Susceptibility Test Methods: Viruses

MAX Q. ARENS AND ELLA M. SWIERKOSZ

114

During the past decade and a half, safe and effective antiviral therapy has been developed for treatment of a number of viral infections (7, 13, 28, 31, 35, 36, 37, 50, 61). Great strides have been made, most notably in the development of antiviral agents for treatment of human immunodeficiency virus (HIV). While the overwhelming majority of clinical virus isolates from drug-naive patients are susceptible to antiviral agents, widespread use of some antiviral agents has led to the emergence of drug-resistant strains, particularly in immunocompromised hosts (7, 8, 10, 11, 12, 14, 44). Diagnostic virology laboratories are increasingly asked to perform in vitro testing of antiviral agents when patients fail to clinically respond to antiviral therapy. This chapter discusses the clinical situations where antiviral resistance has emerged, thus necessitating in vitro susceptibility testing, and provides an overview of the phenotypic and genotypic susceptibility testing methods that have been employed to detect resistance. The major antivirals in use are discussed in chapter 112. Chapter 113 details the mechanisms of resistance of antiviral agents.

CLINICAL INDICATIONS FOR ANTIVIRAL SUSCEPTIBILITY TESTING

Antiviral susceptibility testing is essential for defining mechanisms of antiviral resistance, for determining the frequency with which drug-resistant viral mutants emerge in clinical practice, to test for cross-resistance to alternative agents, and when evaluating new antiviral agents. With the exception of antiviral susceptibility testing for herpes simplex virus (HSV), results of in vitro phenotypic assays are usually not available in a time frame relevant for patient management. Nevertheless, clinical deterioration of patients undergoing antiviral therapy can be associated with resistant virus. Results of antiviral susceptibility testing may be helpful in certain clinical situations. Persistent or worsening HSV or varicella zoster virus (VZV) infection while on acyclovir may indicate drug resistance. Alternative therapy agents such as foscarnet and cidofovir are available. Furthermore, HSV or VZV causing recurrent infection is often thymidine kinase (TK) competent and therefore susceptible to acyclovir, which has minimal toxicity compared to foscarnet (7). Persistent or worsening human cytomegalovirus (HCMV) retinitis, pneumonitis, or colitis unresponsive to ganciclovir may also indicate drug-resistant virus. Cidofovir and foscarnet can be used as alternative agents. Influenza A isolates resistant to amantadine and rimantadine readily emerged during clinical trials of these drugs; therefore, continuous shedding or transmission of influenza A virus in a population undergoing prophylaxis or treatment with these agents may be due to drug resistance. Prolonged influenza virus shedding during therapy with a neuraminidase inhibitor (NI) may be due to the emergence of NI-resistant virus. Monitoring for HIV type 1 (HIV-1) antiretroviral resistance is essential for assessing the failure of a particular regimen to suppress HIV replication and to test for cross-resistance to alternative antiretroviral drugs to aid in the selection of appropriate salvage therapy. Guidelines developed by the U.S. Department of Health and Human Services Panel on Clinical Practices for Treatment of HIV Infection (http://aidsinfo.nih.gov/guidelines/) and by a European panel (130) have recommended that resistance testing be performed in cases of suboptimal viral load reduction after institution or modification of therapy and virologic breakthrough in ongoing therapy and also suggest that resistance testing of acute-phase or recently infected individuals at baseline prior to initiation of therapy will likely optimize the virologic response. Resistance testing at baseline in chronically infected patients may be reasonable if infection with a drug-resistant virus is suspected (http://aidsinfo.nih.gov/guidelines/) or if the prevalence in the population exceeds 10% (130) as it does in some areas of the United States (83).

DEFINITION OF ANTIVIRAL RESISTANCE

Antiviral resistance is a decrease in susceptibility to an antiviral drug that can be clearly established by in vitro testing and can be confirmed by genetic analysis of the virus and biochemical study of the altered enzymes. In vitro drug resistance must be distinguished from clinical resistance, in which the viral infection fails to respond to therapy. Clinical failures may or may not be due to the presence of a drug-resistant virus. Failure to achieve clinical response also hinges on other factors such as the patient's immunologic status and the pharmacokinetics of the drug for that individual patient. For example, limited penetration of the drug into the central nervous system may allow escape of HIV-1 despite suppression of the virus at other sites. Poor oral absorption and binding to plasma proteins may limit the bioavailability of certain drugs. Furthermore, administration of certain antiretroviral drugs in combination may interfere

with absorption or stimulate elimination of one or more of the coadministered drugs. Patient-specific factors such as nonadherence, intolerance to an antiretroviral drug, or an intercurrent infection can also lead to increases in HIV-1 plasma viremia despite in vitro susceptibility (21).

VARIABLES OF ANTIVIRAL SUSCEPTIBILITY TESTING

To date, few standards for antiviral susceptibility testing exist. The Clinical and Laboratory Standards Institute (CLSI; formerly National Committee for Clinical Laboratory Standards or NCCLS) recently published an approved standard for susceptibility testing of HSV as a first step in developing consensus protocols for antiviral susceptibility testing (29). The major obstacle to standardization of antiviral susceptibility testing is that many variables influence the final result. These include (i) cell line, (ii) viral inoculum titer, (iii) incubation time, (iv) concentration range of the antiviral agent tested, (v) reference strains, (vi) assay method, (vii) endpoint criteria, (viii) calculation of the endpoint, and (ix) interpretation of the endpoint. Testing of a single virus isolate may lead to greatly different endpoints, depending on the type of cell culture used (34, 60, 79). For example, the activity of acyclovir appeared greater than that of penciclovir when a plaque reduction assay (PRA) was performed with Vero cells; the converse was true when the assay was performed with WI-38 VA-13 and WISH cell lines. The two drugs had comparable activity when tested in A549 cells (79). The titer of the virus inoculum is also critical; too large an inoculum can make a susceptible isolate appear resistant; too small an inoculum can make all isolates appear susceptible (60). The length of time that the virus incubates in the presence of the drug must be sufficient to allow detection of small plaques, in the case of a PRA, or to allow growth of a subpopulation of resistant virus which may replicate at a slower rate than that of wild-type virus (5). The prolonged incubation times of peripheral blood mononuclear cell (PBMC)-based assays for HIV-1 susceptibility testing have been shown to select for subpopulations of HIV-1 variants not present in the starting inoculum (76). Moreover, different assay methods can produce different results. For example, the dye uptake (DU) assay for HSV susceptibility testing produces 50% inhibitory concentrations (IC_{50}s) higher than those produced by PRA (64). The concentration range of the drug tested affects the quality of the dose-response curve and therefore the validity of endpoint calculations. Susceptibility results are usually expressed as IC_{50}s because of the greater mathematical precision of the 50% endpoint than of a 90 or 99% endpoint. (Synonyms for IC_{50} are 50% inhibitory concentration and 50% effective concentration.) However, debate continues concerning the appropriate endpoint, i.e., 50% versus 90 or 99% inhibition. IC_{50}s are more precise and reproducible, but IC_{90}s may correlate better with clinical response and are better at detecting subpopulations of drug-resistant strains among sensitive ones (7). Moreover, few studies have correlated in vitro results with clinical response (8, 48, 70, 80, 103, 119).

Another critical variable is the heterogeneity within the population of a virus "isolate." A single clinical isolate actually represents a mixture of drug-susceptible and drug-resistant phenotypes (6, 65, 104, 120). A virus population that has never encountered an antiviral agent is predominantly drug susceptible; resistant virus may be present at low levels. The presence of low levels of resistant virus in a population that is predominantly drug susceptible might not be reflected in the IC_{50} but would manifest its presence in higher IC_{90}s or IC_{99}s. At this time it is unknown whether a small fraction of drug-resistant virus is important to the behavior of the virus in vivo or how such a fraction might affect the response of the infection to therapy in an otherwise healthy host. However, in immunocompromised patients, under the continued selective pressure of antiviral therapy, resistant virus can emerge, and its presence can often be correlated with progressive viral disease (8, 23, 42, 44, 48, 70, 97, 105, 106, 107, 116).

The genetic locus at which a mutation occurs also affects susceptibility testing endpoints. For example, DNA polymerase mutations of HSV, VZV, and HCMV usually confer relatively smaller increases in in vitro resistance than do TK mutations, which could go undetected in a mixed population of wild-type and mutant virus. In HIV-1, the level of in vitro resistance to protease (PR) inhibitors increased as the number of PR gene mutations increased (63). A good definition of such mixtures can be obtained only by testing appropriate concentrations of drug and a sufficiently large fraction of the population to detect resistant strains.

TESTING METHODS

Phenotypic versus Genotypic Assays

Phenotypic assays are in vitro susceptibility assays that measure the inhibitory effect of antiviral agents on the entire virus population in a patient isolate. A variety of endpoint measurements have been utilized, including a reduction in the number of plaques; inhibition of viral DNA synthesis; reduction in the yield of a viral structural protein, e.g., hemagglutinin of influenza or p24 antigen of HIV; or reduction in the enzymatic activity of a functional protein, e.g., HIV-1 reverse transcriptase (RT) or influenza virus neuraminidase. Phenotypic assays in use include PRA, DU, DNA hybridization, enzyme immunoassay (EIA), neuraminidase inhibition, and yield reduction assays for herpesvirus group and influenza A viruses; and PBMC cocultivation and recombinant virus assays for HIV-1. Genotypic assays analyze viral nucleic acid to detect specific mutations that cause antiviral drug resistance. Genotyping has been applied primarily to HCMV and HIV-1. Genotypic assays include DNA sequencing by automated sequencers, PCR amplification and restriction enzyme digestion of the products, and hybridization to microarrays of oligonucleotide probes. Phenotypic and genotypic assays have unique features that complement each other. Phenotypic assays are better suited to assess the combined effect of multiple resistance mutations on drug susceptibility. This is especially important for viruses such as HCMV and HIV-1, which acquire resistance-associated mutations in multiple genes that may be manifested as new patterns of resistance, cross-resistance, multidrug resistance, or even reversal of resistance (63, 69, 117, 120). However, most phenotypic assays are labor-intensive and expensive and have a long turnaround time. Genotypic assays are relatively inexpensive and have shorter turnaround times but cannot detect mutations outside the selected target. Interpretation of genotypic assays is problematic due to the complex interactions of resistance mutations which result in a particular drug resistance phenotype. The major phenotypic and genotypic assays in use are discussed below.

Control Strains

Simultaneous testing of control strains is crucial when antiviral susceptibility testing is being done. Reference strains should include genetically and phenotypically well-characterized drug-susceptible and drug-resistant isolates.

Drug-resistant strains chosen for reference should include those with drug resistance phenotypes relevant to the mode of action of the drug to be tested. For example, for testing nucleoside analogs, which require phosphorylation by viral TK, e.g., acyclovir versus HSV and VZV, TK-negative or -deficient strains should be included. Susceptibility testing of HCMV should include both UL97 and UL 54 mutants. For HIV-1 testing, mutants resistant to both nucleoside-analog and non-nucleoside analog inhibitors of RT and mutants resistant to PR inhibitors should be tested. The National Institute of Allergy and Infectious Diseases (NIAID) AIDS Research and Reference Reagent Program (Bethesda, Md.) provides upon request a number of reference strains of HSV, VZV, and HCMV, including the drug-resistant strains mentioned above and laboratory control strains HCMV AD169 and VZV Oka. For susceptibility testing of HIV-1, the NIAID AIDS Research and Reference Reagent Program has a repository of strains with various resistance phenotypes. Pharmaceutical companies and the American Type Culture Collection are also sources of control strains.

PRA for CMV, HSV, and VZV

The PRA has classically been the "standard" method of antiviral susceptibility testing to which new methods are compared (15, 17, 62, 64, 92). Because many variations of the PRA have been reported, the National Committee for Clinical Laboratory Standards (whose name was recently changed to Clinical and Laboratory Standards Institute [CLSI]) developed a standard for PRA testing of HSV (29). Likewise, the HCMV Resistance Working Group of the AIDS Clinical Trials Groups has formulated a standardized PRA for HCMV susceptibility testing (77). The challenges associated with HCMV susceptibility testing by PRA became apparent when, despite adherence to a consensus PRA protocol, some collaborating laboratories had difficulty distinguishing drug-susceptible and drug-resistant HCMV isolates.

The principle of the PRA is the inhibition of viral plaque formation in the presence of antiviral agent. The concentration of antiviral agent inhibiting plaque formation by 50% is considered the IC_{50}. Although the PRA is tedious and consumes more reagents than other methods, it is appropriate for small-scale testing of isolates. Prior to performing the antiviral susceptibility assay per se, titers of HSV isolates must be determined to ensure an inoculum appropriate for the surface area of the assay wells or plates (i.e., approximately 100 PFU/60-mm-wide tissue culture plate). Because clinical strains of HCMV and VZV are cell associated and because low-titer cell-free stocks are less stable during storage, infected cell suspensions (obtained by trypsin treatment of the infected monolayer) can be conveniently used for these viruses. Two to three passages of clinical strains of HCMV and VZV in cell culture are usually necessary to obtain a sufficient titer of virus. Low-passage isolates should be used because they are more likely to be representative of the original mixed population of the clinical isolate than a higher-passage stock would be. Well-characterized drug-susceptible and drug-resistant strains of HSV, HCMV AD169, and VZV Oka or Ellen serve as reference strains. Stepwise instructions for performance of the PRA for HSV, VZV, and HCMV have been published elsewhere (29, 64, 123, 124).

A modified PRA has been described that utilizes Vero or CV-1 cells that have been stably transformed with the *Escherichia coli lacZ* gene under the control of an HSV-1 early promoter and which express beta-galactosidase only after infection with HSV. Plaques were visualized after histochemical staining for beta-galactosidase (126, 127). Proposed susceptibility breakpoints determined by the PRA are listed in Table 1.

DU Assay

The DU assay has been used for many years for susceptibility testing of HSV (64, 92, 127). This assay is based on the preferential uptake of a vital dye (neutral red) by viable cells but not by nonviable cells. The extent of viral lytic activity is determined by the relative amount of dye bound to viable cells after infection with HSV compared with the amount bound to uninfected cells. The dye bound by viable cells is eluted by ethanol and measured colorimetrically. The drug concentration inhibiting viral lytic activity by 50% is considered the IC_{50}.

The DU assay consistently gives IC_{50}s of acyclovir that are three to five times greater than those given by PRA. This difference is most likely due to the higher inoculum used in the DU assay (500 PFU/ml) and to the use of a liquid overlay which allows drug-resistant virus to "amplify," thus resulting in a more sensitive detection of small amounts of drug-resistant virus. Therefore, the DU assay uses a cutoff IC_{50} of >3 μg/ml to denote acyclovir resistance (Table 1).

Advantages of the DU method include its ability to be semiautomated, allowing for efficient testing of large numbers of isolates, and its ability to detect smaller amounts of resistant virus than the PRA can detect. Disadvantages are the relatively high cost of automated equipment and the technical problems caused by overseeding of cells into the culture wells and precipitation of neutral red onto the monolayer. The stepwise procedure for the DU assay has been previously published (64, 136).

DNA Hybridization

DNA hybridization assays have been used to measure the effects of different antiviral compounds on DNA synthesis. These methods semiquantitatively measure the amounts of viral DNA produced in the absence and presence of antiviral drug, and IC_{50}s are calculated from these data. Good correlation between the PRA and a dot blot hybridization assay has been demonstrated (16, 54). The stepwise procedure has been detailed previously (124). DNA-DNA hybridization test kits previously commercially available (Hybriwix Probe Systems, Athens, Ohio) have been used successfully for susceptibility testing of HSV, HCMV, and VZV (24, 25, 26, 33, 44, 70, 105, 106, 107, 117, 125). The Hybriwix assays are no longer commercially available.

EIAs

EIAs have been developed for susceptibility testing of HSV, VZV, and influenza A virus (10, 12, 102, 108). EIA permits quantitative measurement of viral activity by spectrophotometric analysis; IC_{50}s are calculated as the concentrations of antiviral agent that reduce the absorbance to 50% of that of the virus control. EIA is more suited than the PRA and DU assay to the routine diagnostic laboratory. Susceptibility results for HSV and VZV determined by this method have correlated well with those obtained by PRA.

Susceptibility testing of influenza A virus by PRA is tedious and labor-intensive. EIA is technically easier and is more suitable for the testing of multiple isolates (10). The EIA utilizes antibodies to influenza A virus hemagglutinins (H1 or H3); viral hemagglutinin expression correlates with viral growth. Amantadine and rimantadine activities are measured by inhibition of hemagglutinin expression. Amantadine- or rimantadine-susceptible and -resistant isolates, whose M2 gene sequences are known, serve as controls and must be tested in

TABLE 1 Proposed guidelines for antiviral susceptibility results of herpesvirus group and influenza A viruses

Virus	Antiviral agent	Method	IC_{50} denoting resistance	Reference(s)
HSV	Acyclovir	PRA	≥2 μg/ml	92
		DNA hybridization	≥2 μg/ml	44, 125
		DU	≥3 μg/ml	64, 92
	Famciclovir (active metabolite = penciclovir)	PRA and DNA hybridization	Definitive breakpoints cannot be established	79, 121
	Foscarnet	PRA	>100 μg/ml	105
	Vidarabine	PRA	≥2-fold increase of IC_{50} compared to control or pretherapy isolate	107
VZV	Acyclovir	PRA and DNA hybridization	≥3–4-fold increase of IC_{50} compared to pretherapy isolate or to control strain	15, 70, 106
	Famciclovir	PRA and DNA hybridization	Definitive breakpoints cannot be established	121
	Foscarnet	Late antigen reduction assay	300 μM	106
HCMV	Cidofovir	PRA and DNA hybridization	>2 μM	26, 49, 117
	Foscarnet	PRA and DNA hybridization	>400 μM	26, 49
			>324 μM	117
	Ganciclovir	PRA and DNA hybridization	≥3–4-fold increase of IC_{50} compared to pretherapy isolate or control strain (~3 μg/ml)	42, 47, 99
			>6 μM	26, 49
			>8 μM	117
Influenza A	Amantadine, rimantadine	EIA	>0.1 μg/ml	10, 11
Influenza A and B viruses	Oseltamivir and zanamivir	NI assay	>1,000-fold decrease in NA activity	56, 57

parallel with patient isolates. A protocol for the EIA for susceptibility testing of influenza A virus has been published (124). There are no commercial EIA assays available.

Flow Cytometry

Flow cytometry has been applied to susceptibility testing of HSV and HCMV (82, 93, 98). Whereas the IC_{50}s measured by flow cytometry were numerically different from those determined by plaque reduction, drug-susceptible isolates could be readily distinguished from drug-resistant isolates. Advantages of antiviral susceptibility testing by flow cytometry include the potential for automation, the objectivity of the assay, and a shorter turnaround time than that of the PRA.

NI Assay

Recently, two inhibitors of influenza virus neuraminidase (NA), oseltamivir and zanamivir, have been approved for treatment of influenza A and B virus infections (22). Because there are limited data concerning the emergence of resistant virus in vivo, surveillance is important to determine the frequency with which resistance to NIs emerges during active influenza virus infection. Susceptibility studies to date have indicated that assay of NA activity was the best predictor of in vivo response to NIs (56, 94). NA activity is assayed using solubilized supernatant from viral culture as the source of viral NA. After incubation of the viral NA with varying concentrations of NI, a fluorogenic substrate is added. Fluorescence is quantitated by a fluorimeter, and the IC_{50} is calculated relative to the activity of viral NA in the control reaction (no NI). A zanamivir-resistant influenza B isolate from an immunocompromised child and oseltamivir-resistant A (H1N1) isolates from experimentally infected volunteers have been recovered (56, 57).

Yield Reduction Assay

The yield reduction assay reflects the ability of an antiviral agent to inhibit the production of infectious virus, rather than the formation of a plaque. Cell monolayers are infected with virus, incubated in the presence of antiviral compound, and then lysed. Cell-free virus titers are subsequently determined

by plaque assay. The endpoint is defined as the concentration of antiviral which reduces virus yield by 50% in comparison with that of untreated control cultures. When used for susceptibility testing of HSV against penciclovir and acyclovir, the IC_{50}s for penciclovir were equivalent to or lower than those for acyclovir (19, 79). The greater activity of penciclovir is postulated to be the result of the extended half-life of penciclovir triphosphate (19).

Measurement of HSV and VZV TK Activity by Plaque Autoradiography

Functional viral TK is required for initial phosphorylation of acyclovir. To determine whether resistance to acyclovir is due to diminished or altered viral TK, two plaque autoradiograph methods are used (89). Incorporation of [^{125}I]iododeoxycytidine (IdC), a pyrimidine analog selectively phosphorylated by the VZV- or HSV-specific TK, correlates well with the acyclovir-phosphorylating potential of HSV and VZV isolates. Incorporation of [^{14}C]thymidine (dT) specifically assesses the thymidine-phosphorylating activity of these isolates and is useful for analyzing resistance to pyrimidine nucleoside analogs (acyclovir is a purine nucleoside analog). Most acyclovir-resistant HSV and VZV strains fail to incorporate both substrates due to diminished TK activity (TK^-); occasionally, strains with altered substrate (TK^a) activity are seen which fail to incorporate IdC but are able to incorporate dT. For IdC incorporation, Vero cells (HSV) and MRC-5 cells (VZV) are used. For dT incorporation, $LMTK^-$ TK^- mouse LM cells (Roswell Park Memorial Institute, Buffalo, N.Y.) are used for HSV; the TK^- cell line 143B is used for VZV dT incorporation. These assays provide both quantitative and qualitative evaluations of the TK status of a mixed population of TK^+ and TK^-. The IdC and dT plaque autoradiograph methods have been detailed elsewhere (89, 124).

Assays for HIV

A number of phenotypic assays are in use for susceptibility testing of HIV-1 isolates to nucleoside analog RT inhibitors (63, 72, 74, 78, 91, 101, 115, 120, 131, 135). A serious limitation of some of these procedures is that not all clinical isolates grow in the cell culture lines used in these assays. The AIDS Clinical Trials Group developed an assay performed with PBMCs which allowed growth of almost all clinical isolates of HIV-1 (72). Viral activity is quantitated by measurement of p24 antigen of HIV-1. The PBMC assay, however, is labor-intensive, costly, and difficult to control because of the many variables of the assay and has a long turnaround time (weeks). Moreover, this assay requires cocultivation of infected PBMCs with uninfected donor PBMCs to produce a stock of the clinical isolate being tested, which has been shown to select for subpopulations of HIV-1 not present in the original isolate (76).

A new generation of phenotypic assays, recombinant virus assays (RVA), have been developed to circumvent these problems (63, 74, 91, 101, 115). RVA involves PCR amplification of complete RT and PR gene coding sequences directly from the patient's plasma. The amplified RT and PR gene sequences from the patient strain are ligated into a viral vector containing a luciferase gene and then cotransfected along with a plasmid that expresses murine leukemia virus envelope proteins into a suitable receptive cell line. These cells then contain the patient's RT and PR gene-coding sequences in a background of an HIV-1 strain from which the original RT and PR sequences had been deleted. The susceptibilities of the chimeric pseudotyped viruses to all clinically available RT and PR inhibitors are subsequently determined in a single assay in which the ability of virus particles to replicate in the presence of various levels of antiretroviral drug is measured by detection of luciferase activity in the target cells. Recombinant virus assays thus allow determination of the phenotypic resistance patterns of circulating virus in vivo and circumvent the problem of selection of nonrepresentative variants during cultivation. The RVA can be completed in approximately 10 days from the time of cotransfection (63, 74, 91, 101, 115). Two RVAs are commercially available, the Antivirogram assay (developed by Virco, Mechelen, Belgium, and available in the United States at Laboratory Corporation of America [63]) and the PhenoSense assay (ViroLogic, Inc., South San Francisco, Calif. [102]). A recent comparison by Zhang et al. (137) of these two phenotype assays concluded that the PhenoSense (ViroLogic) results are more precise (i.e., show lower variability) and the PhenoSense assay was more likely to detect resistance to abacavir, didanosine, and stavudine. Limitations of RVAs are the necessity for a minimum of 500 to 1,000 copies of HIV-1 RNA per ml of plasma, a lack of consensus as to the appropriate increase in IC_{50} for each drug that correlates with clinical resistance, and uncertainty about the proportion of the total population of virus that a subpopulation of resistant virus must achieve to be detectable by these assays (58, 63).

GENOTYPIC ASSAYS

The genetic basis for antiviral resistance has been extensively studied for HCMV and HIV-1. Although not all resistance-associated mutations are known, the majority have been elucidated, allowing the application of molecular diagnostic methods. The major advantage of genotypic assays is the relatively rapid turnaround time compared to phenotypic assays.

HCMV

Genotypic assays have been used to screen HCMV isolates for mutations associated with ganciclovir resistance. Both UL97 (phosphotransferase) and UL54 (DNA polymerase) mutations can be detected; UL97 mutations are responsible for most ganciclovir resistance found to date (117). A number of approaches have been successfully applied to genotyping HCMV.

PCR amplification of short fragments of the UL97 gene followed by restriction endonuclease digestion has been used to detect mutations at positions 460, 520, 594, and 595 (24, 25, 46, 47). In one study, this assay detected 78% of ganciclovir-resistant UL97 mutants (25). PCR amplification followed by restriction endonuclease digestion could recognize mutant virus when present at 10% of the total virus population (117). The major advantage of this PCR-restriction endonuclease method is the speed with which UL97 mutations can be identified, since HCMV sequences can be directly amplified from many clinical samples. However, the absence of mutations at these key codons in UL97 does not necessarily exclude ganciclovir resistance as it has been shown that resistance can be attributed to other mutations in UL97 or to mutations in UL54 alone (49).

PCR amplification and sequencing of nearly the entire UL54 gene and the fragment of the UL97 gene spanning the conserved domains of the phosphotransferase should theoretically detect all the mutations currently known to confer resistance to ganciclovir (5, 25, 49, 117). Wolf et al. (136) identified a complete set of overlapping primers to be used for sequencing the full UL97 gene. UL97-associated ganciclovir resistance mutations have also been detected directly in patient blood and cerebrospinal fluid (18, 118, 136).

Sequencing of the UL54 gene, for genotypic detection of resistance to ganciclovir, foscarnet, and cidofovir is a large task not generally undertaken by the routine clinical virology laboratory. The UL54 codons that confer resistance to all three anti-HCMV drugs are between codons 408 and 841, inclusive (46, 86). Thus, one must amplify a fragment of about 1,500 bp and use three or four sequencing primers in each direction to obtain a reliable sequence. In a study by Smith et al. (117), UL97 mutations were detected in 89% of ganciclovir-resistant isolates whereas UL54 mutations were present in all high-level ganciclovir-resistant isolates. A caveat that applies to genotypic analysis is that not every mutation is a cause of antiviral resistance. Marker transfer experiments must be performed to definitively determine that a particular mutation is associated with drug resistance. For this purpose, PCR-amplified UL97 and UL54 fragments containing resistance-associated mutations were cotransfected with HCMV strain AD169 (drug susceptible). The resulting recombinant plaques were assayed for antiviral susceptibility by PRA. To further verify transfer of the mutations in question, sequencing was performed across the transfected fragment (5, 26).

The field of HCMV genotyping for detection of drug resistance is still evolving. A standardized protocol for sequencing of the UL97 gene was developed by members of the AIDS Clinical Trials Group HCMV Laboratories and published several years ago (87). Nevertheless, the discovery of new mutations that confer drug resistance is ongoing, as evidenced by the recent description of a deletion at UL97 codon 601 that was responsible for the early development of ganciclovir resistance in a renal transplant recipient (59). A recent review has provided an updated synopsis of the current state of knowledge of drugs and resistance in HCMV (55).

HIV

The development of antiretroviral drug resistance is currently a significant cause of treatment failures in HIV-infected patients (66, 67). Genotyping for detection of mutations that confer resistance has become a routine component of the management of HIV-infected individuals. Because of the lack of proofreading activity in the RT enzyme that copies the genome of HIV, the virus exists in infected individuals as a population of variants or quasispecies (40). This results in the random appearance and subsequent selection of resistant mutants in the presence of a selection pressure such as an inhibitory drug. Initially, a single mutation may occur, confer a low level of resistance, and then grow to predominance in the population. With ongoing replication, additional mutations that confer high-level resistance appear and the population as a whole becomes highly resistant (90). For some drugs, such as lamivudine and nevirapine, a single mutation confers high-level resistance (112).

Genotypic methods that have been used for detection of mutations in HIV include sequencing, selective PCR, oligonucleotide-specific hybridization, microarray hybridization (GeneChip; Affymetrix, Inc., Santa Clara, Calif.) and reverse hybridization (Line Probe Assay; Bayer Diagnostics NAD, Norwood, Mass.). The line probe assay for detection of mutations in HIV is currently not commercially available. Sequencing methods have been developed by several noncommercial laboratories and by two commercial companies, Abbott Diagnostics (Abbott Park, Ill.; formerly available from Applied Biosystems, Inc.) and Bayer Diagnostics (Tarrytown, N.Y.; formerly available from Visible Genetics, Inc.). Shafer (112) has reviewed the various assays available for genotypic analysis of HIV-1.

Dideoxynucleotide sequencing is the most commonly used method of HIV-1 PR and RT gene sequence analysis (41, 112). Two commercially available systems have been used successfully for this purpose, the TrueGene HIV-1 Genotyping Kit and OpenGene DNA Sequencing System (Bayer Diagnostics) and the ViroSeq HIV-1 Genotyping System (Celera/Abbott Diagnostics) (27, 32, 45, 95, 129). Both systems have been approved for in vitro diagnostic use. The sequencing systems rely on initial extraction of viral RNA from patient plasma, RT-PCR of the extracted RNA to amplify about 1,500 bp of PR and RT and then a sequencing reaction with dye terminators (ViroSeq) or dye-labeled primers (TrueGene). Both companies make sequencing instruments for electrophoresis of the samples, and both provide software to assemble the segments and align the assembled patient sequence with a reference sequence to aid in the identification of mutant codons. With the primers for PCR and the sequencing primers, the ViroSeq system provides double coverage at a minimum for the entire 1.5-kb sequence of interest and quadruple coverage may be obtained for certain regions. The ViroSeq software combines the functions of several previously available software packages to trim the sequence segments, generate a contiguous consensus sequence that is generated by assemblage of the overlapping individual segments, and align the consensus sequence with a reference sequence. The operator must manually toggle through the entire sequence, edit (confirm or override) the computer base calls, and also make the final decision about polymorphic sites where a mutant base might constitute a minor proportion in the background of wild-type base. The ABI software prints a complete mutation report which identifies "reported" and "novel" mutations based on the Los Alamos National Laboratory HIV database, which is available online at http://hiv-web.lanl.gov. The ViroSeq system has been used to successfully detect RT and PR gene mutations in pediatric samples and in non-subtype B HIV-1 samples (32, 95).

The TrueGene genotyping kit may be used in conjunction with a number of extraction procedures. The purified viral RNA is amplified in a single-tube RT-PCR step, the product of which can be used directly in the subsequent sequencing reactions. It employs a proprietary methodology using four pairs of sequencing primers whereby the upstream primer of each pair is labeled with one dye and the downstream primer of each pair is labeled with another dye. Each primer pair is present in each of four dideoxy-terminator reactions, one reaction for each of the four dideoxy bases. Thus, this arrangement requires 16 different reactions and 16 lanes on the sequencing gel in order to cover the HIV PR and RT genes in both directions. The data are analyzed with the TrueGene software and interpreted to provide a resistance report. Two studies have demonstrated improved virological outcome when genotyping information is considered in patient management decisions (27, 129).

A number of studies have compared the various "home brew" and commercial sequencing methods. An interlaboratory study compared the abilities of 13 laboratories to detect RT mutations in cultured PBMC pellets. Highly concordant results were obtained overall, with some difficulty encountered with a clinical isolate that contained a mixture of wild-type and mutant codons. A mutant codon which was present at less than 50% of a mixed population of resistant and susceptible genotypes was not consistently detected (41). Two large multicenter studies compared sequencing results among participating laboratories for detection of RT mutations in either coded plasmid mixtures or spiked plasma samples. Laboratories had difficulty in detecting mutations in cases where the mutant represented 25% or less of the

total DNA population at that codon (110, 111). Even the editing process can contribute variability to the overall HIV genotype determination, as shown by Huang et al. (68). In this study, sequence concordance was high even though different editing strategies were used by different labs, but 12% of the resistance mutations present in the 10 electronic files that were distributed and analyzed were not identified in some labs.

The GeneChip method (Affymetrix) utilizes miniaturized, high-density arrays of oligonucleotide probes on a silicon-glass chip that contains oligonucleotide probes complementary to the first 1,200 nucleotides of HIV RT and the entire sequence of PR genes. The probes are positioned in a grid pattern on the array and are available for hybridization with target nucleic acid labeled with a fluorescent reporter group. The labeled target is incubated with the array, and based on patterns of hybridization of the target nucleic acid to the probes, the target sequence can be deduced (75). Studies comparing the performance of the GeneChip to dideoxynucleotide sequencing have found the latter to be more reliable (58, 112). GeneChip is not currently commercially available.

The line probe assay (LiPA) was manufactured by Innogenetics but marketed by Bayer Diagnostics NAD as VERSANT HIV-1 RT Resistance Assay and VERSANT HIV-1 Protease Resistance Assay. It has been withdrawn from the market.

The VircoGen VirtualPhenotype assay (Virco) utilizes a proprietary algorithm to compare a virus genotype to a large database of known genotypes and phenotypes to predict a phenotype based on sequence data (58, 112). Two RT and PR gene sequence analysis programs are available online from Stanford University at http://hivdb.stanford.edu/. One program compares an HIV-1 sequence submitted by the investigator to a consensus reference sequence ultimately linking RT and PR gene sequence variations to the antiretroviral therapy history of the patient from whom the sequences were obtained (113). In the second sequence analysis program, Drug Resistance Interpretation, PR and RT gene sequences are entered by the user and the program produces a phenotypic interpretation based on correlations of genotype and accumulated information on clinical outcome (112).

A concern with each of the genotypic methods is that mutant variants present at low frequency may not be detectable and that mixtures of HIV-1 strains with minor sequence variations may not be distinguishable (58, 112). Genotypic assays do allow more rapid and efficient detection of resistance than phenotypic assays and may allow earlier detection of emerging resistance than phenotypic assays. Also, because of the complex interactions among different combinations of resistance mutations, predictions of phenotype based on genotype alone may not be accurate (20, 112). Moreover, genotypic assays can detect only known resistance-associated mutations. The complexity of these tests makes them impractical for many diagnostic virology laboratories. Measurement of plasma HIV-1 RNA levels (viral load) reflects the extent of virus replication in an infected individual and remains the strongest predictor of clinical outcome. Declining HIV-1 RNA levels during treatment indicate a positive response to therapy, whereas a significant rise in RNA levels indicates treatment failure (21, 88).

None of these genotypic methods is currently able to detect resistance to the newest antiretroviral agent, T-20 or enfuvirtide. This is a synthetic peptide inhibitor that interferes with viral entry by blocking formation of a hairpin structure that is necessary for fusion of the viral membrane with the cell membrane. Resistance to T-20 is conferred rather quickly (within weeks) and is the result of a single mutation, G36D, within the *env* HR1 domain or a combination of mutations that may or may not include the G36D mutation (133). Although the drug is FDA approved, the commercially available genotype methods have not yet included PCR or sequencing primers for this region.

Of recent concern with respect to the now greater availability of antiretrovirals in countries with limited resources is the question of whether the genotyping methods that have been developed for use in Western countries mainly on HIV group M subtype B virus will work on non-B subtypes. This concern is significant because subtype B accounts for only about 12% of the global AIDS pandemic. In a set of 35 HIV isolates from group M subtypes A through J, full-length sequences were created with the ViroSeq reagents in 84% of the specimens tested and with the TrueGene in 53% of the specimens tested (9). Both methods amplified RNA from plasma levels of about 100 to 1,000 copies/ml. Eshleman et al. (51) employed the ViroSeq system to genotype 126 samples (114 of which were non-B subtypes) and successfully sequenced 124 of these. Genotypes performed in a second lab on the same 126 samples were 98 to 100% identical to the primary lab results. Thus, it appears that the two commercially available genotyping systems work tolerably well on subtypes other than B and should be generally usable in geographic regions where non-B subtypes predominate.

Aside from the mechanics of performing HIV genotypes on non-B subtypes is the question of whether these subtypes exhibit drug-resistant mutation patterns in the same way and at the same locations as the subtype B strains. In an authoritative recent paper on this topic, Kantor et al. (73) looked at the correlation of antiretroviral treatment on the distribution of mutations in HIV sequences from 3,686 individuals infected with non-B subtypes and compared this data with mutations in HIV sequences from 4,769 patients with subtype B. All of the known subtype B resistance mutations occurred in the non-B subtypes, and 80% were correlated with antiretroviral treatment of the patients with the non-B subtypes. The authors concluded that it is reasonable for global monitoring of resistance to continue to focus on the known subtype B resistance mutations as there are apparently no unique or previously unrecognized mutations in non-B subtypes.

HBV

Treatment of chronic hepatitis B virus (HBV) infections with antiviral drugs and immune modulators is becoming more widely employed as recent clinical trials have demonstrated efficacy. Three nucleoside analogs, lamivudine (3TC), adefovir dipivoxil (ADV), and entecavir, a carbocyclic deoxyguanosine analog (114), are approved for treatment of chronic HBV and act at the level of the HBV DNA polymerase. Pegylated alpha interferon is approved for use in treatment and has both antiviral and immunomodulating activity.

Three regions of the HBV genome are relevant to treatment, resistance to the various drugs, and type/subtype determination: (i) the active site of the viral DNA polymerase gene, (ii) mutations in the precore region of the HBV genome, and (iii) mutations in the core (C-gene) and the surface (S-gene) proteins.

Lamivudine (3TC) was the first clinically useful drug for treatment of HBV and is still widely used today, although resistance is virtually ensured (20% of patients taking the drug develop resistance each year) if the drug is used long enough in any given patient (85). The active site of the HBV

DNA polymerase enzyme is very similar to that of HIV (they both have the same complement of enzymatic activities), and thus it seemed reasonable that many of the nucleoside analogs that inhibit HIV RT would also inhibit HBV polymerase. In fact, many have been tested in clinical trials but mainly lamivudine and adefovir dipivoxil (an analog of adenosine monophosphate) are currently being used in HBV therapy. Sequencing of the active site of the HBV polymerase is necessary for detection of the mutations now known to confer resistance to these drugs, although other research (134) or a commercial method is available (1, 122). Famciclovir (now rarely used) resistance mutations are in polymerase domain B, lamivudine resistance mutations are in domain C (the "M" of the YMDD motif is at codon 552 [or codon 204 by some counting methods], which corresponds to codon 184 in the HIV RT gene), and the only demonstrated adefovir dipivoxil resistance mutation is in domain D (codon 236) (3, 4, 85). Recent evidence indicates that ongoing lamivudine therapy in the presence of lamivudine resistance mutations is of no clinical value (2, 81), thus possibly accentuating the need for lamivudine resistance testing in the future. Adefovir dipivoxil is active against lamivudine-resistant mutants of HBV and is quite slow to cause the acquisition of resistance mutations during initial therapy.

The U.S. FDA approved in March 2005 a third drug, entecavir, for treatment of chronic HBV. This development is particularly exciting because entecavir is active against lamivudine- and adefovir dipivoxil-resistant HBV; it is easily absorbed, well tolerated, and relatively nontoxic. Entecavir is a carbocyclic deoxyguanisine analog that acts directly on the HBV DNA polymerase to cause delayed or nonobligate chain termination and also blocks priming of the reverse transcription reaction (114). Resistance to entecavir is apparently rare, having occurred in only two patients of the more than 500 enrolled in phase II and III clinical trials (128). Interestingly, resistance to entecavir alone was not observed; the two patients with resistance to entecavir had preexisting mutations to lamivudine which, in combination with new entecavir-induced mutations, resulted in high-level resistance to both drugs. Thus, patients with lamivudine resistance due to mutations at codons 528 and 552 (180 and 204 by the other counting method) when exposed to entecavir may develop mutations at codons 532, 550, and/or 598 (184, 202, and/or 250) and be highly resistant to both drugs (128).

Secondly, the precore (preC) region of the HBV genome has recently gained significance because there are indications that it may be associated with resistance to interferon. There is long-standing evidence (52) that mutations in the preC region have a negative effect on interferon treatment, and more-recent in vitro experiments have supported this contention (132). The development of a G1896A (codon 28) mutation results in a termination codon which interrupts translation of the HBeAg precursor and thus initiates an e-antigen-negative chronic hepatitis. Sequencing of this region is a reasonable method for detection of these mutations. Alternatively, Innogenetics has a LiPA that is capable of detecting this mutation as well as a preC promoter mutation that may also be present (codon 1762).

