medium, formulas as well as inoculation and incubation conditions, quality control, and limitations to the use of the media are not specifically mentioned except in rare instances. Readers are referred to comprehensive references on microbiological media (4, 7, 12, 20, 24, 25, 38, 40, 60, 70), including the *Handbook of Media for Clinical Microbiology*, 2nd edition (5), by R. M. Atlas and J. W. Snyder. In addition, the package inserts or websites from each company with purchased and/or specialized media offer excellent and specific descriptions. Recently, the first edition of a combined manual of both Difco and BBL products has been published as *The Difco and BBL Manual* (9). This manual includes numerous color photographs that depict colony morphology and color reactions as well as extensive descriptions of media and relevant references. *The Difco Manual*, 10th (18) and 11th (19) editions, from BD Biosciences, and other media supplier manuals continue to be good references because of historical media, as are other supplier manuals that may contain their own unique products. The formulations of a given medium from different manufacturers do vary slightly and may have been modified from the original description of the medium. A typical comment from the manufacturer is that the "classical" formula has been adjusted to meet performance standards. Again, the package insert or the formula being prepared from a reference should be followed closely. Chapters in this Manual are noted when appropriate to describe a referenced method cited by the authors for a specific organism. These referenced methods and media are found in the Isolation Procedures section within the chapter cited. Appendix 1 describes additives commonly added to media. Refer to Appendix 2 for suppliers of media and reagents as mentioned throughout this Manual. Media are available as prepared plates, tubes, bottles, or dehydrated products.

Preparation of Media

When preparing media from dehydrated materials, the manufacturers' instructions should be followed closely. Chemically cleaned glassware and distilled and/or demineralized water should always be used unless specified otherwise. Care in terms of accuracy should be taken when measuring liquid and dry ingredients. Mixing and solubilization of ingredients are typically done on hot plates, with magnetic stir bars placed in the bottom of the flask or beaker. Excessive heating should be avoided. Autoclaving or filtration sterilizes the media. Autoclaving of volumes of up to 500 ml at 121°C for 15 min is adequate. Larger volumes may require up to 20 to 30 min. The stir bars should be removed before sterilization. For quality control of autoclaving, specialized tape or paper is placed on the medium flask at the time of autoclaving. Enrichments such as blood and other labile additives such as filter-sterilized antibiotics should be added aseptically after the base medium has cooled.

While many dehydrated media are available, most clinical laboratories rely on prepared media from a commercial manufacturer because of convenience and lack of appropriate medium preparation facilities. In addition, overnight shipping even for small-volume purchases is often available for specialized media from the laboratory's routine medium distributor.

Quality Control

The Clinical and Laboratory Standards Institute (CLSI) has specific requirements for quality assurance of commercially prepared media, as documented in standard M22-A3 (13). However, these recommendations do not apply to all media. In addition, any medium that is prepared by the user requires its own specific quality control. Storage of media should be in the dark at 2 to 8°C. Storage in the dark is preferred because additives, such as dyes, will deteriorate faster in the light. The date that the medium was received in the laboratory and the medium expiration date should be marked and easily visible when stored. Media should be in use only up to the expiration date. Prolonged or incorrect storage of media, including transport media, can lead to desiccation of the media, changing the composition of nutrients and selective agents.

Plating of Specimens on Media and Incubation

Media should be warmed to room temperature before inoculation of specimens. In addition, a medium that has obvious contamination, such as colony growth or turbidity in broth medium, or that looks damaged in any way should not be used. Damage may include such things as a cracked petri dish and agar that has changed color, demonstrates precipitates, or is dehydrated.

Finally, it is important that the appropriate atmospheric incubation and temperature of media be used to optimize those pathogens likely to be in specimens submitted. Examples would include those conditions optimal for *Enterobacteriaceae* and *Campylobacter*. Isolation of *Enterobacteriaceae* from MacConkey agar may not be optimal if the agar is placed in CO_2, since the acidity with increased CO_2 may inhibit some of these organisms (S. M. Kircher, R. J. Cote, N. J. Dick, and W. F. Seip, *Abstr. 2000 Gen. Meet. Am. Soc. Microbiol.*, abstr. C-242, 2000), and *Campylobacter* should always be in a microaerophilic environment and at 42°C.

Bacteriology Media

■ A7 and A8 agars

A7 and A8 agars are selective and differential media used for the cultivation, identification, and differentiation of *Ureaplasma* spp. and *Mycoplasma hominis*. Both media contain soy and casein digests in an agar base and a supplement solution that contains yeast extract, horse serum, cysteine enrichment solution, and penicillin. Incorporation of urea aids in the identification of urease production to differentiate the organisms on the basis of the appearance of golden to dark brown colonies. There are two main differences between the agars: the use of manganous sulfate in A7 agar and putrescine dihydrochloride and calcium chloride in A8 agar for the detection and enhancement of growth of urease-positive colonies. *Ureaplasma* colonies are small golden brown colonies that are usually identified at 72 h. *Mycoplasma* colonies have a fried egg appearance and may have a golden or amber color. See also Mycotrim GU and Mycotrim RS.

■ Alkaline peptone water

Alkaline peptone water is an enrichment broth used for the isolation of small numbers of *Vibrio* and *Aeromonas* organisms from stool specimens. Adjustment of the broth to pH 8.4 and inclusion of sodium chloride at a concentration of 0.5 to 1.0% make it selective for *Vibrio* species.

■ American Trudeau Society medium

American Trudeau Society medium is a nonselective enriched medium used for the isolation and cultivation of mycobacteria. It is an egg-based medium. The coagulated egg provides fatty acids essential for support of mycobacterial growth. Glycerol and potato flour provide other nutrients. Malachite green is a partially selective agent that inhibits bacteria. The concentration of malachite green is low, and no other antibiotics are present in this medium; thus, it is very susceptible to proteolytic damage caused by contaminating organisms. This medium is best for specimens not usually contaminated with other microorganisms, e.g., tissue biopsy specimens or CSF. See also Lowenstein-Jensen and Middlebrook media.

■ Amies transport medium with and without charcoal

Amies transport medium is a modification of Stuart's medium. The glycerol phosphate used to maintain the pH in Stuart's medium has been found to enhance the growth of certain organisms that utilize this as a nutrient and to allow overgrowth of potential contaminants. In Amies medium, phosphate buffer replaced the glycerol phosphate ingredient and other salts were added to control the permeability of bacterial cells. Amies medium with charcoal is preferred for the isolation of *Neisseria* spp. because the charcoal neutralizes metabolic products toxic to the organisms.

■ Anaerobic blood agar (CDC)

The Centers for Disease Control and Prevention (CDC) formulation of anaerobic blood agar is a general-purpose medium used for the isolation and cultivation of anaerobic bacteria. The nutritive base is tryptic soy agar supplemented with yeast extract, vitamin K, hemin, and sheep blood. This medium is best for the isolation of anaerobic gram-positive cocci. See chapter 55 for other selective anaerobic medium recommendations for gram-positive bacteria.

■ 10B arginine broth; Shepard's broth

10B arginine broth is a medium used for the transport and growth of *M. hominis* and *Ureaplasma urealyticum*. The medium contains nitrogenous components, amino acids, and other components necessary for growth, and penicillin G or a semisynthetic penicillin is added to reduce bacterial contamination. Shepard's broth contains cefoperazone. Two primary compounds, namely, urea and arginine, as well as the phenol red indicator, aid in the identification of the organisms. *Ureaplasma* hydrolyzes urea and releases ammonia; *Mycoplasma* deaminates the arginine. Both reactions result in an alkaline pH shift and change the color of the medium from yellow to pink. *Ureaplasma* depletes urea in the medium quickly (<12 h), with subsequent death of the culture. Thus, after the color changes, the cultures need to be subcultured quickly to a medium such as A8 or A7 agar that supports the organisms. Limitations of the medium are that other species of *Mycoplasma* and other bacteria may also change the color of the medium.

■ Ashdown agar

Ashdown agar is a selective and differential medium consisting of Trypticase soy agar with 4% glycerol, 0.005 mg of crystal violet per ml, 0.05 mg of neutral red per ml, and 0.004 mg of gentamicin per ml, specifically designed for the isolation

of *Pseudomonas pseudomallei,* the causative agent of melioidosis. Glycerol and neutral red allow differentiation from other pseudomonads since *P. pseudomallei* appears flat, with rough wrinkled colonies due to the glycerol, and absorbs the neutral red dye, whereas other pseudomonads do not. The medium is made selective by the addition of crystal violet, which inhibits gram-positive organisms, and gentamicin, which inhibits gram-negative organisms. Ashdown broth with 50 mg of colistin per liter enhances recovery over direct plating by 25% (2, 68).

■ *Bacillus cereus* medium

B. cereus medium is an enriched medium used for the isolation of *B. cereus*. The base includes agar, yeast extract, and buffers. Mannitol combined with bromcresol purple as the indicator dye makes the medium differential. An egg yolk emulsion is added for the detection of the lecithinase activity seen with *B. cereus*.