Thirdly, classification of HBV into types A to H based on the genomic sequence has yielded unexpected correlations with the clinical course of disease. It has long been known that some types, for example, type B, are associated with less active liver disease, slower progression, and more likely spontaneous HBeAg seroconversion than other types, for example, type C (96). Recent studies with pegylated interferon (71) have yielded the clinically relevant information that the response was type dependent. In this study, patients with type A had a 47% response (i.e., loss of HBeAg), patients with type B had a 44% response, type C patients had a 28% response, and type D patients had a 25% response. Thus, there is increasing evidence that determination of the HBV type is an important predictive factor in treatment with interferon and the overall course of disease (53). The genotype can be determined by sequencing the entire genome, the core region, or the surface protein region. Innogenetics has a commercially available LiPA that identifies the HBV type via reverse hybridization with an amplicon from the DNA polymerase gene.

Current recommendations for monitoring of patients on therapy for HBV include baseline quantitative HBV DNA levels and additional levels periodically to help determine the endpoint of treatment for patients with chronic hepatitis B (American Association for the Study of Liver Diseases [85]). Genotyping for detection of resistance should be performed if resistance is suspected because of rising DNA levels or appearance of symptoms (84).

INTERPRETATION OF ANTIVIRAL SUSCEPTIBILITY RESULTS

Table 1 lists breakpoint IC_{50}s proposed by various investigators for herpes group viruses and influenza viruses. The concentration of antiviral by which the virus is considered susceptible to the antiviral agent has generally been based on median susceptibilities of large numbers of clinical isolates from patients prior to, during, and after antiviral therapy. Because of the variables that affect antiviral susceptibility results, the absolute IC_{50} value can vary from assay to assay and from laboratory to laboratory. Moreover, in vitro results indicating susceptibility or resistance may not correlate with response of the infection to therapy in vivo. The clinical response of the patient depends on a number of other factors such as immunological status and pharmacokinetics of the drug in that particular patient (the dose or route of administration could be inappropriate). A poor clinical response may occur even though the antiviral susceptibility testing denotes in vitro susceptibility (39). Patients with HSV infections who are immunocompromised may fail to respond to therapy despite in vitro IC_{50}s indicating susceptibility to vidarabine or acyclovir (44, 105, 107). Conversely, HSV isolates for which IC_{50}s of acyclovir are >2 μg/ml can occasionally be recovered from otherwise healthy hosts who have responded to acyclovir therapy (80). Thus, a high IC_{50} derived by in vitro susceptibility testing is not sufficient to designate a viral strain as resistant. Neither can in vitro susceptibility to a drug a priori predict successful clinical outcome. Whenever possible, evidence of genetic alteration of the virus should be considered as well.

Interpretation of antiviral susceptibility results is further complicated by the variability in endpoint due to testing methodologies (30, 64, 92, 99). Because endpoints are dependent on the test method, each new method and antiviral agent must be correlated with a historic standard that has been used to test large numbers of isolates. Also, the absolute IC_{50} may vary from assay to assay and from laboratory to laboratory. Moreover, because small subpopulations of resistant virus may not be reflected in IC_{50}s, IC_{90} values may be more predictive of clinical response. One approach to interpreting susceptibility endpoints is to compare the IC_{50}s of an isolate obtained prior to therapy (or of a well-characterized reference control strain) with that of an isolate obtained during therapy; a significant increase in the ratio of

such IC_{50}s denotes resistance. However, pretherapy isolates are often unavailable, and the IC_{50} ratio considered to be clinically significant is unclear. Large-scale collaborative comparisons of methods with the same viral isolates are necessary to standardize antiviral susceptibility testing and to establish definitive interpretive guidelines. Only when a standardized assay is adopted can prospective studies be performed to correlate in vivo response with in vitro susceptibility. Such studies are essential before definitive interpretive breakpoints are established.

Susceptibility testing of penciclovir illustrates the effect that cell line and testing method have on the endpoint. When acyclovir and penciclovir, which is structurally similar to acyclovir, were tested with HSV isolates in Vero cells by PRA, penciclovir appeared to be less active than acyclovir and HSV-2 isolates appeared to be resistant to penciclovir. In contrast, penciclovir appeared to be more active than acyclovir against some HSV isolates when SCC25 cells were used. The two drugs appeared to have comparable activities when tested in MRC-5 and A549 cells (79). When clinical isolates of VZV were tested by plaque reduction and DNA hybridization, IC_{50}s for DNA hybridization were significantly lower than those by PRA (121). Variability in endpoint was also seen with VZV depending on the composition of the inoculum (cell free versus cell associated). Therefore, breakpoints for susceptibility testing of penciclovir with HSV and VZV cannot be established at this time (79, 121).

A limitation of phenotypic testing for HIV-1 is the lack of consensus as to the absolute IC_{50}s denoting resistance of HIV-1 to antiretroviral drugs. In vitro susceptibility of HIV-1 results are usually expressed as the "fold increase" in the IC_{50} of an isolate obtained on therapy compared to a pretreatment isolate or a drug-susceptible isolate (63, 109). The increase in the IC_{50} considered clinically significant is likely to vary by drug or drug class (58). The Antivirogram assay (Virco) has established cutoffs denoting reduced susceptibility at 2 standard deviations above the mean value for 1,000 isolates from untreated HIV-positive individuals and for several thousand isolates of genetically wild-type virus. Both Virco and ViroLogic are aware of the importance of clinical cutoff values and are making diligent efforts to ascribe accurate values for use by physicians.

The significance and clinical utility of phenotypic and genotypic analysis of HIV-1 are increasingly being recognized. A report that reanalyzed data from previous studies demonstrated that baseline genotypic and phenotypic drug resistance predicted virological failure (38). Genotypic analysis of the PR gene in patients who are on antiretroviral therapy but PR-inhibitor naive has also been shown to be predictive of virological and immune response to therapy with PR inhibitors (100). Prospective studies have demonstrated improved virological outcome when genotyping information is considered in patient management decisions (27, 43, 129). Drug resistance testing is now recommended to help guide the selection of salvage therapy after treatment failure and for guiding therapy for pregnant women (66). However, limitations of genotypic testing include the difficulty in interpretation of resistance mutations and the inability to detect minority variants.

It is important to remember that antiretroviral therapy may fail for reasons other than the emergence of drug-resistant virus such as drug antagonism; nonadherence; increased clearance of one antiretroviral drug when coadministered with another drug; inadequate penetration of drug into a sequestered site, e.g., the central nervous system; or malabsorption of drug from the gastrointestinal tract (58, 63).

FUTURE DIRECTIONS

Consensus protocols for antiviral susceptibility testing are under development. A protocol for HSV plaque assays is now published (29), and a standardized procedure for sequencing of the HCMV UL97 gene (87) has been published. Standardization is hampered by the many variables that affect susceptibility testing results. No single assay method, cell line, or inoculum composition (cell free versus cell associated) appears sufficient for testing all viruses. A major problem with culture-based susceptibility testing of viruses other than HSV is that assays may require weeks to complete, a fact that limits their utility in management of acute cases. Genotypic assays for UL97 and UL54 mutations of HCMV may replace culture-based assays as more resistance-associated mutations are identified. Data attesting to the clinical significance of susceptibility testing of HIV-1 isolates are accumulating. Additional prospective studies are required to delineate the utility of antiretroviral susceptibility testing.

Taxonomy and Classification of Fungi*

DAVID W. WARNOCK

115

There are at least 100,000 named species of fungi. However, it has been estimated that the number of undiscovered species ranges from 1 million to more than 10 million, and it has been calculated that about 1,000 to 1,500 new species are described each year (6). Of the named species of fungi, fewer than 500 have commonly been associated with human or animal disease, and no more than 50 are capable of causing infection in otherwise normal individuals. On the other hand, an increasing number of ubiquitous environmental molds are now being implicated as opportunistic pathogens, capable of producing serious or lethal disease in hosts that are immunocompromised or debilitated. These molds are organisms whose natural habitat is in the soil or on plants, wood, compost heaps, or decomposing food. Many are familiar to mycologists, plant pathologists, and food microbiologists, but they present problems for the clinical microbiologist who often has had no formal training in the identification of fungi. Fungal identification can be challenging and sometimes frustrating because of the importance placed on the morphological characteristics of the organisms and the need to become familiar with a range of different structures and terms. Indeed, it is fair to state that obscure mycological terms are one of the major factors that discourage many microbiologists from mastering fungal identification. However, investing time to learn the basic structures and principles of taxonomy, classification, and nomenclature can result in the ability to recognize and identify correctly many medically important fungi.

MORPHOLOGICAL CHARACTERISTICS OF THE FUNGI

Fungi form a separate group of eukaryotic organisms which differ from other groups, such as the plants and animals, in several major respects. Fungal cells are encased within a rigid cell wall, mostly composed of chitin, glucan, chitosan, mannan, and glycoproteins in various combinations. These features contrast with the animals, which have no cell walls, and the plants, which have cellulose as the major cell wall component. As in other eukaryotic organisms, fungal cells have a true nucleus with a surrounding membrane, and cell division is accompanied by meiosis or mitosis.

Fungi are heterotrophic, that is, lacking in chlorophyll, and therefore require preformed organic carbon compounds for their nutrition. Fungi live embedded in a food source or medium and obtain their nourishment by secreting enzymes into the external substrate and by absorbing the released nutrients through their cell wall. Fungi are found throughout nature, performing an essential service in returning to the soil nutrients removed by plants.

Fungi can be multicellular or unicellular. In multicellular organisms, the basic structural unit is a chain of multinucleate, tubular, filament-like cells (termed a hypha). In most multicellular fungi the vegetative stage consists of a mass of branching hyphae, termed a mycelium or thallus. Each individual hypha has a rigid cell wall and increases in length as a result of apical growth with mitotic cell division. In the more primitive fungi, the hyphae remain aseptate (without cross-walls). In the more advanced groups, however, the hyphae are divided into compartments or cells by the development of more or less frequent cross-walls, termed septa. Such hyphae are referred to as being septate. Fungi that exist in the form of microscopic multicellular mycelium are commonly called molds.

Many fungi that exist in the form of independent single cells propagate by budding out similar cells from their surface. The bud may become detached from the parent cell, or it may remain attached and itself produce another bud. In this way, a chain of cells may be produced. Fungi that do not produce hyphae but just consist of a loose arrangement of budding cells are called yeasts. Under certain conditions, continued elongation of the parent cell before it buds results in a chain of elongated cells, termed a pseudohypha. Unlike a true hypha, the connection between adjacent pseudohyphal cells shows a marked constriction. Yeasts are neither a natural nor a formal taxonomic group, but are a growth form shown in a wide range of unrelated fungi.

Many medically important fungi change their growth form as part of the process of tissue invasion. These so-called dimorphic pathogens usually change from a multicellular mold form in the natural environment to a budding, single-celled yeast form in tissue. *Histoplasma capsulatum, Blastomyces dermatitidis, Paracoccidioides brasiliensis,* and *Sporothrix schenckii* are the best-known examples of this dimorphic change, but many other fungal pathogens show subtle morphological differences between forms found in tissue and in culture.

* This chapter contains information presented in chapter 110 by Robert A. Fromtling, Judith C. Rhodes, and Dennis M. Dixon in the eighth edition of this Manual.

Fungi reproduce by means of microscopic propagules called spores. These may result from an asexual process (involving mitosis only) or a sexual process (involving meiosis, preceded by fusion of the nuclei of two cells). Except for the occasional mutation, asexual spores are identical to the parent. They are generally short-lived propagules that are produced in enormous numbers to ensure dispersion to new habitats. Many fungi are also capable of sexual reproduction. Some species are self-fertile (homothallic) and able to form sexual structures between different cells within an individual thallus. Most, however, are heterothallic and do not form their sexual structures unless two different isolates come into contact. Once two compatible haploid nuclei have fused, meiosis can occur, and this leads to the production of the sexual spores. In some species, the haploid sexual spores are borne singly on specialized generative cells and the whole structure is microscopic in size. In other cases, however, the spores are produced in millions in macroscopic "fruiting bodies" such as mushrooms. Sexual reproduction and its accompanying structures form the main basis for the classification of the fungi.

NOMENCLATURE OF FUNGI

The scientific names of fungi are subject to the International Code of Botanical Nomenclature (ICBN) (http://www.bgbm.org/iapt/nomenclature/code/default.htm), a convention that dates from the time when biologists regarded these organisms as "lower plants." The rules of the ICBN must be followed when proposing the name for a new fungal species; otherwise, the name being proposed can be rejected as invalid. The main requirements for valid publication are that the name must be in Latin binomial form, the publication must contain a concise description of the essential and differential characteristics of the fungus in Latin, and a living culture of the specimen on which the author based his original description of the species must be preserved.

Names of fungi may have to be changed for a number of reasons. Many common and widely distributed species of fungi have been described as new many times and thus have come to have more than one name. In general, the correct name for any species is the earliest name published in line with the requirements of the code of nomenclature. The later names are termed synonyms. To avoid confusion, however, the ICBN permits certain exceptions. The most significant of these is when an earlier generic name has been overlooked, a later name is in common use, and a reversion to the earlier name would cause problems.

Another reason for changing the name of a fungus is when new research necessitates the transfer of a species from one genus to another or establishes it as the type of a new genus. Such changes are quite in order, but with the provision that the specific epithet should remain unchanged, except for inflection according to the rules of Latin grammar. However often a species is transferred to a new genus, the correct species epithet is always the first one that was applied to that particular organism. As an example, when *Phialophora parasitica* was moved to a new genus, it became *Phaeoacremonium parasiticum*.

If there is one complication of fungal nomenclature that is confusing to many microbiologists, it is the fact that a large number of fungi appear to bear more than one name. This is an apparent departure from the basic principle of biological classification, in which an organism can have only one correct name. As described in the previous section of this chapter, many fungi have an asexual stage (or anamorph), characterized by the production of asexual spores (e.g., conidia), and a sexual stage (or teleomorph) characterized by sexual spores (e.g., ascospores or basidiospores). Many fungi propagate asexually, and the teleomorph is unknown or only rarely encountered. Because of this, mycologists have often given separate names to the asexual and sexual stages. Often this is because the anamorph and teleomorph were described and named at different times without recognition of the connection between them. The code of nomenclature permits this practice, and while the name of the teleomorph takes precedence and covers both stages, the name given to an anamorph may be used as appropriate. Thus, it is permissible to refer to a fungus by its asexual designation if this is the stage that is usually obtained in culture. For example, *Blastomyces dermatitidis* is the anamorph of the ascomycete *Ajellomyces dermatitidis*. The anamorph is the stage that is ordinarily encountered in culture, and only under certain special conditions is the sexual stage formed. Although the correct name typified by the teleomorph is *A. dermatitidis, B. dermatitidis* remains the name that is most widely recognized and used.

The taxonomy and nomenclature of fungi that have both asexual and sexual stages are challenging. Some teleomorphic fungi can produce more than one asexual form of propagation, the term synanamorph being used to describe each of these different anamorphs. These may bear separate names. As an example, the teleomorphic species *Pseudallescheria boydii* can also exist in two different synanamorphic forms, named *Graphium fructicola* and *Scedosporium apiospermum*. These three names all refer to one and the same organism (see chapter 125).

TAXONOMY AND CLASSIFICATION OF THE FUNGI

The kingdom Fungi is one of the six kingdoms of life (4). It is organized in a hierarchical manner, each rank being named with, and recognizable by, a particular ending: Phylum (or Division), -mycota; Class, -mycetes; Order, -ales; Family: -aceae (7). Each family is composed of a number of genera, and these are divided into species. The kingdom Fungi is currently divided into four phyla or divisions: the Chytridiomycota, Zygomycota, Ascomycota, and Basidiomycota. One of these phyla, the Chytridiomycota, does not contain any species that are pathogenic to humans. In addition to the true fungi, there are a number of organisms, classified in the kingdoms Chromista and Protozoa, that while not fungi sensu stricto, are "fungus-mimics" or "pseudofungi," i.e., protists that have become similar to fungi in one or more respects.

The classification of fungi is largely based on their appearance, rather than on the physiological and biochemical differences that are of such importance in bacterial classification. The sexual spores and their mode of production form the main basis for classification of fungi into the Zygomycota, Ascomycota, and Basidiomycota. In some fungi, however, the asexual stage or anamorph has proved so successful as a means of rapid dispersal to new habitats that the sexual stage or teleomorph has disappeared or at least has not been discovered. Even in the absence of the teleomorph it is now often possible to assign these fungi to the Ascomycota or Basidiomycota on the basis of DNA sequences of the anamorphs (3). In the past, these asexual fungi were classified in an artificial group, the "Fungi Imperfecti" (also termed the "form-division Deuteromycota") and were divided into artificial form-classes according to the morphological characteristics of their asexual reproductive structures. There is no longer any separate formal grouping for those fungi that appear to be strictly anamorphic or for which no teleomorph has been

TABLE 1 Simplified taxonomic scheme illustrating major groups of the Kingdom Fungi in which medically important fungi are classified

Taxonomic designation	Representative genera
Phylum: Zygomycota	
Class: Zygomycetes	
Order: Mucorales	*Absidia, Rhizopus*
Order: Entomophthorales	*Basidiobolus, Conidiobolus*
Phylum: Basidiomycota	
Class: Basidiomycetes	
Order: Filobasidiales	*Filobasidium*, *Filobasidiella* (teleomorphs of *Cryptococcus* species)
Order: Agaricales	*Schizophyllum*
Phylum: Ascomycota	
Class: Archiascomycetes	
Order: Pneumocystidales	*Pneumocystis*
Class: Hemiascomycetes	
Order: Saccharomycetales	*Clavispora, Debaryomyces, Issatchenkia, Kluyveromyces* (teleomorphs of *Candida* species); *Saccharomyces*
Class: Euascomycetes	
Order: Onygenales	*Arthroderma* (teleomorphs of *Microsporum* and *Trichophyton* species), *Ajellomyces* (teleomorphs of *Blastomyces* and *Histoplasma* species)
Order: Eurotiales	*Emericella, Eurotium, Neosartorya* (teleomorphs of *Aspergillus* species)
Order: Hypocreales	*Gibberella, Nectria* (teleomorphs of *Fusarium* species)
Order: Microascales	*Pseudallescheria* (teleomorph of *Scedosporium* species)

discovered. Nonetheless, mycologists continue to employ the asexual reproductive characteristics of molds, at least for routine identification purposes.

A simplified taxonomic scheme illustrating the major groups of medically important fungi is presented in Table 1. These groups are described in the following sections. A simplified key to their identification is provided in Table 2.

Kingdom Fungi

Phylum Zygomycota

In this group of lower fungi, the thallus is aseptate and consists of wide, hyaline (colorless) branched hyphal elements. The asexual spores (termed sporangiospores) are nonmotile and are produced inside a closed sac, termed a sporangium, the wall of which ruptures to release them. Sexual reproduction leads to the formation of a single large zygospore with a thickened wall. Most of the medically important species are heterothallic and do not form their sexual structures unless two compatible isolates come into contact.

The phylum Zygomycota is divided into two classes, the Zygomycetes and the Trichomycetes. The former class contains two orders of medical importance, the Entomophthorales and the Mucorales. The order Entomophthorales includes the genera *Basidiobolus* and *Conidiobolus,* agents of subcutaneous infections. The order Mucorales is the most clinically important and includes the genera *Absidia, Mucor, Rhizomucor,* and *Rhizopus*.

TABLE 2 Simplified key to the main groups of medically important fungi

1a. Fungus not culturable on routine media, occurs as cyst-like cells in tissue	Archiascomycetes
1b. Fungus culturable	2
2a. Colonies consist of budding cells at 30°C	3
2b. Colonies consist of hyphae at 30°C	5
3a. Colonies black	Black yeasts
3b. Colonies white, cream, pink, or red	4
4a. Urease test positive	Basidiomycetous yeasts
4b. Urease test negative	Ascomycetous yeasts
5a. Hyphae septate	6
5b. Hyphae nearly aseptate	9
6a. Clamp connections present	Filamentous basidiomycetes
6b. Clamp connections absent	7
7a. Fruiting bodies absent	Hyphomycetes
7b. Fruiting bodies present	8
8a. Fruiting bodies containing ascospores in asci	Euascomycetes
8b. Fruiting bodies containing conidia	Coelomycetes
9a. Sporulation abundant	Zygomycota
9b. Sporulation absent; zoospores formed in water cultures	Oomycota

Phylum Basidiomycota

Most members of this group of higher fungi have a septate, filamentous thallus, but some are typical yeasts. Sexual reproduction leads to the formation of haploid basidiospores on the outside of a generative cell, termed a basidium. Three classes are recognized (Basidiomycetes, Urediniomycetes, and Ustilaginomycetes), but only a few members of this large phylum are of medical importance. The most prominent are the basidiomycetous yeasts with anamorphic stages belonging to the genera *Cryptococcus, Malassezia,* and *Trichosporon*. The genus *Cryptococcus,* which contains more than 30 species, has teleomorphs that have been assigned to the genera *Filobasidium* and *Filobasidiella* (2).

In culture, filamentous basidiomycetes often produce fast-growing, nonsporulating (sterile) white colonies with clamp connections. These are hyphal outgrowths which, at cell division, make a connection between the two cells, forming a bypass around the septum to allow the migration of a nucleus. The basidia are often produced in macroscopic structures, termed basidiomata or basidiocarps, and the basidiospores are often forcibly discharged. Asexual reproduction is variable, with some species producing spores like those of the Ascomycota (see below), but many others are not known to produce spores at all. Most filamentous basidiomycetes are wood-rotting fungi or obligate plant pathogens. The most frequently reported clinically important filamentous basidiomycete is *Schizophyllum commune.*

Phylum Ascomycota

This large phylum contains almost 50% of all named fungal species and accounts for around 80% of fungi of medical importance (6). Sexual reproduction leads to the development of haploid spores, termed ascospores, which are produced in a sac-like structure, termed an ascus. The Ascomycota show a gradual transition from primitive forms that produce single asci to species that produce large structures, termed ascocarps or ascomata, containing numerous asci. Variations in ascus structure are of major importance in the classification of these fungi. Asexual reproduction consists of the production of spores, termed conidia (singular, conidium), from a generative or conidiogenous cell. In some species the conidiogenous cell cannot be distinguished from the rest of the mycelium. In others, a special structure is produced, which bears one or more conidiogenous cells.

The phylum Ascomycota includes three classes of medical importance: the Archiascomycetes, the Hemiascomycetes, and the Euascomycetes. The class Archiascomycetes contains a single genus, *Pneumocystis,* formerly classified as a member of the kingdom Protozoa, but now reassigned to the fungi on the basis of small-subunit rRNA and other gene sequence comparisons (1). The class Hemiascomycetes contains the ascomycetous yeasts, while the class Euascomycetes contains the filamentous ascomycetes.

The order Saccharomycetales, which belongs to the class Hemiascomycetes, is characterized by vegetative yeast cells which proliferate by budding or fission. These fungi do not produce ascomata, the ascus being formed by direct transformation of a budding vegetative cell, by "mother-bud" conjugation, or by conjugation between two independent single cells. Many members of this order have an anamorphic stage belonging to the genus *Candida*. This genus, which consists of around 200 anamorphic species, has teleomorphs in more than 10 different genera, including *Clavispora, Debaryomyces, Issatchenkia, Kluyveromyces,* and *Pichia* (8).

In the class Euascomycetes sexual reproduction leads to the formation of ascomata containing asci with ascospores. This class has 12 orders that include species pathogenic to humans. Among the more important are the order Onygenales, which contains the teleomorphs of the dermatophytes and a number of dimorphic systemic pathogens (including *Histoplasma capsulatum* and *Blastomyces dermatitidis*); the order Eurotiales, which includes the teleomorphs of the anamorphic genera *Aspergillus* and *Penicillium;* and the order Hypocreales, which contains the teleomorphs of the anamorphic genus *Fusarium*. In addition, the teleomorphs of numerous melanized fungi of medical importance belong to a number of orders in the class Euascomycetes. These include the Chaetothyriales, Dothidiales, Microascales, Ophiostomatales, Pleosporales, and Sordariales.

Although most of the septate molds that are isolated in clinical laboratories belong to the class Euascomycetes, it is unusual to encounter their sexual reproductive structures in routine cultures. The few species which do produce ascomata in relative abundance include *Pseudallescheria boydii* (anamorph, *Scedosporium apiospermum*) and *Emericella nidulans* (anamorph, *Aspergillus nidulans*). For the most part, however, routine identification of these molds is based on the form and arrangement of the asexual spore-bearing structures and the manner in which the spores are produced (see below).

Kingdom Protozoa

Of the different phyla within the kingdom Protozoa, the Mycetozoa (or Myxomycota) consist of free-living, unicellular or plasmodial slime molds that have acquired aerial spores for dispersion. None of these pseudofungi are human pathogens. The phylum Microspora consists of obligate intracellular parasites. In humans, microsporidia are considered to be etiologic agents of opportunistic infections, mostly in persons with AIDS. Phylogenetic analysis has indicated that these organisms are related to conventional Fungi, rather than to the Protozoa (9). However, parasitologists have been reluctant to part with this group while mycologists have been just as reluctant to accept it. For the time being at least, the microsporidia have been retained alongside the Protozoa, while acknowledging that these organisms are, in fact, fungi (see chapter 143).

Kingdom Chromista

This kingdom contains three "fungal" phyla. In the phylum Oomycota, the thallus is unicellular to mycelial and mainly aseptate. The asexual spores, or zoospores, are motile. Sexual reproduction leads to the development of nonmotile, thick-walled oospores. Members of the order Pythiales occur mostly in the soil or on plants; one species, *Pythium insidiosum,* is of clinical significance (see chapter 128).

IDENTIFICATION OF YEASTS

Yeasts are neither a natural nor a formal taxonomic group but are a growth form found in a wide range of unrelated ascomycetous and basidiomycetous fungi. Their identification relies on a combination of morphological, physiological, and biochemical characteristics. Useful morphological characteristics include the color of the colonies, the size and shape of the cells, the presence of a capsule around the cells, the production of hyphae or pseudohyphae, and the production of chlamydospores. Useful biochemical tests include the assimilation and fermentation of sugars and the assimilation of nitrate. Most yeasts of medical importance can be identified using one of the commercial test systems that are based on sugar assimilation of isolates. However, it is important to

remember that microscopic examination of cultures on cornmeal agar is essential to avoid confusion between organisms with identical biochemical profiles (see chapter 119).

The so-called black yeasts are not a formal taxonomic group, but the description is applied to a wide range of unrelated ascomycetous and basidiomycetous fungi that are able to produce melanized budding cells at some stage in their life cycle (5). Because most of these fungi are also able to produce a true mycelium, their routine identification is largely based on the morphological characteristics of the asexual spore-bearing structures and the manner in which the spores are produced. Most belong to the form-class Hyphomycetes (see below).

CLASSIFICATION AND IDENTIFICATION OF ANAMORPHIC MOLDS

Most of the septate molds that are isolated in clinical laboratories do not produce their sexual reproductive structures in routine cultures, and their identification is based on the manner in which the asexual spores are produced. Two artificial form-classes of anamorphic or "mitosporic" molds are currently recognized, based on the mode of conidium formation. The Hyphomycetes produce their conidia directly on the hyphae or on specialized conidiophores, while the Coelomycetes have more elaborate reproductive structures, termed conidiomata.

Form-Class Coelomycetes

Three artificial orders are recognized: the Sphaeropsidales, Melanconiales, and Pycnothyriales. In the Sphaeropsidales, the conidia are produced in conidiomata that are either spherical with an apical opening and with conidiogenous cells lining the inner cavity wall (termed pycnidia) or open and cup-shaped, in which case the conidiogenous cells cover the conidiomatal surface (termed acervuli). Few members of this class are common pathogens of humans. The most frequently encountered species is *Nattrassia mangiferae,* a plant pathogen which can also cause infections of the skin and nails. Until recently, this species was known by the synanamorph name of *Hendersonula toruloidea*. Another synanamorph of this species is *Scytalidium dimidiatum*.

Form-Class Hyphomycetes

The Hyphomycetes contain a large number of septate anamorphic molds of medical importance, including the genera *Aspergillus, Blastomyces, Cladophialophora, Fusarium, Histoplasma, Microsporum, Penicillium, Phialophora, Scedosporium,* and *Trichophyton*. In addition, numerous Hyphomycetes have been reported as occasional opportunistic pathogens of humans. For this reason, it is important for clinical microbiologists to be able to recognize and correctly identify this group of fungi.

As mentioned earlier, the process of conidiogenesis is of major importance in the identification of these molds. Two basic methods of conidiogenesis can be distinguished: thallic conidiogenesis, in which an existing hyphal cell is converted into one or more conidia; and blastic conidiogenesis, in which conidia are produced as a result of some form of budding process (for a detailed discussion of this topic, see reference 5).

Thallic Conidiogenesis

In this form of conidiogenesis the conidia are produced from an existing hyphal cell. Arthroconidia, which are derived from the fragmentation of an existing hypha, represent the simplest form of thallic conidiogenesis and have evolved many different groups of fungi. The first step in the examination of cultures of these molds should be to ascertain whether another spore form is present. If so, identification should be based upon that form. The few molds of medical importance which produce arthroconidia as their sole means of conidiogenesis include *Coccidioides* species.

Aleurioconidia are formed from the side or tip of an existing hypha, and during the initial stage before a septum is laid down, can resemble short hyphal branches. This form of thallic conidiogenesis is characteristic of the dermatophytes (*Epidermophyton, Microsporum,* and *Trichophyton* species), as well as a number of dimorphic systemic pathogens, including *Blastomyces dermatitidis, Histoplasma capsulatum,* and *Paracoccidioides brasiliensis*.

Blastic Conidiogenesis

Many fungi have evolved some form of repeated budding that allows them to produce large numbers of asexual spores from a single conidiogenous cell. There are two basic forms of blastic conidiogenesis: holoblastic development, in which all layers of the wall of the conidiogenous cell swell out to form the conidium, and enteroblastic development, in which the conidium is produced from within the conidiogenous cell, the outer layers of the cell wall breaking open and an inner layer extending through the opening to become the new spore wall. These two forms of blastic conidiogenesis can be further subdivided according to the details of spore development.

Almost all the molds that produce holoblastic conidia have melanized cell walls and thus are similar in colonial appearance. The morphological characteristics of their conidia and the manner in which the spores are produced serve as the main distinguishing features. Holoblastic conidia range in size from minute unicellular spores to large, thick-walled, multicelled spores. In some species, the first-formed conidium buds to produce a second, and the second produces a third, and so on until a chain of conidia is produced with the youngest at its tip. As each spore can produce more than one bud, a branching chain becomes possible (e.g., *Cladophialophora* species). In another group, the conidiogenous cell that produced the first spore then grows past it to produce a second. If this process is repeated, it will result in an elongated conidiogenous cell with numerous lateral single spores along its sides. This is termed sympodial development and is typical of species of *Bipolaris* and *Exserohilum*.

In molds that produce enteroblastic spores, the wall of the conidium is derived from the inner layer of the wall of the conidiogenous cell. This permits a succession of spores to be produced from the same point. There are two main forms of enteroblastic conidiogenesis: phialidic, in which the specialized conidiogenous cell from which the conidia are produced is termed a phialide, and annellidic, in which the conidiogenous cell is termed an annellide.

In phialidic conidiogenesis, the first blown-out cell breaks open at its tip and remains as a collarette, from the inside of which conidia are produced in succession. In some species, the collarette is distinct (e.g., *Phialophora* species), but in others it is almost invisible at the tip of the phialide. In some phialidic molds, such as species of *Fusarium* and *Acremonium,* the spores are not firmly attached to each other and often move aside to accumulate in a wet mass around the phialide. In other phialidic molds, such as species of *Aspergillus* and *Penicillium,* continuous replenishment of the inner wall of the tip of the phialide results in the formation of an unbranched chain of connected conidia, with the youngest at the base.

Annellides, like phialides, are conidiogenous cells which produce conidia at their tips in unbranched chains (e.g., *Scopulariopsis* species) or in wet masses (e.g., *Scedosporium* species). In annellidic conidiogenesis, the first blown-out cell becomes a spore and subsequent conidia are formed by blowing out through the scar of the previous one. Unlike phialides, annellides increase in length each time a new spore is produced. An old annellide that has produced many conidia has a number of apical scars or annellations at its tip.

IDENTIFICATION OF MOLDS

Most molds can be identified after growth in culture, but the criteria for recognition often differ from the fundamental characteristics that are used as a basis for classification. Macroscopic characteristics, such as colonial form, surface color, pigmentation, and growth rate, are often helpful in mold identification. Although the culture medium, incubation temperature, age of the culture, and amount of inoculum can influence colonial appearance and growth rate, these characteristics remain sufficiently constant to be useful in the process of identification. Molds that fail to sporulate in culture are often impossible to identify to the species level, and it is therefore important to select culture conditions which favor sporulation. Although molds often grow best on rich media, such as Sabouraud's dextrose agar, overproduction of mycelium often results in loss of sporulation.

COMMON MYCOLOGICAL TERMS

Acervulus (pl. -i): an open or cup-shaped structure on which conidia are formed.

Acropetal: describes a chain of conidia, in which new spores are formed at the tip of the chain.

Aleurioconidium (pl. -ia): a thallic conidium that is formed from the end of an undifferentiated hypha, or from a short side-branch.

Aleuriospore: see aleurioconidium.

Anamorph: the asexual form of a fungus.

Annellide: a specialized conidiogenous cell from which a succession of spores is produced, and which has a column of apical scars at its tip.

Annelloconidium (pl. -ia): a blastic conidium that is formed from an annellide.

Annellospore: see annelloconidium.

Apophysis: the enlargement of a sporangium below the columella.

Arthroconidium (pl. -ia): a thallic conidium produced as the result of fragmentation of an existing hypha into separate cells.

Arthrospore: see arthroconidium.

Ascocarp: a structure that contains asci.

Ascoma (pl. -ata): see ascocarp.

Ascospore: a haploid spore produced within an ascus following meiosis.

Ascus (pl. -ci): a thin-walled sac, characteristic of the Ascomycota.

Aseptate: without cross-walls or septa.

Ballistoconidium: a conidium that is forcibly discharged.

Ballistospore: see ballistoconidium.

Basidiocarp: a structure that produces basidia.

Basidioma (pl. -ata): see basidiocarp.

Basidiospore: a haploid spore produced on a basidium following meiosis.

Basidium: a cell upon which basidiospores are produced, characteristic of the Basidiomycota.

Basipetal: describes a chain of conidia in which new spores are formed at the base of the chain.

Blastic: one of the two basic forms of conidiogenesis in which enlargement of the conidial initial occurs before a delimiting septum is laid down.

Blastoconidium (pl. -ia): a blastic conidium produced by the enlargement of a part of a conidiogenous cell before a septum is laid down.

Blastospore: see blastoconidium.

Catenate: in chains.

Chlamydospore: a resting conidium, formed as a result of the enlargement of an existing hyphal cell.

Collarette: a cup-shaped structure at the tip of a conidiogenous cell.

Columella: swollen tip of the sporangiophore projecting into the sporangium in some Mucorales.

Conidiogenesis: the process of conidium formation.

Conidiogenous cell: any cell that produces or becomes a conidium.

Conidioma (pl. -ata): a specialized conidia-bearing structure.

Conidiophore: a specialized hypha or cell on which, or as part of which, conidia are produced.

Conidium (pl. -ia): an asexual spore.

Distoseptate: term used to describe spores in which the individual cells are each surrounded by a sac-like wall distinct from the outer wall.

Enteroblastic: a form of conidiogenesis in which conidia are produced from within a conidiogenous cell.

Heterothallic: a self-sterile fungus; sexual reproduction cannot take place unless two compatible mating strains are present.

Hilum: a scar at the base of a conidium.

Holoblastic: a form of conidiogenesis in which both the inner and outer walls of the conidiogenous cell swell out to form the conidium.

Homothallic: a self-compatible fungus; sexual reproduction can take place within an individual strain.

Hypha (pl. -ae): one of the individual filaments that make up the mycelium of a fungus.

Macroconidium (pl. -ia): the larger of two different sizes of conidia produced by a fungus in the same manner.

Microconidium (pl. -ia): the smaller of two different sizes of conidia produced by a fungus in the same manner.

Mitosporic: term used to describe an anamorphic fungus.

Mold: a filamentous fungus.

Mycelium: a mass of branching filaments which make up the vegetative growth of a fungus.

Oospore: a sexual spore produced in the Oomycota.

Phialide: a specialized conidiogenous cell from which a succession of spores is produced.

Pleoanamorphism: term used to describe a fungus that has more than one anamorph.

Pleomorphic: term used to describe a nonsporing strain of a fungus.

Pseudohypha (pl. -ae): a chain of yeast cells which have arisen as a result of budding and have elongated without becoming detached from each other, forming a hypha-like filament.

Pycnidium (pl. -ia): an enclosed structure with an apical opening inside which conidia are produced.

Rhizoid: a short branching hypha that resembles a root.

Septate: having cross-walls or septa.

Septum (pl. -ta): a cross-wall in a fungal hypha or spore.

Sporangiole: a small sporangium.

Sporangiophore: a specialized hypha upon which a sporangium develops.

Sporangiospore: asexual spore, characteristic of the Zygomycota.

Sporangium (pl. -ia): a closed sac containing asexual spores, characteristic of the Zygomycota.

Synanamorph: term applied to any one of two or more anamorphs which have the same teleomorph.

Teleomorph: the sexual form of a fungus.

Thallic: one of the two basic forms of conidiogenesis in which enlargement of the conidial initial occurs after a delimiting septum has been laid down.

Thallus: the vegetative growth of a fungus.

Yeast: a unicellular, budding fungus.

Zoospore: a motile asexual spore.

Zygospore: a thick-walled sexual spore, produced in the Zygomycota.

Specimen Collection, Transport, and Processing: Mycology

DEANNA A. SUTTON

116

The collection, transport, and processing of clinical specimens encompass some of the most important considerations in determining the etiology of fungal disease. Only with the appropriate handling of specimens can the recovery of fungal organisms be clearly associated with a disease process. As inappropriate specimen collection may introduce potentially confusing indigenous flora and jeopardize culture result interpretation (48), it is critical to employ only those practices most likely to facilitate detection of etiologic agents. This chapter is thus devoted to obtaining, transporting, and processing clinical specimens in a manner consistent with this aim. Diagnostic procedures with direct specimens, including antigen detection, monoclonal antibody immunoassays, and molecular techniques, are addressed elsewhere.

SPECIMEN COLLECTION

Safety Policies Regarding Specimen Management

Specimen collection considerations include safety management policies for the protection of all health care workers involved in obtaining the specimen, collection from appropriate sites, the proper labeling of specimen containers, and completion of necessary requisitions accompanying the specimens (4, 16, 21, 26, 28, 32, 37, 45, 46, 47, 49, 60, 62, 75). As specimens are usually collected in a surgical suite, at the bedside, or in an outpatient setting, it is the laboratory's responsibility to provide these collection areas with appropriate instructions, usually in the form of a specimen collection procedure manual. All specimens for mycologic studies should be considered potentially hazardous, and universal precautions should be observed with all specimen collection procedures (49, 50, 66). Primary specimen collection containers must be leakproof and should have a separate compartment for the requisition. Syringes containing aspirates must have the needle removed and be recapped prior to transport.

Common Specimen Collection Sites and Guidelines

The more common collection sites for the diagnosis of mycotic disease are listed in Table 1. As for all disease processes, the best specimen for determining the etiologic agent is at the active infection site. Specimens peripheral to the primary locus, however, such as blood in hematogenously disseminated infections, may also provide a diagnosis. The recovery of ubiquitous fungal organisms from specimens likely to harbor contaminants, such as sputum samples, should be interpreted with caution, and collection of these specimens should be discouraged in favor of more disease-directed sites. The collection details for fungal cultures are very similar to those for bacterial cultures, although the volume of material required for recovery of fungi may exceed those necessary for bacteria. More material for primary inoculum and concentration of large volumes of fluid greatly increases the likelihood of recovery of fungal species. The use of swab cultures should be limited to the sites indicated in Table 1, as deeper specimens are preferred in most settings. Specimens to be discouraged due to questionable usefulness include superficial cultures of burns, wounds, decubiti, periodontal lesions, perirectal abscesses, varicose ulcers, and gangrenous lesions, as well as Foley catheter tips, gastric aspirates of newborns, lochia, vomitus, or colostomy discharge material. Nail specimens for culture should be thoroughly disinfected with 70% alcohol before collection.