■ BACTEC 12B radiometric medium

BACTEC 12B medium (BD Biosciences) is a liquid nonselective medium used for the isolation and identification of *Mycobacterium* species in conjunction with the BACTEC system. The medium consists of a 7H9 broth base. The radiometric BACTEC system incorporates ^{14}C-labeled palmitic acid and detects radioactive carbon dioxide; the medium is referred to as 7H12 or BACTEC 12B medium. An antibiotic enrichment supplement is added to the medium to make it selective for mycobacteria. This supplement includes the antibiotics polymyxin B, amphotericin B, nalidixic acid, trimethoprim, and azlocillin, with polyoxylene stearate as a *Mycobacterium* growth enhancer. A total of 0.5 ml of processed specimen may be accommodated in the vial. The BACTEC 12B medium is most commonly used for susceptibility testing. Newer nonradiometric systems are available for monitoring for mycobacterial growth and/or used for susceptibility testing. These include the 9200 series (BD Biosciences), MGIT (BD Biosciences), ESPII (TREK Diagnostic Systems), and MB/BacT ALERT 3D (bioMérieux, Inc.). Manual medium systems also exist for the detection of mycobacteria, such as the Isolator (Wampole Laboratories) and Septi-Chek AFB (BD Biosciences). The reader is referred to chapters 36 and 77 for specifics on medium formulations and antibiotic supplements for each system.

■ *Bacteroides* bile esculin agar

Bacteroides bile esculin agar is an enriched, selective, and differential medium used for the isolation and presumptive identification of members of the *Bacteroides fragilis* group and *Bilophila wadsworthia*. The nutritive base includes casein and soybean peptones, hemin, and vitamin K. The differential characteristic of esculin hydrolysis is identified by the product, esculetin, which reacts with the ferric ammonium citrate to form a complex and produce brown-black coloration around the colony. The selective agents include bile, which inhibits most gram-positive bacteria and anaerobic organisms other than members of the *B. fragilis* group, and gentamicin, which inhibits facultative anaerobes. Bile esculin agar with kanamycin and enriched with vitamin K and hemin is a formulation that is more enriched and selective than *Bacteroides* bile esculin agar for isolation of the *B. fragilis* group. This medium includes beef extract and pancreatic digest of gelatin, vitamin K, and hemin as the nutritive base. Bile inhibits the same organisms as described above, and kanamycin is inhibitory for facultatively anaerobic and aerobic gram-negative bacilli.

■ Baird-Parker agar base

Baird-Parker agar base is a beef extract, peptone, and yeast extract base used to prepare egg-tellurite-glycine-pyruvate agar (ETGPA). ETGPA is an enriched, selective, and differential agar used for the detection of coagulase-positive staphylococci *(S. aureus)* from food and other nonclinical sources. Glycerol and lithium make the medium selective by inhibiting many bacteria. Tellurite is also inhibitory to bacteria. The egg yolk emulsion is an enrichment. Tellurite and the egg yolk emulsion also act as differential determinants. When *S. aureus* reduces tellurite, it imparts a black color to the colony, and lecithinase activity is demonstrated by a clearing around the colony. *S. aureus* appears as black-brown colonies with clear zones around them.

■ Barbour-Stoenner-Kelly medium (Sigma-Aldrich Co., St. Louis, Mo.)

Barbour-Stoenner-Kelly medium is a complicated medium for the isolation of *Borrelia burgdorferi*. Bovine serum albumin, rabbit serum, and sodium bicarbonate are significant components. While a defined medium has been described, variability in components makes for differences in the ability to isolate the organism (59).

■ Bile esculin agar

Bile esculin agar is a selective and differential medium used for the isolation and differentiation of *Enterococcus* and *Streptococcus bovis* (group D *Streptococcus*) from non-group D *Streptococcus*. The nutritive base includes peptone and beef extract. The selective agent is bile (oxgall), which inhibits gram-positive organisms and most strains of streptococci except *S. bovis* and *Enterococcus*. Esculin hydrolysis is a characteristic to differentiate enterococci and *S. bovis* from other organisms. Esculin in the medium is hydrolyzed to esculetin and dextrose. A black-brown pigment forms when the iron salt (ferric citrate) is used as the color indicator of esculin hydrolysis and subsequent esculetin formation. *S. bovis* and *E. faecalis* grow on the medium and exhibit blackening around the colony.

■ Bile esculin agar plus vancomycin at 6 µg/ml

Bile esculin agar plus vancomycin is a selective and differential medium used to identify vancomycin-resistant streptococci and enterococci. Colonies appear the same as they do on bile esculin agar. Growth of group D streptococci and enterococci occurs with esculin hydrolysis in the presence of bile, appearing as blackening of the medium.

■ Bile esculin azide agar and broth (Enterococcosel)

Bile esculin azide agar or broth is a selective and differential medium for *S. bovis* (group D streptococcus) and enterococci. As with bile esculin agar, esculin is incorporated into the medium, and precipitation with ferric ions forms a brown-black pigment, which identifies these species. Bile esculin azide medium has a reduced percentage of bile and makes the medium less inhibitory to non-group D streptococci.

Sodium azide is incorporated to inhibit gram-negative organisms. The addition of 6 μg of vancomycin per ml makes the medium selective for vancomycin-resistant enterococci. Incorporation of aztreonam subsequently increases the selectivity by inhibiting other organsims, especially gram-negative organisms, contaminating specimens.

■ Bismuth sulfite agar

Bismuth sulfite agar is a highly selective and differential medium used for the isolation of *Salmonella enterica* serovar Typhi and other enteric bacilli. Beef extract, peptones, and dextrose are the nutritive base. Bismuth sulfite, a heavy metal, and brilliant green are selective agents which inhibit most commensal gram-positive and gram-negative organisms. Ferrous sulfate is an indicator for hydrogen sulfide production, which occurs when the hydrogen sulfide produced by *Salmonella* reacts with the iron salt. This reaction causes a black or green metallic colony and a black or brown precipitate. Colony morphology and color help differentiate *Salmonella* species. This medium may be inhibitory for some species of *Shigella*. Readers are referred to chapter 42 for other selective media for enteric organisms.

■ Blood agar

See Columbia agar with 5% sheep blood.

■ Blood culture media

All blood culture medium formulations are based on a nutrient peptone broth with variations due to hydrolysis or digestion of the source protein. Additives for neutralization of serum components and/or inactivation of antibiotics, such as SPS, chelators, or resins, vary with the manufacturer. The reader is referred to chapter 15 for formulations for specific blood culture media and various commercial systems.

■ Bordet-Gengou medium

Bordet-Gengou medium is an enriched medium used for the isolation and cultivation of *Bordetella pertussis* from clinical specimens. The medium contains potato infusion, glycerol, and peptones as the nutritive base. Sheep blood allows detection of hemolytic reactions and provides other nutrients for *Bordetella*. The medium can be supplemented with methicillin, which inhibits some of the normal oral flora that is obtained upon collection of the specimen. Culture plates should be held for at least 7 days. Incubation up to 12 days identifies *Bordetella parapertussis*. Bordet-Gengou medium is not as effective for the recovery of *Bordetella* as Regan-Lowe medium, and freshly prepared medium must be used for optimum recovery.

■ Brain heart infusion agar

Brain heart infusion agar is a general-purpose medium used for the isolation of a wide variety of pathogens, including yeasts, molds, and bacteria. The basic formula includes brain heart infusion from solids as well as meat peptones, yeast extract, and dextrose. One variation that exists is brain heart infusion agar with vitamin K and hemin for the enrichment of anaerobes. The anaerobic formulation may be optimal for the isolation of *Eubacterium* spp. but inferior for the isolation of anaerobic gram-negative organisms, especially those that produce pigment.

■ Brain heart infusion agar with 7% horse blood and brain heart infusion agar with 1% serum (see Brain heart infusion agar)

Brain heart infusion agar with horse blood or serum enriches the medium for isolation of *Helicobacter* spp.

■ Brain heart infusion broth

Brain heart infusion broth is a general-purpose clear liquid medium that is used to cultivate a wide variety of organisms. It is also used for the preparation of inocula for susceptibility tests and identification. The medium is especially useful as a blood culture medium. The main nutritive base includes infusion from brains and beef heart. Peptones, glucose, sodium chloride, and buffers are other additives. Sodium chloride acts as an osmotic agent, and disodium phosphate acts as a buffer. Formulations with 6.5% NaCl are used for the isolation of salt-tolerant streptococci, formulations with 0.1% agar that reduce O_2 tension favor anaerobes, and formulations with Fildes enrichment are used for the isolation of fastidious organisms such as *Haemophilus* and *Neisseria*. Brain heart infusion broth is also used for the preparation of inocula for antimicrobial susceptibility testing and broth dilution MIC testing procedures. The medium contains infusions of brain, casein, and meat peptones.