Requisitions and Specimen Labeling

A properly constructed and completed requisition form is critical for the mycology laboratory to elicit the necessary information and to properly analyze the specimen for optimal patient care. The requisition should include the following: patient name, age, sex, room number or address; physician name and address or how he/she may be contacted; specific anatomic culture site; date and hour of specimen collection; the clinical diagnosis, special culture request, and relevant patient history; special procedures used to obtain the specimen; name of individual transcribing the orders; and any antifungal agents the patient has recently or is currently receiving. This requisition must accompany the specimen. The specimen must be identified with a firmly attached label indicating the patient's name, hospital number, room number, physician, culture site, and date and time of collection. Specimens thought to contain particularly dangerous organisms should be marked appropriately.

SPECIMEN TRANSPORT AND STORAGE

In addition to proper collection, the appropriate transport and storage of specimens is necessary for fungal elements to remain viable. Guidelines are indicated in Table 1, as well as

TABLE 1 Common specimen collection sites for recovery of fungi[a]

Specimen type[b] (reference)	Collection		Transport[c]	Comments
	Guidelines	Device and/or minimum vol	Local/distant time and temp	
Blood				
Yeasts (1, 2, 7, 8, 10, 13–15, 17, 34, 37–39, 40, 42, 52–54, 57, 59, 60, 62, 64–66, 69, 71–74, 76)	Collect as for bacterial cultures; disinfect skin with tincture of iodine. Use maximum amt of blood recommended.	Automated (BacT/Alert, BACTEC, ESP)	≤2 h, RT/ ≤24 h, RT; follow manufacturers' instructions.	bioMérieux, BD Diagnostic Systems, Accumed International
		Lysis-centrifugation (Isolator or manual)	As above; process in ≤16 h	Wampole
		Biphasic bottles (Septi-Chek)	≤2 h, RT/ ≤24 h, RT	BD Diagnostic Systems
Dimorphics/filamentous fungi (8, 9, 13, 38, 72)	As above	Lysis-centrifugation (Isolator or manual)	As above	As above
CSF (57)	Collect as for bacterial culture.	Screw-cap tube, ⩾2 ml, concentrate	≤15 min, RT or 30°C/ ≤24 h, RT	Never refrigerate; aspirate or biopsy of brain abscess may be necessary.
Sterile fluids (pericardial, peritoneal, pleural, and pynovial)	Collect as for bacterial cultures. Concentrate by centrifugation; use sediment for inoculation.	Sterile container with >10 ml; may use blood culture bottle for yeasts.	≤15 min, RT/ ≤24 h, 4°C	May also concentrate small volumes by syringe filtration
Bone marrow	Prepare site for surgical incision.	Lysis-centrifugation (Isolator or manual)	As above	Pediatric Isolator
Catheter, i.v. (41, 46)	Collect as for bacterial culture.	5-cm distal tip of catheter into a sterile tube with a few drops of sterile H_2O/saline	≤15 min, RT or ≤ 24 h, 4°C	Acceptable i.v. catheters for semiquantitative culture (Maki et al. method): central, CVP, Hickman, Broviac, Swan-Ganz, arterial, peripheral, hyperalimentation, umbilical
Ear, external	Firmly rotate swab in outer ear canal.	Swab	≤2 h, RT/ ≤24 h, 4°C	
Eye				
Corneal scrapings (3, 34)	Inoculate scrapings directly onto media and slides for staining.	Direct inoculation	≤15 min, RT/ ≤24 h, RT	Inoculate plates in "C" shape.
Vitreous fluid (3, 34)	Needle aspiration	Screw-cap tube or direct inoculation	≤15 min, RT/ ≤24 h, RT	
Hair	With forceps, collect 10–12 hairs with shaft intact.	Dry container, envelope	≤72 h, RT/ ≤72 h, RT	Also scrape active borders of lesions if present.
Medical devices	Collected surgically	Sterile container with a few drops of sterile H_2O/saline: gently scrape device with a sterile scalpel to dislodge biofilm material before direct inoculation into liquid medium.	≤15 min, RT	Valves, hardware, other devices

(Continued on next page)

TABLE 1 Common specimen collection sites for recovery of fungi[a] *(Continued)*

Specimen type[b] (reference)	Collection		Transport[c]	Comments
	Guidelines	Device and/or minimum vol	Local/distant time and temp	
Nails	Disinfect with 70% alcohol; clip affected areas; collect debris under nail.	Dry container, envelope	≤72 h, RT/ ≤72 h, RT	For *Candida,* dermatophytes and agents of dermatomycoses
Prostatic fluid (46)	Bladder emptied followed by prostatic massage	Direct inoculation onto media	≤15 min, RT/ ≤24 h, RT	Primarily for blastomycosis
Respiratory, lower BAL, brush, wash, aspirate, sputum (5)	Collect as for bacterial culture.	Sterile container, >1 ml	≤2 h, RT/ ≤24 h, 4°C	Short survival time for thermally dimorphic pathogens
Respiratory, upper				
Oral (11, 58)	Swab active lesions; saline swish for *Candida.*	Swab or sterile container	≤2 h, RT/ ≤24 h, RT	Selective media useful for yeasts
Nasal sinus	Surgical removal of sinus contents	Direct inoculation or in sterile, moist gauze	≤15 min, RT/ ≤24 h, RT	Maxillary and ethmoid sinuses most common sites
Skin (64)	Disinfect with 70% alcohol; scrape surface of skin at margin of lesion.	Clean container or between taped glass slides	≤72 h, RT/ ≤72 h, RT	For dermatophytes and agents of dermatomycoses
Subcutaneous granules	Collect from pus, exudate, biopsy specimen, draining sinus tracts.	Wash granules several times in saline containing antibiotics.	≤2 h, RT/ ≤24 h, RT	Fungal grains or granules seen in eumycotic mycetoma
Subcutaneous sites				
Abscess (63)	Aspirate abscess with sterile needle and syringe.	Anaerobic transport or direct inoculation; ≥1 ml	≤2 h, RT/ ≤24 h, RT	Sample base of lesion and abscess wall.
Open wound (63)	Aspirate or swab deeply.	Swab transport system	≤2 h, RT/ ≤24 h, RT	As above
Tissue biopsies	Surgical collection	Sterile container; add a few drops of sterile saline to keep moist.	≤15 min, RT/ ≤24 h, RT	Punch biopsies may be used for skin lesions.
Urine (12)	As for bacterial cultures; early-morning specimen preferred	Sterile, wide-mouth container, ≥1 ml	≤2 h, RT/ ≤24 h, 4°C	Use midstream collection technique.
Vagina (19)	As for bacterial cultures	Swab transport	≤2 h, RT/ ≤24 h, RT	Primarily for refractory vaginal candidiasis

[a] Abbreviations: CSF, cerebrospinal fluid; RT, room temperature; i.v., intravascular; BAL, bronchoalveolar lavage fluid.
[b] Specimen collection sites are not all-inclusive. Other specimen types are generally collected as for bacterial cultures.
[c] All specimens are to be transported in leakproof plastic bags having a separate compartment for the requisition. The optimum time for arrival of most specimens from the hospital floor to the laboratory (local) is within 2 h (see exceptions) so as to maintain viability and guard against desiccation of small tissue fragments or specimens not protected by adequate transport systems. Specimens submitted from distant sites should be sent within appropriate transport devices and should generally be maintained at room temperature. Exceptions include 30°C storage of CSF specimens and 4°C extended storage for specimens likely to be bacterially contaminated.

in other areas of this Manual pertaining to specimen collection. Fungal viability may be affected by excessive heat and cold; thus, room temperature transport and storage, ideally within 2 h, is recommended. Exceptions include 30°C storage of central nervous system specimens and 4°C extended storage for specimens likely to be bacterially contaminated. A clean, dry envelope may be used for submitting skin, hair, and nail specimens.

SPECIMEN PROCESSING

Specimen Acceptability

Unacceptable specimens should not be processed. These may include specimens from inappropriate sites, specimens in leaking collection containers, and specimens/requisitions lacking necessary patient/specimen information. Physicians should be notified immediately of any rejected specimens

TABLE 2 Pretreatment of clinical specimens before plating

Specimen	Pretreatment	Comments
Blood	Lysis and centrifugation (30 min) at 3,000 × *g*, 35° fixed-angle rotor, or 2,400–3,000 × *g*, swinging bucket	Method of choice, and necessary for *H. capsulatum*
Body fluids	Filtration or centrifugation at 2,000 × *g* for 10 min	Necessary for optimal recovery; used on all specimens >2 ml
Exudates, pus, drainage	Washing, centrifugation, and crushing of granules	Recommended if granules are present
Medical devices	Gentle scraping of device with a sterile scalpel to dislodge biofilm material	
Nails	Cutting into small pieces	Necessary for optimal recovery of fungi
Respiratory secretions	Liquefication with mycolytic agent	Necessary (with centrifugation) on induced sputum specimens for *P. jiroveci.* Optional for other mycoses; centrifugation may improve yield but also increases numbers of interfering organisms, e.g., bacteria and colonizing yeasts.
Tissue	Mincing, grinding, or use of Stomacher	Necessary for optimal recovery of all fungi; specimens must be cut into small pieces if a zygomycete is suspected or ground if *H. capsulatum* is suspected.
Urine	Centrifugation at 2,000 × *g* for 10 min	Necessary for optimal recovery, especially for agents of systemic mycoses

and apprised of the compromised nature of the results if specimens are processed. If a new specimen is received, the unacceptable one should be autoclaved and discarded (46, 47). In addition to being analyzed by direct microscopy, antigen detection procedures, and/or direct molecular methods, all acceptable specimens should be cultured for recovery and identification of the fungal organisms. These results should be correlated with those of smear/tissue findings to confirm the etiologic agent.

Properly collected, identified, and transported specimens should be processed as soon as possible after reaching the laboratory. Most can be stored at 4°C, with a few exceptions identified below (39, 40). Pretreatment of selected specimens is necessary to optimize fungal recovery. These procedures are outlined in Table 2 and include centrifugation (concentration of fungal elements), blood cell lysis (releasing fungal elements from within cells), and slicing or maceration (to increase the surface area of the specimen).

The handling and culture of specimens should be done in a certified, laminar-flow biologic safety cabinet whenever possible. Both plates and tubes may be used; however, plates provide a larger surface area and are more useful for isolation of colonies. A volume of 40 ml retards dehydration, and surrounding the plate with a shrink seal or air-permeable tape prevents the inadvertent opening of the petri dish. If tubes are used, they should have a large slant area, have the screw cap loose for proper aeration, and be incubated horizontally for the first 24 h to ensure that the inoculum remains on the slant.

Specimen Pretreatment, Culture, and Processing Guidelines

Blood

Disseminated fungal infections are more prevalent than previously recognized, and blood cultures are an important diagnostic tool in the absence of focal manifestations or when foci are not easily reached (18, 22, 70). While several systems for the detection of fungemia are available, the volume of blood obtained for culture is still the most important factor in recognizing bloodstream infections, with 20 to 30 ml per culture being optimal for maximal recovery of microorganisms (70). The ratio of blood to broth is also critical, with a ratio near 1:5 enhancing detection (2, 61). If blood culture bottles are used, a biphasic system is preferred (Septi-Chek; BD Diagnostic Systems, Sparks, Md.). Several automated continuously monitoring blood culture systems are also available, with a variety of media modifications to enhance fungal recovery. These include the ESP system (Trek Diagnostics, Inc., Cleveland, Ohio), the BacT/Alert system (bioMérieux, Durham, N.C.), and the Bactec system (BD Diagnostic Systems). The salient features of each instrument are explained in chapter 15 regarding automated systems for the detection and identification of clinically significant microorganisms. All the above continuously monitoring blood culture systems provide adequate detection of bloodstream infections due to most *Candida* species and *Cryptococcus neoformans* (35, 42, 43, 55), with a higher inoculum providing earlier detection (23). Recent studies evaluating the BACTEC 9240 and the BacT/ALERT 3D systems suggest that, for *Candida glabrata,* incubation times beyond 5 days may be required, terminal subcultures may be necessary, and selective fungal media provide enhanced detection (29, 30, 44). The commercially available lysis-centrifugation system, the Isolator (Wampole Laboratories, Princeton, N.J.), or manual lysis-centrifugation (9) appears to be the more sensitive method for recovery of *Histoplasma capsulatum,* other dimorphic pathogens, and filamentous fungi (24, 25, 27, 39). Its combination with the BACTEC MYCO/F Lytic bottle may be useful as a selective fungal blood culture method (67). Isolator specimens should remain at room temperature until

processing, optimally within 16 h of collection. The sediment from lysis-centrifugation should be streaked onto a variety of enriched media not containing cycloheximide. A recent evaluation of chocolate agar suggests its use for recovery of most fungi, excluding *H. capsulatum* (56). Plates for *H. capsulatum* may require up to 3 weeks of incubation. The introduction of the BACTEC MYCO/F Lytic medium for the detection of mycobacteria has also proved to be useful for the detection of fungemia (68). While normally used with the BACTEC 9240 blood culture system, it may also be used independently and requires only 5 ml of blood. In a study to detect fungemia in less-developed countries, growth was detected by fluorescence caused by shining UV light ($\lambda = 365$ nm) onto the indicator on the bottom of the bottle, and this method appeared to be as sensitive as the Septi-Chek bacterial system or the Isolator concentrate plated onto chocolate or Inhibitory Mold Agar (1).

Bone Marrow

Heparinized bone marrow may be inoculated onto enriched media at the bedside, but preferably into pediatric Isolator tubes. At least 0.5 ml of aspirated marrow is required. Lysis-centrifugation enhances fungal recovery, particularly for *H. capsulatum* and other filamentous fungi. Blood culture bottles are not recommended for bone marrow culturing.

Intravascular Catheter Tips

Intravascular catheter tip cultures should be performed only in conjunction with concurrent blood cultures. The most common technique utilized is the semiquantitative method of Maki et al. (41), in which a 5-cm distal portion of the catheter is rolled across a blood agar plate four times and the growth of more than 15 colonies is considered significant. Acceptable intravascular catheters include the Hickman, Broviac, Swan-Ganz, arterial, peripheral, central venous, hyperalimentation, and umbilical catheters, as well as other less frequently submitted types.

Medical Devices

Various medical devices may be submitted for culture. These are collected surgically and should be transported immediately. They may include heart valves, artificial joints, intrauterine devices, and other prosthetic devices or hardware. Any obvious areas of biofilm formation or vegetation should be gently scraped with a sterile scalpel before direct inoculation into a broth medium.

Sterile Body Fluids

Body fluids that are normally sterile include pericardial, peritoneal, synovial, and cerebrospinal fluids. Small volumes (less than 2 ml) may be inoculated directly or filtered through a membrane filter. The filter is placed particle side down and is periodically moved to another area on the medium to examine for growth. Specimens greater than 2 ml require centrifugation at $2{,}000 \times g$ for 10 min, with 1 to 2 ml of the sediment being used for the inoculum. Sterile fluids may be refrigerated before processing, but cerebrospinal fluids should be maintained at room temperature.

Tissue

Most tissue requires pretreatment before processing. Tissue for *H. capsulatum* should be ground or homogenized, and the fragments/homogenates should be inoculated onto enriched media containing antibacterial agents. Media containing cycloheximide may be included if contaminating organisms are anticipated. Tissue suspected of containing zygomycetes or other fungi must be minced or finely sliced, rather than ground, as grinding is detrimental to the survival of zygomycetous fungal elements.

Exudates, Pus, and Drainage

Drainage specimens should be examined for grains or granules under a dissecting microscope. If none are present, material may be inoculated directly onto isolation media. If granules are present, they should be teased apart, crushed between two glass slides, and examined microscopically for fungal hyphae. The granules in the remainder of the specimen should be washed in sterile distilled water, crushed in a sterile manner, and inoculated onto a variety of media with and without cycloheximide. Pus and exudates may be plated directly on the media indicated above.

External Eye Specimens

Specimens from patients with presumed mycotic keratitis should be obtained by an ophthalmologist and inoculated directly onto the medium and an alcohol-cleaned, flamed slide. Corneal scrapings are transferred from the surgical instrument to a noninhibitory agar plate by making a series of C- or X-shaped cuts on the medium. Inoculated plates are maintained at room temperature if transport to the laboratory is delayed.

Upper Respiratory Tract

Oropharyngeal candidiasis is readily diagnosed by smear and culture. The newer selective, chromogenic agars for *Candida* species provide preliminary identification as well as isolation and are useful for detecting infections with more than one species of *Candida.* Nasal sinus contents obtained surgically should be plated on a variety of media containing antimicrobics but lacking cycloheximide, as several agents of fungal sinusitis are inhibited by cycloheximide.

Lower Respiratory Tract

Sputum should be collected as a first early-morning sample after the patient's teeth have been brushed and the mouth has been rinsed. Flecks containing pus, blood, or caseous material should be sought and used in culture and smears. Very viscous specimens can be liquefied with crystalline *N*-acetyl-*l*-cysteine, but sodium hydroxide (used for decontamination of cultures for mycobacteria) must not be used because it inhibits the growth of many fungi. Surgically collected specimens such as bronchoalveolar lavage fluids, washes, and aspirates should also be examined for bloody, purulent, or mucus-laden portions and plated onto antibacterial media with and without cycloheximide. Centrifugation may increase yield but also increases the number of interfering organisms, e.g., bacteria and colonizing yeasts.

Urine

Urine samples (10 to 50 ml) are centrifuged, and the sediment is inoculated onto antibacterial media with and without cycloheximide. If quantification is required, uncentrifuged urine can be streaked with a calibrated loop onto a plate of noninhibitory medium. The quantity of yeasts in a urine sample does not have the same interpretative value as that of bacteria. The persistence of yeast in several carefully collected midstream urine samples and the clinical picture of the patient in whom candiduria of any count develops are the most important factors in interpreting its significance (20).

Vaginal Secretions

Vaginal candidiasis is usually diagnosed by clinical symptoms and direct microscopic examination. As yeast cells are part of the normal vaginal flora in up to 20% of healthy women, the

recovery of *Candida* on culture without considering other factors is meaningless. Cultures are useful, however, in monitoring therapy in refractory disease. Antibacterial media with and without cycloheximide should be inoculated (19).

Hair, Skin, and Nails

Hair fragments and skin scrapings are placed directly on the agar surface. Nails yield the best culture results if they are cut into smaller pieces with a scalpel before culturing. Light pressure should be applied to submerge pieces slightly under the agar surface. Media containing both antibiotics and cycloheximide should be employed for the recovery of dermatophytes. Stored cultures should be maintained at room temperature rather than 4°C, as some dermatophytes do not tolerate refrigeration. Specimens may also be mailed utilizing a clean, dry envelope.

Media for Primary Isolation

Table 3 lists a variety of media that are suitable for primary isolation and that are all commercially available. Many other media, including homemade varieties, may perform equally well, and their choice may depend on availability, cost, and personal preference. Some basic tenets, however, apply to all media used for primary recovery. A medium that supports

TABLE 3 Media for primary isolation

Type of medium[a]	Additive	Use and comments
Without antibacterial or antifungal agents		
SDA	None	Classic pigment and colony formation for dermatophytes
BHI agar	Sheep blood optional	Cultivation of all fungi including fastidious dimorphics; blood inhibits conidiation.
Sabhi agar	Sheep blood optional	Cultivation of all fungi including fastidious dimorphics; blood inhibits conidiation.
PDA or PFA	None	Production of conidia and fruiting bodies; particularly useful for filamentous, opportunistic fungi.
Any of the above	Olive oil on surface	Cultivation of *Malassezia furfur*
With antibacterial agents		
Any of the above	Separate or in combination: chloramphenicol, ciprofloxacin, gentamicin, penicillin, streptomycin	Inhibition of bacteria; BHI agar, Sabhi, and IMA are more enriched than other media and may better support the more fastidious fungi.
IMA	Contains chloramphenicol.	
With antibacterial and antifungal agents		
Mycosel or Mycobiotic agar	SDA with chloramphenicol and cycloheximide	Inhibition of bacteria and many saprobic fungi that may overgrow more fastidious fungi; may also inhibit opportunistic etiologic agents. Useful for dermatophyte recovery
BHI agar or Sabhi	Any antibacterial agent in previous group plus cycloheximide	As above
Selective for dimorphic fungi		
Yeast extract phosphate medium	Add ammonia to surface.	Inhibition of bacteria, yeasts, and many molds and enhancement of slow-growing dimorphic fungi
For dermatophytes		
DTM	Chloramphenicol, gentamicin, cycloheximide	Both are meant to isolate dermatophytes and show a color change of the medium; some nondermatophytic fungi may also produce a color change.
DIM	Penicillin, streptomycin, cycloheximide, with bromcresol purple	
Mycosel or Mycobiotic	As above	
Selective and differential for yeasts		
CHROMagar Candida, Albicans ID	Antimicrobial agents and chromogenic substrates	Isolation of yeasts with color development in colonies allows for presumptive identification of some common species of *Candida*.

[a] SDA, Sabouraud dextrose agar; BHI, brain heart infusion agar; PDA, potato dextrose agar; PFA, potato flakes agar; IMA, inhibitory mold agar; DTM, dermatophyte test medium; DIM, dermatophyte identification medium.

fungal growth while inhibiting bacteria must be used with specimens from nonsterile sites. The most commonly used media are brain heart infusion (BHI) plus antibiotics, Sabhi agar plus antibiotics, or inhibitory mold agar (IMA). Antibiotics that have been traditionally added, alone or in combination, include chloramphenicol (<16 μg/ml), gentamicin (5 to 100 μg/ml), penicillin (20 U/ml), streptomycin (40 μg/ml), and ciprofloxacin (5 μg/ml). As antibacterial agents inhibit actinomycetes, they should not be included when these organisms are suspected.

Various media may also be made selective by incorporation of the eukaryotic protein synthesis inhibitor cycloheximide. While cycloheximide (0.5 μg/ml) suppresses many saprobic fungi, it also inhibits several clinically significant fungal pathogens, namely, *C. neoformans, Trichosporon asahii, Nattrassia mangiferae (Scytalidium dimidiatum),* some species of *Candida* and *Aspergillus,* and most zygomycetes. Cycloheximide is traditionally added to Sabouraud's dextrose agar (SDA), Emmons modification with 2% dextrose at neutral pH, or Sabhi agar, in combination with the antibacterial agent chloramphenicol. In facilities where a large portion of the patient population may be neutropenic or immunocompromised, the rapid identification of opportunistic fungi, which may quickly disseminate in these individuals, is critical. The addition of cycloheximide and/or antibiotics to potato dextrose agar (PDA) or potato flakes agar (PFA) may be more appropriate in this setting, because it facilitates identification of these organisms by providing plates for tape mounts of diagnostic structures from primary media.

A battery of enriched media is generally employed for the recovery of fastidious thermally dimorphic fungi. The most common include BHI and Sabhi augmented with antibacterial agents and 5 to 10% sheep cells. While sheep cells appear to improve the yield of organisms slightly, they also inhibit conidiation. Dimorphic organisms recovered on media containing blood should be subcultured to blood-free media for macroscopic/microscopic morphology and DNA probes. The addition of ammonium hydroxide to the medium may facilitate recovery of fastidious fungi from heavily contaminated specimens. Chromogenic media (CHROMagar Candida [CHROMagar, Paris, France], BD CHROMagar Candida [Becton Dickinson BBL, Cockeysville, Md.], and Candida ID [BioMérieux, Hazelwood, Mo.]) are useful for the recovery/identification of *Candida* species (33). The addition of fluconazole to the media facilitates determining fluconazole resistance in these species (6, 51, 54). CHROMagar may also be reliably used for direct isolation of yeast from blood cultures (31). Additional media for isolation/identification of specific organisms include media containing substrates L-dopa, caffeic acids, etc., for detection of *C. neoformans* by its phenol oxidase activity, media containing or overlaid with a long-chain fatty acids source (e.g., olive oil) for the recovery of *Malassezia furfur,* or dermatophyte test medium (DTM) or dermatophyte identification medium (DIM) specifically designed for the culture and isolation of dermatophytes. Refer to chapter 117 for more detailed information on media.

Incubation Conditions

All cultures should be incubated at ≤30°C (±1°C), as this temperature is optimal for most medically significant fungi. If 30°C is not available, they should be incubated at room temperature (near 25°C). While routine incubation has traditionally been for 4 weeks, a recent study suggests that 3 weeks may be adequate for most clinically relevant isolates, excluding those from skin, hair, and nail or from specimens for the recovery of dimorphic pathogens (36). Specimens being screened primarily for yeasts, e.g., oropharyngeal and vaginal sites, need to be incubated for only 7 days. Cultures should be examined at least every 2 or 3 days for the first 2 weeks and weekly thereafter.

Reagents, Stains, and Media: Mycology

MARK T. LAROCCO

117

The medical mycology laboratory uses a variety of stains, media, and reagents for the isolation and identification of yeasts and molds. Familiarity with the composition and characteristics of these materials is critical to the diagnostic approach when processing specimens from patients with suspected mycotic disease. The direct microscopic examination of properly stained clinical material is rapid and cost-effective and may denote the presumptive etiologic agent (4, 5, 14). Results of direct examination can also guide the laboratory in the selection of media that best support fungal growth in vitro (15). Stained preparations made from fungal cultures are essential for definitive identification.

A plethora of media are available for the primary inoculation and cultivation of fungi from clinical specimens. No one specific medium or combination of media is adequate for all specimens. Media should be carefully selected based on specimen type and suspected fungal agents. Media can be dispensed into containers such as 25- by 150-mm screw cap tubes or 100-mm-diameter petri dishes. Petri plates offer the advantage of a large surface area for isolation and dilution of inhibitory substances in the specimens, but they must be poured thick, with at least 25 ml of medium, in order to resist dehydration during incubation. Because plates are vented, they are more likely to become contaminated during incubation. Plates may be placed in gas-permeable bags or sealed with gas-permeable tape to offset this disadvantage. Plates must be opened only within a biological safety cabinet to prevent contamination of the plate and exposure of personnel to potentially dangerous fungi. Media in tubes have a smaller surface area but offer maximum safety and resistance to dehydration and contamination. If the specimen is from a contaminated site, it is important to include media that contain inhibitory substances such as chloramphenicol, gentamicin, or cycloheximide. Chloramphenicol or gentamicin inhibits most bacterial contaminants, while cycloheximide inhibits most saprobic molds. Remember that cycloheximide may also inhibit opportunistic fungi such as some species of *Aspergillus, Fusarium, Scopulariopsis, Pseudallescheria,* zygomycetes, some dematiaceous fungi, and yeasts such as *Cryptococcus neoformans* and some *Candida* species. Antibacterial agents may inhibit the growth of aerobic actinomycetes like *Nocardia* spp. It is important to use media with and without inhibitory agents. Specimens from normally sterile sites can be inoculated to media without inhibitory substances.

Each new lot of medium, whether purchased or prepared in-house, must be subjected to a quality control protocol that verifies appearance, pH, and performance (7). Media for primary isolation should be tested for optimal growth of several fungal pathogens. Selective media should be tested with strains known to be sensitive and resistant to the inhibitory agents in the media, while differential media should be evaluated with fungi that produce both positive and negative reactions.

Unless stated otherwise, the reagents and media listed in this chapter should be prepared by dissolving the components in the stated liquid with a magnetic stirring bar. The standard sterilization technique of autoclaving at 121°C at 15 lb/in^2 for 15 min should be used when needed. However, certain solutions such as those containing antibiotics or carbohydrates cannot be autoclaved because they will be denatured. These solutions are sterilized by filtration through a 0.22-μm-pore-size filter.

Storage of prepared reagents in sterile, airtight, screw-cap containers is recommended. Some reagents require storage in dark containers, and some need to be stored refrigerated (2 to 8°C) instead of at room temperature. Special storage instructions are given when appropriate. Standard safety precautions should be taken when preparing the reagents. Follow the safety guidelines for the chemicals being used, in addition to the laboratory safety protocols. For reagents that are prepared in-house, proper quality control measures must be taken with appropriate positive and negative controls.

The stains, media, and reagents listed in this chapter include those commonly used and a few specialized items. For more specific information not included here, refer to literature cited in the chapter.

REAGENTS

■ *N*-Acetyl-L-cysteine (NALC) (0.5%)

NALC (Alpha Tec Systems, Inc.) is a mucolytic agent used for digestion of sputum specimens submitted for detection of *Pneumocystis jirovecii* by microscopic examination. Sodium citrate (0.1 M) is included in the mixture to exert a stabilizing effect on the acetylcysteine.

■ Dithiothreitol (sputolysin), 0.0065 M

Dithiothreitol is a mucolytic agent that can be purchased commercially and has also been used to prepare sputum specimens for detection of *P. jirovecii.* Equal volumes of sputum and dithiothreitol are mixed and incubated at 35°C. The mixture is periodically mixed vigorously until it is *almost* completely liquefied (complete liquefaction disperses the cells of *P. jirovecii*, making microscopic detection difficult).

■ Potassium hydroxide (KOH)

Wet mounts prepared in 10% KOH are used to distinguish fungi in thick mucoid specimens or in specimens with keratinous material such as skin, hair, or nails. The proteinaceous components of the host cells are digested partially, leaving the fungal cell wall intact and more apparent. An aliquot of specimen is added to a drop of 10% KOH, which can be preserved with 0.1% thimerosal (Sigma Chemical Co.). The slide is held at room temperature for 5 to 30 min after the addition of KOH, depending on the specimen type, to allow digestion to occur. Digestive capabilities can be enhanced with gentle heating or the addition of 40% dimethyl sulfoxide.

■ Potassium hydroxide (10%) with LPCB

The wet mount with KOH and lactophenol cotton blue (LPCB) is used for the same purposes as the KOH preparation but incorporates the LPCB dye (see below). LPCB enhances the visibility of fungi because aniline blue stains the outer cell wall of fungi and lactic acid acts as an additional clearing agent. The phenol component in LPCB acts as a fungicide.

■ Sodium hydroxide (10 or 25% with added glycerin)

Solutions of sodium hydroxide may be used as alternatives to potassium hydroxide for the direct microscopic examination of hair, skin, and nails for dermatophytic infections. Visualization of fungal elements may be enhanced by the addition of glucan-binding fluorescent brighteners such as calcofluor white or Congo red.

STAINS

■ Alcian blue stain

Alcian blue and the more commonly used mucicarmine stain (see below) are mucopolysaccharide stains. These stains are very useful for visualizing *C. neoformans* in histological sections of tissue.

Basic procedure

Deparaffinized sections are stained in Alcian blue (1 g in 100 ml of acetic acid, 3% solution) for 30 min, washed in running tap water, and then rinsed in distilled water. The sections are counterstained in nuclear fast red (0.1 g in 100 ml of aluminum sulfate, 5% solution). After dehydration through 95% and absolute alcohol, the sections are cleared with xylene and mounted in Permount (Fisher Scientific). Capsular polysaccharides stain blue against a pink background.

■ Ascospore stain

Ascomycetous fungi may produce ascospores when grown on media that promote their formation. Visualization of ascospores can be accomplished with a differential staining procedure consisting of malachite green and safranin. Ascospores stain green, while the vegetative portion of the fungus stains red. The classic Kinyoun acid-fast stain (see chapter 21) may also be used for visualizing ascospores, as these structures tend to be acid-fast.

Basic procedure

A thin smear of growth is applied to a glass slide and heat fixed. The slide is flooded with malachite green (5 g in 100 ml of distilled water) for 3 min, washed with tap water, decolorized with 95% ethyl alcohol for 30 s, and counterstained with aqueous safranin (5%) for 30 s. The slide is washed with tap water, allowed to dry, and examined at ×400 to ×1,000 magnification.

■ Calcofluor white

Calcofluor white and related compounds such as Uvitex 2B and Blankophor are nonspecific fluorochromes that bind to β1,3 and β1,4 polysaccharides, specifically, cellulose and chitin of cell walls in fungi. Like the auramine-rhodamine stain, calcofluor white has become commonplace in microbiology laboratories because of the rapidity with which specimens can be observed. The fluorochrome can be mixed with KOH to clear the specimen for easier observation of fungi, including *P. jirovecii.* Fungal elements appear bluish white against a dark background when excited with UV or blue-violet radiation. Optimal fluorescence occurs with UV excitation. A barrier filter such as 510, 520, or 530 should be used for eye protection. Organisms will impart a green fluorescence (1). Typical *P. jirovecii* cysts are generally 5 to 8 μm in diameter, round, and uniform in size, and they exhibit a characteristic peripheral cyst wall staining with an intense internal "double-parenthesis-like" structure (2). Yeast cells are differentiated from *P. jirovecii* by budding and intense internal staining**.** Care must be used in interpreting the calcofluor white staining result because nonspecific reactions may be observed. Cotton fibers fluoresce strongly and must be differentiated from fungal hyphae. Additionally, tissues such as brain biopsy specimens from patients with tumors may fluoresce and resemble *Aspergillus* hyphae.

Basic procedure

KOH (10%) is mixed in equal proportion with calcofluor white solution (0.1 g of calcofluor white M2R and 0.05 g of Evans blue in 100 ml of H_2O). The specimen is covered with this mixture, a coverslip is applied, and the preparation is examined with UV light at ×100 to ×400 magnification.

■ Colloidal carbon wet mounts (India ink, nigrosin)

Colloidal carbon wet mounts are used for visualization of encapsulated microorganisms, especially *C. neoformans*. The polysaccharide capsule of organisms excludes the particles of ink, and the capsules appear as clear halos around the organism. Artifacts such as erythrocytes, leukocytes, and talc particles from gloves, bubbles, and globules after a myelogram may displace the colloidal suspension and mimic yeast. These artifacts make it necessary to perform a careful examination of the wet mount for properties consistent with the organisms (e.g., rounded forms with buds of various sizes and double-contoured cell walls). Interpretation can also be hindered if the emulsion with the colloid suspension is too thick, blocking the transmission of light.

Basic procedure
Mix equal parts of the patient's cerebrospinal fluid with either Pelikan India ink or nigrosin on a slide. Add a coverslip and examine at ×100 to ×1,000 magnification.

■ Giemsa stain

The Giemsa stain is used for the detection of intracellular yeast forms of *Histoplasma capsulatum* in bone marrow and buffy coat specimens. The fungus is usually seen as small oval yeast cells that stain blue and have a hyaline halo that represents poorly staining cell wall. The stain can also be used to visualize the trophozoite stage of *P. jiroveci.*

Basic procedure
A thin smear is prepared on a glass slide and placed in 100% methanol for 1 min. The slide is drained and then flooded with freshly prepared Giemsa stain (stock Giemsa stain diluted 1:10 with phosphate-buffered water). After 5 min the slide is rinsed with distilled water and air dried. Examine at ×100 to ×400 magnification.

■ Lactophenol cotton blue

Lactophenol cotton blue is a basic mounting media for fungi consisting of phenol, lactic acid, glycerol, and aniline (cotton) blue dye. The solution may be filtered to remove precipitated dye and stored at room temperature. It is commonly used for the microscopic examination of fungal cultures by tease or tape preparation. The addition of 10% polyvinyl alcohol (LPCB-PVA) makes an excellent permanent stain or fixative for mounting slide culture preparations (3).

Basic procedure
Concentrated phenol (20% [vol/vol]) is added to a mixture of glycerol (40%), lactic acid (20%), and water (20%), followed by the addition of aniline blue (0.05 g). The solution may be filter sterilized to remove precipitated dye. A drop is added to a glass slide, and a tease or tape mount is prepared. Add a coverslip and examine at ×100 to ×400 magnification.

■ Masson Fontana stain

The Masson Fontana stain was originally developed for demonstrating melanin granules in mammalian tissue. It has a mycological application in detecting dematiaceous fungi, and to a lesser extent C. *neoformans*, in histological sections. Fungal elements appear brown to brownish black against a reddish background.

Basic procedure
A silver solution is prepared by adding concentrated ammonium hydroxide to 10% silver nitrate until the precipitated form disappears. Deparaffinized sections of tissue are hydrated and placed in heated silver solution for 30 to 60 min. The slides are then rinsed in distilled water and toned in gold chloride (0.2 g in 100 ml of distilled water) for 10 min followed by fixation in 5% sodium thiosulfate for 5 min. The slides are washed and counterstained in nuclear fast red (0.1 g in 100 ml of distilled water) for 5 min. The sections are dehydrated through increasing concentrations of alcohol, cleared in xylene, and mounted with a coverslip.

■ Methenamine silver stains

Methenamine silver stains are perhaps the most useful stains for visualizing fungi in tissue. Fungal elements are sharply delineated in black against a pale green or yellow background. They are, however, specialized stains that are more often performed in the histology laboratory rather than the microbiology laboratory. Grocott's modification of the Gomori methenamine silver stain is commonly used for the histopathological examination of deparaffinized tissues for fungi.

Basic procedure
Stock methenamine silver nitrate solution is prepared by adding 3% methenamine (3 g in 100 ml of distilled water) to 5% silver nitrate (5 g in 100 ml of distilled water) until a white precipitate forms that clears upon shaking. This solution is then diluted 1:2 with distilled water to which 5 ml of 5% photographic-grade borax is added. Prepared slides are oxidized in a solution of chromic acid (5 g in 100 ml of distilled water), neutralized in sodium bisulfite (1 g in 100 ml of distilled water), placed in the diluted methenamine silver nitrate solution, and heated in an oven to 58 to 60°C until the material turns yellowish brown. After rinsing vigorously in distilled water, the slides are toned in gold chloride (0.1 g in 100 ml of distilled water). Unreduced silver is removed by placing the slides in a sodium thiosulfate solution (2 g in 100 ml of distilled water) and finally counterstained in 0.03% light green. Rinse, blot dry, and examine at ×100 to ×400 magnification.

■ Mucicarmine stain

The mucicarmine stain is very useful for differentiating C. *neoformans* from other fungi of similar size and shape when found in samples of tissue. The mucopolysaccharide in the capsular material of the fungus stains deep rose to red, whereas the other tissue elements stain yellow.

Basic procedure
Fixed tissue sections on glass slides are stained first with Weigert's iron hematoxylin and then placed in a solution of mucicarmine (1 g of carmine combined with 0.5 g of anhydrous aluminum chloride in 2 ml of distilled water and then diluted in 100 ml of 50% ethanol) for 30 to 60 min. The slides are rinsed in distilled water and then counterstained in mentanil yellow (0.25 g in 100 ml of distilled water). Rinse, blot dry, and examine at ×100 to ×400 magnification.

■ Periodic acid-Schiff (PAS)

The periodic acid-Schiff (PAS) stain is used to detect fungi in clinical specimens, especially yeast cells and hyphae in tissues. Fungi stain a bright pink-magenta or purple against an orange background if picric acid is used as the counterstain or against a green background if light green is used. The procedure is a multistep method combining hydrolysis and staining. The periodic acid step hydrolyzes the cell wall aldehydes, which are then able to combine with the modified Schiff reagent, coloring the cell wall carbohydrates a bright pink-magenta. The PAS stain is an excellent general stain, because most fungi in clinical material take up the stain. However, the PAS staining procedure is rather involved, requiring several different reagents and time-consuming steps, and has been replaced in many laboratories by the calcofluor white staining procedure. The PAS stain cannot be used with undigested respiratory secretions, since mucin also stains bright pink-magenta.

Basic procedure
The prepared slide is fixed on formalin-ethanol for 1 min and is then air dried. The slide is then immersed in 5%

periodic acid for 5 min, followed by 2 min in basic fuchsin (0.1 g of dye in 5 ml of 95% alcohol and 95 ml of H_2O). The slide is rinsed in water and immersed in zinc or sodium hydrosulfite solution for 10 min (1 g of zinc or sodium hydrosulfite in 0.5 g of tartaric acid and 100 ml of H_2O). Rinse in water and counterstain with saturated aqueous picric acid for 2 min or with light green stain (1 g of dye in 0.25 ml of acetic acid and 100 ml of 80% alcohol) for 5 s. Rinse, blot dry, and examine at ×100 to ×400 magnification.

■ Toluidine blue O

Toluidine blue O is used primarily for the rapid detection of *P. jirovecii* from lung biopsy specimen imprints and bronchoalveolar lavage specimens**.** Toluidine blue O stains the cysts of *P. jirovecii* reddish blue or dark purple against a light blue background. The cysts are often clumped and may be punched in, appearing crescent shaped. Trophozoites are not discernible. Although the silver stain, monoclonal antibody, and calcofluor white stains are also used, the toluidine blue O stain is easy and rapid and yields reliable results with appropriate specimens (e.g., bronchial lavage specimens) (11).

Basic procedure

After the slide is air dried, place it in the sulfation reagent (45 ml of glacial acetic acid mixed with 15 ml of concentrated sulfuric acid) for 10 min. Rinse in cold water for 5 min, drain, and place in toluidine blue O (0.3 g of dye in 60 ml of H_2O) for 3 min. Rinse in 95% ethanol, followed by absolute ethanol and then xylene. Examine at ×100 to ×1,000 magnification.

MEDIA

■ Acetate ascospore agar

Acetate ascospore agar is used for the cultivation of ascosporogenous yeasts such as *Saccharomyces cerevisiae*. A potassium acetate formulation has been shown to be a better sporulation medium than the previously used formulation with sodium acetate. Ascospores produced on this medium are visible microscopically after staining with Kinyoun carbolfuchsin acid-fast stain.

■ Antifungal susceptibility testing media

Recent advances in methods for antifungal susceptibility testing have resulted in several media that are now used for this type of testing (see chapter 131). The broth dilution method for yeasts and filamentous fungi described in the M27-A and M38-A CLSI (formerly NCCLS) documents (8, 9) uses RPMI 1640 synthetic medium without sodium bicarbonate and supplemented with L-glutamine. The medium is buffered to pH 7.0 with 0.165 M morpholinepropanesulfonic acid (MOPS). Although this medium supports the growth of most fungi, it is not optimal for *C. neoformans* (13), nor does it accurately discriminate amphotericin B-resistant *Candida* spp. (12). Alternatives to RPMI 1640 for broth dilution testing include yeast nitrogen base broth with 2% glucose and antibiotic medium 3 broth.

■ Aspergillus differential medium

Aspergillus differential medium is a differential medium used for the presumptive identification of *Aspergillus flavus*. Tryptone and yeast extract serve as the source of nutrients to support fungal growth. Ferric ion in the medium promotes pigment production and imparts a yellow, yellow-green, or olive color to the growth of the organism.

■ Assimilation broth media for yeasts (carbohydrate)

Assimilation broth media for yeasts are used for the detection of assimilation, i.e., carbohydrate utilization by yeasts in the presence of oxygen. The medium uses a yeast nitrogen base, distilled water, and an individual carbohydrate. The assimilation patterns of various carbohydrates help to distinguish between different species of yeast. Since all yeasts assimilate glucose, it acts as a positive control. Usually, the media are prepared as liquids in tubes, and a positive test is growth that is observed as turbidity. Commercially prepared systems such as the Uni-Yeast-Tek (Remel) and the API 20C (bioMérieux, Inc.) system are available.

■ Assimilation broth media for yeasts (nitrogen)

Carbon assimilation broth media are used to determine the ability of yeasts to utilize different carbohydrates as a sole source of carbon in a chemically defined growth medium. The growth medium, yeast nitrogen base, contains vitamins required for growth but is insufficient to support growth without supplementation with glucose or other carbohydrates.

■ Birdseed agar-niger seed agar

Birdseed agar is a selective and differential medium used for the isolation of *Cryptococcus* species and *C. neoformans. C. neoformans* is unique in that it produces the enzyme phenol oxidase. The breakdown of the substrate (*Guizotia abyssinica* seeds or niger seed) produces melanin, which is absorbed into the yeast wall and which imparts a tan to brown pigmentation on the colonies. Colonies of other yeasts are beige or cream in color. Chloramphenicol is the selective agent that inhibits bacteria and some fungi. Creatinine enhances melanization of some strains of *C. neoformans.*

■ Bismuth sulfite-glucose-glycine yeast (BiGGY) agar

Bismuth sulfite-glucose-glycine yeast agar is a selective and differential medium used for the isolation and differentiation of *Candida* spp. Peptone, glucose, and yeast extract are the nutritive bases. *Candida* species reduce the bismuth sulfite to bismuth sulfide, which results in pigmentation of the yeast colony and, with some species, the surrounding medium. The specific colonial morphologies and growth patterns of the different *Candida* species are also detected. The bismuth sulfite also acts as an inhibitor of bacterial growth, making the medium selective.

■ Blood-glucose-cysteine agar

The blood-glucose-cysteine agar medium is used to promote the mold-to-yeast conversion of *H. capsulatum, Blastomyces dermatitidis, Paracoccidioides brasiliensis,* and *Sporothrix schenckii.* The medium contains tryptose blood agar base, L-cysteine, and defribrinated sheep blood. Penicillin is added to inhibit bacterial contamination.

■ Brain heart infusion agar (fungal formulation)

Brain heart infusion agar with sheep blood is a medium used for the cultivation and isolation of all fungi including

fastidious dimorphic fungi. The nutritive base is brain heart infusion agar with 10% sheep blood for added enrichment. The antibiotics chloramphenicol and gentamicin are added to make the medium selective by inhibiting bacterial organisms and saprophytic fungi.

■ Bromcresol purple-milk solids-glucose medium

Bromcresol purple-milk solids-glucose is a differential medium used for the identification of some dermatophytes. The medium's differential capacity is based on the type of growth (profuse versus restricted) and change in the pH indicator due to the production of alkaline by-products.

■ Canavanine glycine bromthymol blue agar

Canavanine glycine bromthymol blue agar is a differential medium for distinguishing the two varieties of *C. neoformans*. The medium contains glycine, thiamine, L-canavanine sulfate, and bromthymol blue. A colony of *C. neoformans* is streaked onto the surface of the agar and incubated at 30°C for 1 to 5 days. *C. neoformans* var. *gatti* (serotypes B and C) turns the medium cobalt blue, whereas *C. neoformans* var. *neoformans* (serotypes A and D) leaves the medium greenish yellow.

■ Candida bromcresol green (BCG) agar

Candida bromcresol green agar is a selective and differential medium used for the isolation and differentiation of *Candida* spp. Peptone, dextrose, and yeast extract serve as the nutritive base. Utilization of glucose in combination with the color indicator bromcresol green yields a specific colonial morphology and color for each *Candida* spp. Neomycin makes the medium selective by inhibiting bacteria.

■ CHROMagar

CHROMagar (Hardy Diagnostics, BD Biosciences) is a commercially available differential and selective medium used for the isolation and differentiation of clinically important yeast. The nutritive base is peptone and glucose. Chloramphenicol makes the medium selective by inhibiting bacteria. The medium is available with and without fluconazole, the former providing the additional selection of fluconazole-resistant yeast such as *C. krusei*. A proprietary chromogenic mixture allows the differentiation of many yeast species. For instance, *Candida albicans* forms yellow-green to blue-green colonies. Colonial morphology as well as distinctive color patterns has been shown to make the presumptive identification of yeast species very reliable (10). The medium has been shown to be more selective than Sabouraud agar and helpful in identifying mixed cultures of yeasts and as a source medium may enhance the rapid assimilation of trehalose by *Candida glabrata* (6). The colonies on the medium should be evaluated at 48 h. *C. neoformans* and *Geotrichum* species require additional incubation for identification.

■ Converse medium

Converse medium is a liquid medium designed to induce spherule formation from the mold phase of *Coccidioides immitis*. The medium is composed of glucose, ammonium acetate, tamol, potassium phosphate, magnesium sulfate, and zinc sulfate. Incubating shaken cultures at 35 to 40°C in 10% CO_2 optimizes conversion.

■ Cornmeal agar with dextrose

Cornmeal agar with dextrose is used for the cultivation of fungi and the differentiation of *Trichophyton mentagrophytes* from *Trichophyton rubrum* on the basis of pigment production. Dextrose in place of Tween 80 differentiates *T. mentagrophytes* from *T. rubrum* on the basis of the growth of *T. rubrum* with a red pigment.

■ Cornmeal agar with Tween 80

Cornmeal agar with Tween 80 is used for the cultivation and differentiation of *Candida* species on the basis of mycelial characteristics. Tween 80 or polysorbate 80 is specifically incorporated for demonstration of chlamydospore formation by *C. albicans*. The basic nutrients for yeast growth are provided by cornmeal infusion.

■ Christensen urea agar

The ability to hydrolyze urea is an important phenotypic characteristic for identifying yeasts such as *Cryptococcus* spp., *Trichosporon* spp., and *Rhodotorula* spp. Urea hydrolysis also facilitates separation of certain dermatophytes, in particular *T. mentagrophytes* and *T. rubrum*. The medium contains 2% urea. Phenol red is the indicator.

■ Czapek-Dox agar

Czapek-Dox agar is a reference medium for the identification of *Aspergillus* species (14). Sucrose is the sole carbon source. Sodium nitrate is the sole nitrogen source. Any bacteria or fungi that can utilize sodium nitrate as a nitrogen source will grow on this medium.

■ Dermatophyte milk agar

Dermatophyte milk agar is a medium used for the cultivation and differentiation of certain dermatophytes, particularly *T. rubrum, T. mentagrophytes,* and *Microsporum persicolor*. Skim milk powder and glucose serve as the nutritive base. The indicator bromcresol purple produces a diffuse violet color in the presence of *T. mentagrophytes* due to the alkalinization of casein in the milk solids, while *T. rubrum* shows a restricted growth pattern and no pH changes in the medium. A yellow color appears when the medium is acidified from contaminating bacterial or yeast isolates.

■ Dermatophyte test medium (DTM)

Dermatophyte test medium is a selective and differential medium used for the isolation of dermatophytes *(Microsporum, Epidermophyton,* and *Trichophyton)* from cutaneous specimens. Nitrogenous and carbonaceous compounds are provided by soy peptone. Cycloheximide inhibits saprophytic molds, and chloramphenicol inhibits many bacteria. Gentamicin inhibits gram-negative bacteria. The morphology and microscopic characteristics are easily identified with this medium. Pigmentation cannot be discerned because of the presence of the phenol red indicator. The medium is yellow and turns red with growth of dermatophytes.

■ Glucose peptone agar

Glucose peptone agar is a recommended medium for demonstrating the typical morphologies of the mucoraceous fungi. The medium is made with either mycological peptone or malt extract agar.

■ Inhibitory mold agar

Inhibitory mold agar is a selective and enriched medium that is used for the general cultivation of cycloheximide-sensitive fungi (e.g., *Cryptococcus, Zygomycetes*, and *H. capsulatum*) from contaminated specimens. Casein and animal tissue provide growth nutrients. Yeast extract provides a source of vitamins. Chloramphenicol inhibits many gram-positive and gram-negative bacteria. Gentamicin is another additive that inhibits some gram-negative bacteria.

■ Kelley's medium

Kelley's medium is an enriched medium used for the isolation and cultivation of the dimorphic fungi. The nutritive base includes beef extract, peptone, sodium chloride, and starch.

■ Lactrimal agar (Borelli's medium)

Lactrimal agar (Borelli's medium) is a medium composed of whole-wheat flour, skim milk, and honey that favors the sporulation of dermatophytes, particularly *Microsporum canis*. The medium is also used for the morphological examination of dematiaceous fungi.

■ Littman oxgall agar

Littman oxgall agar is a selective general-purpose medium used for the isolation of fungi from contaminated specimens. Crystal violet and streptomycin are the selective agents and inhibit bacteria. Oxgall restricts the spreading of fungal colonies. The isolation characteristics of this medium are similar to those of Sabouraud dextrose agar with chloramphenicol and inhibitory mold agar in that it allows the growth of fungi that are sensitive to cycloheximide.

■ Malt extract (2%) agar

A medium used for the cultivation of yeasts and molds is 2% malt extract agar. A variety of formulations have been described, but it typically includes malt extract with agar and is supplemented with peptones, glucose, maltose, and dextrin and/or glycerol.

■ Mycobiotic agar (Mycosel agar)

Mycobiotic (Remel) and Mycosel agar (BD Diagnostic Systems) are trade names for a selective medium principally designed for the isolation of dermatophytes but have been used for the isolation of other pathogenic fungi from specimens contaminated with saprophytic fungi and bacteria. The medium primarily consists of peptones from a pancreatic digest of soybean meal and dextrose. The selective agents are cycloheximide and chloramphenicol. Cycloheximide inhibits the faster-growing saprophytic fungi but is also inhibitory to some clinically relevant species. These inhibited fungi include some *Candida* and *Aspergillus* species, *Zygomycetes,* and *C. neoformans*. Chloramphenicol inhibits gram-negative and gram-positive organisms.

■ Mycosel agar (see Mycobiotic agar)

■ Niger seed agar (see Birdseed agar)

■ Potato dextrose agar

Potato dextrose agar is a medium used to stimulate conidium production by fungi. The medium also stimulates pigment production in some dermatophytes. This medium is most commonly used with the slide culture technique to view morphological characteristics. Infusions from potatoes and dextrose provide nutrient factors for excellent growth. The incorporation of tartaric acid in the medium lowers the pH, thereby inhibiting bacterial growth.

■ Potato flake agar

Potato flake agar is a medium useful in the stimulation of conidium production by fungi. Its advantages over potato dextrose agar may be preparation and stability. Potato flakes and dextrose provide the nutrient factors that allow excellent growth. The pH is adjusted to 5.6 to enhance the growth of fungi and to slightly inhibit bacterial growth. The medium may be made selective by the addition of cycloheximide and chloramphenicol.

■ Rapid trehalose medium

Rapid trehalose medium is a broth medium that provides a screening method for *C. glabrata* on the basis of rapid trehalose assimilation at 42°C. *C. glabrata* is capable of utilizing trehalose more quickly than other *Candida* species. The elevated incubation temperature increases test specificity. The medium consists of a yeast nitrogen base as a source of nitrogenous compounds. Bromcresol green is the indicator, allowing visualization of an acid shift that is indicative of a positive reaction. Trehalose is incorporated at a high concentration as the carbon source.

■ Rice medium with and without Tween 80

Rice medium that simply contains rice and deionized water is used for the identification of *Microsporum audouinii* and sometimes for the identification of nonsporulating isolates of *M. canis*. The addition of Tween 80 to the medium can enhance chlamydospore formation in *C. albicans.*

■ Sabouraud-brain heart infusion agar

Sabouraud-brain heart infusion agar is a general-purpose medium used for the isolation and cultivation of all fungi. The medium is a combination of brain heart infusion agar and Sabouraud dextrose agar. The combined formula allows the recovery of most fungi including the dimorphic fungi. Sheep blood provides essential growth factors for the more fastidious fungi and enhances the growth of *H. capsulatum*. Selectivity is attained by the addition of chloramphenicol, cycloheximide, penicillin, and/or streptomycin.

■ Sabouraud dextrose agar

Sabouraud dextrose agar was formulated by Sabouraud for cultivating dermatophytes. The medium consists of pancreatic digest of casein, peptic digest of animal tissue, and dextrose at a 4% concentration and buffered to a pH of 5.6. Emmons modified the original formulation by lowering the dextrose concentration from 4 to 2% and adjusting the pH nearer to neutrality at 6.9 to 7.0. Antibiotic additives in various combinations including cycloheximide, chloramphenicol, gentamicin, ciprofloxacin, penicillin, and/or streptomycin, which inhibit some fungi and gram-positive and gram-negative bacteria, achieve selectivity for this medium. Mycobiotic agar and Mycosel agar with antibiotics are similar in performance to Sabouraud dextrose agar (Emmons modification). This medium is also available as a broth.

■ Soil extract agar

Soil extract agar is a medium composed of garden soil, yeast extract, and glucose, which is used to promote sporulation in some saprobic fungi and for mating strains of *B. dermatitidis* (14).

■ Tomato juice agar

Tomato juice agar is a medium containing tomato juice and yeast powder, which is used to promote ascospore formation (5, 14).

■ Trichophyton agars #1 to #7

Trichophyton agars are a set of seven media that allow the identification of *Trichophyton* species on the basis of their growth factor requirements. The basic ingredients in the media are listed below. Growth in all seven media is then scored on a scale of 1 to 4, and an identification is assigned.

#1: Casamino Acids, vitamin-free
#2: Casamino Acids plus inositol
#3: Casamino Acids plus inositol and thiamine
#4: Casamino Acids plus thiamine
#5: Casamino Acids plus niacin
#6: Ammonium nitrate
#7: Ammonium nitrate plus histidine

■ V9 agar

V9 agar is a medium consisting of dehydrated potato flakes and tomato juice that induces early sporulation of some environmental fungi. The naturally low pH makes the medium inhibitory to most bacteria.

■ Yeast carbon agar

Yeast carbon agar is a solid medium recommended for use in qualitative procedures for the classification of yeasts according to their ability to assimilate nitrogenous compounds. The yeast carbon base provides amino acids, vitamins, trace elements, and salts, which are necessary to support growth. The ability to assimilate nitrogen is tested by the addition of various nitrogen sources such as potassium nitrate.

■ Yeast extract phosphate agar with ammonia

Yeast extract phosphate agar with a drop of ammonium hydroxide is used for isolation of *H. capsulatum* and *B. dermatitidis* from contaminated specimens. The medium is a mix of a phosphate buffer adjusted to pH 6.0 and a yeast extract agar solution. An ammonium hydroxide solution is applied to the agar surface with a dropper and is allowed to diffuse into the medium. Ammonium hydroxide and chloramphenicol suppress bacteria and many molds and yeast, thus permitting detection of the slowly growing dimorphic fungi.

Algorithms for Detection and Identification of Fungi*

YVONNE R. SHEA

118

As the number of invasive fungal infections increases, the rapid and accurate diagnosis of the etiologic agent becomes even more vital for the initiation of appropriate antifungal therapy. This chapter is a review of non-culture-based detection and identification methods that can be performed directly with clinical materials in a clinical laboratory. These methods include direct microscopic examination, antigen detection, detection of fungus-specific metabolites, detection of cell wall components, detection of fungus-specific nucleic acids, and serologic diagnosis. All methods discussed should be used as an adjunct to proper culturing, as culture remains the standard for detection and identification of fungi in clinical specimens. Culture methodology for the isolation of fungi is reviewed in chapter 116.

DIRECT MICROSCOPIC EXAMINATION

Gross examination of clinical material should be performed before specimen processing occurs. Specimens should be examined for areas of caseous necrosis, microabscesses, grains and granules, and firm nodules which may indicate granulomas. Granulomas and caseous necrosis may indicate histoplasmosis, and microabscesses can be seen with hepatosplenic candidiasis, whereas grains or granules can be seen in chromoblastomycosis and mycetoma. Certain fungal organisms are more likely to be recovered from specific body sites (64) (Table 1). The pathology associated with fungal organisms may vary according to the competence of the host immune defenses.

Knowledge of the patient's residence and recent travel history may provide diagnostic clues to fungal disease because some fungal pathogens are more common in certain regions of the world (Table 2). For example, although eumycetoma has been reported worldwide, most cases come from tropical and subtropical regions around the Tropic of Cancer (25). *Madurella mycetomatis, Scedosporium apiospermum, Leptosphaeria senegalensis,* and *Madurella grisea* account for 95% of eumycetoma infections (8). Grains and granules should be examined for color, size, shape, and consistency because these characteristics can help to identify the etiologic agent (Table 2).

The ability to recognize typical staining characteristics of fungi can assist in the diagnosis, guide appropriate testing, and facilitate proper antifungal therapy. A number of stains or procedures can be used to detect fungal organisms by direct examination of clinical specimens (Table 3). Stain details can be found in chapter 117.

The value of the Gram stain should not be underestimated, as it is the front-line stain in most laboratories and the stain with which most technologists are familiar. Differentiating yeast from mold is important because yeast may represent normal colonization, while mold can indicate a deeper infectious process. Although Gram reactions can vary, yeast cells and pseudohyphae generally stain gram positive and hyphae (septate and aseptate) stain gram negative. The size and shape of budding yeast-like cells can indicate a presumptive species identification. *Cryptococcus neoformans* yeast cells are generally very round and display an amorphous orange-staining material, presumably the capsule.

Examination of smears for specific morphologic patterns can help to establish the identification of the organism. *Aspergillus* species tend to form hyphae of a consistent diameter (4 to 6 μm) and commonly demonstrate 45° branching and less commonly exhibit 90° branching. *Fusarium* and *Scedosporium* species look very similar to *Aspergillus* species in tissue (38). Sporulation in clinical material may occur. Aleurioconidia can be indicative of *Aspergillus terreus* (80), and the detection of phialides and phialoconidia can assist in the preliminary identification of *Fusarium, Paecilomyces,* and *Acremonium* species. When fungal stains show both unicellular forms and filaments that appear to be hyphae or pseudohyphae, infection with *Fusarium, Paecilomyces,* or *Acremonium* species should be considered (42). Zygomycetes exhibit aseptate (or rarely septate) hyphae of irregular diameter that tend to branch at 90 degrees. The lack of regular septations causes an absence of internal support for the hyphae, and the hyphae can become twisted and folded in a ribbon-like manner. Often the hyphae of zygomycetes are very irregular and pleomorphic. Dematiaceous molds may display multiple forms such as septate hyphae with parallel walls, rounded forms arranged in chains, or muriform bodies. The diagnosis of phaeohyphomycosis can be made only if pigmented hyphae are observed. Sometimes pigmentation can be observed by using a traditional KOH preparation. Some structures can provide definitive diagnosis of the etiologic agent (e.g., spherules of *Coccidioides* spp.). Specimens obtained from patients treated with antifungal drugs may demonstrate uncharacteristic formations such as variations

* This chapter contains information presented in chapter 112 by William G. Merz and Glenn D. Roberts in the eighth edition of this Manual.

TABLE 1 Selection of clinical specimens for recovery of opportunistic fungal pathogens[a]

Suspected pathogen	Blood	Bone marrow	Brain and CSF	Catheter/ catheter exit site	Eye	Respiratory sites	Skin, mucous membranes	Urine	Multiple systemic sites

[a] Adapted from reference 55a. The anatomic site of the fungal infection can be an indicator of what mycotic agent to suspect, but in an immunocompromised patient population, virtually any fungus can be an opportunistic pathogen.

of hypha size within the same hyphal structure, clearing of septations within the hyphae, or bulb forms within the hyphae or in the hyphal tips.

Artifacts seen in smears can hinder correct diagnosis. Lysed lymphocytes in cerebrospinal fluid (CSF) have been mistaken for *Cryptococcus neoformans,* collagen fibers and swab fibers may be mistaken for hyphae as each can fluoresce with calcofluor white, and fat droplets may be confused with budding yeast-like cells. A careful smear review in each of these situations should help avoid misinterpretation, but when in doubt, a second reader or second procedure should be employed. Correct interpretation is critical to appropriate patient care.

Detection of fungi in clinical material can be difficult because the specimen may be inadequate, relatively few fungi may be present, or similarly appearing organisms may be indistinguishable on initial examination. When specimen volume is minimal, the culture should take precedence over the smear, because direct examinations are less sensitive than culture. When possible, always perform both smear and culture, given that culture alone cannot distinguish between colonization and tissue invasion. Conversely, only nonviable organisms may be present in specimens obtained while the patient is receiving antifungal therapy and microscopy may be the only method for detecting the etiologic agent. Specimen quantity and quality may be compromised when multiple clinical laboratories process portions of the specimens. Good communication between the pathology and microbiology services in union with the clinician can greatly enhance diagnostic accuracy.

Any positive smear result must be reported promptly and clearly convey what has been seen, so that the clinician understands what type of organism has been detected. When possible, additional comments should be entered to clarify the type of structures or possible organism identification. For example, "Budding yeast-like cells seen" can indicate many different species of yeasts, while "Budding yeast-like cells resembling *Malassezia* group" offers a clue to the type and significance of the infection. Figures 1 through 26 illustrate characteristic fungal structures seen in the direct examination of clinical specimens.

ANTIGEN DETECTION

Aspergillus spp.

A diagnostic marker for invasive aspergillosis (IA) is galactomannan (GM). GM is a polysaccharide cell wall component that is released into blood by growing hyphae. The Platelia *Aspergillus* GM immunoassay (Bio-Rad, Hercules, Calif.) was cleared by the Food and Drug Administration for diagnostic use in the United States in May 2003. The Platelia *Aspergillus* GM immunoassay has been evaluated in numerous studies as a diagnostic tool for IA, but the reported sensitivities and specificities have been variable. Explanations for this variability include number and type of collected specimens (serial samples, single samples, blood, bronchoalveolar lavage [BAL] fluid), the time the specimen was obtained during the course of the infection, varying test cutoff values (47), and receipt of prophylactic or empirical antifungal therapies (46). As the use of the Platelia *Aspergillus* test has increased, causes for false positives have been revealed. False positives have been associated with dietary GM, autoantibodies, mycosis with shared antigens (86), drug therapies with amoxicillin-clavulanic acid (48) or piperacillin-tazobactam (79), the galactoxylomannan component of the *Cryptococcus neoformans* capsular polysaccharide (14), and bifidobacterial lipoglycan (52). Additionally, patients undergoing hemodialysis may have falsely high titers

TABLE 2 Characteristic fungal elements seen by direct examination of clinical specimens

Morphologic fungal element found	Organism(s)	Diam range (μm)	Characteristic features	Geographic distribution
Yeast forms	*Histoplasma capsulatum*	2–5	Small; oval to round budding cells; often found clustered within histiocytes; difficult to detect when present in small numbers; often intracellular (Fig. 23)	var. *capsulatum:* Ohio and Mississippi river valleys, Mexico, Central America var. *duboisii:* tropical areas of Africa
	Sporothrix schenckii	2–6	Small; oval to round to cigar shaped; single or multiple buds present; uncommonly seen in clinical specimens (Fig. 21)	Most often reported from Mexico, Central and South America, also common in Asia. More widespread in temperate and tropical zones
	Cryptococcus spp.	2–15	Cells vary in size; usually spherical but may be football shaped, buds usually single and "pinched off"; capsule may or may not be evident; rarely, pseudohyphal forms with or without capsule may be seen (Fig. 7, 15, and 16).	*Cryptococcus gatti:* tropics and southern hemisphere, eucalyptus trees; endemic to Vancouver Island (Douglas fir zone)
	Blastomyces dermatitidis	8–15	Cells usually large and spherical, double refractile; buds usually single, but several may remain attached to parent cells; buds connected by broad base (Fig. 22).	Southeast/South central United States, Great Lakes region, near St. Lawrence River
	Paracoccidioides brasiliensis	5–60	Cell usually large and surrounded by smaller buds around periphery (mariner's wheel appearance); smaller cells (2–5 μm) that resemble *H. capsulatum* may be present; buds have "pinched off" appearance (Fig. 25).	South and Central America
Yeast forms (fission)	*Penicillium marneffei*	3	Fission yeast, not budding, elongated, curved with septa visible (Fig. 26)	Southeast Asia and China
Cysts and trophozoites	*Pneumocystis jirovecii*	1–4 4–5	Trophozoites: small pleomorphic forms Cysts: round to cup shape with up to 8 intracystic bodies (Fig. 18)	Worldwide
Spherules	*Coccidioides immitis, Coccidioides posadasii*	10–200	Spherules vary in size; some contain endospores, others are empty and collapsed; hyphae may be seen in cavitary lesions (Fig. 24).	Southwestern United States, Mexico, Central and South America (*C. posadasii* organisms are non-Californian strains)
Yeast forms and pseudohyphae or true hyphae	*Candida* spp.	3–4 (yeast forms); 5–10 (pseudohyphae)	Cells usually exhibit single budding; pseudohyphae, when present, are constricted at ends and remain attached like links of sausage; true hyphae, when present, have parallel walls and are separated (Fig. 4, 5, and 6).	Worldwide
Yeast forms and pseudohyphae	*Malassezia* species	3–8 (yeast forms); 5–10 (pseudohyphae)	Short, curved hyphal elements may be present along with round yeast cells that are round at one end and flattened at point of conidiation (Fig. 8).	Worldwide
Wide nonseptate hyphae	*Zygomycetes*	10–30	Hyphae are large, ribbonlike, often fractured or twisted. Occasional septa may be present, branching usually at right angles (Fig. 3, 11, and 12).	*Basidiobolus ranarum:* tropical areas of Asia, Africa, South America (mostly Brazil), Mexico, Australia (children); *Conidiobolus coronatus* and *C. incongruus*: tropical and subtropical regions of Africa and Southeast Asia (adults)

(Continued on next page)

TABLE 2 Characteristic fungal elements seen by direct examination of clinical specimens *(Continued)*

Morphologic fungal element found	Organism(s)	Diam range (μm)	Characteristic features	Geographic distribution
Hyaline septate hyphae	Dermatophytes (skin and nails)	3–15	Hyaline septate hyphae commonly seen; chains of arthroconidia may be present (Fig. 19).	Also consider *Scytalidium hyalinum:* Caribbean and West Africa
	Dermatophytes (hair)	3–12	Arthroconidia on periphery of hair shaft that produce sheaths indicate ectothrix infection. Arthroconidia formed by fragmentation of hyphae within hair shaft indicate endothrix infection. Long hyphal filaments or channels within hair shaft indicate favus hair infection.	
Hyaline septate hyphae	*Aspergillus* spp.	4–6	*Aspergillus* spp. are generally septate with consistent diameter throughout, often show repeated dichotomous, 45° angle branching (Fig. 1, 9, 10, 13, and 14).	Worldwide
	Scedosporium spp. (not eumycetoma); *Fusarium* spp.; *Paecilomyces* spp.	3–12	Hyphae are septate, difficult to distinguish from other hyaline molds. May exhibit less 45° angle and more 90° angle branching.	
Dematiaceous septate hyphae	Dematiaceous fungi	1.5–6	Dematiaceous polymorphous hyphae, budding cells with single septa and chains of swollen rounded cells may be present. Occasionally, aggregates may be present when infection is caused by *Phialophora* or *Exophiala* spp. (Fig. 2).	*Phaeoannellomyces werneckii:* subtropical coastal locations; *Piedra hortae:* tropical climates of Central and South America, Southeast Asia, and the South Pacific Islands; *Ramichloridium mackenziei:* Middle East
Sclerotic bodies (muriform cells)	*Cladosporium carrionii; Fonsecaea compacta; Fonsecaea pedrosoi; Phialophora verrucosa; Rhinocladiella aquaspersa*	5–20	Brown, round to pleomorphic, thick-walled cells with transverse septa. Commonly, cells contain two fission plates that form tetrads of cells. Occasionally, branched septate hyphae may be found in addition to sclerotic bodies (Fig. 20).	Occurs worldwide, although the majority of reported cases are from tropical and subtropical regions of the Americas and Africa
Granules (white grain eumycetomas)	*Acremonium* spp. *(falciforme, kiliense, recifei)*	200–300	White, soft granule, cement-like matrix absent	Asia, North, South and Central America, Europe, Oceania
	Aspergillus nidulans	65–160	White, soft granule, cement-like matrix absent	Africa
	Fusarium spp. *(F. moniliforme, F. oxysporum, F. solani)*	80–200	White-yellowish color of the grains, edges are entire or lobed; surrounded by an eosinophilic homogeneous material. Hyphae comprising the granules are not embedded in cement.	Europe, South America, Caribbean, Africa, Asia
	Neotestudina rosatii	300–600	White, soft granule with cement-like matrix at periphery	West Africa
	Pseudallescheria boydii	200–300	White-yellow, soft granules composed of hyphae and swollen cells at periphery in cement-like matrix (Fig. 17)	Worldwide, most common in North America
Granules (black grain eumycetomas)	*Curvularia* spp. *(geniculata, lunata)*	500–1,000	Black, hard grains with cement-like matrix at periphery	Worldwide
	Exophiala jeanselmei	200–300	Black, soft granules, vacuolated, cement-like matrix absent, made of dark hyphae and swollen cells	Worldwide
	Leptosphaeria senegalensis; Leptosphaeria tompkinsii	400–600	Black, hard granules; cement-like matrix; in tissue sections, the	West Africa (specifically Senegal and Mauritania)

(Continued on next page)

TABLE 2 *(Continued)*

Morphologic fungal element found	Organism(s)	Diam range (μm)	Characteristic features	Geographic distribution
			central part consists of hyphae, and a black cement-like substance is seen at the periphery	
	Madurella grisea	300–600	Black and soft with a brown cement-like material in the periphery of the granules	India, Africa, Central and South America
	Madurella mycetomatis	200–900	Black to brown hard granules of two types: (i) rust, brown, compact, and filled with cement-like matrix and (ii) deep brown, filled with numerous vesicles, 6–14 μm in diameter, cement-like matrix in periphery and central area of light-colored hyphae	India, Africa, and South America
	Pyrenochaeta romeroi; P. mackinnonii	40–100 by 50–160	Black, soft granules composed of polygonal swollen cells at periphery, cement-like matrix	Africa, India, and South America

because hemodialysis is unable to clear *Aspergillus* antigen from serum (19). Reduced detection of GM may occur in patients with chronic granulomatous disease or Job's syndrome (78), low fungal burdens, or walled-off infections or in those with IA who are receiving antifungal therapy active against molds. Weisser et al. (82) established that GM does not precede major signs on pulmonary computerized tomographic scans suggestive of invasive aspergillosis in patients with hematological malignancies. Immunodiagnosis, metabolite detection, and molecular techniques for the diagnosis of aspergillosis are further described in chapter 121.

Blastomyces dermatitidis

Antigen detection methods are generally not used for the diagnosis of blastomycosis. A *Blastomyces dermatitidis* enzyme immunoassay (EIA) (Mira Vista Diagnostics, Indianapolis, Ind.) for the detection of antigenuria has been evaluated, demonstrating a sensitivity of 92.9%, specificity of 79.3%, and cross-reactivity with patients with histoplasmosis, paracoccidioidomycosis, penicilliosis marneffei, cryptococcosis, and aspergillosis (16). Further evaluations are needed.

Candida Species

Distinguishing colonization from disease complicates the diagnosis of candidiasis by antigen detection (62). To detect candidiasis, diagnostic markers of mannan and mannoproteins have been evaluated. Mannan, which is highly immunogenic, is one of the major cell wall components of *Candida* species and is shed into the blood during infection.

The Platelia *Candida* antigen test (Bio-Rad, Marnes-La-Coquette, France) has good specificity, but frequent testing is required because mannan is rapidly cleared from the blood (72).

The Cand-Tec latex agglutination test (Ramco Laboratories, Houston, Tex.) is designed to detect a heat-sensitive circulating antigen associated with *Candida* species. Studies using the Cand-Tec have demonstrated extreme variability in both sensitivity and specificity, and thus, it is not reliable for the diagnosis of disseminated candidiasis (1, 54, 61, 65).

Pitarch et al. (66) identified numerous novel *C. albicans* antigens that elicit a specific immune response in systemic candidiasis patients with malignant hematological disorders by using immunoproteomics. In this work, differences in antigen recognition patterns that correlated with infection progression were revealed. These data can be accessed at http:/babbage.csc.ucm.es/2d/2d.html.

Coccidioides Species

Antigen tests are not generally used for the diagnosis of *Coccidioides* infection.

Cryptococcus neoformans

The glucuronoxylomannan component of the *Cryptococcus neoformans* capsular polysaccharide is used for diagnosis of cryptococcosis. Five serotypes of *C. neoformans* are recognized: A, B, C, D, and AD. Commercially available cryptococcal antigen detection methods detect all serotypes. Most clinical isolates are serotype A (53). Latex antigen detection methods (Meridian Cryptococcal Antigen Latex Agglutination System, Meridian Diagnostics, Inc., Cincinnati, Ohio; Murex Cryptococcus Test, Murex Corp., Norcross, Ga.; Crypto-LA Test, Wampole Laboratories, Cranbury, N.J.; and Latex Antigen Detection System, Immuno-mycologics, Norman, Okla.) and the enzyme immunoassay (Premier Cryptococcal Antigen sandwich EIA; Meridian Diagnostics, Inc.) are sensitive (93 to 100%) and specific (93 to 100%) diagnostic tools (32, 37, 75). All methods are well established for the detection and quantitation of circulating capsular polysaccharide antigen from *C. neoformans* in serum and CSF. Titer determinations resulting from different latex kits should not be used interchangeably because results may vary considerably. When comparing titers between current and previous specimens, titrations should be performed using the same kit at the same time. Studies for the detection of cryptococcal antigen in BAL fluid have met with variable results (2, 39).

With both the latex and EIA methodology, false-negative as well as false-positive results have been described. False-negative results can occur with low titers of cryptococcal antigen, early infection, poorly encapsulated strains with low production of polysaccharide, and prozone phenomenon (22). False-positive results have been well documented with latex agglutination systems (5, 6, 9, 20, 27, 50, 83). Most false-positive reactions have been eliminated through procedural modifications (24, 90) and incorporation of control reagents (3).

TABLE 3 Methods and stains available for direct microscopic detection of fungi in clinical specimens[a]

Method	Use	Time required (min)	Color of fungus	Comments
Alcian blue	Detection of *C. neoformans* in CSF	2	Capsule stains blue against a pink background.	Mucopolysaccharide stain, not commonly used; like India ink, does not detect all cases.
Calcofluor white	Detection of all fungi and cysts of *Pneumocystis jirovecii*	1–2	Depending on which barrier filter is used, fungal elements appear blue-white or bright green against a dark background (Fig. 10 and 12). Cysts have "double parenthesis-like" structure in center.	Requires fluorescence microscope; collagen and swab fibers also fluoresce, fat droplets may look similar to yeast cells. Counterstain minimizes background fluorescence.
Fontana-Masson (FM)	Detection of melanin of dematiaceous fungi and *C. neoformans*	60	Cell walls black. Background pale pink.	Many nondematiaceous fungi (some *Aspergillus, Zygomycetes,* and *Trichosporon* species) can be FM positive. If hyaline in H&E, examine morphology carefully.
Giemsa stain	Primarily used for the examination of bone marrow and peripheral blood smears	15	Detects trophozoite stage of *P. jirovecii*	Detects intracellular *H. capsulatum* and fission yeast cells of *P. marneffei* (Fig. 26).
Diff-Quick	Also applied to other specimens, such as BAL fluid, CSF	2–3	Yeast cells and trophozoites appear blue-purple (Fig. 15).	Differentiate from *Leishmania*.
Wright		7		Also stains other fungi.
Gomori methanamine silver stain (GMS)	Detection of fungi and *Pneumocystis jirovecii*	5–60	Fungi and *P. jirovecii* cysts stain gray to black. Background is green (Fig. 9, 11, 13, and 21).	Often stains fungi too densely to observe structural details. Yeast cells and cysts of *Pneumocystis* may appear similar in size and shape.
Gram stain	Detection of bacteria and fungi	3	Generally yeast and pseudohyphae stain gram positive and hyphae (septate and aseptate) appear gram negative (Fig. 1–8).	*Cryptococcus* spp. stain weakly in some instances and exhibit only stippling. Often have orange amorphous material around yeast (Fig. 7). Not all fungi are detected.
H&E	General purpose histologic stain	30–60	Stains some fungal elements violet to bluish purple, tissue background is displayed as shades of red. Demonstrates natural pigment of dematiaceous fungi (Fig. 14, 17, and 24).	Permits visualization of host tissue response to the fungus. *Aspergillus* spp. and *Zygomycetes* stain well.
India ink, nigrosin	Detection of *C. neoformans* in CSF	1	Capsules around yeast cells clear halos against a black background (Fig. 16)	When positive in CSF, diagnostic of meningitis. Negative in many cases of meningitis, not reliable. Cryptococcal antigen testing recommended.
Mucicarmine	Stains mucin	60	Stains capsule of *Cryptococcus* pinkish red	May also stain cell walls of *B. dermatitidis* and *Rhinosporidium seeberi.*
Papanicolaou	Cytologic stain used primarily to detect malignant cells	30	Depending on cell type detected, background stains in subtle range of green blue, orange to pink hues. *Candida* stains	Further stains should be performed.

(Continued on next page)

TABLE 3 *(Continued)*

Method	Use	Time required (min)	Color of fungus	Comments
			gold, while other fungi may not stain at all.	
PAS	Detection of fungi	20–25	Fungi stain pink, background stains shades of purple.	PAS stain-positive artifacts can appear as yeast cells. *B. dermatitidis* appears pleomorphic.
Potassium hydroxide (KOH)	Clearing of specimen to make fungi more readily visible	5–30	Hyaline molds and yeasts appear transparent, while dematiaceous molds may display golden brown hyphae.	Addition of lactophenol cotton blue or methylene blue enhances the visibility of fungi.
Toluidine blue	Detection of *P. jirovecii* in respiratory specimens	25	Cyst walls are purple (Fig. 18).	The background and other fungi stain the same color.