■ Brain heart infusion-vancomycin agar (see Brain heart infusion agar)

Brain heart infusion-vancomycin agar is a selective medium used for the isolation of vancomycin-resistant enterococci. The base is brain heart infusion agar. Vancomycin (6 μg/ml) is added to select for vancomycin-resistant enterococci.

■ Brilliant green agar

Brilliant green agar is a highly selective and differential medium used for the isolation of *Salmonella* species except for serovar Typhi. The nutritive base contains meat and casein peptones. Brilliant green dye at a high concentration is the selective agent and inhibits most gram-positive and gram-negative bacteria, including *Shigella* species and serovar Typhi. Phenol red is the pH indicator. Yeast extract provides additional nutrients. Sugars included in the medium are sucrose and lactose. Acid production in the fermentation of these sugars produces yellow-green colonies with a yellow-green zone. Nonfermenters of sucrose and lactose may range in color from white to reddish pink with a red zone around the colony *(Salmonella)*.

■ Brucella agar

Brucella agar is a medium designed originally for the purpose of isolating *Brucella* spp. from dairy products. Brucella agar with 5% horse blood can be used as a general-purpose medium for the isolation of both fastidious aerobic and anaerobic organisms. The nutritive base includes a peptone mix, including meat peptones, dextrose, and yeast extract.

■ Brucella agar with cefoxitin and cycloserine

Brucella agar with cefoxitin and cycloserine is a selective and differential sheep blood medium used for the isolation of *Clostridium difficile*. Brucella agar is the nutritive base. Vitamin K and sheep blood provide other growth enhancers. Cefoxitin and cycloserine inhibit most gram-positive and

gram-negative organisms, respectively. *Enterococcus* is not inhibited. Another differential characteristic is that *C. difficile* colonies fluoresce yellow-green under UV light.

■ Brucella agar with hemin and vitamin K

Brucella agar with hemin and vitamin K is a general-purpose nonselective and enriched medium used for the isolation and cultivation of anaerobic bacteria. Casein peptones, dextrose, and yeast extract are the nutritive base. Hemin and vitamin K provide further enrichments. Defibrinated sheep blood allows determination of hemolytic reactions. Because of the high carbohydrate content, colonies with beta-hemolytic reactions may have a greenish hue. The medium is better for gram-negative organisms.

■ Brucella agar with 5% horse blood

Horse blood enriches brucella agar for fastidious organisms, such as *H. pylori*, by providing both hemin (factor X) and NAD (factor V) factors. The use of horse blood also allows determination of hemolytic reactions. However, hemolytic reactions for *Streptococcus* and *Haemophilus* on horse blood differ from those on media with sheep blood.

■ Brucella broth

Brucella broth is a liquid medium that is used to cultivate *Campylobacter* species and to identify the organisms to the species level. Brucella base that contains peptones, dextrose, and yeast extract is the nutritive base.

■ Buffered charcoal yeast extract (BCYE) (selective and nonselective)

BCYE is a specialized enriched agar medium used for the isolation and cultivation of *Legionella* species from environmental and clinical specimens. *Legionella* species, especially *L. pneumophila*, require specific nutrients for growth. One is iron and the other is the amino acid L-cysteine. These are provided in BCYE by ferric pyrophosphate and L-cysteine hydrochloride. The nutritive base is yeast extract and α-ketoglutarate. *N*-(2-Acetamido)-2-aminoethanesulfonic acid buffer maintains the pH of the medium. Charcoal acts as a detoxifying agent and surface tension modifier. Antibiotics may also be added to the medium. Typically, manufacturers provide the medium in two combinations of three antibiotics. One is polymyxin B, anisomycin, and vancomycin, and the other is polymyxin B, anisomycin, and cefamandole (PAC). In these combinations polymyxin B inhibits gram-negative rods, anisomycin inhibits yeasts, vancomycin inhibits gram-positive organisms, and cefamandole inhibits both gram-positive and gram-negative organisms. BCYE with PAC may be inhibitory to some strains of *L. micdadei*. Nonselective BCYE can support the growth of other fastidious organisms such as *Nocardia* and *Francisella*. BCYE can also be a differential medium with the addition of the dyes bromcresol purple and bromthymol blue. *L. pneumophila* produces light blue colonies with a pale green tint. This differential medium is also called Wadowsky-Lee medium and can be used for isolation of actinomycetes.

■ Buffered glycerol saline

Buffered glycerol saline is a multipurpose transport medium. The transport medium has been used for the isolation of bacteria, such as *Aeromonas* spp., as well as viruses. In addition, glycerol-containing media may also be used for long-term storage of isolates and for transport and storage of biopsy specimens.

■ *Burkholderia cepacia* selective agar

B. cepacia selective agar is an enriched and selective medium used for the isolation of *B. cepacia*. Trypticase peptone, yeast extract, sodium chloride, sucrose, and lactose are the nutritive base. The medium is made selective by the addition of polymyxin B, gentamicin, vancomycin, and crystal violet. The medium supports the growth of *B. cepacia* and inhibits >90% of other isolates. This agar is more sensitive and more selective than *Pseudomonas cepacia* (PC) agar, oxidative-fermentative polymyxin B-bacitracin-lactose medium, and other selective media for isolation of *B. cepacia* from patients with cystic fibrosis (35). See chapter 49.

■ *Campylobacter* blood agar

Campylobacter blood agar is an enriched selective blood agar medium used for the isolation of *Campylobacter* species. The nutritive base is brucella agar. Sheep blood provides heme and other growth factors. The selectivity of the medium comes from the incorporation of five antimicrobial agents: trimethoprim, vancomycin, amphotericin B, polymyxin B, and cephalothin. These agents inhibit normal stool flora such as members of the family *Enterobacteriaceae*, staphylococci, and yeasts. Plates should be incubated in a microaerophilic environment. Due to the dextrose content of the brucella base, weak oxidase reactions may be exhibited. Some species of *Campylobacter* (e.g., *Campylobacter fetus* subsp. *fetus* and *Campylobacter upsaliensis*) are inhibited by cephalosporins. Media with cephalothin have been shown to be more inhibitory to *C. jejuni* and *Campylobacter coli* than those with cefoperazone. See chapter 59 for additional selective media.

■ *Campylobacter* charcoal differential (CCD) agar

CCD agar is a blood-free selective medium used for the isolation of *Campylobacter* from stool specimens. Cefoperazone replaces cefazolin in other selective agars. The nutritive base is Preston agar, which consists of beef extract and peptones. This agar has been shown to be less inhibitory than other *Campylobacter* agars for all *Campylobacter* species as well as more inhibitory to contaminating organisms (36).

■ *Campylobacter* thioglycolate medium

Campylobacter thioglycolate medium is a selective holding medium used for the isolation of *Campylobacter* species. The low concentration of agar in thioglycolate broth provides a reduced oxygen content. The selective agents include the same as those in *Campylobacter* agar: trimethoprim, vancomycin, polymyxin B, cephalothin, and amphotericin B.

■ Cary-Blair transport medium

Cary-Blair transport medium was specifically designed to enhance the survival of enteric bacterial pathogens. The medium has a low nutrient content, which allows organism survival without replication; sodium thioglycolate, which allows a low oxidation-reduction potential; and a high pH, which minimizes the destruction of bacteria when acid is produced.

■ Cefoperazone-vancomycin-amphotericin B (CVA) medium

CVA medium is a selective and enriched blood agar medium used for the isolation of *Campylobacter* species. The nutritive agar base is brucella agar. Sheep blood provides hemin and other growth nutrients. The antibiotics in this medium are vancomycin, amphotericin B, and cefoperazone, which inhibit gram-positive organisms, fungi, and anaerobic gram-negative organisms. The limitations of this medium are that some campylobacters (e.g., *C. fetus* subsp. *fetus*) are inhibited and that weak oxidase reactions may occur due to the dextrose in the brucella agar base. CVA is a good medium to use if only a single selective medium for *Campylobacter* can be used.

■ Cefsulodin-Irgasan-novobiocin (CIN) medium (*Yersinia* selective agar)

CIN, or *Yersinia* selective agar, is a selective and differential medium used for the isolation and differentiation of *Yersinia enterocolitica* from clinical specimens and food sources. The nutritive base includes peptones and beef and yeast extracts. The selective agents are sodium desoxycholate, crystal violet, cefsulodin, Irgasan (triclosan), and novobiocin. The medium is available with various concentrations of cefsulodin (4, 8, or 15 μg/ml). The lower concentration is recommended for better growth of clinically significant *Yersinia* spp. as well as growth of *Aeromonas* spp. Mannitol is the sugar, and neutral red is the indicator. Organisms that ferment mannitol in the presence of the neutral red dye cause a pH drop around the colony. The colony becomes transparent, with the absorption of the red dye to form a red bulls-eye appearance in the center with *Yersinia*, and *Aeromonas* will have a pink center with an uneven clear apron. Most other bacteria, including other enteric mannitol fermenters, are inhibited. Some yersiniae may require cold enrichment at 4°C and subsequent subculture to CIN medium. See also chapters 44 and 46.

■ Cetrimide agar

Cetrimide agar is a selective and differential medium used for the identification of *Pseudomonas aeruginosa*. Cetrimide is the selective agent and inhibits most bacteria by acting as a detergent. *Pseudomonas* produces a number of pigments. Two pigments can be detected with this medium. The magnesium chloride and potassium sulfate stimulate the blue-green pyocyanin pigment, and the fluorescent yellow-green pigment can be seen with a UV light. The low iron content of the medium also stimulates pigment production.

■ Charcoal selective medium

Charcoal selective medium is an enriched selective medium used for the isolation of *Campylobacter* species. In this medium the nutritive base is a Columbia agar base, and charcoal is used to effectively replace blood components. The selective agents used in this medium include vancomycin, cefoperazone, and cycloheximide. Vancomycin and cefoperazone effectively inhibit gram-positive and gram-negative organisms, including *Pseudomonas*. Fungi are inhibited by cycloheximide. The limitation of this medium is that some *Campylobacter* species, e.g., *C. fetus* subsp. *fetus*, are inhibited by cephalosporins.

■ Chocolate agar

Chocolate agar is a general-purpose medium used for the isolation and detection of a wide variety of microorganisms, including fastidious species such as *Neisseria* and *Haemophilus*. Chocolate agar originated as a GC agar base which includes meat and casein peptones, phosphate buffer to maintain pH, and cornstarch to detoxify fatty acids in the medium. Hemoglobin is added to the medium to provide hemin (X factor). The appearance of hemin in dry powdered form is reddish brown. When hemoglobin is hydrated and added to the medium, it gives the agar base the "chocolate" appearance. Other enrichments added include defined supplements, such as IsoVitaleX or Vitox, which provides NAD (V factor). Both of these components added to the GC agar base make the enriched chocolate agar. Levinthal agar is a variation on chocolate agar. The medium is a selective and differential medium used for the isolation and identification of *Haemophilus influenzae* type b. The medium is a chocolate agar base that is made transparent by the removal of particulate matter by either centrifugation or filtration through sterile filter paper. The medium contains bacitracin to inhibit respiratory flora and *H. influenzae* type b antiserum, allowing detection of an immunoprecipitation reaction. Colonies of encapsulated strains show a bright iridescence (red-blue-green-yellow) when light is transmitted from behind the clear medium.

■ Chopped meat glucose broth

Chopped meat glucose broth is an enriched medium that supports the growth of most anaerobes. It is most commonly used to isolate *Clostridium botulinum* from mixed bacterial growth. Beef heart, peptones, and dextrose supply the essential nutrients. The −SH groups from cooked and denatured muscle protein are the reducing agents in the medium. Vitamin K and hemin are additives used to maximize the growth of specific anaerobes. The medium helps to induce sporulation of *Clostridium* spp.

■ CHROMagar (Rambach agar)

CHROMagar is a microorganism-specific, chromogenic culture medium used for isolation and identification for a variety of organisms. CHROMagar was developed by Alain Rambach, who first formulated agars that were monochromogenic for the detection of *E. coli* and *Salmonella* spp. Second-generation agars are multicolor. Both types are differential and selective. The nutritive agar base includes peptone and glucose. Different additives, proprietary chromogenic mixtures, and antibiotics have resulted in a series of media specific for such organisms as *Listeria, S. aureus,* methicillin-resistant *S. aureus* (MRSA), *E. coli* O157, yeasts, and other organisms. BD Biosciences has a licensing agreement for development of the CHROMagar media. Many other chromogenic media with proprietary components are also now available through a number of manufacturers. Most commonly evaluated are chromogenic media for the detection of MRSA. These include MRSA ID (bioMérieux), MSA-CFOX (Oxoid), and MRSA*Select* (Bio-Rad) (17, 64). Greater recovery of organisms, increased specificity, and elimination of nonselective media are benefits of chromogenic agar use. Cost per plate compared to those of standard media and limited shelf life need to be considered before implementation.

■ Columbia agar with 5% sheep blood

Columbia agar with 5% sheep blood is a general-purpose medium used for the isolation of a variety of microorganisms, including fastidious organisms. This medium contains meat

and casein peptones and beef extract, yeast extract, and cornstarch as the nutritive base. Sheep blood allows determination of hemolytic reactions and provides X factor. However, the substantial carbohydrate content may make beta-hemolytic streptococci appear to be alpha-hemolytic or take on a greenish hue. NADase enzyme in sheep blood destroys the V factor (NAD); thus, organisms that require this factor do not grow. Incorporation of horse or rabbit blood allows beta-hemolysis to be seen better. Addition of 20 μg of ampicillin per ml is helpful in isolation of *Aeromonas*.

■ Columbia broth

Columbia broth is a general-purpose clear liquid medium used especially for blood culture medium. The broth supports the growth of a wide range of microorganisms. The base is similar to Columbia agar, with meat peptones, casein, and yeast extract. Salt and Tris buffers have been added to enhance the growth of microorganisms and increase the buffering capacity, respectively. For the purpose of blood culture medium, additional ingredients include carbon dioxide, which is stimulatory for many organisms; cysteine, which improves isolation of anaerobic and aerobic organisms from blood; SPS, a polyanionic anticoagulant which inactivates aminoglycosides and which interferes with the complement, lysozyme activity, and the phagocytic activity inherent in a blood specimen; and glucose, which provides a hypertonic medium for the isolation of cell wall-deficient forms.

■ Columbia-colistin-nalidixic acid agar with 5% sheep blood

Columbia-colistin-nalidixic acid agar with 5% sheep blood is a selective and differential medium commonly used in the isolation of gram-positive aerobic and anaerobic organisms from mixed clinical specimens. The base is Columbia agar with 5% sheep blood, which allows the detection of hemolytic reactions and provides additional enrichment and X factor (heme). The medium is made selective by the inclusion of the antibiotics colistin and nalidixic acid, which inhibit gram-negative organisms. Swarming *Proteus* spp. are inhibited. Supplementation with glutathione and lead acetate allows a selective and differential medium for anaerobic gram-positive cocci.

■ Cycloserine-cefoxitin-fructose agar

Cycloserine-cefoxitin-fructose agar is a selective and differential agar medium used for the isolation of *C. difficile*. The nutritive base includes animal peptones and fructose. The selective agents include cycloserine and cefoxitin. Cycloserine inhibits gram-negative organisms, especially *E. coli*, and cefoxitin is a broad-spectrum antibiotic that is active against both gram-positive and gram-negative organisms. *Enterococcus* is not inhibited. The medium is made differential by the addition of neutral red. *Clostridium* raises the pH of the medium and allows the neutral red indicator to change to yellow. Both the colony and the surrounding medium turn yellow. In addition, *C. difficile* colonies yield a gold-yellow fluorescence when viewed under long-wave UV light.

■ Cysteine-albumin broth with 20% glycerol

Cysteine-albumin broth with 20% glycerol is used for transport and storage of gastric biopsy specimens for the recovery of *H. pylori* (37).

■ Cystine glucose blood agar

Cystine glucose blood agar is an enriched medium used for the isolation of *Francisella* spp. The nutritive base is beef heart infusion, peptones, and glucose. *Francisella* requires cystine for growth. Rabbit blood provides hemoglobin enrichment.

■ Cystine-tellurite blood agar

Cystine-tellurite blood agar is a modification of Tinsdale agar and is both a selective and differential medium used for the detection of *C. diphtheriae*. Casein peptones, beef infusion, and yeast extract are the nutritive base. Potassium tellurite is both the selective and differential agent. Gram-negative organisms and most organisms of the upper respiratory flora are inhibited; *Corynebacterium* spp. are the exception. The potassium tellurite also allows differentiation of *C. diphtheriae* from other biotypes by the dull metal gray or black colony appearance indicative of tellurite reductase activity and the brown halo around the colony consistent with cystinase activity. Other organisms, such as staphylococci, may reduce tellurite and produce black colonies. These are easily differentiated by Gram staining.

■ Cystine tryptic agar

Cystine tryptic agar is a pancreatic digest of casein-enriched medium that is most commonly used for cultivation and maintenance of fastidious organisms. Addition of 1% carbohydrates and phenol red for determination of fermentation reactions is especially helpful for differentiating *Neisseria* spp.

■ Diagnostic sensitivity agar

Diagnostic sensitivity agar is a medium used in the cultivation of organisms for susceptibility testing. The base is proteose peptone, veal infusion solids, agar, and glucose, with other additives. The medium is available as a premixed powder from Oxoid.