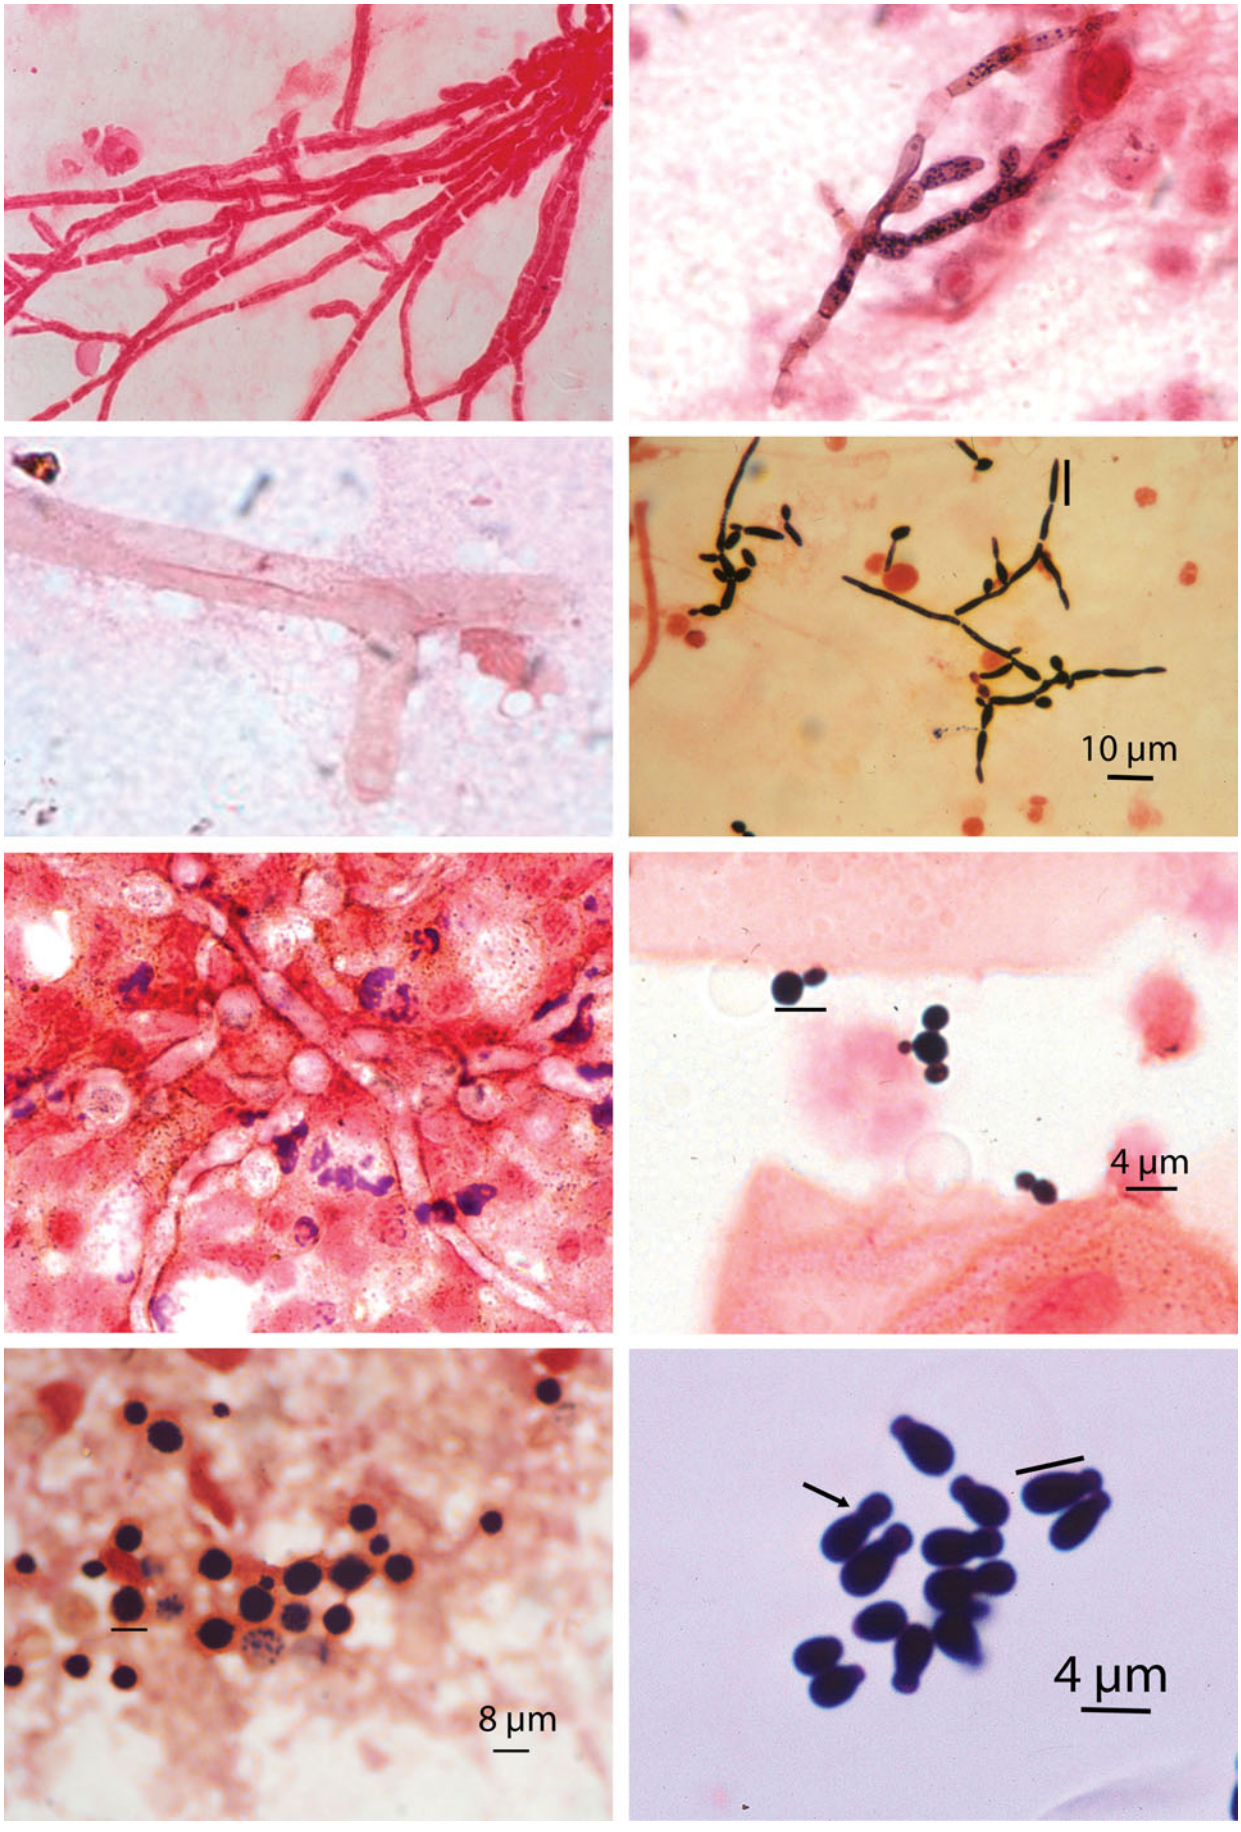
[a] H&E, hemoxylin and eosin; PAS, periodic acid-Schiff.

The Premier Cryptococcal Antigen EIA yields few false-positive results, including cross-reaction with *Trichosporon* and unidentified causes (23). EIA titers are not numerically equivalent to latex titers.

Histoplasma capsulatum

The diagnosis of histoplasmosis is usually made by a combination of culture, histopathology, measurement of antibodies, or detection of antigen. The sensitivities of histopathology of tissue for the detection of *Histoplasma capsulatum* are 43, 17, and 9% for disseminated, chronic pulmonary, and self-limited histoplasmosis, respectively (91).

In active infections, antigens are released into tissues and enter body fluids adjacent to the sites of the infection. *H. capsulatum* antigen is detected in the blood, urine, CSF, or BAL fluid using an EIA. Antigen can be detected in the blood or urine in up to 92% of patients with disseminated histoplasmosis and in up to 75% of those with diffuse lung involvement during acute pulmonary histoplasmosis. The sensitivity of urinary antigen detection in disseminated histoplasmosis varies with patients with AIDS (95%), nonimmunosuppressed patients (80%), and immunosuppressed patients (82%) (87). Urine antigen is more sensitive than that in blood. Antigen is detected in the CSF of 25 to 50% of patients with *Histoplasma* meningitis and in BAL fluid of 70% of patients with diffuse pulmonary histoplasmosis. The antigen test can be used to monitor therapy and diagnose relapse. Cross-reactions occur with paracoccidioidomycosis, blastomycosis, penicilliosis, and African histoplasmosis (84).



False-positive *Histoplasma* antigen results were identified for patients who received rabbit anti-thymocyte globulin (ATG) [Thymoglobulin(R)] to prevent allograft rejection. Of 107 patients receiving ATG, 17 (15.9%) demonstrated false-positive tests for *Histoplasma* antigenemia (85). It was determined that repeated administration of the rabbit immunoglobulin stimulates production of heterophile antibodies which cross-reacted with the first version of the *Histoplasma* antigen assay. In November 2004, MiraVista Diagnostics (444 Decatur Blvd., Suite 300, Indianapolis, IN) implemented its second-generation *Histoplasma* antigen EIA, which does not cross-react with patient heterophile antibodies. Currently, MiraVista Diagnostics is the only laboratory using the second-generation *Histoplasma* antigen EIA. More information about this test can be found at http://www.miravistalabs.com.

(1→3) BETA-D-GLUCAN PANFUNGAL DETECTION

The measurement of (1→3)-beta-D-glucan (BG) in blood can be used as a diagnostic marker for invasive fungal infections. BG is a cell wall polysaccharide component found in most fungi, except for the zygomycetes, which do not produce BG, and *Cryptococcus* species, which produce low levels of BG.

Although commercial assays for the detection of BG are available (FUNGITEC G TEST MK series [Seikagaku Kogo Corporation, Tokyo, Japan]; Beta-D-glucan Test Wako [Wako Pure Chemical Industries, Tokyo, Japan]; B-G Star MARUHA [Maruha Corp., Tokyo, Japan]), there is little experience in the use of these tests outside Japan (28). Comparison of the various BG tests is difficult because each utilizes different reagents and methodologies. The only commercially available test in the United States is the Fungitell (Glucatell) test (Associates of Cape Cod, Falmouth, Mass.), which was FDA approved in 2004. The Fungitell assay is based upon a modification of the Limulus Amebocyte Lysate assay (56). Briefly, BG binds to the alpha subunit of factor G found in *Limulus polyphemus* amebocyte lysates and activates Factor G, a serine protease zymogen beta subunit. Activated Factor G converts the inactive proclotting enzyme to the active clotting enzyme, which in turn cleaves the attached chromogenic peptide substrate. This chromophore is quantified spectrophotometrically at 405 nm. The recommended positive cutoff value is >80 pg/ml (Fungitell Product Insert [October 2004], Associates of Cape Cod, Inc., Falmouth, Mass.).

Studies have shown that the Fungitell serum BG detection assay is a highly sensitive and specific diagnostic tool for invasive fungal infections (including aspergillosis, fusariosis, trichosporonosis, and candidiasis) (36, 59, 60, 63). Difficulties arise when comparing the data from these studies because different cutoff values were used to interpret the results. Additionally, analysis of the patient population must be considered because test results vary with proven, probable, or possible invasive fungal infection classifications. The sensitivity and specificity results for the Fungitell BG test also vary with the frequency of sampling. Serial sampling studies tend to report a higher sensitivity than once-a-week or once-per-episode studies. Overall, the range of predicted assay accuracy is unsatisfactory (sensitivity of 60 to 100% and specificity of 64 to 99%; positive predictive values, 43 to

10 µm
4 µm
8 µm
4 µm

100%; negative predictive values, 73 to 100%). The assay appears to be less sensitive for *Candida parapsilosis*.

With all BG tests, false positives occur with patients who are on hemodialysis using cellulose membranes (35), are being treated with certain blood products (such as serum albumin and immunoglobulins) (30, 57), or have been exposed to gauze, cotton, or sponges containing glucan (58). Sera which are hemolytic or lipemic or contain bilirubin have been shown to give inconsistent results and should not be tested (70). Additionally, some mushroom extracts under investigation as antitumor drugs (including lentianan, crestin, *Sclerotinia sclerotiorum* glucan [SSG], and schizophyllan) (7) are reported to contain BG and may lead to false-positive BG assay results. All false-positive results generally show similar kinetics, displaying a sudden rise and fall in BG levels in serum. True-positive results generally show a constant rise of BG levels, which then decrease and become negative if the patient responds to antifungal therapies. Patients not responding to antifungal treatment do not show a decrease in BG levels. BG testing must always be utilized in conjunction with other diagnostic tests (e.g., GM, histopathological diagnosis, culture of samples, and radiological exams) for the conclusive diagnosis of invasive fungal infection.

FUNGUS-SPECIFIC METABOLITE DETECTION

In addition to antigen detection methods, fungus-specific metabolites have been used as markers to detect fungal infections. The fungal polyols D-arabinitol (DA) and D-mannitol (DM) and the ratio of D-arabinitol (DA)/L-arabinitol have been studied. The detection of DA in urine and serum can aid in the diagnosis of invasive candidiasis (11, 40, 68, 73, 76). DA is a 5-carbon sugar alcohol produced by most *Candida* spp., but not *Candida krusei* and perhaps *Candida glabrata*. Sensitivity differences in studies conducted for DA may relate to the prevalence of the yeast species infecting study patients (17). Human serum DA and L-arabinitol increase during renal dysfunction, so DA levels are generally reported as a ratio of DA to creatinine as serum creatinine levels are required to normalize results. Numerous techniques have been used to detect the presence of DA or determine DA/L-arabinitol ratios in human serum and urine, including gas-liquid chromatography, gas chromatography-mass spectrometry, and enzymatic methods, and are reviewed in references 12, 29, 69, 81, and 93.

DM is produced by some but not all pathogenic fungi and is not a known product of mammalian metabolism. DM has been studied primarily as a marker for *Cryptococcus neoformans* infection. DM production may contribute to *C. neoformans* pathogenesis by protecting the organism from oxidative damage (10). High concentrations of DM may cause increased intercranial pressure resulting in brain edema. No quantitative correlation can be made between the mannitol concentration and the cryptococcal antigen titer (51).

NUCLEIC ACID DETECTION

Molecular amplification techniques offer increased sensitivity over traditional staining and culture methods but may give positive results in asymptomatic individuals because of colonization or subclinical infection. Molecular methods have been applied directly to clinical materials or the contents of blood culture bottles. Numerous studies have been performed utilizing molecular methods for the direct detection and identification of fungi from specimens. (Examples can be seen in Table 4.) The process of detecting nucleic acids involves three fundamental steps. First, the nucleic acids must be extracted from the sample. Clinical materials may require further processing than fungal isolates due to the presence of PCR inhibitors found in specimens or blood culture bottles. A large number of methods for the extraction of nucleic acids from clinical materials exist (44). Cost, time, and sensitivity need to be considered when selecting an extraction method. Automated DNA extraction methods may significantly reduce contamination rates and may allow for a method of standardization between institutions performing molecular detection methods (49).

Second, an amplification target must be selected. Targets include the fungal nuclear rRNA, which consists of three genes that include the large subunit gene (26S or 28S), the small subunit gene (18S) and the 5.8S gene, separated by internal transcribed spacer (ITS) regions and housekeeping genes such as beta tubulin and actin. In general, universal primers are used to amplify the initial target, and then species-specific primers are used to identify the organism (89). The failure to amplify specific DNA may result from fungal DNA concentrations below detection limits, a focal

FIGURE 19 (row 3, left) Arthroconidia and hyphae of a dermatophyte. Magnification, ×200. This picture is compliments of Deanna Sutton.

FIGURE 20 (row 3, right) Sclerotic cells in tissue characteristic of the tissue form of the etiologic agents of chromoblastomycosis. Magnification, ×1,200. This picture is compliments of Deanna Sutton.

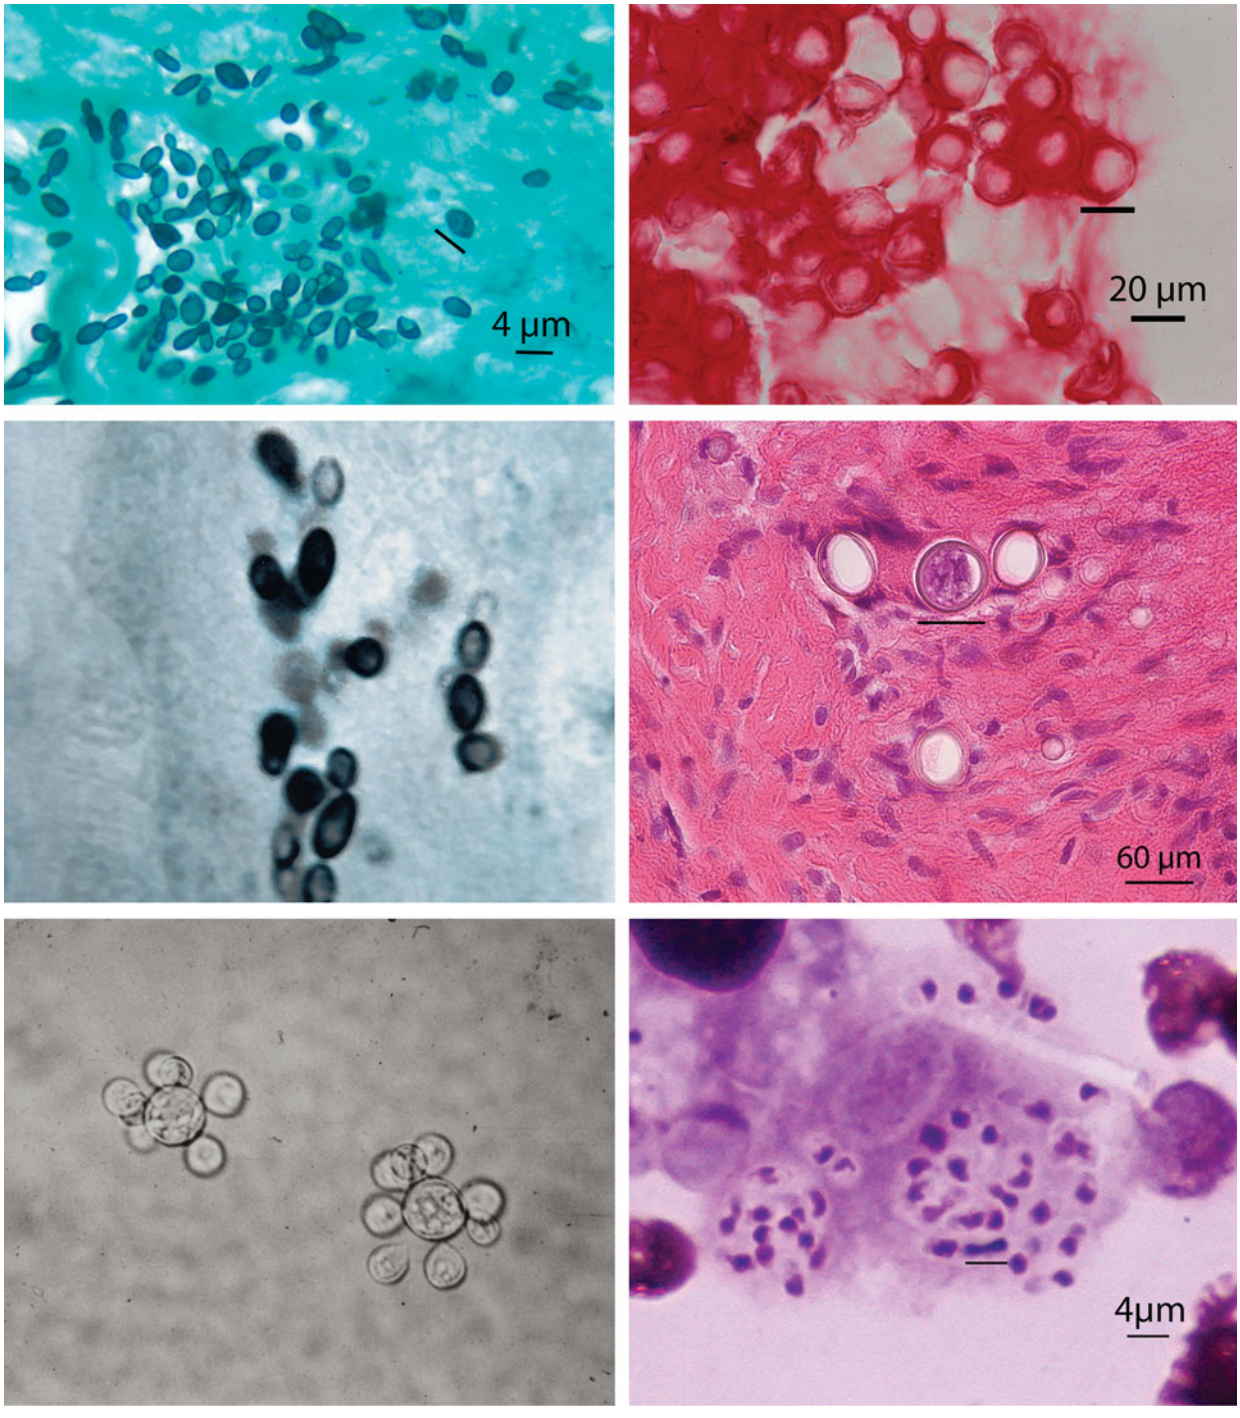

FIGURE 21 (row 1, left) GMS stain of lymph node showing characteristic cigar-shaped yeast cells of *Sporothrix schenckii*.

FIGURE 22 (row 1, right) Gram stain of abscess material showing large, broad-based, budding yeast cell with thick refractile wall characteristic of *Blastomyces dermatitidis*.

FIGURE 23 (row 2, left) GMS stain of lymph node showing blastoconidia of *H. capsulatum*. Magnification, ×625.

FIGURE 24 (row 2, right) Hematoxylin and eosin stain of *Coccidioides immitis*. Large, round, thick-walled spherules (10 to 80 µm in diameter) filled with endospores (2 to 5 µm in diameter). Young spherules have a clear center with peripheral cytoplasm and a prominent thick wall.

FIGURE 25 (row 3, left) Bright-field photomicrograph of *Paracoccidioides brasiliensis*, showing multiple budding yeast cells resembling mariner's wheels. Magnification, ×1,590.

FIGURE 26 (row 3, right) Wright-Giemsa stain of BAL specimen showing characteristic fission yeast cells of *Penicillium marneffei*.

TABLE 4 Molecular methods used for the direct detection and identification of fungi

Disease	Method	Sensitivity	Specificity	Comment
Aspergillosis	NASBA involving isothermal process of amplification and detection of *Aspergillus* spp. mRNA (94)	92.9%	62.5%	Blood samples were collected twice per week from 128 patients with hematologic diseases and neutropenic fever; 2 patients with proven IA, 14 patients with probable IA. Cutoff value, 5.24.
	Quantitative PCR targeting the 18s rRNA for the detection of *Aspergillus* spp. (55)	67%	100%	BAL specimens from 49 patients with proven or probable IA.
	PCR-ELISA for the detection of *A. fumigatus* and *A. flavus* (21)	63.6%	89.7%	1,205 serum samples from 167 patients with hematological malignancies.
	Real-time PCR to amplify the *A. fumigatus* cyp51A gene and pyrosequencing to sequence the codon for glycine 54 (77)	Not determined	Not determined	56 blood samples evaluated for mutations in the glycine 54 codon can result in reduced susceptibility to itraconazole and posaconazole.
Candidiasis	TaqMan-based PCR assay using primers for the 5.8S and 28S rRNA regions and *Candida* species-specific probes (45)	100%	97%	Prospective study 52 serum samples from 39 hematology or oncology patients with clinically proven or suspected systemic *Candida* infections.
Cryptococcosis	Nested-PCR-based assay using the ITS region for the detection of *C. neoformans* in CSF (67)	100%	100%	Detected purified DNA corresponding to as few as 10 cryptococcal cells.
	Nested PCR amplifying the *C. neoformans* URA5 gene in patients with pulmonary crytococcosis (74)	Positive for 4/5 culture-positive samples	Negative for 1 culture-positive, 10 culture-negative, and 1 undetermined	5 patients with various underlying diseases.
Zygomycosis	Evaluated two seminested PCR assays targeting the 18S rRNA of zygomycetes and the mitochondrial DNA of *Aspergillus* spp. (4)	25/40 samples with amplifiable human DNA identified fungal pathogens by both PCR assays corresponded to histopathological diagnosis; 2/8 histopathology negative detected concomitant infection with zygomycete and *A. fumigatus*	No false positives were determined	Blinded comparison of molecular identification with histopathological diagnosis; 42 paraffin wax blocks and 10 paraffin wax-embedded tissue sections from patients at risk for invasive fungal infections; all blinded.
Endemic mycoses	Detected organism by in situ hybridization and PCR assays targeting 18S and 28S rRNA (26)	*Coccidioides immitis,* 94.3%; *Blastomyces dermatitidis,* 95.0%; *Histoplasma capsulatum,* 75.0%	*Coccidioides immitis,* 100%; *Blastomyces dermatitidis,* 100%; *Histoplasma capsulatum,* 96.2%	98 formalin-fixed, paraffin-embedded tissue specimens. Each specimen had correlating culture-positive result.
Panfungal	PCR assay amplifying the complete ITS 1 and 2 regions of the rRNA complex (31)	100%	100%	Evaluated 210 ESP blood cultures; 183 were PCR/culture negative, while 27 were PCR/culture positive.
	Real-time PCR LightCycler TM technology assay amplifying 18s rRNA (33)	Sequential positive results: proven, 80%; proven/probable, 75%; proven/probable/possible, 63%	Sequential positive results: proven, 69%; proven/probable, 70%; proven/probable/possible, 72%	78 hemato-oncology patients screened twice weekly. Detected 10 CFU/ml for *C. albicans* and 20 CFU/ml for *A. fumigatus.*

infection with varying amounts of fungal elements within the tissue or destruction of DNA during formalin fixation.

Third, a method to identify the presence of the amplified target region must be determined. Numerous methodologies have been evaluated, including DNA probes, microarrays, fluorescent in situ hybridization, PCR, reverse-hybridization line probe assays, nucleic acid sequence-based amplification (NASBA), and pyrosequencing.

Real-time PCR methods, such as Taqman (Perkin-Elmer, Wellesley, Mass.) and Lightcycler (Roche Molecular Systems, Pleasanton, Calif.) techniques, enable rapid amplification, hybridization, and amplicon detection in a single reaction. Real-time technology can provide quantitative results because the point where the PCR enters the log/linear phase is detectable and reflects the amount of target DNA in the original sample.

NASBA is a technique that involves amplification and detection of mRNA. Unlike PCR, NASBA is an isothermal process, uses RNA polymerase, and amplifies mRNA. RNA is generally less stable than DNA in dead cells; therefore, its detection may indicate the viability of the organism. Because thermal denaturation is absent, there is little contaminating background of genomic DNA (43).

Pyrosequencing is a real-time, nonelectrophoretic sequencing method. This method relies on the sequential addition and incorporation of nucleotides in a primer-directed polymerase extension reaction. The pyrophosphate released on incorporation of a base-paired nucleotide is coupled to the enzymes ATP sulfurylase and luciferase to generate detectable light. The light is proportional to the number of nucleotides incorporated, allowing for the sequence to be determined in real time (15). (For detailed illustrations on pyrosequencing, go to http://www.pyrosequencing.com.)

Although molecular assays for the detection of fungi in clinical materials continue to improve, variability in PCR protocols is unavoidable due to the lack of standardization in PCR assays. Before implementation in the clinical laboratory, proper validation must be performed (13). Molecular diagnostic methods depend not only on improved methodology but also on an adequate, well-trained workforce.

SEROLOGY

Although immunocompromised patients may exhibit poor or variable antibody responses, antibody detection tests are often helpful for the diagnosis of fungal infections in immunocompetent hosts. Further information about serologic diagnosis can also be found in the appropriate organism chapters of this Manual.

Aspergillus Species

The detection of antibodies against *Aspergillus* for the diagnosis of invasive aspergillosis has produced conflicting results (34). The sensitivity and specificity of the immunodiffusion and counterimmunoelectrophoresis tests are similar. Complement fixation (CF) testing has low sensitivity and is not recommended.

Blastomyces dermatitidis

Serologic diagnosis of blastomycosis is generally performed using immunodiffusion (ID) or CF. The yeast form of *B. dermatitidis* releases two surface antigens, A antigen and W1-1. Antibodies directed against W1-1 also recognize the A antigen. The positive ID test using purified A antigen is specific and diagnostic for blastomycosis. A negative ID test does not rule out a diagnosis of blastomycosis, as this test is reported to be negative in 10% of patients with disseminated infection and over 60% of patients with localized disease. The CF test has poor sensitivity compared with the ID test (41).

Candida Species

Antibody assays generally display a low specificity for discriminating between systemic candidiasis and colonization. Ellepola et al. (18) have summarized the numerous methods developed to detect *Candida* antibodies and antigens. The Platelia *Candida*-specific antigen and Platelia *Candida* antibody (Bio-Rad Laboratories, Marnes-la Coquette, France) are EIA which can be used for the serologic diagnosis of candidiasis (71, 92). Neither test is commercially available in the United States.

Coccidioides Species

The serologic diagnosis of coccidioidomycosis is performed using ID, latex agglutination (LA), CF, or EIA methods. The ID and LA tests are useful for the initial screening of specimens and can be confirmed by other tests if positive. The ID and LA tests detect early immunoglobulin M (IgM) antibody responses to coccidioidal infection, while the CF test detects primarily IgG antibodies produced during the convalescent phase of disease or during chronic infection. Performing both the ID (or LA) and CF tests in parallel provides the highest sensitivity and specificity. The *Coccidioides* EIA (Meridian Diagnostics, Inc.) detects both anti-*Coccidioides* IgG and IgM antibodies in sera from patients with coccidioidomycosis. Although the sensitivity (97%) and specificity (94%) are high, confirmation of positive ID results is recommended (95).

Cryptococcus neoformans

Antibody detection is useful for the early diagnosis of cryptococcal disease, because antibodies are not yet neutralized by the large amount of capsular antigen released during the progression of the infection (41).

Histoplasma capsulatum

The primary serologic tests for histoplasmosis are the ID and CF tests. The ID test is an immunodiffusion test which identifies H and M precipitin bands to *Histoplasma capsulatum*. The ID test is less sensitive than the CF test. The CF test uses yeast and mycelial antigens. Serological methods are faster than culture, but false-positive results occur. The titer of specific antibodies against *Histoplasma* can remain high for months or years after the primary infection. In addition, cross-reactivity can occur in up to 40% of patients with paracoccidioidomycosis, blastomycosis, and aspergillosis; 16% of patients with coccidioidomycosis; and 8% of patients with candidiasis (88). False-negative results due to low antibody titers can be observed in immunocompromised patients with active infection.

Candida, Cryptococcus, and Other Yeasts of Medical Importance

KEVIN C. HAZEN AND SUSAN A. HOWELL

119

TAXONOMY OF YEASTS

Yeasts of medical importance (and relevant to this chapter) belong to three classes: Hemiascomycetes (Endomycetes), Heterobasidiomycetes, and the mitosporic fungal form class Blastomycetes. Thus, the medically important yeasts present a taxonomic conundrum for the laboratorian because many of the originally classified asexual (imperfect) yeasts were subsequently shown to undergo sexual reproduction. By taxonomic convention, the yeast should no longer be classified in the Blastomycetes but rather in the phylum determined by its means of sexual reproduction. It should also be renamed with a new genus-species epithet. If this convention is followed, however, communication of the new species epithet (e.g., *Issatchenkia orientalis*) to a physician is likely to lead to confusion. A report of simply *Candida krusei* would possibly prevent the physician's inquiry. For this reason, laboratories should be mindful that most physicians will be unaware of taxonomic technicalities and should report the older, blastomycetous binomial, perhaps along with the correct binomial (e.g., *Issatchenkia orientalis* [formerly *Candida krusei*]). An exception has been made for the strictly anamorphic *Candida* species which were shown to have an ascomycetous affinity. Rather than change the names of these organisms from names that are deeply entrenched in the literature and in the minds of physicians and laboratorians, the species have retained their *Candida* genus taxon but have been placed in the family Candidaceae within the order Saccharomycetales of the Hemiascomycetes.

DESCRIPTION OF AGENTS

Yeasts are unicellular, eukaryotic, budding cells, generally round to oval or, less often, elongate or irregular in shape. They multiply principally by the production of blastoconidia (buds), such that a typical medically important yeast is composed of a progenitor cell with one or more attached progeny. When blastoconidia are produced one from the other, in a linear fashion without separating, a structure termed a pseudohypha is formed. Under certain circumstances such as growth under reduced oxygen tension, some yeasts may produce true septate hyphae.

Cultures of yeasts are moist, creamy, or glabrous to membranous in texture. Several produce a capsule which makes the colony mucoid. With rare exceptions, aerial hyphae are not produced. Colonies may be hyaline or brightly colored or may be darkly pigmented due to the presence of melanins. The latter group, referred to as phaeoid fungi and belonging to the form class Hyphomycetes, is discussed in chapter 125. Dimorphic fungal pathogens possessing a yeast phase in tissue are also discussed elsewhere.

Yeasts are generally identified (classified) by observing the macroscopic and microscopic features mentioned above. Usually, biochemical tests also are required for definitive identification to the species level. Molecular methods are currently under development and offer tremendous promise for facilitating species identification.

Genus *Blastoschizomyces*

Blastoschizomyces capitatus is a taxon derived from the combination of the obsolete taxa *Blastoschizomyces pseudotrichosporon* and *Trichosporon capitatum* (192). The teleomorph is *Dipodascus capitatus* (59). It is recognized as an emerging cause of invasive fungal disease in leukemic patients (43, 139) and endocarditis (178), is widely distributed in nature, has been recovered as normal skin flora, and has been associated with onychomycosis (55). Disseminated disease, which is usually diagnosed by blood culture, is often associated with immunosuppressive conditions (11), in particular neutropenia. Mortality from invasive disease is high in neutropenic patients, and survival is associated with neutrophil count recovery. Infections are mostly treated with amphotericin B; 5-fluorocytosine or azoles have been used, but MIC data are sparse and variable (29, 140). Macroscopically, colonies are glabrous with radiating edges, white to cream-colored, and shiny. Microscopically, isolates produce true hyphae, pseudohyphae, and annelloconidia resembling arthroconidia (Fig. 1f). Based on morphologic features alone, *B. capitatus* can be difficult to separate from *Trichosporon* spp., and physiologic tests are needed. *B. capitatus* is nonfermentative and can be separated from *Trichosporon* spp. by growth on Sabouraud glucose agar at 45°C and on cycloheximide-containing agar at room temperature and failure to hydrolyze urea.

Genus *Candida*

The heterogeneous genus *Candida* belongs to the family *Candidaceae* within the ascomycetes. The genus contains approximately 200 species. This number is not immutable. Technological advances that affect apparent taxonomic relationships will continually result in reassignments of present species and discovery of new species. These advances may also lead to the designation of new genera. Teleomorphs

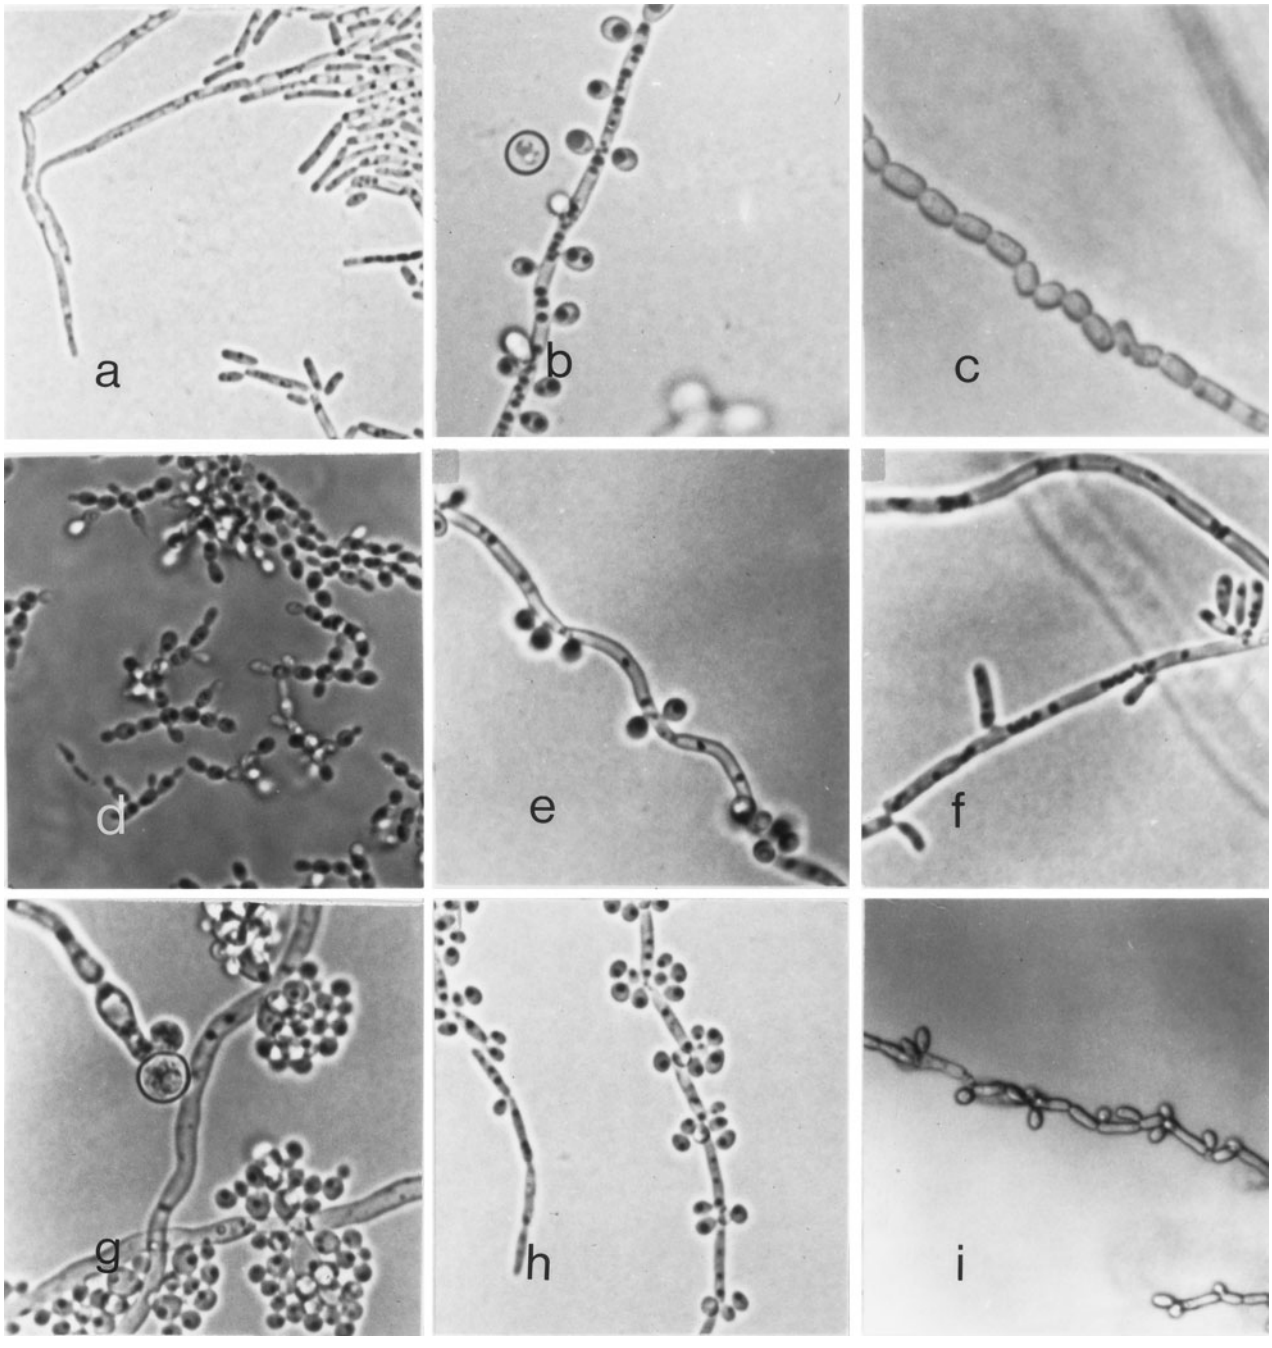

FIGURE 1 Morphologic features of some yeast and yeast-like-organisms on cornmeal agar at 24 to 48 h, ambient temperature. (a) *Candida krusei:* extremely elongated, rarely branched pseudohyphae; few blastoconidia. (b) *Candida tropicalis:* blastoconidia formed at septa and between septa. (c) *Geotrichum candidum:* arthroconidia. (d) *Candida guilliermondii:* chains of blastoconidia forming sparse pseudohyphae in a young culture. (e) *Candida lusitaniae:* short distinctly curved pseudohyphae with blastoconidia formed at, and occasionally between, septa. (f) *Blastoschizomyces capitatus:* true hyphae, annelloconidia resembling arthroconidia. (g) *Candida albicans:* blastoconidia, chlamydospores, true hyphae, and pseudohyphae. (h) *Candida parapsilosis*: elongated, delicately curved pseudohyphae with blastoconidia at septa. (i) *Trichosporon* spp.: blastoconidia formed at the corners of arthroconidia. Magnification, approximately ×339. (Courtesy of B. A. Davis.)

encompassing several genera have been demonstrated for different species of *Candida.* The teleomorphic genera include *Clavispora, Debaryomyces, Issatchenkia, Kluyveromyces, Pichia,* and *Yarrowia.* This large number of teleomorphic relationships demonstrates that the previously designated form genus *Candida* within the mitosporic fungi (formerly Deuteromycota) was a mixture of unrelated species. One reason for the wide variety of species is due to the definition

of *Candida.* The genus designation is used for any asexual yeast which does not have one of the following features: (i) acetic acid production; (ii) visually detectable red, pink, or orange pigments; (iii) arthroconidia; (iv) unipolar or bipolar budding on a broad base; (v) blastoconidia formed on sympodulae; (vi) buds formed on stalks; (vii) needle-shaped terminal conidia; (viii) triangular cells; (ix) enteroblastic-basipetal budding, usually with mucoid colonies and the ability to grow on inositol as a sole carbon source; and (x) ballistoconidia (117).