■ DNA-toluidine blue agar

DNA-toluidine blue agar is a differential medium used most commonly for the detection and differentiation of *Staphylococcus* spp. The nutritive base is tryptic soy agar. Supplementation with DNA permits detection of DNase activity (or heat-stable staphylococcal nuclease) that has endo- and exonucleolytic properties and can cleave DNA or RNA produced in most coagulase-positive staphylococci. The medium is blue due to the toluidine blue O, and DNase activity is detected by a pink zone around the colony secondary to the metachromatic property of the dye.

■ Dubos Tween-albumin broth

Dubos Tween-albumin broth is a nonselective medium used for the isolation and cultivation of mycobacteria. Polysorbate 80 (Tween 80) is an oleic acid ester and acts as an essential fatty acid necessary for the growth of mycobacteria. In addition, Tween 80 acts as a dispersal agent and allows a small inoculum to grow more homogeneously. Casein peptone and asparagine provide other nutrients. Phosphates provide a buffering system, and albumin, a source of protein, provides protection from toxic substances in the medium. Cultures of *M. tuberculosis* may form cords in the medium, and other mycobacteria grow more diffusely. See also Middlebrook 7H9 broth.

■ Egg yolk agar (modified McClung-Toabe agar)

Egg yolk agar medium (modified McClung-Toabe agar) is a selective and differential medium used for the isolation and differentiation of *Clostridium* spp. McClung and Toabe (51a) reported on the use of egg yolk medium for the identification of species of clostridia by the detection of lecithinase and lipase activities. Degradation of lecithin results in an opaque precipitate around the colony, and lipase destroys fats in the egg yolk, which results in an iridescent sheen on the colony surface. Proteolysis can also be determined with egg yolk agar, as indicated by a translucent clearing of the medium around the colony. The medium should be incubated anaerobically for a minimum of 48 h. It should be held for up to 7 days for the detection of lipase activity. Addition of neomycin makes the egg yolk agar moderately selective by inhibiting some facultative anaerobic gram-negative rods. Lecithinase positivity is also seen with some *Bacillus* spp. Lipase and proteolytic activity can also be demonstated with some anaerobes.

■ Ellinghausen-McCullough/Johnson-Harris medium

Ellinghausen-McCullough/Johnson-Harris medium is an enriched semisolid medium used for the isolation and cultivation of *Leptospira*. Stuart's medium is the base to which multiple modifications for optimization of the recovery of *Leptospira* have been made since the original description. Bovine albumin and Tween provide lipids and long-chain fatty acids. B vitamins and ammonium ion provide essential vitamins and a nitrogen source. Lysed erythrocytes provide other essential supplements, such as iron. The medium is made selective by adding 5-fluorouracil either alone or with fosfomycin and nalidixic acid (21). This medium is available as a dehydrated medium base and supplement from BD Biosciences.

■ Enterococcosel agar

See Bile esculin azide agar and broth.

■ Eosin-methylene blue (EMB) agar

EMB agar is a selective and differential medium used for the isolation and differentiation of enteric pathogens from contaminated clinical specimens. Pancreatic digest makes up the nutritive base. Eosin and methylene blue are the selective agents and inhibit gram-positive organisms. The sugars are lactose and, in certain modifications, sucrose. Organisms that ferment lactose bind to the dyes under acidic conditions and appear as blue-black colonies with a metallic sheen. Under less acidic conditions, other coliforms appear as mucoid and brown-pink colonies. Nonfermenters such as *Salmonella, Shigella,* and *Proteus* will appear amber or transparent (colorless). EMB agar should be stored in the dark because of the loss of support of growth when it is exposed to visible light.

■ ESP Culture System II

ESP Myco medium is used with ESP Culture System II (TREK Diagnostic Systems) for the detection of mycobacterial growth. The medium is a Middlebrook 7H9 broth enriched with glycerol, Casitone, and cellulose sponge disks. OADC enrichment is added prior to use.

■ ETGPA

See Baird-Parker agar base.

■ Fastidious anaerobic agar (*Fusobacterium* selective agar)

Fastidious anaerobic agar is an enriched sheep blood medium used for the isolation and cultivation of anaerobic organisms. Peptone, glucose, agar, and starch make up the solid base. Sheep blood, vitamin K, and hemin are enrichments for anaerobes. A greater amount of hemin is used in fastidious anaerobic agar than in other anaerobic media. This medium is used for the isolation of *Fusobacterium* spp. and formate-fumarate-requiring species.

■ Fletcher's medium

Fletcher's medium is an enriched semisolid medium used for the isolation and growth of *Leptospira*. The medium is a peptone and beef extract base with a 1.5% agar concentration. Rabbit serum supplies long-chain fatty acids and albumin and has been found to be superior to other serum sources for the isolation of *Leptospira*. 5-Fluorouracil may be added to select for *Leptospira*. Cultures should be incubated in air and at 28 to 30°C. See Ellinghausen-McCullough/Johnson-Harris medium.

■ FlexTrans viral and chlamydia transport medium

FlexTrans viral and chlamydia transport medium (Trinity Biotech) is intended to be used as a transport medium for viruses and/or chlamydiae. The medium consists of minimal essential medium, bovine serum albumin, glutamine, and sucrose, with a phenol red indicator. Microbial growth is inhibited by the incorporation of the antibiotics amphotericin B, gentamicin, and streptomycin.

■ GC agar base

GC agar base is a chocolate agar base used with various additives for the purpose of isolating *Neisseria gonorrhoeae* and other fastidious organisms, such as *Haemophilus* spp., including *Haemophilus ducreyi*, and for susceptibility testing of *N. gonorrhoeae*. GC agar base includes digest of casein, animal peptones, cornstarch, NaCl, and buffers. A 1% defined growth supplement with yeast and X (hemin) and V (NAD) factors is added. The supplement contains a low concentration of cysteine to avoid activation of various beta-lactam antibiotics such as penems, carbapenems, and clavulanic acid. GC agar base with 5% fetal bovine serum and 10% CVA enrichment allows for isolation of *H. ducreyi* (53).

■ GN broth

GN broth is an enriched selective broth medium used for the isolation of gram-negative rods. Specifically, *Salmonella* and *Shigella* are isolated more effectively in GN broth than on solid medium alone. The nutritive base includes casein and meat peptones as well as mannitol and dextrose. The concentration of mannitol limits the growth of some other contaminating enteric organisms. Sodium deoxycholate and sodium citrate inhibit gram-positive and some gram-negative organisms. Enteric organisms do not overgrow the pathogens in the first 6 h of incubation, at which time the broth should be subcultured.

■ Haemophilus test medium (HTM) and broth

HTM is an enriched medium used for susceptibility testing of *Haemophilus* species. The medium contains beef and casein

extracts. Yeast extract, hematin, and nicotinamide (NAD) provide necessary growth factors and enrichments. Antagonists to sulfonamides and trimethoprim are removed by thymidine phosphorylase. The calcium and magnesium concentrations are adjusted to the concentrations recommended by the CLSI. Although the agar medium is a clear agar base and should exhibit clear endpoint interpretations, some investigators have reported difficulties with interpreting zone sizes and poor growth with some strains. Broth microdilution methods also use HTM, which consists of cation-adjusted Mueller-Hinton broth and the supplements described above. Broth dilution methods with HTM provide clearer endpoints. See chapter 75 for specific formulations and references.

■ Heart infusion agar and broth

Heart infusion agar and broth are general-purpose media used for the isolation of a variety of microorganisms. Heart muscle infusion, casein peptones, and yeast extract are the nutritive base. Fastidious organisms do not grow well on or in this medium because no additional enrichments or sheep blood is incorporated. Incorporation with 5% rabbit blood allows detection of the more fastidious *Actinomyces.*

■ Hektoen enteric agar

Hektoen enteric agar is a selective and differential medium used for the isolation and differentiation of enteric pathogens from contaminated clinical specimens. Animal peptones and yeast extract provide the nutritive base. Bile salts and the indicator dyes (bromthymol blue and acid fuchsin) in the medium are the selective agents and inhibit gram-positive organisms. Lactose, sucrose, and salicin are the carbohydrates incorporated to differentiate fermenters from nonfermenters. In addition, differentiation of species occurs with the use of sodium thiosulfate and ferric ammonium citrate, which allow detection of hydrogen sulfide production. Organisms that produce hydrogen sulfide appear with the formation of a black precipitate on the colony. Fermenters such as *E. coli* produce colonies which are yellow-pink, *Shigella* spp. are green or transparent, and *Salmonella* spp. are green or transparent with black centers.

■ Hemin-supplemented egg yolk agar

See Neomycin egg yolk agar.

■ Isolator or lysis-centrifugation tube (Wampole Laboratories)

The Isolator is a unique system for the purpose of recovering organisms from blood through a simultaneous process of lysis and centrifugation. The tubes contain saponin, a lysing agent, and EDTA, an anticoagulant as well as a fluorocarbon that acts as a cushioning agent during centrifugation. The system creates a layer that is subsequently plated onto media appropriate for organism recovery. The system is especially good for the recovery of dimorphic fungi, yeasts, mycobacteria, and *Bartonella* spp. Recovery of anaerobes, *Haemophilus* spp., and pneumococci may be reduced.

■ Iso-Sensitest agar and broth

Iso-Sensitest agar and broth are media used for susceptibility testing in countries outside the United States. The base includes hydrolyzed casein, peptones, and glucose, with other additives. The medium is available as a premixed powder from Oxoid Unipath. See chapter 70 for specific uses.

■ John E. Martin Biological Enrichment Chamber (JEMBEC) (BBL) and InTray GC System transport medium (Biotest)

The JEMBEC and InTray GC devices are transport/inoculation media for direct plating of specimens for the detection of *N. gonorrhoeae.* JEMBEC contains GC-Lect agar, and InTray GC contains modified Thayer-Martin medium, both of which are a chocolate agar base. Each system is self-contained with a tablet that allows production of a CO_2 atmosphere and enhances recovery of the pathogen. The InTray GC system can be stored and transported at room temperature. GC-Lect helps to specifically inhibit *Capnocytophaga* spp. See chapter 39 for specific antibiotic components for various media used for the purpose of isolating *Neisseria* spp.

■ Kanamycin-vancomycin laked sheep blood agar

Kanamycin-vancomycin laked sheep blood agar is an enriched, selective, and differential medium used for the isolation and cultivation of anaerobic bacteria, especially slowly growing and fastidious anaerobes from clinical specimens, such as *Bacteroides* spp. and *Prevotella* spp. The base is CDC anaerobic blood agar. The selective agents are kanamycin and vancomycin (7.5 μg/ml) to prevent growth of obligate facultative gram-negative and gram-positive bacteria and facultative anaerobic bacteria, respectively. Use of a medium with 2 μg of vancomycin per ml allows better growth of *Porphyromonas* spp. Laked blood is used to allow optimal pigmentation of anaerobes such as the pigmented *Prevotella* spp.

■ Lactobacillus MRS broth

Lactobacillus MRS (deMan, Rogosa, and Sharpe) broth is a nonselective liquid medium used for the isolation and cultivation of lactobacilli from clinical specimens and dairy and food products. The nutritive base includes peptones, yeast extract with buffers, and glucose. Polysorbate 80 (Tween 80) supplies fatty acids and magnesium for additional growth requirements. Sodium acetate and ammonium citrate may inhibit normal flora, including gram-negative bacteria, oral flora, and fungi, and improve the growth of lactobacilli. The growth of lactobacilli is favored when the pH is adjusted to 6.1 to 6.6. Gas production can help identify *Leuconostoc* from *Pediococcus* in conjunction with arginine degradation to differentiate these organisms from *Lactobacillus* (16). See chapter 31.

■ Levinthal agar with bacitracin and *H. influenzae* antiserum

See Chocolate agar.

■ Lim broth

Lim broth is a modification of Todd-Hewitt broth and is an enriched selective liquid medium used for the isolation and cultivation of *Streptococcus agalactiae*. Peptones, salts, and dextrose provide the nutritive base. Yeast extract provides B vitamins and additional enrichment. The antibiotics colistin and nalidixic acid inhibit gram-negative organisms. Lim broth has shown better recovery of GBS than Todd-Hewitt broth with gentamicin and nalidixic acid (22). See also StrepB carrot broth and GBS broth.

■ Lithium chloride-phenylethanol-moxalactam agar

Lithium chloride-phenylethanol-moxalactam agar is an enriched and selective agar used for the isolation and cultivation of *Listeria monocytogenes*. Peptones and beef extract are the nutritive base. Phenylethyl alcohol, glycine anhydride, and lithium chloride suppress the growth of gram-positive and gram-negative organisms. Moxalactam makes the agar more selective by inhibiting gram-negative organisms such as *Pseudomonas* and additional gram-positive organisms. Enrichment of *Listeria* in a broth for 24 h is subsequently subcultured onto the selective medium for isolation when trying to isolate the organisms from contaminated sites. The medium is not differential, but use of oblique lighting may show *Listeria* colonies to be blue, while other colonies appear yellow or orange (14, 46, 67).

■ Loeffler's medium

Loeffler's medium is an enriched nonselective medium used for the cultivation of corynebacteria, especially *C. diphtheriae*. The nutritive base is heart infusion and peptones with dextrose. Horse serum and egg cause the medium to coagulate during sterilization and provide other nutritive proteins. The medium enhances the production of metachromatic granules within the cells of the organisms. These granules are seen when smears of the organism are viewed with the methylene blue stain.

■ Lombard-Dowell egg yolk agar

See Neomycin egg yolk agar.

■ Lowenstein-Jensen medium

Lowenstein-Jensen medium is an enriched nonselective medium used for the isolation and cultivation of mycobacteria. It is similar to American Trudeau Society medium in its content and its ability to grow mycobacteria. Lowenstein-Jensen medium is an egg-based medium with glycerol and potato flour and, as with all egg-based media, is susceptible to liquefying when specimens are contaminated with other bacteria. The concentration of malachite green is twice that in American Trudeau Society medium, and thus, the malachite green is somewhat more inhibitory for contaminating organisms. Inorganic salts may make the medium more enriched for mycobacteria.

■ Lowenstein-Jensen medium (Gruft modification)

The Gruft modification of Lowenstein-Jensen medium is an enriched selective medium used for the isolation of mycobacteria. Penicillin and nalidixic acid are added to the medium and inhibit gram-positive and gram-negative organisms, respectively. RNA is added as a growth stimulant.

■ Lowenstein-Jensen medium (Mycobactosel modification)

The Mycobactosel modification of Lowenstein-Jensen medium is an enriched selective medium for the isolation of mycobacteria. Different antibiotics from the Gruft modification are added to make the medium more selective against bacteria. Cycloheximide, lincomycin, and nalidixic acid inhibit saprophytic fungi, gram-positive organisms, and gram-negative organisms, respectively. No RNA is added.

■ Lowenstein-Jensen medium with 1% ferric ammonium citrate

Lowenstein-Jensen medium with 1% ferric ammonium citrate is an enriched and selective egg-based medium used for the recovery of *Mycobacterium haemophilum*. Ferric ammonium citrate is the additive which allows this organism to grow.

■ Lowenstein-Jensen medium with 5% NaCl

Lowenstein-Jensen medium with 5% NaCl is an enriched selective medium used to differentiate sodium chloride-tolerant strains of *Mycobacterium*. Most rapid growers, e.g., the *Mycobacterium fortuitum* complex, as well as the more slowly growing organism *Mycobacterium triviale*, will grow on this medium. The exception is the more resistant organism *Mycobacterium chelonae*, which will not grow on this medium.

■ Lysis-centrifugation tube

See Isolator.

■ MacConkey agar

MacConkey agar is a selective and differential medium used for the isolation of gram-negative organisms. The nutritive base includes a variety of peptones. The medium is made selective by the incorporation of bile (although at levels less than those used in other enteric media) and crystal violet, which inhibit gram-positive organisms, especially enterococci and staphylococci. An agar concentration greater than that described in the original reference helps to inhibit swarming *Proteus*. The medium is made differential by use of the combination of neutral red and lactose. When an organism ferments lactose, the drop in pH causes the colony to take on a pink-red appearance.

■ MacConkey agar with sorbitol (SMAC)

SMAC is a selective and differential medium used for the isolation and differentiation of sorbitol-negative *E. coli.* Shiga toxin-producing strains of *E. coli,* such as *E. coli* O157:H7, which may cause hemorrhagic colitis, are indistinguishable from other *E. coli* serotypes on routine stool isolation media such as MacConkey agar because they all ferment lactose. SMAC has D-sorbitol instead of the lactose in the MacConkey agar formulation. Shiga toxin-producing strains of *E. coli* do not ferment sorbitol and appear as colorless colonies. Sorbitol-fermenting strains are pink. The medium inhibits enterococci with crystal violet and other gram-positive organisms with bile salts. SMAC with cefixime and tellurite may be more selective for detection of *E. coli*. However, some strains may be inhibited. SMAC does not identify all Shiga toxin-producing strains of *E. coli.*

■ MacConkey broth

MacConkey broth is a differential medium containing the indicator bromcresol purple used for the detection of coliform organisms from contaminated food, water, or stools. The broth contains peptone, lactose, bile salts, and sodium chloride. Bromcresol purple is less inhibitory than neutral red for coliforms. The color change from purple to yellow is a more sensitive and definitive indication of acid formation.