The genus *Candida* no longer contains species that are diazonium blue B positive, which is associated with yeasts having a basidiomycetous affinity (such as *Cryptococcus*). Diazonium blue B-positive organisms (e.g., *Candida humicola, Candida curvata, Candida diffluens,* and *Candida scottii*) have been reassigned to either *Cryptococcus* or *Rhodotorula* genus.

Candida claussenii and *Candida langeronii* have also been merged into *C. albicans* (235). Another change in species epithets includes the controversial fusion of *Candida stellatoidea* with *Candida albicans.* Genetic evidence supporting the fusion of *C. stellatoidea* indicates that two types (designated I and II) of *C. stellatoidea* exist (187). Type II, which does not assimilate sucrose, appears to be a sucrose-negative mutant of *C. albicans* (121). A definitive association of type I *C. stellatoidea* with *C. albicans* has not been established (22, 145), thus making the designation *C. albicans* subspecies *stellatoidea* controversial. This subspecies, unlike other *C. albicans* subspecies, is not resistant to cycloheximide. Three groups of *C. parapsilosis* have recently been described. Based on genetic and phenotypic evidence, Tavanti et al. (218) have recommended that groups II and III be designated *Candida orthopsilosis* sp. nov. and *Candida metapsilosis* sp. nov., respectively.

Candida species are ubiquitous yeasts, being found on many plants and as normal flora of the alimentary tract of mammals and mucocutaneous membranes of humans (163). Essentially all areas of the gastrointestinal tract of humans can harbor *Candida.* The most commonly isolated species (50 to 70% of yeast isolates) from the gastrointestinal tract of humans is *C. albicans,* followed by *C. tropicalis, C. parapsilosis,* and *C. glabrata.*

C. glabrata is regarded as a symbiont of humans and can be isolated routinely from the oral cavity, and genitourinary, alimentary, and respiratory tracts of most individuals. As an agent of serious infection, it has been associated with endocarditis (37), meningitis (5), and multifocal, disseminated disease (102). It is recovered often from urine specimens and has been estimated to account for as many as 21% of urinary yeast isolates (76). As it may be slow growing, routine urine cultures should be incubated for at least 2 days. A reddish colony variant of *C. glabrata,* which would otherwise have been confused with *Rhodotorula,* has been described (168). Bile-dependent strains of *C. glabrata* have also been isolated from urine (100). These isolates do not grow on routine media, or they appear as pinpoint colonies on MacConkey agar containing bile.

Candida spp. can be present in clinical specimens as a result of environmental contamination, colonization, or actual disease processes. An accurate diagnosis requires proper handling of clinical material. *Candida* spp. that are normal flora can invade tissue and produce life-threatening pathology in patients whose immune defenses have been altered by disease or iatrogenic intervention. *C. albicans* is the most common species isolated from nearly all forms of candidiasis (163). Contributing to its high association with disease is its high prevalence in the normal population, as described above. In addition, *C. albicans* appears to possess a number of virulence determinants that may promote successful parasitism. These attributes include relatively rapid germination upon seeding tissue from the bloodstream (97), protease production (122), surface integrin-like molecules for adhesion to extracellular matrix proteins (90, 220), a complement protein binding receptor (36, 81), phenotypic switching (206), and surface variation and hydrophobicity (98). These attributes have been reviewed (34, 35, 53, 159). Only *C. tropicalis* appears more virulent than *C. albicans* when present in patients with leukemia or lymphoreticular malignant disease (241). Other medically important *Candida* spp. include *C. catenulata, C. ciferrii, C. guilliermondii, C. haemulonii, C. kefyr, C. krusei, C. lipolytica, C. lusitaniae, C. norvegensis, C. parapsilosis, C. pulcherrima, C. rugosa, C. utilis, C. viswanathii,* and *C. zeylanoides* (96, 189). This list is not exclusive, as other rare agents will certainly be added in the future. The species that are emerging as opportunistic pathogens include *C. (Yarrowia) lipolytica, C. lusitaniae,* and *C. krusei.* These three species have been isolated from cases of fungemia. *C. lusitaniae*, which is generally a low-virulence organism, exhibits clinical resistance to amphotericin B (91). *C. krusei* isolates appear to be susceptible to ketoconazole but not fluconazole (242). Two other fluconazole-resistant species, *C. inconspicua* and *C. norvegensis,* are rare agents of candidiasis. *C. glabrata* is emerging as a significant pathogen with a relatively high proportion of strains exhibiting reduced susceptibility to fluconazole. *Candida* species are susceptible to caspofungin, although there is variation among the species.

An extensive review of the genus and diseases produced by *Candida* spp. has been presented by Odds (163). Regardless of the species, a single isolate of *Candida* from blood should be considered significant whether it comes from an immunocompromised or immunocompetent patient (65). Taken together with the reported rate of 10% for nosocomial bloodstream infections caused by *Candida* species (13, 24), it is evident that *Candida* fungemia represents a serious patient management problem. Ninety-seven percent of candidemias are caused by *C. albicans, C. glabrata, C. parapsilosis, C. tropicalis,* and *C. krusei* (64).

Acute pseudomembranous oral candidiasis is the presentation seen in immunocompromised patients such as those with AIDS. It is most often caused by *C. albicans* and *C. dubliniensis*. It may be present in the prodromal stages of AIDS or accompany late stages of AIDS (CD4 T-cell count of <400 cells/μl) (171, 219). Mucocutaneous forms of candidiasis are often related to defects in cell-mediated immunity, whereas systemic spread is generally associated with neutropenia (60, 74). Thus, despite the presence of oral or esophageal candidiasis, systemic spread of *Candida* spp. organisms is uncommon in AIDS patients. When it occurs, systemic spread is associated with a drop in the neutrophil count (62).

There are two serotypes, designated A and B, of *C. albicans,* and these are distributed approximately equally among immunocompetent individuals. However, serotype B is more prevalent in immunocompromised patients (31). The importance of this observation is unclear. Serotype B isolates are physiologically different from serotype A isolates in that B serotypes exhibit greater karyotype variability and are more likely to develop resistance to 5-fluorocytosine (8, 10). It is not clear how the two serotypes are distributed within the recently described geographically distributed genetic clades of *C. albicans* (207).

Blastoconidia of *Candida* spp. vary in shape, from round to oval to elongate. Occasional initial isolates, especially from patients receiving antimicrobial agents, may be highly

pleomorphic. Asexual reproduction is by multilateral budding, and true mycelium may be present. If sexual reproduction occurs, the yeasts are classified in their teleomorphic state. The appearance of pseudohyphae and attachment of blastoconidia are important characteristics to observe when identifying *Candida* spp. Figure 1 illustrates these morphologic features. Observation of germ tubes and chlamydospores is also helpful in identifying *C. albicans*. Growth on fungal media can be detected as early as 24 h; however, colonies usually are visible in 48 to 72 h and are white to cream-colored or tan. They are creamy in texture and may become more membranous and convoluted with age. Occasionally, initial isolates of *C. albicans* on Sabouraud glucose agar are wrinkled or rugose but revert to smooth colonies on subculture. In our experience, many isolates of *C. albicans* produce "colonies with feet" (i.e., colonies with short marginal extensions) on blood agar, while most other yeasts do not (note that 25% of isolates of *C. tropicalis* and *C. krusei* will also form colonies with feet [33]). These colonies should not be used to perform germ tube tests because hyphal/pseudohyphal cells will be present in the inoculum. Most *Candida* spp. grow well aerobically at 25 to 30°C, and many will grow at 37°C or above. Several species of *Candida,* most notably *C. albicans,* are diploid (190, 232).

Carbon assimilation and occasionally fermentation studies are needed to differentiate the species (Table 1), but rapid confirmation tests for particular species are becoming available (see "Rapid Identification Tests" below). Of the *Candida* spp. usually recovered from clinical specimens, *C. guilliermondii* is the only one to assimilate dulcitol (galactitol), and *C. kefyr* (previously *C. pseudotropicalis*) assimilates lactose. The assimilation of rhamnose can be helpful in separating *C. lusitaniae* from the biochemically similar but rhamnose-negative variants of *C. tropicalis* (196). For atypical isolates of *C. lusitaniae,* which can be confused with *C. tropicalis,* good growth on Trichophyton agar #1 with biotin but weak growth on vitamin-free medium indicates *C. tropicalis* (217). Certain rare strains of *C. tropicalis* may assimilate cellobiose weakly and exhibit an assimilation pattern similar to that of *C. parapsilosis*. The inclusion of arabinose is helpful, since *C. parapsilosis* readily assimilates this carbohydrate, while most strains of *C. tropicalis* do not. Urease generally is not produced, nor is KNO_3 utilized by the *Candida* species listed in Table 1. However, occasional isolates of *C. krusei* may be urease positive.

Genus *Clavispora*

Clavispora lusitaniae is the teleomorph of *Candida lusitaniae*. It is a normal component of the human gastrointestinal tract but is an emerging opportunist causing fungemia mainly of patients with malignancy. Other occasional infections include peritonitis, urinary tract infection, and meningitis (95). *C. lusitaniae* may exhibit secondary resistance to amphotericin B; therefore, clinical response to amphotericin B may be poor despite in vitro susceptibility tests indicating strains to be sensitive to the drug (95, 115). Sensitivities may be variable for 5-fluorocytosine and fluconazole. *C. lusitaniae* is sensitive to caspofungin but less so than *Candida albicans*.

C. lusitaniae cells are oval or elongated; multilateral budding occurs on a narrow base, and pseudohyphae are produced. Colonies are white to cream, smooth, and shiny or occasionally dull. The organism is heterothallic, and conjugation of opposite mating types produces asci that quickly disintegrate, releasing one or two smooth clavate ascospores. Growth occurs at 42°C. Fermentation reactions are variable, but *C. lusitaniae* will grow on a variety of sugars including sucrose, but not on mannitol or inositol. Nitrate and urease are negative.

Genus *Cryptococcus*

The genus *Cryptococcus* contains many species, six of which are given in Table 1. Of these, *Cryptococcus neoformans* is considered the only human pathogen, although *C. albidus* (105, 116) and a few others, including the recently described *C. adeliensis,* rarely have been implicated in disease in severely debilitated individuals (92, 188). *Cryptococcus* is a round to somewhat oval yeast-like fungus ranging greatly in size, from 3.5 to 8 μm or more in diameter, with single budding and a narrow neck between parent and daughter cells (Fig. 2). Unusually large yeast cells (up to 60 μm) have been observed, and this size appears to be associated with higher incubation temperatures (132). Occasionally several buds may be seen; pseudohyphae are rarely observed. The cell wall is quite fragile, and it is not unusual to find collapsed or crescent-shaped cells, especially in stained tissue sections. Cells are characterized by the presence of a polysaccharide (galactoxylomannan) capsule varying from a wide halo to a nearly undetectable, lighter zone around the cells, depending upon the strain and the medium used. Use of India ink with wet preparations, or the mucicarmine stain for polysaccharide with fixed tissue preparations, may be helpful in elucidating the capsule. Colonies typically are mucoid due to the presence of capsular material, become dry and duller with age, and exhibit a wide range of color (cream, tan, pink, and yellow). The color may darken with age. Strains possessing only a slight capsule may appear similar to colonies of *Candida.* All members of the genus produce urease, utilize various carbohydrates, and are nonfermentative.

C. neoformans was the first serious fungal pathogen of humans to be identified as a heterobasidiomycetous yeast. At least five serotypes of *C. neoformans* have been identified: A, B, C, D, and the hybrid serotype A/D. Serotypes A and D were found to produce the teleomorphic state *Filobasidiella neoformans*, and serotypes B and C produce the teleomorph originally named *Filobasidiella bacillispora* (120). The latter species was found to be identical to *C. neoformans* var. *gattii* (223). All are considered varieties of *F. neoformans,* and all are known to produce disease. Differences in disease manifestation among patients from areas where various serotypes are endemic appear to be more dependent on host immune status than on the *C. neoformans* variety (41). Serotypes A and D are opportunistic pathogens in that they attack immunocompromised individuals. Serotypes B and C attack immunocompetent individuals and are therefore primary pathogens. Standard laboratory tests do not differentiate among the serotypes. However, media have been recommended for separating serotypes A and D from serotypes B and C, but these media (glycine-cycloheximide-phenol red agar and canavanine-glycine-bromthymol blue agar) are not available commercially (123, 193). Proposals to designate the different serotypes of *C. neoformans* as separate species are under consideration, but the impact on the clinical mycology laboratory is uncertain.

The different serotypes of *C. neoformans* exhibit epidemiologic differences also (20). *C. neoformans* var. *grubii* and *C. neoformans* var. *neoformans* (serotypes A and D, respectively) are the most common worldwide, with the highest prevalence of serotype A being seen in Japan and in tropical and subtropical areas such as Southeast Asia, Brazil, Australia, and Southern California. *C. neoformans* var. *gattii*

TABLE 1 Cultural and biochemical characteristics of yeasts frequently isolated from clinical specimens[a]

Species	Growth at 37°C	Pellicle in broth	Pseudo- or true hyphae	Chlamydospores	Germ tubes	Capsule, India ink	Assimilation of:												Fermentation of:						Urease	KNO_3 utilization	Phenol oxidase	Ascospores

[a] Modified from references 175 and 229. Symbols: +, growth greater than that of the negative control; −, negative reaction; *, some isolates may give the opposite reaction; R, rare; F, the sugar is fermented (i.e., gas is produced); W, weak reaction.

[b] *C. albicans* typically produces single and no more than two terminal chlamydospores, whereas some isolates of *C. dubliniensis* produce terminal chlamydospores in pairs, triplets, and clusters. See discussion in the text for additional methods to differentiate *C. dubliniensis* and *C. albicans*.

[c] *C. lipolytica* assimilates erythritol; *C. krusei* does not. Maximum growth temperatures: 43 to 45°C for *C. krusei* and 33 to 37°C for *C. lipolytica*.

[d] *C. lusitaniae* assimilates rhamnose; *C. tropicalis* usually does not.

[e] *C. parapsilosis* assimilates L-arabinose; *C. tropicalis* usually does not.

[f] *C. pintolopesii* is a thermophilic yeast capable of growth at 40 to 42°C.

[g] Rare strains of *C. tropicalis* produce teardrop-shaped chlamydospores.

[h] Not yeasts but may be confused with several yeast genera.

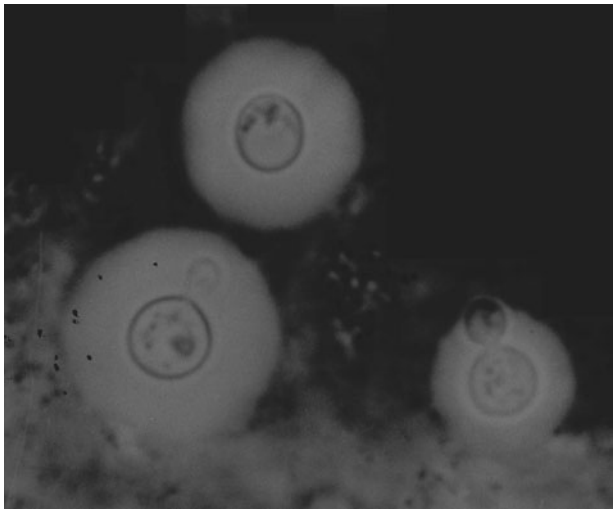

FIGURE 2 India ink preparation of *Cryptococcus neoformans*. Magnification, ×400. (Courtesy of E. S. Jacobson.)

(serotype B) is much more prevalent than serotype C strains of *C. neoformans* var. *gattii,* and the majority of serotype C has been found in Southern California (119).

C. neoformans was first detected in the environment in the late 19th century when Sanfelice recovered the yeast from peach juice. Since then, however, *C. neoformans* var. *grubii* and *C. neoformans* var. *neoformans* have been most frequently associated with aged pigeon (and other bird) droppings and soils contaminated with these droppings. The yeast usually is not found in fresh droppings but is most evident in the bird excreta that have accumulated over long periods of time on window ledges, vacant buildings, and other roosting sites (119). It has only been recently that the environmental habitat of the *gattii* variety has been identified. Recovery of *C. neoformans* var. *gattii* (serotype B) from the environment coincides with the flowering of the river red gum tree (*Eucalyptus camaldulensis*). Likewise, the global distribution of cryptococcal disease due to *C. neoformans* var. *gattii* has been thought to correlate with the distribution of this tree (68). However, other sources may exist, particularly given a recent outbreak of disease in Vancouver Island, British Columbia (208, 210).

Initial cryptococcal infection begins by inhalation of the fungus into the lungs, usually followed by hematogenous spread to the brain and meninges. Involvement of the skin, bones, and joints is seen, and *C. neoformans* is often cultured from the urine of patients with disseminated infection. In patients without human immunodeficiency virus (HIV) infection, cryptococcosis, particularly cryptococcal meningitis, usually is seen in association with underlying conditions such as lupus erythematosis, sarcoidosis, leukemia, lymphomas, and Cushing's syndrome.

For nearly 45% of AIDS patients, cryptococcosis was reported as the first AIDS-defining illness. Because none of the presenting signs or symptoms of cryptococcal meningitis (such as headache, fever, or malaise) are sufficiently characteristic to distinguish it from other infections that occur in patients with AIDS, determining cryptococcal antigen titers and culturing blood and cerebrospinal fluid (CSF) are useful in making a diagnosis (45).

All species of *Cryptococcus* are nonfermentative aerobes. Separation of species is based upon assimilation of various carbohydrates and KNO_3 reduction (Table 1). *C. neoformans* may be distinguished from other species of *Cryptococcus* by these biochemical studies, as well as growth at 37°C, which may be seen with *C. albidus* and *C. laurentii*. *C. neoformans* may be differentiated from other yeasts and from other species of *Cryptococcus* by its production of brown colonies on birdseed agar, although with occasional isolates (particularly serotype C) the production of phenol oxidase may have to be induced. Differentiation from the genus *Rhodotorula,* which also occasionally forms a capsule, produces urease, and is nonfermentative, usually is accomplished by noting the utilization of inositol (Table 1) and the absence of carotenoid pigments characteristically present in *Rhodotorula. C. neoformans* can be distinguished from other non-dematiaceous yeasts in fixed tissue by the use of a Fontana-Masson stain, which detects melanin precursors in the cell wall. Mucicarmine stains stain the capsule, which helps to distinguish *Cryptococcus* spp. from yeasts with similar morphologies.

Genus *Debaryomyces*

The genus *Debaryomyces* contains at least 15 species that may be found in the environment, in the gastrointestinal tract of vertebrates, in processed foods, in dairy products, and in meat. The species of human importance is *D. hansenii*, the teleomorph of *Candida famata*. *D. hansenii* has been isolated from pigeon droppings (143) and is an infrequent cause of fungemia and endophthalmitis (183, 211).

On culture the yeast may be grayish white to yellowish, soft, shiny or dull, and smooth or with wrinkles. Budding yeasts and very occasional pseudohyphae may be seen. Conjugation between mother cell and bud occurs, and asci containing 1 to 4 round or oval warty ascospores are formed. Fermentation reactions are variable, urease is negative, nitrate is negative, inositol is negative, and the maximum growth temperature is 35°C.

Genus *Dipodascus*

Dipodascus capitatus is the teleomorph of *Blastoschizomyces capitatus*. There are two species in the genus *Dipodascus,* but only *D. capitatus* has clinical importance. *D. capitatus* is heterothallic, and asci are round to ellipsoidal and contain hyaline ellipsoidal ascospores. Only glucose, galactose, glycerol, D,L-lactate, and succinate assimilation tests are positive; hyphae, arthroconidia, and clavate conidia with truncated bases may be seen. The organism grows at 37°C.

Genus *Malassezia*

There are currently 11 species of *Malassezia: M. dermatis, M. furfur, M. globosa, M. japonica, M. nana, M. obtusa, M. pachydermatis, M. restricta, M. slooffiae, M. sympodialis,* and *M. yamatoensis* (83, 103, 213–215). These yeasts are isolated from the skin of warm-blooded animals and humans as commensals but can be agents of dermatological diseases, for example, pityriasis versicolor. The main causative agents of pityriasis versicolor are *M. globosa*, *M. sympodialis,* and occasionally *M. slooffiae* or *M. furfur* (9, 51, 89, 158). The diagnostic feature of pityriasis versicolor in skin scrapings is the presence of short, blunt-ended *Malassezia* hyphae among *Malassezia* yeasts ("spaghetti and meatballs"), observed by direct microscopic examination of the skin after digestion in a 10 to 30% KOH solution. Visualization of *Malassezia* species can be enhanced by the use of the calcofluor white stain with UV fluorescence. Other dermatological diseases, including seborrheic

dermatitis and folliculitis, have been associated with *Malassezia* yeasts often because there was a clinical response following antifungal therapy, with a reduction in yeast numbers. However, as *Malassezia* may be present on the skin in high numbers and there are no other characteristic features to provide laboratory diagnosis, the exact role of the organisms in these diseases remains unclear. Recently there have been reports of onychomycosis caused by *Malassezia* species (44, 52, 204); however, whether these yeasts are true invaders of nail or secondary colonizers remains to be decided. In addition, *M. furfur* and *M. pachydermatis* may rarely cause systemic infections, usually of neonates in intensive care units (138, 148). *M. pachydermatis* is associated with animal skin, while the other 10 species have been recovered from normal and diseased human skin. *M. sympodialis, M. slooffiae, M. globosa,* and *M. restricta* were the most frequent human colonizers (27, 28, 50, 83).

Malassezia species have a basidiomycetous affiliation within the class Ustilaginomycetes (71). Species may be distinguished genetically by karyotyping (25), large subunit rRNA gene sequencing (83), using PCR (88, 137), using PCR-restriction fragment length polymorphism (150), by amplified fragment length polymorphism and sequence analysis (87), and by phenotype, using cell morphology and a series of biochemical tests (83, 86). Ten of the 11 species require lipid for growth; only *M. pachydermatis* can grow independently of lipid supplementation of the media.

In order to isolate *Malassezia,* the growth medium has to contain a lipid supplement. Van Abbe (222) and Leeming and Notman (126) have designed media optimal for the growth and isolation of all of the *Malassezia* species. These media are not commercially available, and the alternative of overlaying Sabouraud glucose agar with a few drops of sterile olive oil has been used, but some of the more fastidious species do not survive on this medium (148). The inoculated media should be incubated aerobically at 32 to 35°C in a moist atmosphere for up to 2 weeks to permit development of the slower-growing species. Colonies are cream to beige in color and smooth to deeply folded and have a brittle texture that is frequently difficult to suspend.

Malassezia organisms are distinguished microscopically from other yeasts by the formation of a prominent monopolar bud scar, or collarette, resulting from the continued formation of daughter cells at that site (Fig. 3d). These structures are absent from *C. glabrata,* which could otherwise be confused with *Malassezia* species due to its small size and typical unipolar budding. Additional sympodial budding has been observed only in cultures of *M. sympodialis*. The species vary in shape from spherical to oval or elongated, have thick cell walls, and range in length from 1.5 to 8 μm. Identification of the individual species is not routinely attempted but can be achieved based on morphology, utilization of certain lipids including Tween 20, 40, and 80 and cremophor (castor oil), and reactions with esculin and catalase (86, 148). Organisms that are identified as *Candida lipolytica* (glucose, glycerol, and sorbitol positive) with the API 20C AUX (bioMérieux SA, Marcy l'Etoile, France) may actually be *M. pachydermatis* (138). In this case, morphology is helpful.

Genus *Pichia*

The teleomorphic genus *Pichia* encompasses several species of *Candida* (for example, *C. guilliermondii* var. *guilliermondii* and *C. norvegensis*). Generally, the anamorphic (asexual) state is the one recovered from clinical specimens, as mating studies usually are needed to produce the teleomorphic (sexual) form. *Pichia anomala* and *Pichia augusta* are the teleomorphs of the obsolete species *Hansenula anomala (Candida pelliculosa)* and *Hansenula polymorpha*, respectively, and are the two species in this genus that are most commonly associated with disease in humans. *Pichia anomala* is found mainly in the environment but is an opportunistic pathogen that can colonize human skin and has been a cause of fungemia in neonates (12, 39). It has also been associated with catheter-related infections (4, 114, 160). *Pichia augusta* has been recovered from the mediastinal lymph nodes of a child with chronic granulomatous disease (146). Variations in colony morphology may cause confusion with *Cryptococcus* and *Candida* spp. The texture may be smooth to wrinkled, and the color may be white, cream, or tan. Microscopically, multilateral budding cells are observed; yeasts and pseudohyphae may be seen. Individual species of *Pichia* are either homothallic or heterothallic. *P. anomala* is heterothallic, but the sporogenous diploid form occurs naturally and is the one usually recovered from clinical specimens. These diploid cells convert to form asci which will disintegrate to reveal one to four hat (or saturn)-shaped ascopores (Fig. 3a), a morphology which is characteristic of *Pichia* species. Carbohydrate assimilation and fermentation studies are needed to identify the individual species, although urease is negative, nitrate is positive, inositol is negative, and growth at 37°C can be variable. *Kodomaea ohmeri*, previously classified as *Pichia ohmeri*, is the teleomorph of *Candida guilliermondii* var. *membranaefaciens*. This species has been increasingly reported as an agent of disease in immunocompromised patients (reviewed in reference 94).

Genus *Rhodotorula*

Rhodotorula spp. are normal inhabitants of moist skin and can be recovered from such environmental sources as shower curtains, bathtub grout, and toothbrushes (48). In rare instances *Rhodotorula* spp. have been reported to cause septicemia (173), meningitis (181), systemic infection (107, 191), peritonitis associated with peritoneal dialysis (66), and sepsis related to complications from indwelling central venous catheters (113).

Rhodotorula spp. share many similar physiologic and morphologic properties with *Cryptococcus* spp. Both are round to oval, multilateral budding yeasts with capsules, produce urease, and fail to ferment carbohydrates. *Rhodotorula* spp. differ from cryptococci by their inability to assimilate inositol and their obvious carotenoid pigment. When a capsule is present, it is typically small, unlike *C. neoformans.*

Genus *Saccharomyces*

Saccharomyces cerevisiae is the most common species of the genus *Saccharomyces* to be recovered in the clinical laboratory. Usually thought to be nonpathogenic, it has been reported to cause thrush, vulvovaginitis, empyema, and fungemia (48, 70, 96). Person-to-person contact and exposure to commercial strains associated with health foods and baking may contribute to the ability of the organisms to colonize and infect human hosts (144).

Multilateral budding yeast cells are round to oval, and short, rudimentary (occasionally well-developed) pseudohyphae may be formed. Ascospore production can be enhanced easily by growing the yeast on Fowell's acetate agar for 2 to 5 days at room temperature. Asci contain one to four round, smooth ascospores (Fig. 3c). Other physiologic properties are listed in Table 1. Assimilation of raffinose by *S. cerevisiae* is noteworthy. Very few yeasts encountered in the clinical laboratory utilize this carbon source.

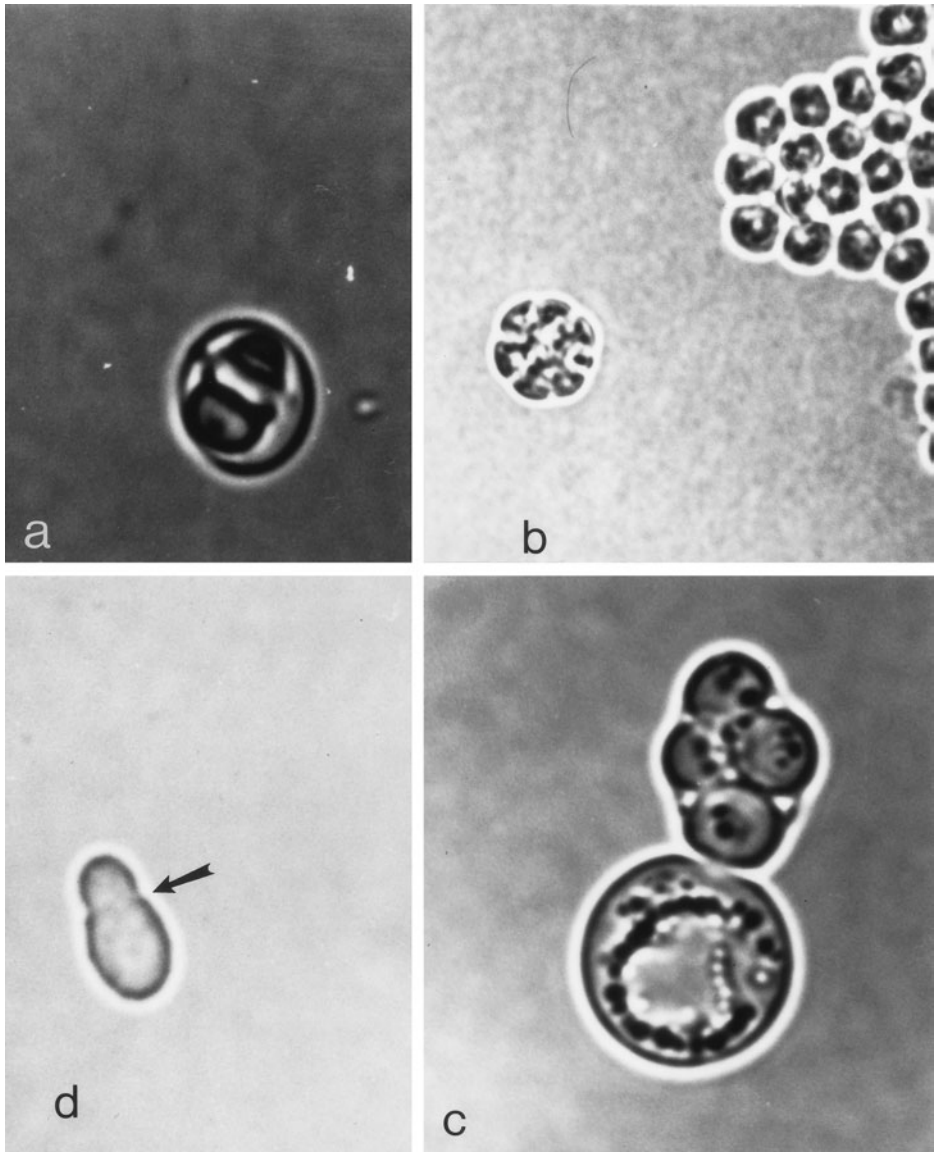

FIGURE 3 Diagnostic features of selected yeasts. (a) Ascus of *Pichia anomala* containing hat-shaped ascospores. (b) Sporangium of *Prototheca wickerhamii* containing sporangiospores. (c) *Saccharomyces cerevisiae* with vegetative cell and ascus containing four globose ascospores. (d) Bottle-shaped, budding yeast demonstrating annelloconidium and collarette (arrow) of *Malassezia furfur*. Magnification, ×910. (Courtesy of B. A. Davis.)

Genus *Sporobolomyces*

Sporobolomyces species are basidiomycetous yeasts that are environmental organisms, some of which have been linked to human disease including dermatitis (21), respiratory disease (47, 202), and AIDS (153, 177) and have been found to be a cause of endophthalmitis (203). Three species have been isolated from human infection, *S. roseus, S. holsaticus,* and *S. salmonicolor,* the last two species having the teleomorphs *Sporidiobolus johnsonii* (homothallic) and *Sporidiobolus salmonicolor* (heterothallic), respectively.

The colonies are soft and display shades of salmon pink. Budding oval to ellipsoidal yeasts, pseudohyphae, and ballistoconidia on large sterigmata may be seen. Fermentation is absent and assimilation is variable, with sucrose, urease, and nitrate being positive, inositol being negative, and growth at 37°C being variable.

Genus *Trichosporon*

Trichosporon beigelii used to be known as the major human pathogen of the genus *Trichosporon,* primarily causing the superficial hair infection white piedra, and rarely causing the systemic disease referred to as trichosporonosis. However, isolates of *T. beigelii* have been described as variable in their morphology and physiology (125). In 1992 (85), this genus underwent a major revision and 19 taxa were recognized, 6 of which could be found on humans, casting doubt on the use of *T. beigelii* as a valid species name. However, some mycologists continue to designate *T. beigelii* as the etiologic agent responsible for clinical disease caused by *Trichosporon* yeasts because differentiating between species can be problematic.

Yeasts of this genus may be isolated from soil, animals, and humans, but nearly all human infections are usually caused by one of six species: *T. asahii*, *T. asteroides*, *T. cutaneum*,

TABLE 2 Characteristics of clinically important *Trichosporon* species[a]

Characteristic	*T. asahii*	*T. asteroides*	*T. cutaneum*	*T. inkin*	*T. loubieri*	*T. mucoides*	*T. mycotoxinivorans*	*T. ovoides*

[a] Modified from references 84, 151, 166, and 229. Symbols: +, growth greater than negative control; −, negative; V, variable; W, weakly positive; ?, not reported.

T. inkin, *T. mucoides*, and *T. ovoides*. *T. loubieri* is an apparently rare cause of disseminated trichosporonosis (142, 166), and the recently described species *T. mycotoxinivorans* sp. nov. (151) has also been associated with disseminated disease (K. C. Hazen, C. C. Moore, and D. Padgett, unpublished data). White piedra is a superficial infection characterized by nodules of approximately 0.5 mm attached to the hair shafts on the head, axilla, or genital area. Infections in the genital area are usually due to *T. inkin*, and rarely encountered infections of hairs on the head are caused by *T. ovoides*. *T. asteroides* and *T. cutaneum* have been associated with superficial skin lesions, and *T. asahii*, and less often *T. mucoides*, is the cause of disseminated infection associated mainly with neutropenic patients with hematological malignancy or receiving immunosuppressive therapy (63). Others at risk for trichosporonosis include patients with AIDS, extensive burns, or intravenous catheters or patients receiving corticosteroids or who have undergone heart valve surgery (38, 49, 152). In addition, *T. asahii* and *T. mucoides* are thought to be the major causes of summer-type hypersensitivity pneumonitis in Japan, a condition that results from inhalation of *Trichosporon* arthroconidia present in the homes of the patients (161).

Patients with neutropenia tend to have a poor prognosis because achievable concentrations of antifungals in the serum are only inhibitory to growth and not sufficient to kill the yeast in vivo (49). MICs of the six human *Trichosporon* species indicate all species to have resistance to 5-fluorocytosine (6.25 to 50 μg/ml), to have higher MICs to fluconazole than most *Candida* species (0.15 to 25 μg/ml), and to be variably susceptible to amphotericin B (0.01 to >4 μg/ml), ketoconazole, and itraconazole (0.1 to 0.6 μg/ml) (89). Studies suggest that while in vitro levels of amphotericin B can be achieved in the sera of treated patients, the drug is inhibitory only to *Trichosporon* species (227). Echinocandins (caspofungin) are considered ineffective against *Trichosporon* species.

Trichosporon yeasts have no known sexual state, are basidiomycetes, and are closely related to *Cryptococcus*. They grow easily on standard mycological laboratory media, do not ferment carbohydrates, can assimilate various complex sugars, and are urease positive. Colonies form usually within a week on solid media and are cream colored and smooth. They may become dry, moist or shiny, folded, cerebriform, and elevated, with or without marginal zones with age.

They produce blastoconidia of various shapes, well-developed hyphae, pseudohyphae, and arthroconidia (Fig. 1i). *T. loubieri* also produces one- and two-celled giant cells (166), while *T. mycotoxinivorans* produces giant cells with up to eight cells depending on the growth medium (Hazen et al., unpublished). In cases where a *Trichosporon* isolate produces only few blastoconidia, differentiation from *Geotrichum* spp. may be difficult. Inoculation of malt extract broth at room temperature will encourage blastoconidia production in *Trichosporon* spp., usually within 48 to 72 h. These morphological and physiological characteristics have been used to distinguish between the species in the laboratory (89) (Table 2).

EPIDEMIOLOGY AND TRANSMISSION

Medically important yeasts are found on humans and warm-blooded animals and in the environments they inhabit (reviewed in reference 163). There are some yeasts which appear obligatory saprobes of humans and some warm-blooded animals. These include *Candida albicans, Candida glabrata,* and most likely *Candida dubliniensis.* Environmental sampling of foods, plants, potable water, and juices (pasteurized and not pasteurized) reveals an amazing array of yeast species known as opportunistic pathogens. In all cases, the presence of these yeasts could be attributed to direct and indirect contamination by warm-blooded animals. For example, Arias et al. (7) noted the presence of *C. parapsilosis, C. tropicalis, Clavispora lusitaniae, Candida zeylanoides,* and several other yeast species in single-strength orange juice which had been pasteurized but subsequently contaminated. These observations make clear that immunocompromised patients are repeatedly exposed to potential yeast pathogens other than those residing as part of their normal microbiota and care should be exercised in preparing foods and in monitoring the level of contamination associated with devices or creams which may be applied to the patient (134, 169). Parenteral nutrition fluids and devices are particularly prone to contamination with yeasts, especially *C. parapsilosis* (230). It is also noteworthy that the hospital environment can contribute to

the development of colonization with *Candida* species as well as facilitate replacement of less virulent colonizing species with more virulent species (26).

Person-to-person transmission has a negligible impact on disease development, except in nosocomial outbreaks where hands or fomites are often the source. Invasive yeast infections are associated with opportunism; thus, the yeasts causing disease must be present when the conditions are such that disease can be initiated. Several studies have shown that transmission of yeasts through sexual contact (including oral) does occur, but establishment of the transferred organisms in the recipient is affected by a variety of factors, most notably, the recipient's current normal microbiota, immunological status, and antifungal status (61, 184). Regarding the last factor, recipients with HIV and on low-dose fluconazole have been documented to develop oral colonization of a partner's fluconazole-resistant isolate through salivary exchange (61).

CLINICAL SIGNIFICANCE

As in clinical bacteriology, the significance of isolating a species known to be a member of the normal microbiota or a common contaminant depends on numerous factors, including, but not limited to, the patient's underlying disease, geographic and hospital environment, specimen site, preceding antimicrobial and device management, specimen collection and quality, and specimen processing. In general, the isolation of yeasts from sterile body sites is suggestive of infection, but the caveat to consider is the influence of the method of collection (e.g., *C. albicans* in CSF collected by lumbar puncture). The more challenging decision about significance is when the yeast is present in specimens obtained from nonsterile body sites.