■ Mannitol-egg yolk-polymyxin B agar

Mannitol-egg yolk-polymyxin B agar is an enriched, selective, and differential medium used for the isolation of *B. cereus* from mixed clinical specimens. The nutritive base includes peptone and beef extract. Egg yolk emulsion is added for the detection of lecithinase activity, which is usually limited to *B. cereus*. Phenol red and mannitol are combined to make the medium differential. Contaminating gram-negative organisms are inhibited by the polymyxin B.

■ Mannitol salt agar

Mannitol salt agar is a selective and differential medium used for the isolation of *S. aureus*. The nutritive base includes peptones, beef extract, and mannitol. Phenol red is the indicator. The selective nature of the medium is the high salt content (7.5% NaCl), which inhibits most organisms except staphylococci. The differential component for identification of *S. aureus* is the combination of mannitol and phenol red. The color change around the colony from red to yellow upon the fermentation of mannitol and the subsequent drop in the pH of the medium identify staphylococci.

■ Martin-Lewis agar

Martin-Lewis agar is an enriched and selective medium for the isolation of *N. gonorrhoeae.* Martin-Lewis agar is a modification of the modified Thayer-Martin formulation. The nutritive base is chocolate agar. The specific differences from the modified Thayer-Martin formulation are the use of a greater concentration of vancomycin (4.0 versus 3.0 μg/ml), which inhibits more gram-positive organisms, and the replacement of nystatin with anisomycin, which improves the inhibition of *Candida* species. Trimethoprim and colistin are incorporated as well for inhibition of other commensal organisms. Some strains of pathogenic *Neisseria* have been reported to be inhibited by vancomycin and trimethoprim. See also JEMBEC and Thayer-Martin agar. Chapter 39, Table 3, lists antimicrobial agent amounts for each *Neisseria* selective medium.

■ MB/BacT ALERT (bioMèrieux)

MB/BacT ALERT contains a modified Middlebrook 7H9 medium supplemented with casein, bovine serum albumin, and catalase. It is used with MB/BacT ALERT 3D (bioMérieux, Inc.) for the cultivation and detection of mycobacterial growth.

■ MGIT (mycobacteria growth indicator tube) (BD Diagnostic Systems)

MGIT is a Middlebrook 7H9-based broth system that contains a fluorescence indicator, which is used for the detection of mycobacterial growth. The 7H9 broth is supplemented with multiple growth enrichments prior to use. Chapter 36, on *Mycobacterium,* describes and compares this system with the BACTEC system in more detail.

■ Middlebrook 7H10 agar

Middlebrook 7H10 agar is an enriched nonselective agar-based medium used for the isolation and cultivation of mycobacterial species. Essential ingredients include inorganic salts, glycerol, and OADC enrichment. The OADC enrichment includes oleic acid, which is a fatty acid used in the metabolism of mycobacteria; albumin, which protects against toxic agents and which is a source of protein; dextrose, which is used as a source of energy; and catalase, which destroys toxic peroxides in the medium. This is the recommended medium for mycobacterial susceptibility testing. However, because standard formulations of the agar and especially the OADC supplement may vary, quality control is critical. Middlebrook medium allows visualization of mycobacterial colonies 1 to 2 weeks earlier than Lowenstein-Jensen formulations.

■ Middlebrook 7H11 agar

Middlebrook 7H11 agar is a nonselective agar-based medium used for the isolation and cultivation of *Mycobacterium* species. The formulation is identical to that of Middlebrook 7H10 medium except for the addition of casein hydrolysate. Casein hydrolysate is added as a growth stimulant for drug-resistant strains of *M. tuberculosis*. The formulation of Middlebrook 7H11 thin-pour agar is identical to that of Middlebrook 7H11 agar except that the agar plate has a reduced volume. The plates are sealed and every 2 days are examined along the isolation streak lines for evidence of microcolonies. This technique allows for faster detection on solid medium than in standard tube media or on thick media on plates.

■ Middlebrook 7H9 broth with glycerol

Middlebrook 7H9 broth with glycerol is an enriched nonselective broth for the isolation of *Mycobacterium* species. Glycerol, inorganic compounds, and cations supply essential nutrients and stimulate growth. ADC enrichment is added to the broth. ADC enrichment includes albumin, which binds to free fatty acids that are toxic to *Mycobacterium* species; dextrose, which supplies energy; and catalase, which destroys toxic peroxides that may be present in the medium.

■ Mitchison 7H11 selective agar

Mitchison 7H11 selective agar is an enriched selective agar-based medium used for the isolation of *Mycobacterium* species. The basic formulation is Middlebrook 7H11 agar: glycerol, inorganic salts, casein hydrolysate, malachite green, and OADC enrichment. Antibiotics are added to make the medium very selective for mycobacteria. Carbenicillin and polymyxin B, amphotericin B, and trimethoprim are active against most members of the family *Enterobacteriaceae*, yeasts, and *Proteus* species, respectively.

■ Modified Irgasan-ticarcillin-potassium chromate broth

Modified Irgasan-ticarcillin-potassium chromate broth is a selective broth used for the isolation of *Y. enterocolitica*. The base is the modified Rappaport-Vassiliadis enrichment broth with minor alterations. Irgasan and ticarcillin replace the carbenicillin. The chromate makes the medium more selective by inhibiting members of the family *Enterobacteriaceae. Enterobacteriaceae* have A nitrase activity, which splits chlorate to toxic by-products. *Yersinia* spp. have B nitrase activity, which cannot split the chlorate.

■ Modified Thayer-Martin agar

Modified Thayer-Martin agar is an enriched and selective agar for the isolation of pathogenic *Neisseria* species from

clinical specimens with mixed flora. The nutritive base is chocolate agar. Modified Thayer-Martin agar has three significant changes from the original Thayer-Martin medium. The medium has less agar and less dextrose, and these characteristics improve the growth of *Neisseria*. The third change is the addition of trimethoprim, which inhibits swarming *Proteus* spp. Vancomycin and colistin inhibit gram-positive and gram-negative bacteria, respectively. This medium is recommended over the original formulation for the isolation of pathogenic *Neisseria*. Some strains of pathogenic *Neisseria* have been reported to be inhibited by vancomycin and trimethoprim. See also Martin-Lewis agar.

■ Mueller-Hinton agar with and without 5% sheep blood

Mueller-Hinton agar is the agar recommended by the CLSI for routine susceptibility testing of nonfastidious microorganisms by the Kirby-Bauer disk diffusion susceptibility method. Mueller-Hinton agar with 5% sheep blood is used for susceptibility testing of *S. pneumoniae*. Beef and casein extracts and soluble starch in an agar base make up the nutritive base of the medium. Starch protects the organism from toxic materials that may be in the medium. Calcium and magnesium concentrations are controlled. Mueller-Hinton agar with 5% chocolatized blood plus 1% IsoVitaleX and 3 μg of vancomycin per ml is used for the isolation of *H. ducreyi.* See GC agar and chapter 41.

■ Mueller-Hinton agar with 2% NaCl

Mueller-Hinton agar with 2% NaCl is a selective medium used for testing the susceptibility of *Staphylococcus* to the penicillinase-resistant penicillins methicillin, nafcillin, and oxacillin by agar dilution or with the gradient-based system (E test). The sodium chloride added to the medium enhances the growth of staphylococci. Heteroresistant methicillin-resistant strains are more easily detected with this medium by increasing the incubation time to 24 h and by incubation at cooler temperatures (30 to 35°C).

■ Mueller-Hinton agar with 4% NaCl and 6 μg of oxacillin per ml

Mueller-Hinton agar with 4% NaCl and 6 μg of oxacillin per ml is the selective, differential medium used to screen *S. aureus* (not coagulase-negative staphylococci) for resistance to penicillinase-resistant penicillins (e.g., nafcillin, methicillin, and oxacillin). A sample from overnight growth on nonselective medium is used. Incubation for a full 24 h at 35°C in ambient air is recommended before interpretation of growth.

■ Mueller-Hinton broth

Mueller-Hinton broth is a magnesium and calcium cation-adjusted liquid medium used in procedures for susceptibility testing of aerobic gram-positive and gram-negative organisms by both macrodilution and microdilution methods. The nutritive base includes beef extract and peptones. Starch is a detoxifying agent.

■ Multiprobe media (M4-3, M5, and M4-RT) (Remel)

M4-3 contains vancomycin, amphotericin B, and colistin and is suitable for transport of viruses, chlamydiae, *Mycoplasma,* and *Ureaplasma*. M5 is similar to M4-3, but it does not contain gelatin. M5 is suitable for transport of viruses, chlamydiae, *Mycoplasma,* and *Ureaplasma*. M4-RT contains gentamicin and amphotericin B and is suitable only for transport of viruses and chlamydiae. All the media are supplemented Hanks' balanced salt solution buffered with HEPES buffer, with phenol red as the pH indicator. The antibiotics are added to inhibit bacterial organisms, and therefore, the medium cannot be used for bacterial culture.