Review of the literature reveals a surprising lack of evidence-based studies regarding the development of criteria for establishing significance in nonsterile body sites. Clinical microbiology laboratories will typically apply bacterial criteria to assess specimens for possible fungal infection. An example of this is to not report yeasts unless they are predominating (above bacteria). There are several problems with this approach. First, yeasts are not as abundant as bacteria in the normal microbiota, so an increase in relative abundance may reflect a yeast infection. Roughly 10 times more bacteria than yeast can occupy the same volume of tissue. Secondly, a specimen from a patient who is on antibacterial agents may contain more-abundant yeasts, the reporting of which may mislead the patient's physician about the yeast's significance. Third, when the abundance of a yeast is considered insufficient to warrant further investigation, the species may not be reported. This could lead to unfortunate consequences because certain yeasts, such as *C. tropicalis*, are considered particularly aggressive in immunocompromised patients.

The presence of yeasts in sputum has little significance (157) unless (i) no other etiology for infectious pneumonia can be determined, (ii) the yeast is consistent with an endemic dimorph, or (iii) there is evidence of minimal oropharyngeal contamination in the specimen and the yeast is relatively abundant. The presence of a few *C. neoformans* CFU in sputum does not necessarily imply etiologic significance unless there is patient information which is strongly suggestive of cryptococcosis.

The significance of yeasts in urine is also controversial due to lack of adequate studies. In one study to address levels of yeasts associated with urinary tract infection (UTI), Ahearn et al. (1) demonstrated that quantification of yeast levels provides useful information when correlated with identification of the species. Based on their study, high levels ($\geq 10^5$ CFU/ml of urine) were clearly associated with UTI, although levels of 10^4 CFU/ml should be regarded with suspicion. High levels of *C. albicans* were also seen in women during uncomplicated pregnancy but with little relationship to UTI. *C. glabrata* is also present in high numbers during UTI, especially in diabetics. However, other studies have shown that persistence of *C. glabrata* in urine regardless of level (10^3 CFU/ml or greater) is suggestive of chronic infection (100). *C. tropicalis* at levels of 10^3 to $\geq 10^5$ CFU/ml may be associated with UTI. Other species were much less often isolated from urine during the study by Ahearn et al., so correlations to disease are less clear. The presence of the same species of yeast in urine as in blood may suggest disseminated disease arising from a different site.

The importance of identifying to the species level urine isolates considered potential agents of UTI, especially in debilitated patients, is not trivial. Specific identification provides an indication of the severity of underlying disease and provides information needed for therapeutic management. Debilitated patients are more likely to have infections caused by unusual, as well as azole-resistant, species.

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

No special practices for collection or transport of specimens with suspected yeast infection need to be followed. The reader is referred to chapter 116 of this Manual for standard practices for collection, transport, and storage. However, when specimens are collected and sent to the laboratory consideration should be given to the possibility that a particular fungus is highly infectious (e.g., *Coccidioides immitis*) or has unusual growth requirements (e.g., lipids for *Malassezia* species). Such information regarding the suspected etiologic agent should be provided to the laboratory in a manner that precedes manipulation of the specimen.

Transportation of specimens should be accomplished in less than 2 h. If a delay is anticipated, then normally sterile specimens should be stored at 37°C. Specimens obtained from sites potentially contaminated with normal flora should be stored at 4°C. Yeasts can withstand normal refrigeration temperatures.

DIRECT EXAMINATION OF SPECIMENS

The appropriate examination of a clinical specimen is essential prior to proper processing of the material. Additionally, it often will aid the laboratorian and the physician to obtain a preliminary identification and in either ruling in or ruling out certain pathogenic yeasts. Some methods are universal for the preliminary observation of fungi in a specimen, e.g., Gram stain, calcofluor white, and 20% KOH. However, others, such as the India ink preparation for the demonstration of a capsule, are used for yeasts only. This preparation is used with cultures and specimens of urine, cerebrospinal fluid, etc., which have been centrifuged. It generally is not useful for primary specimens such as sputum or other material which do not allow an even distribution of the ink. If 20% KOH is used on a preparation, neither India ink nor Gram stain may be subsequently added.

In performing the microscopic examination of a specimen for yeasts, structures that may aid in identification may be observed as follows (Fig. 4): (i) size and shape of the organism, (ii) morphology of the bud attachment site and number of

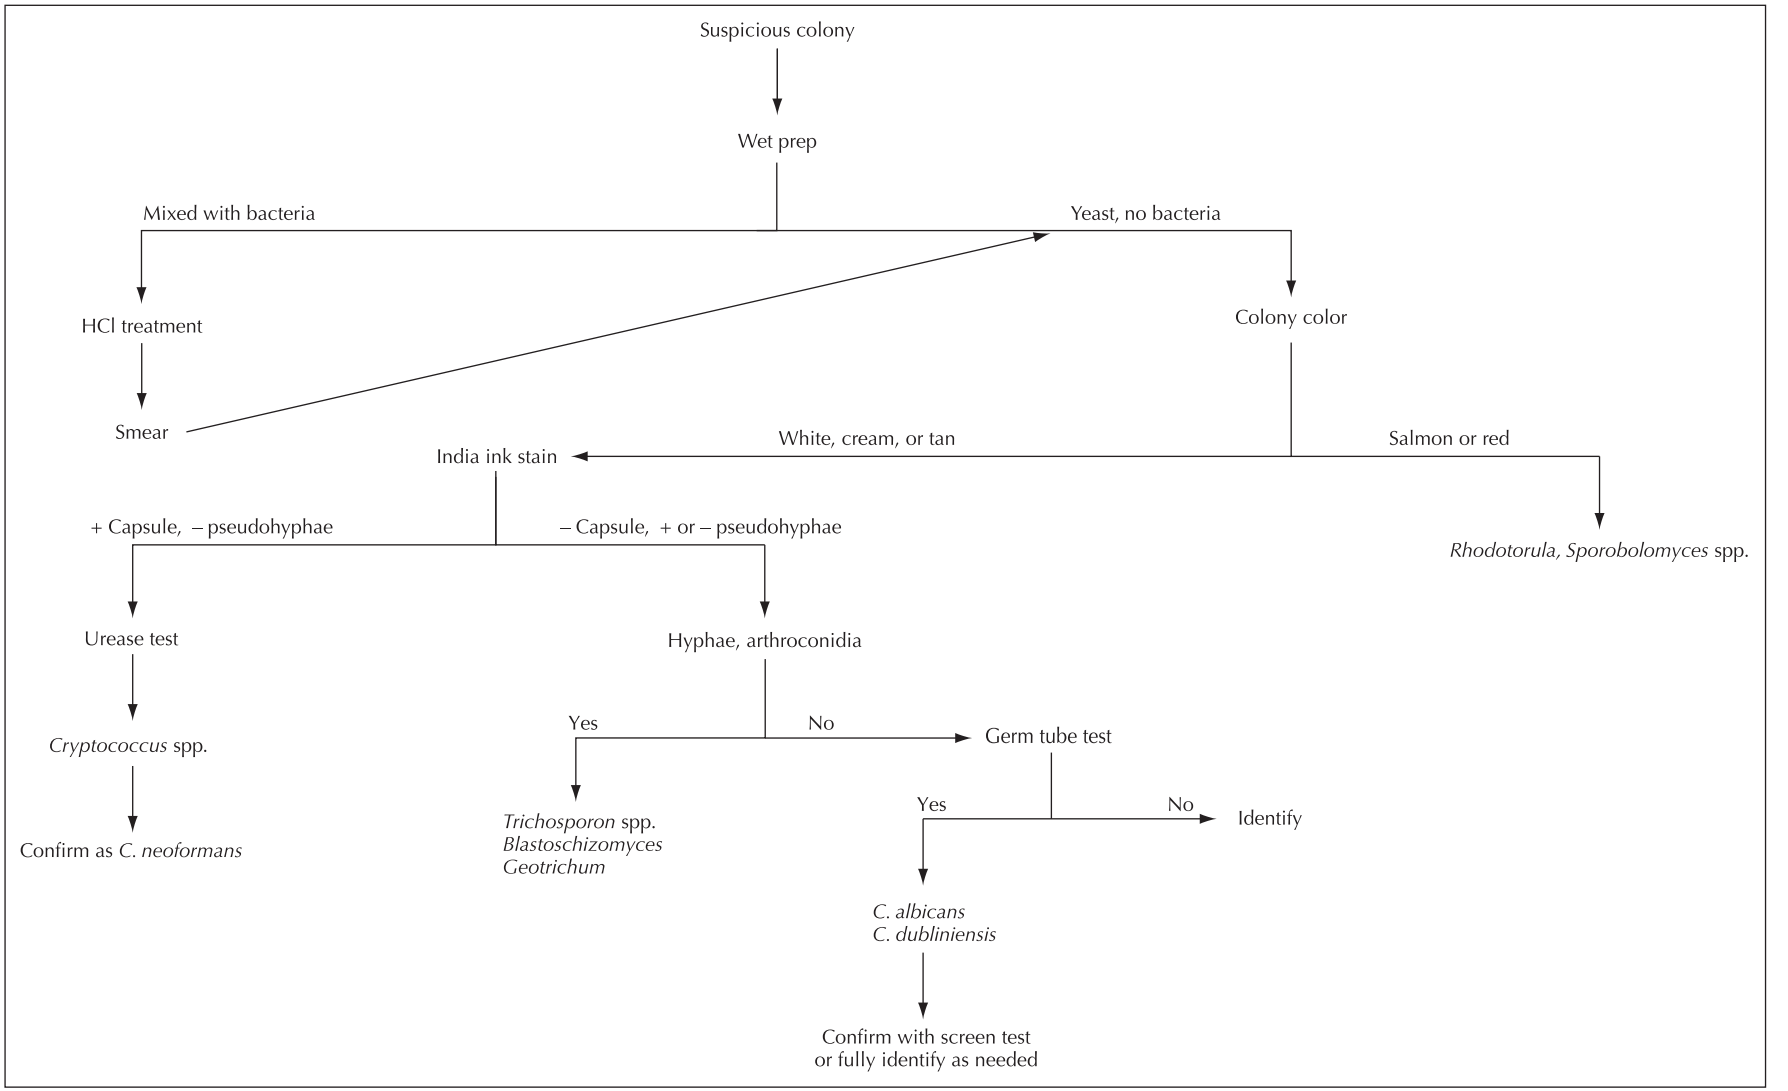

FIGURE 4 Scheme for identification of yeasts from clinical specimens.

buds, (iii) presence or absence of a capsule, (iv) thickness of the cell wall, (v) presence of pseudohyphae, and (vi) presence of arthroconidia. A great deal of information can be gleaned from careful direct microscopic examination of an appropriately prepared and stained specimen.

KOH

Wet mounts prepared in a 10 to 30% potassium hydroxide solution may be used to distinguish fungi in mucoid secretions or in skin, hair, or nail. The KOH digests the proteinaceous material, leaving the fungal elements intact. Gentle warming may speed this process, but care should be taken when using strong concentrations of KOH because the KOH rapidly crystallizes if overheated or left for prolonged periods before examination. The specimen is prepared by placing an aliquot onto a slide, adding to it a drop of KOH, and placing a coverslip on top. Ensure that enough KOH is present to completely cover the specimen. For skin and nail the specimen may be gently squashed while removing excess KOH. In these thick materials this makes visualization of the fungus easier. Hairs should always be viewed without squashing to obtain maximal information about the type of fungal infection. Dimethyl sulfoxide may be added to the KOH reagent to facilitate clearing without the need for heating or incubation, but the specimen should be examined quickly. Bubbles can be confused with yeast cells. Budding cells with internal heterogeneous material should be seen in order to enhance confidence that the object is a yeast. Round and oval objects lacking buds are common in tissue specimens and could be erroneously identified as yeasts.

The calcofluor white stain (Blankophore or Uvitex 2B) fluoresces under filtered UV light to enhance the detection of fungus as it binds to polysaccharides in chitin in the cell wall showing as bright green (4). A specimen may be prepared as above; after the coverslip is removed and a drop of calcofluor white is added, excess fluid is removed and the specimen can be viewed. Alternatively, a drop of calcofluor white can be added at the time of mounting in KOH. However, the stain may fail to penetrate thick nail samples when prepared in this way.

India Ink

India ink is used to visualize capsules which are transparent by bright-field illumination alone, as the ink is excluded from the capsule, showing a clear halo around the yeast. This stain is used to examine specimens of CSF, urine, and other body fluids for the presence of *Cryptococcus* species. Artifacts such as erythrocytes or talc from gloves appear to cause a halo effect; therefore, careful examination for the presence of yeast cells and bud formation is essential. A specimen should be prepared by placing a drop of the centrifuged sediment of a fluid specimen on a slide, adding a drop of Pelikan India Ink or Nigrasin solution, and placing a coverslip on top. While this method is relatively rapid and is generally satisfactory, a preferred method is to place a coverslip on the specimen and place of drop of ink on the side of the coverslip to allow the ink to diffuse underneath. This provides a gradient of ink which contains an optimal region to detect a capsule. India ink solution should be replaced regularly as it becomes contaminated, or alternatively a solution of 10% nigrasin in 10% formalin (using appropriate safety precautions) can be prepared.

Antigen Detection

With the exception of cryptococcal antigen tests for serum and CSF, efforts to develop other antigen detection systems have focused primarily on candidemia and disseminated candidiasis. No commercially available tests have been developed for body fluids and tissues other than blood and CSF. As described below in "Serologic Diagnosis of Yeast Infections," carbohydrate antigens have provided useful targets for several commercial kits for the detection of disseminated candidiasis. Protein antigens have also been investigated. Extracellularly secreted aspartyl proteinases appear promising (154, 244), but no commercial test is available. Another antigen, D-arabinitol, has been under investigation for over a decade and has recently been incorporated into the COBAS FARA II centrifugal autoanalyzer (Roche Diagnostic Systems) (244). Although only a limited number of laboratories have evaluated D-arabinitol as a marker for candidiasis, the antigen appears to be promising. D-Arabinitol levels appear to correlate with therapeutic success (67).

Nucleic Acid Detection

There are currently no FDA-approved nucleic acid detection systems for detection of yeasts directly from a specimen. Most efforts have been directed toward identification of yeasts which grow in blood culture bottles. Several different DNA amplification assays have been developed in research laboratories for this situation (reviewed in reference 67). A commercial peptide nucleic acid fluorescent in situ hybridization (PNA-FISH) kit has been recently approved (*C. albicans* PNA-FISH; AdvanDx, Woburn, Mass.); it specifically detects *C. albicans* in blood cultures by targeting species-specific rRNA sequences. Peptide-nucleic acid chains that mimic 26S rRNA are used to hybridize to target rRNA in *C. albicans*. The probe is also coupled to a fluorochrome which is detectable when the probe binds to its target. Several studies have shown that this assay is 100% specific (165, 186, 240). In the most comprehensive study, the test was found to have excellent sensitivity (99%), specificity (100%), positive predictive value (100%), and negative predictive value (99.3%) (240). The test can rapidly (2.5 h) indicate whether *C. albicans* is present or not and can thus indicate whether a non-*C. albicans* yeast is present (165, 186). The test does not replace subculture because blood cultures may contain mixed species. PNA-FISH-positive blood cultures should be subcultured to ensure that no other yeast species is present. *C. dubliniensis* is not detected with the PNA-FISH-probe. With this test, laboratories can report whether a positive blood culture with yeast contains *C. albicans* within a few hours after the culture becomes positive (109).

ISOLATION PROCEDURES

Processing specimens for fungal recovery is usually performed in conjunction with, and as an extension of, the processing procedure for recovery of bacteria. The primary difference is not the processing method but the selection of media onto or into which the specimen inoculum will be placed. One processing step that has unproven advantages for the isolation of yeasts from sputum specimens is the use of mucolytic agents (*N*-acetyl-L-cysteine or sputolysin).

There are, however, yeast infections for which specialized processing steps should be considered. For example, recovery of *C. neoformans* from blood or bone marrow is enhanced when lysis-centrifugation followed by inoculation onto solid media is used (80). If *C. neoformans* is suspected to be present in a respiratory specimen, setting up primary media which include a niger seed or related medium will enhance detection.

For some yeasts, a medium supplement (such as lipid) may be needed to either enhance or support growth during primary culture. A recent report showed that this approach facilitates

the detection of bile-dependent and bile-enhanced isolates of *C. glabrata*. Bile-dependent isolates have defects in the ergosterol synthesis pathway and are fluconazole resistant (14, 100). The addition of 8 μg of fluconazole per ml to primary media also helps to select for possible fluconazole-resistant isolates. This becomes a particularly powerful method when combined with a primary medium containing a chromogenic indicator used for presumptive identification of some yeasts (e.g., CHROMagar) (167).

IDENTIFICATION

Use of a sound, systematic approach to yeast identification is important. With the numerous yeast identification systems available today, most yeast species can be identified easily; however, repeat testing sometimes is necessary and morphologic characteristics on cornmeal-Tween or similar morphology agars should be mandatory.

Macroscopic Characteristics of Yeasts

Most yeasts grow well (*Malassezia* species are an exception) on common mycological and bacteriological media. Growth is usually detected in 48 to 72 h, and subcultures or lab-adapted strains may grow more rapidly. Colonies have a smooth to wrinkled, creamy appearance; some pigment may be observed initially or intensify with age. Heavily encapsulated yeasts give a very moist, mucoid appearance.

The ability of yeasts to grow at 37°C is a very important characteristic. Most pathogenic species grow readily at 25 and 37°C, whereas saprobes usually fail to grow at the higher temperature. Additionally, some yeast species, e.g., *Candida albicans*, grow in the presence of the cycloheximide (Actidione) found in Mycosel, Mycobiotic, and similar agars, whereas most other yeasts, including *Cryptococcus neoformans*, are inhibited.

Pellicle growth on the surface of liquid media such as Sabouraud glucose broth or malt extract broth has been used in the past to assist with yeast identification. More-recent evidence suggests that this characteristic can be variable; however, as an ancillary test, it may be helpful with identifying *Candida tropicalis* and *Candida krusei.*

Microscopic Characteristics of Yeasts

Upon isolation of a suspected yeast from a clinical specimen, the first examination should be a wet preparation of a colony. This provides an initial clue to the organism's identity. Observations should include the size and shape of the yeast, the method of bud attachment, and the presence or absence of pseudohyphae, true hyphae, or arthroconidia. Any round or slightly oval budding yeast with rare or no pseudohyphae seen in this preparation should be examined further for the presence of a capsule.

The same wet preparation used for the initial microscopic examination can be used for an India ink examination. The preparation then can be examined for the presence of encapsulated yeasts (Fig. 2). False-positive preparations usually are the result of contaminated ink or artifacts which can exhibit ragged edges. Capsular size cannot be used for identification purposes, as this characteristic may be influenced by culture age, media composition, and strain variation. The presence of a capsule does not automatically ensure that the yeast is *Cryptococcus neoformans* because other cryptococci, *Rhodotorula* spp., and rare *Candida* spp. produce capsule-like structures. In practice, any nonpigmented, round, encapsulated yeast recovered from CSF should be considered to be *C. neoformans* until proven otherwise.

Purity of Cultures

Before any additional physiologic tests are performed, it is essential to ensure that the culture is pure. A Gram stain of the culture can verify purity, but often bacterial contamination can be detected during the wet preparation examination. If the culture is mixed with bacteria, the isolate should be inoculated onto a blood agar plate and individual colonies should be picked or alternately, treated with hydrochloric acid (Fig. 4). The HCl procedure is performed by inoculating a colony into three tubes of Sabouraud glucose broth (each containing 5 ml). A capillary pipette is used to add 4 drops of 1 N HCl to the first tube, 2 drops to the second tube, and 1 drop to the third tube. After incubation at 25°C for 24 to 48 h, 0.1 ml of each broth is subcultured onto fresh Sabouraud glucose agar plates.

It is possible that more than one yeast species will be recovered from a clinical specimen, especially if the specimen is from a normally nonsterile site (243). In addition, multiple yeast species may be responsible for fungemia episodes. Careful attention to colonial morphology and microscopic characteristics can offer clues to a mixed population. Subculturing individual isolates to additional media can be helpful (243), and the use of a chromogenic medium may delineate the presence of more than one yeast species.

Morphology Studies

While examination of a wet preparation gives a primary indication of the yeast involved, more extensive study of morphology on cornmeal agar or other similar agars offers the opportunity to correlate morphologic characteristics with results of biochemical testing. Microscopic examination should reveal the thick-walled chlamydospores of *Candida albicans*/*Candida dubliniensis*. For features of other yeasts, see Table 3. Special attention also should be given to the size and shape of the pseudohyphae and the arrangement of blastoconidia along the pseudohyphae (Fig. 1).

Germ Tube Test

One of the most valuable and simple tests for the rapid presumptive identification of *C. albicans* is the germ tube test (Fig. 5a). The test is considered presumptive because not all isolates of *C. albicans* will be germ tube positive and false positives may be obtained, especially with *C. tropicalis,* despite well-trained staff (57). Also, *C. dubliniensis* is germ tube positive, although most isolates do not form germ tubes in a commercial synthetic germination medium (56). Microscopic observation of the preparation reveals that the short hyphal initials produced by *C. albicans* are not constricted at the junction of the blastoconidium and germ tube. Frequently, so many *C. albicans* blastoconidia produce germ tubes that the germ tubes become entwined with each other, producing clumps, especially when incubated longer than 3 h. *Candida tropicalis* also can produce hyphal initials, but the blastoconidia are larger than those of *C. albicans*, and there is a definite constricture where the hyphal initial joins a blastoconidium (Fig. 5b). In addition to using a known culture of *C. albicans* as a positive test control, negative controls using *C. tropicalis* and *C. glabrata* also should be included. Optimum conditions are obtained by using colonies grown on Sabouraud glucose agar or blood agar at 30°C for 24 to 48 h (unpublished observations). The test is performed by first lightly touching a colony with a bacteriological loop so that a thin film of organism is obtained and then transferring the inoculum into the test substrate (such as fetal bovine serum) followed by incubation at 37°C for 3 h. When *C. tropicalis* produces germ tube-like structures, less

than 15% of the cells do so. The preparation should not be incubated at 37°C longer than 4 h because other hypha-producing yeasts will begin to germinate after this time. In addition, a heavy inoculum of yeasts and the presence of bacteria can each lead to false-negative results.

PNA-FISH

The PNA-FISH test is described above (see "Direct Examination of Specimens"). Although the test is marketed for evaluation of positive blood cultures, the test could be used to facilitate identification of *C. albicans* growing as colonies on solid media.

Ascospore Formation

Homothallic yeasts recovered from clinical specimens may be present in their teleomorphic (sexual) state. In order to enhance production of ascospores by ascomycetous yeasts, cultures should be inoculated onto media such as Fowell's acetate agar, V-8 juice agar, or yeast extract-malt extract agar incubated at room temperature for 2 to 5 days and examined by wet preparation for the presence of ascospores within asci. Some mycologists prefer to perform special stains to detect ascospores. The Ziehl-Nielsen stain routinely employed in mycobacteriology can be used if needed; however, most ascospores can be detected easily in a drop of sterile distilled water. Ascospore production in *Saccharomyces cerevisiae* is evidenced by the presence of one to four globose spores (Fig. 3c); *Pichia anomala* produces one to four hat-shaped spores (Fig. 3a). Ascospore formation is a valuable test to aid in identification when equivocal results are obtained by other identification methods (Table 4).

Phenol Oxidase Test

The phenol oxidase screening procedure detects the ability of *Cryptococcus neoformans* to produce phenol oxidase on substrates containing caffeic acid. The most frequently used medium is "birdseed" agar (containing niger or thistle seeds), and a number of formulations showing varying degrees of success have been described. Test performance is related to the glucose content of the medium; the more glucose in the medium, the less likely a valid test result will be obtained. *C. neoformans* colonies turn a dark brown in 2 to 5 days. Because of the wide variation in media formulations, the test must be subjected constantly to quality control measures. Some laboratories advocate the use of birdseed agar as part of the primary plating for respiratory cultures for early detection of *C. neoformans* isolates. A rapid phenol oxidase test utilizes a caffeic acid disk that is rehydrated and then inoculated with several yeast colonies and incubated at 35 to 37°C for up to 4 h. The disk should be examined every 30 min for the production of a brown pigment. If pigment is produced, it is presumptive for *C. neoformans;* if no pigment is detected but *C. neoformans* is suspected, further identification should be conducted.

Urease Test

The urease test detects a yeast's ability to produce the enzyme urease. In the presence of suitable substrates, urease splits urea, producing ammonia, which raises the pH and causes a color shift in the phenol red indicator from amber to pinkish red. The urease test aids in the identification of *Cryptococcus* spp. and *Rhodotorula* spp., which are urease positive. Most strains of *Trichosporon* spp. are positive, whereas *Geotrichum* spp. and *Blastoschizomyces capitatus* are negative. Nearly all *Candida* spp. encountered in clinical specimens are urease negative, exceptions being *Yarrowia (Candida) lipolytica* and some strains of *C. krusei*, both of which do not assimilate inositol. A rapid disk test can take from 4 to 72 h for a reaction to develop, while the more definitive urea agar slants can take from 24 to 72 h.

Rapid Trehalose Test

The rapid trehalose test can provide a presumptive identification of *C. glabrata* within 3 h. The Clinical and Laboratory Standards Institute (CLSI) has recently approved a rapid test procedure (document M35-A) for identification of *C. glabrata* (17) based primarily on rapid trehalose assimilation. False positives occur with trehalose tests (73), but these can be reduced if the results are correlated with small cell size and failure to produce germ tubes. Several modifications of

TABLE 4 Appearance of asci/ascospores of ascomycetous yeasts[a]

Anamorphic spp.	Previous synonym or obsolete name	Teleomorph (alternative spp.)	Hetero- or homothallic	Ascospores

the rapid trehalose assay have been introduced. The GLABRATA RTT (Fumouze Diagnostics, Levallois-Perret, France) combines hydrolysis of trehalose and maltose and includes a control (a sugar-free basal medium). *C. glabrata* hydrolyzes the trehalose rapidly, but not the maltose (which other yeasts may hydrolyze). The test provides acceptable sensitivity and specificity, but the choice of growth medium for the test inoculum influences the likelihood of obtaining false positives. Blood agar should be avoided, as both *C. albicans* and *C. tropicalis* cause high numbers of false-positive results (75, 239). The most suitable media appear to be CHROMagar and Sabouraud glucose (4%) agar. Combining colony color on chromogenic agars with the GLABRATA RTT or the rapid trehalose test could help improve specificity (156, 174). Rapid trehalose and maltose hydrolysis has also been modified into a 30-s dipstick assay. This test provides adequate specificity and sensitivity, but these parameters are affected by the medium used to grow the test inoculum (174).

Chromogenic Agars

Presumptive identification of one or two yeast species based on colony characteristics can be obtained with chromogenic agar media. CHROMagar *Candida* (CHROMagar France; Paris, France; distributed in the United States by Becton Dickinson/BBL, Sparks, Md.) allows differentiation of over 10 species and is marketed for the presumptive identification of *C. albicans, C. tropicalis*, and *C. krusei*. Colony identification is based on the differential release of chromogenic breakdown products from various substrates following exoenzyme activity. It is important to recognize that identifications are presumptive. Evidence suggests that variation in colony appearance occurs among the species (18, 170). The directions of the manufacturer must be strictly followed, as is the case in any rapid test based on exoenzyme activity. Incubation time and temperature significantly affect the colony appearance. The medium is useful for the detection of mixed yeast infections, especially in blood, and for resolving identification problems. Other chromogenic media are now commercially available. CandidaID (bioMerieux) and CandiSelect (Bio-Rad, Marnes La Coquette, France) performances are similar to that of CHROMagar. No one medium detects all instances of mixed yeast blood cultures (127, 238, 239). Approximately 2 to 10% of *C. albicans* isolates produced white colonies, rather than colored colonies, on these chromogenic media, strongly supporting the concept that these media provide only a presumptive identification. Other chromogenic media, namely Oxoid Chromogenic Candida Agar (OCCA, Basingstoke, Great Britain) and HiChrome (HiMedia Laboratories, Mumbai, India), have

been introduced recently, but published papers describing extensive comparative trials against other chromogenic media are not available.

Phenotypic Systems

A variety of manual and semiautomatic single- to multiphenotypic assay systems have been commercialized (Table 5). Most are designed to help identify the most common yeast etiologic agents. The systems vary in ease of use and accuracy. Generally the systems designed to identify multiple genera and their species are less reliable with unusual or rare pathogens (e.g., *C. inconspicua*), although sometimes rare isolates of common species such as *C. parapsilosis, C. guilliermondii,* and *C. krusei* can result in misidentification or poor species discrimination (32, 82).

Carbohydrate Assimilation Tests

The mainstay of yeast identification to the species level is the carbohydrate assimilation test (Table 1), which measures the ability of a yeast to utilize a specific carbohydrate as the sole source of carbon in the presence of oxygen. There are several reliable commercially available kits (such as API 20C AUX [bioMérieux SA], API ID32C [not available in the United States], and BBL Minitek Yeast Set [Becton Dickinson/BBL]) and automated and semiautomated systems on the market today that make the classical Wickerham and Burton method (234) unnecessary for routine clinical isolates. None of these tests are 100% concordant with the Wickerham-Burton method, and they do not uniformly agree with each other. Assimilation reactions provided in reference books, such as those by Barnett et al. (16) and Kurtzman and Fell (117) are based on the Wickerham-Burton method. Because commercial assimilation tests are only similar to the Wickerham-Burton tests, assimilation reaction profiles may differ from those provided in reference books.

Nitrate Assimilation Test

The rationale behind the nitrate assimilation test is similar to that of the carbon assimilation test. It tests the ability of a yeast to utilize nitrate as a sole nitrogen source. The test is most beneficial when trying to identify *Cryptococcus, Rhodotorula,* and *Pichia* spp.

Carbohydrate Fermentation Tests

Fermentative yeasts recovered from clinical specimens produce carbon dioxide and alcohol; therefore, production of gas is indicative of fermentation. The pH of the medium may not change. Rarely are fermentation studies needed to identify most of the commonly isolated yeasts if the mycologist is familiar with typical morphology on cornmeal agar. The test is most helpful in differentiating the various species of *Candida; Cryptococcus* and *Rhodotorula* spp. are nonfermentative.

Rapid Identification Tests

Rapid identification of yeasts impacts patient management. This is particularly true given the recognition that various yeast species (such as *C. glabrata, C. krusei, C. parapsilosis, C. lusitaniae, C. tropicalis,* and *C. neoformans*) are inherently or potentially resistant to amphotericin B, the newer azole agents, or echinocandins (78, 228).

Rapid tests are divided into those that provide definitive or presumptive identification within the same day (<24 h) of colony formation and either are specific to a single species, are limited to a few species, or apply to multiple genera (Table 5). In general, tests listed within groups 1 and 2 of Table 5 are presumptive and confirmation of the identification is needed.

Tests based on preformed enzymes may be acutely affected by incubation temperature (99) and are effectively limited to the more common yeast species isolated in the clinical laboratory. However, detection of specific exoenzymes can be useful for resolution of the confusion between two or three possible species. In particular, several rapid tests

[a]*, test not available in the United States.

are available for this purpose, particularly for detection of *Candida albicans* (for example, the *Candida albicans* screen [Carr-Scarborough Microbiologicals, Decatur, Ga.] and the Albistrip [Lab M Ltd., Bury, United Kingdom]). These tests are excellent for confirmation of a germ tube-positive organism as *C. albicans* and could be used in place of more long-term identification tests for this purpose. However, similar results are obtained for *C. dubliniensis*. To date this organism is most frequently isolated from the oropharynx of HIV-positive patients, but it may infrequently be recovered from blood, urine, vaginal, or other specimen sites, especially if the patient is immunocompromised. Using these tests for confirmation purposes can provide a financial saving to the clinical laboratory. Both tests depend on the production of two enzymes (proline aminopeptidase and β-galactosaminadase) instead of a single enzyme (β-galactosaminadase), which could otherwise lead to spurious results (209). Distinguishing *C. albicans* from *C. dubliniensis* is important, especially if the patient has been exposed to fluconazole, because the latter species can be induced to develop resistance under azole pressure. Several single tests have been suggested to help differentiate these two species from one another. These include, but are not limited to, growth at 45°C (positive for *C. albicans*), reduction of 2,3,5-triphenyltetrazolium chloride (positive for *C. dubliniensis*), production of a dark green color on CHROMagar (*C. dubliniensis*), production of β-glucosidase (*C. albicans*), and abundant chlamydoconidia on Staib agar (*C. dubliniensis*) (2, 164, 176, 198, 224). These tests are generally not rapid and are not definitive (e.g., some isolates of *C. albicans* do not grow at 45°C). Other differential agar media have been suggested (3, 112). Molecular tests and serologic tests appear to be promising rapid alternatives with higher sensitivity and specificity.

Serological identification tests, which use rabbit antisera directed against specific polysaccharides on the cell walls of *Candida* species and *Cryptococcus neoformans*, are available (Mitsubishi Kagaku Iatron, Inc., Tokyo, Japan). *C. albicans* cannot be differentiated from *C. dubliniensis* by the antisera, and *C. neoformans* serotypes B and C cannot be distinguished from each other.

Molecular Methods

At present yeasts are not identified in the routine clinical environment by use of nucleic acid technology. However, as methods are being developed for use in research, diagnostics, and epidemiology, this technology is beginning to emerge. Some reference texts (59) have included restriction maps of ribosomal operons for described fungi, Public sequence databases, most famously GenBank, are available via the Internet for laboratorians to find genetic matches for their organisms.

In order to develop a universal genetic identification system for yeasts, the most reproducible, specific, and sensitive sequence for comparison must be identified. Much of the recent research has focused on the rRNA gene regions. The large subunit, specifically the D1/D2 region, was shown to be highly discriminatory for the ascomycetous yeasts (118) and similarly for the basidiomycetous yeasts (72, 199), although differentiation of closely related species in the last study was achieved using the internal transcribed spacer (ITS) region. More recent studies have also used the ITS1 and ITS2 regions (42, 221). The potential of these methods was demonstrated by Massonet et al. (142a) when comparing 61 isolates of *Candida*, *Cryptococcus*, *Blastoschizomyces*, and *Saccharomyces* by ITS2 fragment length polymorphism with the ID32C and VITEK 2. The genetic analysis correctly identified 55 or 59 isolates depending on the method of extraction, the ID32C identified 58 isolates, and the VITEK 2 (fluorometric card) identified only 41 isolates. Hall et al. (93) used a commercially available MicroSeq D2 large-subunit ribosomal DNA sequencing kit to identify 131 clinical yeast isolates and compared the results to those obtained by conventional methods, which included the API 20C AUX system. Comparisons of 100 isolates representing 19 species of *Candida* using the MicroSeq kit matched 98% with identifications using the API 20C AUX. For the remaining isolates, representing nine species, there was 81.3% concordance between the systems. Most of the discrepancies were attributed to a lack of available data in the relevant databases. However, more research is needed before a universal genetic database can be devised because the D1/D2 and ITS regions do not appear to identify all yeasts. Using the ribosomal 5.8S-ITS sequence only 6 of 15 *Debaryomyces* species were correctly identified; the remaining species were differentiated using the sequences of the ACT1 gene (141).

For organisms that are difficult to grow or require non-commercially available materials, these methods hold great potential. For example, identification of *Malassezia* species requires both specialized growth media and phenotypic identification tests. The use of DNA technology has led to the identification of four new species in recent years (*M. yamatoensis* [213], *M. japonica* [214], *M. nana* [103], and *M. dermatis* [215]), and rapid identification methods for this genus have been developed using D1, D2, and ITS sequences (87) and by PCR-restriction fragment length polymorphism (150).

Many laboratories do not possess sequencing equipment or facilities to develop the use of these technologies for mycology; however, there are a number of other DNA-based methods available to aid in identification. Restriction enzyme analysis (REA) using the enzyme Hinf1 has been very useful in providing simple and characteristic DNA band patterns for a large number of *Candida* species, with the bonus that it is particularly good at strain differentiation for some species (77, 194). A number of species-specific probes have been developed for use with Southern blots of REA samples. These include 27A (195) and Ca3 (197) for *Candida albicans* and *Candida dubliniensis*, Ct-3 for *Candida tropicalis* (110), Cg6 and Cg12 for *Candida glabrata* (130), and Cp3–13 for *Candida parapsilosis* (69). Pulsed-field gel electrophoresis (PFGE) separates whole chromosomes (karyotyping) or large pieces of DNA that are not resolvable by conventional electrophoresis. The extraction facilitates this by taking place inside an agarose block to prevent damage and shear of the nucleic acids. Some species have characteristic karyotypes with no strain variation, for example, *Malassezia* (25), whereas other species, such as *C. albicans* (46) and *C. glabrata* (58), can be strain typed using this method.

PCR is a powerful tool and is the basis of the amplification used for sequence analysis. When sequencing is not permissible, genetic targets can be amplified and compared for size or for structure by digesting the amplicon with a suitable restriction endonuclease (237). An alternative is to use a universal sequence as a primer to generate species-specific patterns. The microsatellite sequence M13 has been found to be very useful for species identification and has even been used to identify anamorph and teleomorph pairs (124). By using a low annealing temperature for primers in PCR, a technique known as random amplification of polymorphic DNA, or RAPD, can be used for strain typing. However, problems of reproducibility prevent interlaboratory comparisons of the generated fingerprint patterns (205), confining

this to a useful method for investigation of local outbreaks or for intralaboratory studies of strain relatedness.

White et al. (233) and Ellepola and Morrison (67) have reviewed developments for rapid diagnosis of invasive candidiasis, including PCR-based methods. New techniques combining enzyme immunoassay formats for the rapid detection of species-specific amplicons and the use of real-time PCR are discussed. Standardization remains an issue before any of these tests become commonplace, but the benefits to earlier and more specific diagnosis are clear and these tests will complement those used currently in the clinical environment.

Troubleshooting Difficult Identifications

Laboratories encounter yeast isolates that do not fit easily into a specific species, particularly when commercial identification systems are used. There are key features that help separate troublesome organisms from others. For example, urease production separates basidiomycetous yeasts from ascomycetous yeasts. Maximum growth temperature, cycloheximide resistance, and the ability to assimilate cellobiose, inositol, or trehalose are helpful. For more difficult identifications, use of traditional auxanographic methods but with carbon source-impregnated disks on yeast carbon base agar plates (rather than spotting the sugar on the edge of the plate as done by Beijerinck [19]) may provide the most accurate assimilation information. Differential media such as chromogenic agars or eosin methylene blue agar (*C. glabrata* and *C. kefyr* produce distinct colonies) may sometimes help (155). Fermentation tests should also be considered, as should a second commercial system that utilizes a different endpoint (e.g., growth versus exoenzyme production). One of the molecular methods of identification could be tried for isolates that consistently fail to be identified by conventional tests.

ORGANISMS RESEMBLING YEASTS

Occasionally organisms such as molds, algae, etc., may grow on mycologic media and produce colonies that resemble those produced by yeasts. However, careful attention to morphologic characteristics can differentiate them. The following are several examples of such organisms that are recovered from clinical specimens and superficially can be confused with yeasts.

Genus *Geotrichum*

Members of the genus *Geotrichum* may be confused with yeasts because they produce a white to cream-colored, mealy, subsurface colony on fungal media. Occasionally aerial mycelium may be produced, giving a colony which superficially resembles *Coccidioides immitis*. Microscopic examination reveals septate, hyaline hyphae which break into arthroconidia upon maturation (Fig. 1c). No other structures are observed. *Geotrichum candidum* may be separated from *Trichosporon* spp. by carbohydrate assimilations and the lack of urease and blastoconidia production. *Geotrichum* spp. occasionally may be isolated from patient specimens but is rarely considered a pathogen except in extremely debilitated individuals.

Genus *Ustilago*

The genus *Ustilago* represents a heterobasidiomycetous fungus which is parasitic on seeds and flowers of many cereals and grasses. It may be inhaled and, therefore, isolated from sputum specimens. The colonies are slow growing and, when young, are moist, compact, and white. With age, short hyphae are produced and the colonies become velvety or powdery. Microscopically the cells are irregular and yeast-like or elongate to spindle-shaped and may resemble arthroconidia. With the production of short hyphae, clamp connections are formed. Physiologically, most isolates are nitrate positive and have a carbohydrate assimilation pattern similar to that of *Cryptococcus albidus*.

Black Yeasts

Occasional isolates of *Sporothrix schenckii, Aureobasidium pullulans,* and agents of phaeohyphomycosis initially produce white to tan yeast-like colonies on primary isolation media. Identification methods for these organisms are quite different from yeast identification methods and are discussed in chapter 125.