■ Mycobactosel agar

Mycobactosel is a BBL trade name for an enriched selective agar-based medium used for isolation of *Mycobacterium* species. The medium is called by other names, depending on the manufacturer. The basic formulation is a Middlebrook 7H11 base, glycerol, inorganic salts, casein hydrolysate, malachite green, and OADC enrichment. Antibiotics are added to make the medium selective. The principle used for the Middlebrook 7H11 formulation to which antibiotics are added is the same as that used for Mitchison 7H11 medium. The antibiotics differ between Mycobactosel agar and Mitchison 7H11 medium. The antibiotics in Mycobactosel agar are cycloheximide, lincomycin, and nalidixic acid, which inhibit saprophytic fungi, gram-positive organisms, and gram-negative organisms, respectively.

■ MycoTrim GU and MycoTrim RS (Irvine Scientific)

The MycoTrim GU and MycoTrim RS culture systems are unique triphasic flask systems specifically designed for the isolation and identification of *M. hominis, U. urealyticum* (GU), and *Mycoplasma pneumoniae* (RS). The flask systems contain both agar and an enriched broth formulated for growth of these organisms that contain PPLO broth, containing meat digests, peptones, beef extracts, glucose, arginine, urea, horse serum, yeast extract, phenol red indicator, calcium, phosphate, and agar at a concentration that allows spreading growth of the colonies. The specimen is inoculated into the flask, and antibiotic disks (cefoperazone and nystatin) are added to prevent bacterial contamination. The system is incubated agar side up. Growth of the organism results in a pH change and is indicated by a color change in the media from red to orange and/or yellow. If no color change occurs in the first 24 h, the agar surface is reinoculated with the growth media. Because mycoplasmas do not cause turbidity, the color change is crucial. Colonial growth is confirmed by visualizing colonies using a light microscope and the 10× objective. The color change and colony morphology, including size and appearance, distinguish between *M. hominis, U. urealyticum,* and *M. pneumoniae*.

■ NAG medium

NAG medium is an enriched and selective medium used for the isolation and cultivation of *Haemophilus* species from clinical specimens with mixed flora. The agar base is blood agar with *N*-acetyl-D-glucosamine (NAG), hemin, and NAD. NAG medium allows spheroblastic *H. influenzae* to revert morphologically. Spheroblastic forms may be seen in specimens from patients receiving beta-lactam antibiotics. Bacitracin makes the medium selective by inhibiting gram-positive organisms that occur as normal respiratory flora. This medium has been found to be especially helpful in isolating *H. influenzae* from respiratory specimens from cystic fibrosis patients. Placement of cefsulodin disks on the primary streak helps to inhibit *Pseudomonas* spp. to make the medium more selective.

■ Neomycin egg yolk agar

Neomycin egg yolk agar is a selective and differential medium used for the differentiation of anaerobic organisms that are lipase positive, including *Clostridium* spp., *Prevotella intermedia, Fusobacterium necrophorum*, and some strains of *Prevotella loescheii*. The nutritive base includes peptones and yeast extract. Vitamin K and L-cystine make the medium optimal for the isolation of anaerobes. Egg emulsion adds enrichment and makes the medium differential by detecting lipase activity. Neomycin makes the medium selective by inhibiting both gram-positive and gram-negative organisms and differential by the fermentation of lactose.

■ Neomycin-vancomycin agar

Neomycin-vancomycin agar is an enriched and selective medium that is particularly good for the isolation and cultivation of *Fusobacterium* from clinical specimens. The nutritive base is fastidious anaerobe agar with 5% sheep blood. The selective agents include neomycin and vancomycin, which inhibit gram-negative and gram-positive organisms, respectively.

■ New York City medium

New York City medium is an enriched and selective medium for the isolation of pathogenic *Neisseria* from clinical specimens. It also supports the growth of large-colony mycoplasmas and *U. urealyticum*. The medium is a clear peptone-cornstarch agar base with lysed horse erythrocytes, horse plasma, and yeast dialysate, which are used instead of the hemoglobin and the supplements used for the other enriched and selective media for *Neisseria*. The antibiotics that make the medium selective include vancomycin, colistin, and amphotericin B, which inhibit gram-positive bacteria, gram-negative bacteria, and fungi, respectively. While human blood products can replace the horse blood products, sheep blood cannot be used.

■ Nucleic acid transport (NAT) (Medical Packaging Corporation)

NAT is a nucleic acid transport device that is FDA cleared for use with multiple amplification and hybridization testing formats.

■ Oxford agar

Oxford agar is an enriched and selective medium used for the isolation of *L. monocytogenes.* Columbia agar is the base, and it is supplemented with esculin and ferric ammonium citrate for the detection of esculin hydrolysis by listeriae. Suppression of contaminants is accomplished by the addition of lithium, cycloheximide, colistin, acriflavine, cefotetan, and fosfomycin. A modified Oxford agar replaces cycloheximide, acriflavine, cefotetan, and fosfomycin with moxalactam. *Listeria* spp. appear black with a black halo.

■ Oxidative-fermentative polymyxin B-bacitracin-lactose agar

Oxidative-fermentative polymyxin B-bacitracin-lactose medium is a selective and differential medium used for the isolation of *B. cepacia* from respiratory specimens from patients with cystic fibrosis. The nutritive base is an oxidative-fermentative medium with peptones. When acid is produced from the utilization of the lactose sugar, as occurs with *B. cepacia*, the bromthymol blue indicator changes the colony from green to yellow. Polymyxin B and bacitracin are the selective agents and inhibit some gram-negative and gram-positive organisms, respectively. Other organisms seen in cystic fibrosis patients may grow on this medium and are differentiated by the inability to produce acid from lactose. See also *Burkholderia cepacia* selective agar and *Pseudomonas cepacia* (PC) agar.

■ P agar

P agar is an enriched medium used for cultivation and isolation of staphylococci. The agar base includes peptone, yeast extract, NaCl, and glucose.

■ Peptone yeast extract broth

Peptone yeast extract broth is used in the analysis of metabolic products by gas-liquid chromatography because there is negligible acid volatility within the medium.

■ Petragnani medium

Petragnani medium is an egg-based medium. It contains more than twice the concentration of malachite green in Lowenstein-Jensen medium and is most commonly used for the isolation and cultivation of mycobacteria from heavily contaminated specimens. It is also used for the cultivation and maintenance of *Mycobacterium smegmatis*.

■ Phenylethyl alcohol agar

Phenylethyl alcohol agar is an enriched and selective blood agar medium used for the detection and isolation of anaerobic organisms, particularly fastidious and slowly growing bacteria, from clinical specimens with mixed flora. The base is Trypticase soy agar with yeast extract, vitamin K, cystine, and hemin. The medium is selective as a result of the incorporation of phenylethyl alcohol, which reversibly inhibits DNA synthesis and thus inhibits facultative anaerobic gram-negative bacteria, such as members of the family *Enterobacteriaceae.* Phenylethyl alcohol agar inhibits swarming by *Proteus* spp. and *Clostridium septicum.*

■ PLM-5 TM

PLM-5 TM is a proprietary medium formulation (Intergen Co., Purchase, N.Y.) similar to Ellinghausen-McCullough/Johnson-Harris medium that is used for the isolation and cultivation of *Leptospira*. It has less agar and 5-fluorouracil.

■ Polymyxin B-acriflavine-lithium chloride-ceftazidime-esculin-mannitol (PALCAM) agar

PALCAM agar is an enriched, differential, and selective agar medium used for the isolation of *L. monocytogenes*. Columbia agar supplemented with glucose, mannitol, and yeast extract is the nutritive base. Esculin and ferric ammonium citrate are added to detect esculin hydrolysis by listeriae. Fermentation of mannitol is detected with the indicator dye phenol red. Lithium, acriflavine, ceftazidime, and polymyxin B are added as selective agents. For contaminated specimens an enriched broth is inoculated and incubated for 24 h. Subsequently 0.1 ml is subcultured onto PALCAM agar. Listeria colonies appear gray-green with a sunken black center.

■ Polymyxin B-lysozyme-EDTA-thallous acetate agar

Polymyxin B-lysozyme-EDTA-thallous acetate agar is a selective agar used for the isolation of *B. anthracis* from environmental specimens. Heart infusion agar is the base. Thallous acetate and EDTA are additional additives speculated to have advantages for the recovery of *B. anthracis*. Lysozyme is an additive which inhibits *Bacillus* spp. other than *B. cereus* and *B. anthracis*. The addition of thallous acetate, EDTA, and lysozyme together has an additive effect which results in the inhibition of most non-*B. anthracis* species. Polymyxin B inhibits gram-negative organisms. Colonies of *B. anthracis* grown on polymyxin B-lysozyme-EDTA-thallous acetate agar are smaller and smoother than those grown on plain heart infusion agar and are creamy white with a ground-glass texture. *B. cereus* is usually inhibited (43).

■ Polymyxin B-pyruvate-egg yolk-mannitol-bromthymol blue agar