Genus *Prototheca*

Prototheca species are ubiquitous achlorophyllous algae, living on decaying organic matter, and rarely produce disease in humans and animals (111, 180). Human infection usually involves the skin and underlying tissues or olecranon bursa. Systemic protothecosis with algaemia is an extremely rare manifestation (30). *Prototheca wickerhamii* is recovered most often from human specimens, whereas *P. zopfii* usually is associated with animal infections. Colonies are white to cream-colored, yeast-like, and dull or moist to mucoid in appearance. The optimal growth temperature is 30°C, and growth is inhibited by media containing cycloheximide. Microscopically the cells are variable in size and shape and do not bud (Fig. 3b). Asexual reproduction is by release of sporangiospores from sporangia. Generally, sporangia of *P. zopfii* (14 to 16 μm) are larger than those of *P. wickerhamii* (7 to 13 μm), but this characteristic can be influenced by environmental conditions. Cells of *P. wickerhamii* are round, whereas most strains of *P. zopfii* exhibit cells which are oval to cylindrical in shape. Carbon assimilation studies can be used for identification purposes, and most commercial identification systems provide accurate identification of *P. wickerhamii*. Both species assimilate glucose and galactose; additionally, *P. wickerhamii* assimilates trehalose. *Prototheca* is a nonfermentative genus (179). *P. wickerhamii* is sensitive to voriconazole (129).

STRAIN IDENTIFICATION AND DIVERSITY

To understand the epidemiology of infection, to distinguish between endogenous and exogenous infection, and in the latter to locate the source, to examine transmission, or to monitor the spread of drug resistance, it is necessary to be able to distinguish between isolates within species.

Phenotypic typing schemes have been developed (106, 172, 182), which have the advantage of being inexpensive, but they can be prone to problems with reproducibility and the effects of storage on expression of characteristics. DNA-based schemes were developed to overcome these problems. Occasionally the results of phenotype and genotype have been combined to improve on the discrimination of either technique alone (79).

One of the oldest genetic typing techniques is REA, but the results depend on the restriction enzyme used, with EcoRI (136) and HinfI (77) being very useful for the discrimination of strains from a number of *Candida* species. However, not all species can be typed in this way; for example, isolates of C. *parapsilosis* show few differences when REA is used. Sometimes strain discrimination can be enhanced by Southern blotting the restriction digest gel and hybridizing with a DNA probe, such as the non-species-specific

poly(GT) (6, 236) or (CT)8 (216), or with species-specific probes, most notably the *Candida albicans* probe Ca3, which can demonstrate microevolution within one strain over a period of time (131).

PFGE has been used to produce electrophoretic patterns of whole chromosomes (karyotyping) for a number of species and has been used for strain typing of *C. albicans* (46), *C. glabrata* (58), *C. parapsilosis* (79), and several other *Candida* species (205). In some cases greater discrimination can be obtained by REA using a rare-cutting enzyme like SfiI or BsshII to generate large DNA fragments that are then separated using PFGE (226). However, as with ordinary REA, the discrimination of these enzymes differs between the species, with optimal results obtained using BsshII to differentiate isolates of *Candida tropicalis* (185), whereas SfiI was better for distinguishing isolates of *Clavispora lusitaniae* (115).

RAPD has been a very popular PCR-based strain typing technique (128, 245), although reproducibility can be a problem (205). Furthermore, a number of primers may have to be screened for each yeast species investigated before maximal discrimination can be established (79, 212). Successful discrimination of strains of *Cryptococcus neoformans* var. *grubii* from AIDS patients was achieved using a combination of PCR fingerprinting and RAPD analysis, with each patient having a unique strain and occasional patients being infected with more than one strain (108). Therefore, successful strain typing requires the choice of technique(s) and experimental conditions for maximum discrimination to be established for each species tested.

SEROLOGIC DIAGNOSIS OF YEAST INFECTIONS

Signs and symptoms of invasive yeast infections generally overlap those of bacterial infections, necessitating development of rapid non-culture-based methods for diagnosis. Non-culture-based tests for discriminating fungal versus bacterial infection and for detection of specific genera have been developed. Of all of these tests, the cryptococcal antigen test has proven to be the most successful, but recent progress suggests that a similarly successful *Candida* serology test may be available in the near future.

Discrimination of Fungal Infection from Other Microbial Etiologies

The unique composition of the fungal cell wall makes it particularly well suited as a focus for fungal serological tests. Many of the more common pathogenic yeasts contain β-1,3-glucan in the wall. β-1,3-Glucan is detected by two commercial kits, the Glucatell (Associates of Cape Cod) and the Fungitek G (Seikagaku Corp.). Repeat testing of patients who appear to be negative is recommended because single-test positive results provide generally good single positive test sensitivities and specificities (162) and repeatedly negative tests have a high negative predictive value. Repeat testing of patients who tested positive also improves the specificity of the test (162, 225). A positive test, however, does not provide information about the specific etiology, which is a weakness if tailored antifungal therapy is desired.

Cryptococcosis

Detection of cryptococcal antigen (capsular galactoxylomannan) in serum and CSF has been available for over 2 decades. During this time commercial tests have evolved to overcome early problems with specificity and sensitivity. The chief problem was false positives due to rheumatoid factor. Once this factor is destroyed, the sensitivity and specificity of the current generation of cryptococcal antigen tests are high. The test has been recommended as the primary evaluative tool in lieu of an India ink stain for screening CSF in suspect cases of cryptococcal meningitis. This is because the sensitivity of the India ink stain is low.

False-positive tests due to causes other than rheumatoid factor have been observed. These have been associated with trichosporonosis, *Capnocytophaga canimorsus* septicemia, malignancy, *Stomatococcus* bacteremia, some soaps and disinfectants, and hydroxyethyl starch (used in fluid resuscitation) (23, 40, 104, 135, 147, 149, 231). Interestingly, the cryptococcal galactoxylomannan contains an epitope that cross-reacts with the galactomannan antigen of *Aspergillus* spp., which is the antigen target of the Platelia *Aspergillus* assay (54).

Monitoring a decrease in antigen titer as an indication of effective anticryptococcal therapy has been suggested. However, while the titer may decrease after initiation of therapy in non-HIV patients, it may remain greater than 200 despite microbiological clearance (133). Lu et al. (133) have suggested that a better indicator of successful therapy is the return of CSF glucose, chloride, and leukocyte count to normal limits.

Candidiasis

Invasive *Candida* infections are life threatening, but detection by relatively noninvasive methods such as blood cultures is problematic. A test for the detection of antibody to *Candida* mannan is also available. Its utility is maximized when combined with the detection of antigen levels, as the antibody and antigen levels may show an inverse correlation during disease progression. The Cand-Tec test (Ramco), which detects an unspecified mannan antigen in the cell wall of *Candida* species, appeared to be relatively robust during initial studies in the 1980s, but subsequent studies during the 1990s suggested that the test provided inadequate sensitivities. A more promising test, the Platelia *Candida* Ag test (Bio-Rad), utilizes a monoclonal antibody EB-CA1, which targets an α-1,2-oligomannoside common among multiple species of *Candida*. The test has shown reasonable sensitivity and high specificities, although these vary from study to study. Sendid et al. (200) have recommended that both the antigen and the antibody tests (Platelia *Candida* Ab) be performed to maximize early diagnosis of invasive candidiasis. The specificity of the antigen test can be further enhanced by including a test for a second antigen, β-1,2-oligomannan, which is found in only a limited number of *Candida* species, *C. albicans, C. glabrata,* and *C. tropicalis* (201). *C. dubliniensis* variably expresses the antigen (101).

Specific Tests for Invasive Infections Caused by Other Yeasts

Not surprisingly, little effort has been undertaken to develop serologic tests for detection of invasive infections caused by yeasts other than *Candida* and *Cryptococcus* species. With the growing awareness of bloodstream infections caused by *Trichosporon* species, specific serologic tests for their detection may be developed. Before this occurs, a possible strategy is to use the serum cryptococcal antigen test in combination with compatible signs and symptoms and underlying disease to suggest a diagnosis of trichosporonosis.

ANTIFUNGAL SUSCEPTIBILITIES

Antifungal resistance profiles and mechanisms of yeasts and molds are described in other chapters of this Manual.

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

As with bacteria, the clinical significance of an isolated yeast, especially one that may be part of the normal host microbiota, depends on a number of factors, especially the patient's signs and symptoms and underlying disease. Two specimens that are particularly problematic are sputum and urine (clean catch, indwelling catheter, and "in and out" catheter). The significance of *Candida* species in sputum regardless of quantity has been questioned (15, 157). Unfortunately, clinical microbiology laboratories often are not provided information about a patient's oropharyngeal status. Also, *Candida* species can cause pneumonia in debilitated patients. To prevent unnecessary testing but still provide useful information to physicians, Barenfanger et al. (15) recommend reporting "yeast, not *Cryptococcus*" for all respiratory secretion specimens in which a rapidly growing yeast is obtained. *Cryptococcus* species are ruled out using a rapid urease test. This approach allows physicians the opportunity to request further identification if desired. A similar approach to rapidly growing yeasts isolated from routine urine specimens (UTI is the only presentation) could also be used. However, in this situation, differentiation of *C. glabrata* from other common yeast uropathogens is the concern. As *C. albicans (C. dubliniensis)* and *C. glabrata* can be ruled out with simple rapid tests, a report of "yeast, not *C. albicans*/*C. dubliniensis*, not *C. glabrata*" could be made for those urines for which the laboratory director considers that yeast identification is indicated.

A common practice is to not identify rapidly growing yeasts present in clinically significant quantities from nonsterile body sites beyond a simple screen for *C. albicans*. This practice is potentially harmful but depends on the patient's condition. Yeast species express different antifungal profiles especially to the expanding spectrum of new antifungal agents.

Pneumocystis

MELANIE T. CUSHION

120

TAXONOMY

Organisms once known collectively by the single genus and species *"Pneumocystis carinii"* are nonfilamentous fungi that inhabit the lungs of mammals, but not birds or poikilotherms. Current evidence suggests that they can exist without consequence in mammalian hosts with intact immune systems (48, 83), but once the immune system becomes compromised, the organisms proliferate within the lung alveoli and cause a lethal pneumonia if untreated. No species of *Pneumocystis* can be cultivated outside the mammalian lung, impeding diagnostic capabilities as well as basic scientific research. Limited therapy is available with which to treat the pneumonia, since these organisms are not susceptible to standard antifungal drugs such as amphotericin B and fluconazole.

Taxonomic problems have plagued the organisms known as *"P. carinii"* since their original description in 1909 by Carlos Chagas. He included developmental forms of a cryptic *Pneumocystis* lung infection in trypanosome-infected animals as life cycle stages of the protozoan parasite *Trypanosoma cruzi* (14). In 1914, these organisms were provided an identity of their own and given the binomial epithet that reflected their predilection for the lung, *pneumo-;* the characteristic morphological form, *-cystis;* and *carinii,* to honor the Italian investigator, Antonio Carini, who provided the slides for study (29). Presumed to be a protozoan parasite at the time of identification, the potential fungal nature of *P. carinii* was raised in the 1950s (16, 58), and the controversy of the protozoan or fungal nature of these organisms continued to the late 20th century (87).

In the late 1980s, phylogenetic analyses based on the nuclear small subunit rRNA sequence alignments showed that *P. carinii* was a member of the fungal kingdom (33, 96, 97). Subsequently, additional gene sequence comparisons and cDNA and genomic sequence data emerging from the *Pneumocystis* Genome Project showed that the closest extant relative to *P. carinii* was the fission yeast *Schizosaccharomyces pombe* (18, 25). Based on genetic and morphologic criteria, *P. carinii* was placed with *S. pombe* in the Phylum Ascomycota within a newly described Class, Archiascomycetes, without designation of an order (1). In contrast, Erikkson proposed the creation of the Family *Pneumocystidaceae,* Order *Pneumocystidales,* based solely on gene sequence comparisons (35).

The morphological characteristics of *Pneumocystis* organisms are very similar regardless of the host origin. Until 1976, *"P. carinii"* was thought to represent a single zoonotic species. At that time, Frenkel described serological differences between human- and rat-derived organisms that he suggested were representative of distinct species (37), but these assertions were largely ignored by the medical community. However, it is now clear that the organism first identified as *"P. carinii"* is actually a family of related organisms that exhibit mammalian host specificity. Almost every mammal examined to date appears to harbor at least one species of *Pneumocystis* that is not found in any other mammal. Four species have been formally described (87): *P. carinii* (37, 38) and *P. wakefieldiae* (21, 26) infect rats; *P. murina* is found in the lungs of mice (53); and *P. jirovecii* is the name given to the organisms that cause infection in human beings (37, 38). The name *P. jirovecii* has not been without controversy (27, 40), and it remains to be seen if this epithet will be retained by the scientific community.

DESCRIPTION OF GENUS *PNEUMOCYSTIS*

The terminology used to describe the various life cycle stages of *Pneumocystis* bears remnants of its earlier classification as a protozoan parasite (7, 13). This discussion introduces terms more suitable for its fungal identity but retains those commonly found in the literature for continuity. Three developmental forms are generally recognized: the trophozoite (trophic stage), 1 to 5 μm (Fig. 1A); the precyst (sporocyte), 5 to 8 μm (Fig. 1B); and the cyst (spore case), about 8 μm (Fig. 1C to E). *Pneumocystis* organisms reproduce extracellularly within the mammalian lung alveoli. The trophic forms appear ameboid in structure in electron micrographs, but in freshly prepared specimens, they are ellipsoidal and often occur in clusters with other trophic forms and developmental stages. The nucleus and (often) the mitochondrion are visible in rapid Wright-Giemsa-stained specimens by light microscopy. The trophic forms do not stain with fungal stains designed to complex with the cell wall, such as methenamine silver. The sporocyte is smaller than the mature cyst and frequently oval. This stage contains a rigid cell wall lacking in the trophic forms and is visualized with fungal cell wall stains. At the sporocyte stage, the nuclei are at varying levels of nuclear division (from 2 to 8 nuclei) but have not yet been compartmentalized into separate spore structures. Aggregates of mitochondria can also be seen in this stage. The mature cyst is spherical; contains eight spores, although these may not all be visible; has a thick cell

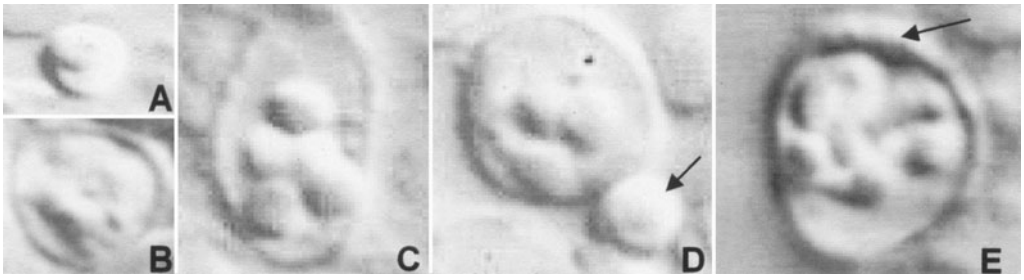

FIGURE 1 Major developmental forms of *Pneumocystis.* (A) Single trophic form; (B) sporocyte (precyst); (C) cyst with four visible spores (intracystic bodies); (D) cyst with three intracystic spores and a spore that has apparently excysted (arrow); (E) cyst with localized thickening of the cell wall (arrow) and eight visible spores. Nomarski Interference Contrast microscopy; magnification, ×1,000.

wall that excludes stains such as the rapid Wright-Giemsa stain; and stains with cell wall complexing stains such as methenamine silver. It is considered the diagnostic morphological form. All developmental forms and various poorly defined intermediate stages are often found in tightly adherent aggregates or clusters in clinical specimens, making identification of each stage difficult.

EPIDEMIOLOGY AND TRANSMISSION

In the late 1970s and early 1980s Walzer et al. (108) and Hughes (46) conducted a series of animal studies that showed that *Pneumocystis* infection was likely transmitted by an airborne route. *Pneumocystis*-free rats could acquire the infection from infected rats housed in the same room or from infected cage mates. Transmission through water, food, or ingestion of infected lungs was not observed in the same experimental studies. Although *Pneumocystis* DNA could be detected in air samples from patient rooms (5) and from an orchard after extensive sampling (104), no laboratory has been able to identify the agent of transmission.

Putative Life Cycle

Histochemical and ultrastructural studies form the basis of the current understanding of the life cycle of *Pneumocystis,* due to a historic lack of a long-term cultivation method outside the lung. Thus, any life cycle should be considered presumptive until definitive kinetic analyses are able to be performed. Human- and rat-derived *Pneumocystis* have been the most extensively studied of the organisms in this group, and discussion of the life cycle is based on these findings (6, 7, 13, 24, 64). There is no evidence for an intracellular phase, although the organisms can be frequently observed within macrophages as a result of the host response to the infection.

A schematic of a proposed life cycle can be found in Fig. 2, with a detailed description provided in the legend. Trophic forms are presumed to be the vegetative stages of the *Pneumocystis* life cycle and reproduce asexually by binary fission, not budding, as do most yeasts. It is likely that they also participate in the sexual mode of reproduction using a process similar to yeast mating type systems, although these processes are only now beginning to be defined (90, 99, 103). Several fungal meiosis-specific and mating type gene homologs have been identified in cDNA and genomic *P. carinii* databases, lending credence to the existence of these processes (17, 18, 25). Subsequent to the mating process and karyogamy (nuclear fusion), the zygotic nucleus undergoes meiosis and sporogenesis is initiated, resulting in formation of the precyst, or sporocyte. Following meiosis, an additional mitotic replication occurs, with subsequent compartmentalization of the nuclei and organelles into eight ascospores. The end product of sporogenesis is the spherical cyst, or spore case. The process of spore release has not been described but may involve a localized thickening at one pole of the spore case (cyst) (114). It should be noted that unlike other fungi, all the developmental stages of *Pneumocystis* contain a double membrane (30).

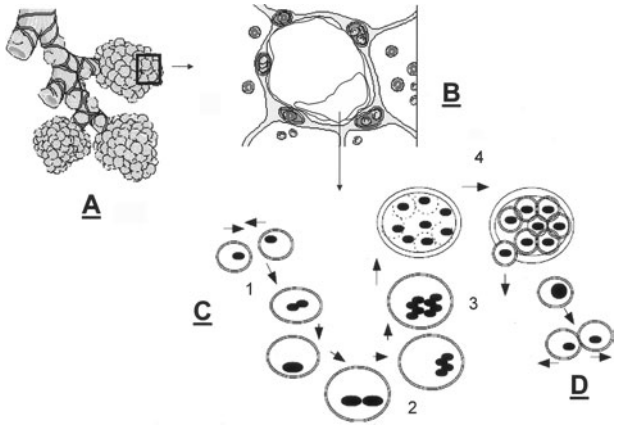

FIGURE 2 Proposed life cycle of *Pneumocystis.* (A) The primary site of *Pneumocystis* infection is the lung alveoli. Three clusters of alveoli are illustrated. An expanded schematic of an alveolus (box) is shown in panel B. (B) Single alveolus with *Pneumocystis* organisms depicted as hatched shape attached to the cells lining the alveoli in some areas (type I pneumocytes) and unattached to other alveolar cells (type II pneumocytes). (C) Putative sexual cycle of *Pneumocystis* in the lung alveoli: (1) opposite mating types fuse and undergo karyogamy, resulting in a diploid zygote; (2) the zygote then undergoes meiosis, resulting in four nuclei; (3) additional postmeiotic mitotis increases the number of nuclei to eight; (4) the nuclei and mitochondria (not shown) are compartmentalized by invagination of the inner plasma membrane, resulting in eight spores. Spores are released from the ascus (cyst) and presumably enter into the vegetative phase of the cycle. (D) Asexual replication cycle of *Pneumocystis*. Trophic forms undergo binary fission after mitotic replication of the nucleus. (Drawn with SmartDraw Suite, ed. 7.3.)

Despite numerous attempts to do so, an environmental cycle for *Pneumocystis* has not been identified. A growing body of evidence suggests that the reservoir for *Pneumocystis* is its mammalian host, a situation similar to that of other host-dependent pathogens like *Entamoeba histolytica* or *Mycobacterium tuberculosis*. Studies with humans and animal models further support a role for neonates and immunocompetent hosts as potential reservoirs, perhaps transiently or longer term.

Transmission and Epidemiology

Evidence from several different studies suggests that (i) *Pneumocystis* is transmitted by an airborne route; (ii) it is likely to be acquired early in life; (iii) it can be transmitted among immunologically intact individuals; (iv) immunosuppressed and infected hosts are able to transmit the infection to immunologically intact hosts; and (v) transmission requires a short period of exposure and low numbers of organisms.

Beard et al. reported that the expansion of *P. jirovecii* carrying a double mutation in the DHPS gene in selected members of the human immunodeficiency virus (HIV)-infected population provides strong support for transmission of *P. jirovecii* by a person-to-person route as well as a positive selective mechanism (10, 70). Previous and recent epidemiological surveys showing the clustering of *P. jirovecii*-specific genotypes with patients' place of residence are consistent with the hypothesis of person-to-person transmission of *P. jirovecii* via the airborne route (12, 68).

Serological studies performed in the 1970s through the 1980s showed that *P. jirovecii* was acquired early in life (82, 84). Most human beings become seropositive to *P. jirovecii* organisms or antigens by the ages of 2 to 4 years. Vargas et al. detected *P. jirovecii* DNA in nasopharyngeal aspirates in 24 of 72 infants (32%) suffering from mild respiratory infections (101). Seroconversion developed in 67 of 79 (85%) of the same cohort of infants by 20 months of age. In the rat model of infection, newborn rats acquired *Pneumocystis*-specific DNA in their oral cavities by 1 to 2 h after birth (49). No evidence for in utero transmission in rats was found after extensive analysis of fetal tissue by PCR, suggesting that the neonates were infected through close contact with the mother or through the air.

Experimental evidence indicates that very few organisms are required to initiate *Pneumocystis* infection and that the organism is very efficient in its method of transmission. Studies have shown that fewer than 10 *P. carinii* organisms were sufficient to establish a fulminate infection in immunosuppressed rats (22, 52) and that a 1-day period of exposure was all that was needed to transmit the infection from an infected *scid/scid* mouse to a *scid/scid* noninfected mouse (91). Likewise, transmission from infected patients to immunocompetent health care workers has been reported (102). The widespread prevalence of *Pneumocystis* in commercial colonies housing healthy rats (20, 28, 48) not only supports the very efficient dissemination of the infection throughout the members of a colony but also shows that the organism thrives in the immunocompetent host. Evidence that healthy human populations may also serve as reservoirs or sources of infection is accumulating. A recent study conducted with humans without underlying lung disease or immunosuppression found that 20% of the oropharyngeal wash samples from 50 persons were positive for *P. jirovecii* by nested PCR targeting the mitochondrial large subunit ribosomal gene (65). Further studies employing quantitative PCR should help to resolve the potential use of PCR as a diagnostic tool versus its use as a detection method.

Colonization

Emerging reports of the detection of *P. jirovecii* in populations without underlying immunosuppression as well as in those with chronic underlying diseases that have not been historically associated with its presence may suggest colonization or expansion of host range (65, 70, 71, 83). Colonization, carriage, asymptomatic infection, and subclinical infection have all been used to describe the presence of *Pneumocystis* organisms or DNA in the absence of *Pneumocystis* pneumonia (PCP). The effects of the presence of low numbers of *P. jirovecii* on the host have yet to be determined, and the role of carriage in mild respiratory infections, chronic lung disease, and progression to PCP is now being actively investigated. The most common underlying conditions in non-HIV-positive individuals associated with the presence of *P. jirovecii* include asthma and chronic lung diseases, chronic obstructive pulmonary disease, cystic fibrosis, Epstein-Barr virus infection, lupus erythematosis, rheumatoid arthritis, thyroiditis, ulcerative colitis, and pregnancy; the presence of *P. jirovecii* has also been noted in patients receiving high doses of corticosteroids (83).

CLINICAL SIGNIFICANCE

PCP remains the leading opportunistic infection associated with AIDS patients, even in the era of highly active antiretroviral therapy (51). Within the mammalian lung, the trophic forms of *Pneumocystis* adhere to the type I pneumocytes presumably through macromolecular bridges (60, 85, 113). Type I cells are responsible for the gas exchange between the alveolar capillaries and the alveolar lumen. Besides attachment to the type I cells, the various developmental stages of the parasite adhere to one another, producing large clusters that extend outwardly into the alveolar lumen. In severe, untreated infections, most of the alveoli are filled with organisms. Direct attachment to the cells responsible for gas exchange combined with the accumulation of organisms within the alveoli results in impaired gas exchange and altered lung compliance, as well as other physiologic changes associated with the pneumonia, such as hypoxia (44, 112).

Histopathologic findings can be characterized by two traits: (i) alveolar interstitial thickening and (ii) a frothy eosinophilic honeycomb-like exudate in the lumina of the lung. The interstitial thickening is a result of hyperplasia and hypertrophy of the type II pneumocyte, interstitial edema, mononuclear cell infiltration, and in some cases mild fibrosis. The exudate is apparent upon staining with hematoxylin and eosin, which does not stain the organisms. Methenamine silver or another yeast cell wall stain must be used to visualize the cyst form of the organism, considered the diagnostic stage.

Presentation in Children

PCP was first described as occurring in children and was considered a pediatric infection in its early history (39). Prominent epidemics of "interstitial plasma cell pneumonia" in undernourished children housed in suboptimal conditions after World War II were manifestations of the disease that was later identified as *P. jirovecii* pneumonia (47). The infection in these children was characterized by a plasma cell infiltrate, in contrast to the type II cell hypertrophy and scanty mononuclear infiltrate described in adults with the pneumonia (109). PCP in children can be associated with cyanosis, flaring of the nasal alae, a mild cough without fever, and retractions of intercostals in severe disease (109). Of note, whereas adults with $CD4^+$ cell counts of less than 200 per microliter are at increased risk for PCP, children less than a

year old who developed the pneumonia had $CD4^+$ counts greater than 1,000 per microliter (63).

Presentation in Adults

Adults with PCP frequently present with dyspnea, nonproductive cough, inability to breathe deeply, chest tightness, and night sweats (44). A low-grade fever (e.g., 38.5°C) and tachypnea are often present, while hemoptysis or sputum production is rare. Upon physical examination, few pronounced abnormalities are detected, but various degrees of respiratory distress, small respiratory volumes, and fine basilar rales can be observed. Patients with AIDS often have a more insidious progression to clinical disease than do those not infected with HIV but who are immunosuppressed.

The chest X ray may appear normal or reflect a disease state. Diffuse, symmetrical, interstitial infiltrates are most commonly present, while focal infiltrates, lobar consolidations, cavities, and nodules are less common. Infiltrates in early infection may be widely distributed, but consolidation increases as the disease progresses. Administration of aerosolized pentamidine as a prophylactic measure has been associated with increased frequency of apical infiltrates and pneumothoraces (92). The severity of abnormalities on the chest radiograph is considered prognostic and can be correlated with higher mortality.

The oxygenation impairment induced by pneumocystosis can be detected in most patients by a widening of the alveolar-arterial oxygen gradient [(A-a)DO_2] correlated with severity of disease and respiratory alkalosis (69). However, it should be noted that a significant number of patients can have a normal (A-a)DO_2 gradient at rest. Impaired diffusing capacity, alterations in lung compliance, total lung capacity, vital capacity, and hypoxemia are other physiologic changes that may be associated with *P. jirovecii* infection (44). Abnormalities in surfactant proteins also occur in infected individuals, with increases in surfactant protein A and D being most notable, since these proteins are considered components of innate immunity (3, 59, 86).

Extrapulmonary Pneumocystosis

The incidence of *Pneumocystis* organisms in sites other than the lung has been reported in 1 to 3% of postmortem examinations of patients with pulmonary *P. jirovecii* infections (79, 98). This is likely an underestimate due to the limited number of autopsies performed and the lack of suspicion of extrapulmonary pneumocystosis. Methenamine silver staining or immunofluorescent kits served to identify the cyst stage of *Pneumocystis* in tissue samples and fine needle aspirates in antemortem cases. The lymph nodes were the most frequent site of extrapulmonary involvement in a series of 52 patients (44%), followed by the spleen, bone marrow, and liver (33%). *P. jirovecii* has been detected in the adrenal glands, gastrointestinal tract, genitourinary tract, thyroid, ear, liver, pancreas, eyes, skin, and other sites. Infection of multiple extrapulmonary sites was associated with a rapidly fatal outcome. Pathological findings correlated with the organ where the infection was present. For example, retinal cotton wool spots were reported in infected eyes and pancytopenia was observed in patients with bone marrow lesions.

COLLECTION AND HANDLING OF SPECIMENS

P. jirovecii pneumonia should be considered in any immunocompromised patient who presents with fever, respiratory symptoms, or infiltrates on chest X ray. Although they are mostly restricted to the lung, *P. jirovecii* organisms have been found as extrapulmonary masses (e.g., pleura, intra-abdominal) in HIV-positive patients and should be included in a differential diagnosis for such patients. As no symptoms are specific for *P. jirovecii* pneumonia, a definitive diagnosis must be made by morphologic identification of the organism. An algorithm from the NIH for clinical evaluation and treatment of PCP was recently updated, and the reader is referred to this review for further details (54).

The diagnosis of PCP relies on efficient sampling. The organism can be detected in a variety of respiratory specimens including induced sputum, bronchoalveolar lavage fluid (BALF), tracheal aspirate fluid, tissue obtained by transbronchial biopsy, cellular material obtained by bronchial brush, pleural fluid, and tissue obtained by open-thorax lung biopsy. The diagnostic yield is dependent upon the underlying disease state of the patient and the expertise of the staff obtaining the sample. In some hospitals where the staff is trained to obtain sputum samples and there is a large population with AIDS, 80% of diagnoses of PCP were made from induced sputum (42). In contrast, the diagnostic yield from non-AIDS patients can be quite low and BAL or other methods may be needed to ensure an appropriate diagnosis (9, 45). It is recommended that multiple slides from non-AIDS patients be examined, especially when there is a high degree of suspicion. Hospitals serving a diverse population often rely on methods other than induced sputum. A notable drawback of using induced sputum as the primary procedure for the diagnosis of PCP is the lack of information concerning other infections or disease processes that may be present in the lung. The diagnosis of extrapulmonary pneumocystosis relies on accurate sampling of the infected organ and subsequent staining of the histological sections. For infants and young children who are unable to produce sputum or for whom this method is not warranted, tracheal aspirate fluid, open-thorax lung biopsy, or respiratory specimens must be obtained by a special pediatric bronchoscopy service (11, 101).

BAL

Fluid obtained by BAL is sufficiently liquid and does not require treatment with mucolytic agents. Twenty to 30 ml should be concentrated by centrifugation at $3,000 \times g$ for 15 min. The resultant pellet is reconstituted in 0.5 to 1.0 ml of buffer or saline, and a sterile wooden applicator is used to smear the sediment on glass slides, which are then fixed in absolute methanol, acetone, or a commercial fixative in rapid staining kits. Samples in limited quantities can be concentrated by use of a Cytospin Centrifuge (Shandon Southern, Sewickley, Pa.) or the equivalent. Addition of 1 drop of 22% bovine serum albumin to 500 μl of sample aids in adherence to the slide. The slides are air dried and then processed for staining. Morphological criteria for recognition of *P. jirovecii* stained by various procedures are discussed below and summarized in Table 1.

Induced Sputum Collection

Sputum collection is best done in a centralized facility by pulmonary function laboratory technicians, respiratory therapists, or specially trained assistants. Deep inhalation of nebulized 3% sodium chloride solution by the patient results in osmotic accumulation of fluid in and irritation of the respiratory passages with subsequent coughing and expectoration of bronchoalveolar contents. It is important to have the patient vigorously brush the teeth, tongue, and gums with a toothbrush and normal saline for 5 to 10 min prior to

TABLE 1 Comparison of stains used to detect *P. jirovecii*

Stain (reference[s])	Time to perform staining	Cyst wall	Trophic and other forms	Advantages	Disadvantages
Giemsa (2, 23)	30–60 min	Unstained. Cyst wall appears as a clear ring around spores or intracystic bodies.	Nuclei stain red-purple; cytoplasm stains light to dark blue, depending on thickness and depth of cluster.	Inexpensive. Stain simple to perform. Stains all life cycle stages of *Pneumocystis*. Stains most other pathogens (e.g., bacteria, parasites, fungi) and host cells.	Experienced reader required to distinguish *Pneumocystis* clumps from stained host cells.
Rapid Giemsa-like stains (e.g., Diff-Quik) (2, 23, 78)	<5 min				
Fluorescein-conjugated monoclonal antibody kits (direct and indirect immuno-fluorescence) (34, 41, 55, 76–78, 80)	15–30 min	Stains and fluoresces apple green. Cyst contents usually unstained (appears black) or dull. Fold in cyst wall sometimes apparent, giving a crinkled, raisin-like appearance.	Stained. Appear as small polygons or spheres outlined in apple green. Nuclei may stain. Clusters can stain with a diffuse green glow.	Recommended for less inexperienced personnel. Immunofluores-cent staining is sensitive and specific for *Pneumocystis*.	Requires fluorescent microscope. Reagents are expensive.
Methenamine silver (Gomori/Grocott) (15, 61)	30 min (microwave); 1–2 h (rapid); 6–24 h (con-ventional).	Stains brown to black. Cyst wall thickenings (double comma) and fold in the cyst wall stain dark brown to black. Does not differentiate empty cysts from those with spores.	Unstained	Easy to detect cysts. Host cells not stained.	Prolonged staining time for conventional method. Moderate costs. Strong acids used. Only the cyst form is stained. Stains other fungi.
Toluidine blue O/cresyl echt violet (15, 80)	1–6 h	Stains violet to purple. Cyst wall thickenings and folds stain darker violet to purple. Does not differentiate empty cysts and cysts with spores.	Unstained	Easy to detect cysts. Host cells not stained.	Prolonged staining time. Moderate costs. Strong acids used. Only the cyst is stained. Stains other fungi.
Calcofluor white (8, 94)	<5 min	Stains blue-white or green, depending on filter. Cyst wall and thickenings intensely fluorescent.	Unstained	Cyst fluoresces brilliantly. Simple to perform. Inexpensive.	Requires fluorescent microscope. Strong alkali used. Only cyst is stained. Stains other fungi. Some expertise is required to distinguish *Pneumocystis* cysts from other fungi.
Gram-Wiegert (4)	<5 min	Unstained wall. Intracystic bodies stain purple.	Trophic forms faintly visible.	Commonly available in cytopathology laboratories.	Faint staining. Can be overcome by experienced observer, but better stains are available.
Papanicolaou (89)	1–6 h	Unstained wall. Intracystic bodies stain purple.	Trophic forms faintly visible.	Commonly available in cytopathology laboratories.	Faint staining. Can be overcome by experienced observer, but better stains are available.

sputum induction, followed by thorough rinsing, to remove as much cellular debris of oral origin as possible. Toothpaste should not be used, as it can interfere with subsequent processing and staining of the specimen. The induced-sputum specimen is usually mucoid and translucent in appearance; only rarely is it purulent. When *P. jirovecii* clusters are present in the unstained sputum, they are typically 0.1 to 0.2 mm in diameter and cream to light tan in color. Smearing of the sputa directly onto slides and subsequent staining were shown to be a less sensitive method than treatment with a mucolytic agent followed by concentration of the specimen (62, 76).

Induced sputum is mucolyzed by the addition of an equal volume (at least 2 ml) of freshly prepared 0.0065 M dithiothreitol (Stat-Pak Sputolysin; Caldon-Biotech, Carlsbad, Calif.) or 0.5% *N*-acetyl-L-cysteine and incubation on a rotary shaker at 35°C with intermittent vigorous vortexing until the specimen is almost completely liquefied (complete liquefaction leads to dispersal of the *P. jirovecii* clusters, making microscopic detection more difficult). Some protocols require the addition of a clearing reagent for optimal results (e.g., kits for direct fluorescent-antibody [DFA] staining available from Chemicon International, Inc., Temecula, Calif.). The specimen is then concentrated by centrifugation at 3,000 × *g* for 5 min, and the sediment is smeared on glass slides, which are air dried and heat fixed by exposure to a heating block (50 to 60°C). Prolonged heat fixation is important in fixing the material to the slide (~30 min), since most of the natural cellular adhesions are removed during mucolysis. Slides containing the fixed material are then stained and examined microscopically (see below). Samples can be concentrated using a Cytospin centrifuge as described for BALF (above).

Open-Thorax Lung Biopsy

Open-thorax lung biopsy is the most invasive of the sampling procedures and is not routinely performed. This technique also suffers from a lack of sensitivity (54). However, should the laboratory receive such a specimen, the tissue should be blotted onto sterile gauze to reduce excess fluid, (which would interfere with a diagnostic imprint) and used to make touch imprints by pressing several cut surfaces onto sterile glass slides. The remainder of the tissue can be used for histological sections or for microbiological cultures after mincing or grinding. Glass slides with touch imprints should be air dried and then treated with absolute methanol or fixatives included in commercial kits of rapid Wright-Giemsa-like stains, such as Hema 3 (Fisher Scientific Inc., Cincinnati, Ohio). Infected tissue stained in this manner reveals the presence of clusters of trophic forms and cysts with reddish purple nuclei and blue cytoplasm surrounded by a halo of dye exclusion (see "Microscopic Identification" for a more detailed description). Slides should be fixed in acetone or a vendor-recommended fixative for immunofluorescent staining. Alternatively, a more concentrated sample can be achieved by maceration of the tissue with sterile scissors followed by homogenization in a Lab Blender designed to reduce the risk of aerosolization or potential contact by laboratory personnel (i.e., Stomacher Lab Blender; Tekmar Inc., Cincinnati, Ohio) for 10 to 20 min in 5 ml of saline or buffer/g of tissue. After sieving through sterile gauze to filter out large tissue particulates, the supernatant is concentrated by centrifugation (3,000 × *g* for 10 min) and then reconstituted in 1 to 5 ml of saline or buffer. Slides are prepared with 10-μl drops of the homogenate, which are then air dried, fixed, and stained as desired.

Transbronchial Biopsy

Fiberoptic bronchoscopy is the most common invasive technique for collection of tissue, but like open-thorax lung biopsy, this procedure is rarely performed today. Tissue should be handled as described above for open-thorax lung biopsy.

Nasopharyngeal Aspirates

Recent studies with humans reported the ability to detect *P. jirovecii*-specific DNA in nasopharyngeal aspirates (101) and oropharyngeal washes (71, 100) after amplification by PCR with *P. jirovecii*-specific primers. Current studies are exploring the use of oropharyngeal swabs as an additional sampling method. Although further studies addressing the correlation of the presence of *P. jirovecii* in the oral cavities and the disease state of the host are needed, handling and staining of nasopharyngeal aspirates are presented here because the use of PCR is becoming widespread for the diagnosis of infectious diseases. This method is extremely useful for sampling of pediatric populations where more invasive techniques of sampling are problematic or where the yield is low.

The aspirates are collected using a suction catheter and sterile saline. If the amount of collected specimen is small or it is highly viscous, sterile saline should be washed through the catheter to dilute the specimen or added to the final collection tube. The sample can then be treated with a mucolytic agent and subsequently stained (as described above) or prepared for PCR by DNA extraction (described below).

IDENTIFICATION AND DIAGNOSIS

Microscopic Identification

A variety of stains have been used for the identification of *P. jirovecii* organisms. One of the most common stains used by pathologists for tissue sections, hematoxylin and eosin, does not stain the organism but rather the foamy exudates within the lung alveoli, often described as "honeycombed" in appearance. Stains that illustrate the morphology of the organism by microscopic examination are those used for diagnosis in the clinical laboratory.

A common staining procedure used for the diagnosis of PCP is methenamine silver, which also stains other fungi (Table 1). Cell wall and membrane polysaccharides of fungi are oxidized to aldehydes by treatment with periodic acid, which in turn reduce the silver ion to metallic silver at alkaline pH. Addition of gold salts stabilizes the complex, and excess silver is removed by a sodium thiosulfate rinse. Variations of the methenamine silver stain (e.g., Grocott's or Gomori's) are used for both tissue sections and bodily fluids such as BALF or induced sputum (15, 61, 89). The disadvantages to use of the silver staining process have been the instability of solutions, the capricious nature of the metal impregnation, and the length of time required for staining (1 to 2 h [rapid process], or 6 to 24 h [conventional process] [Table 1]). These disadvantages have been largely overcome with kits using standardized laboratory microwave ovens for controlled processing and supplied reagents (e.g., Modified GMS Microwave staining kit; EBSciences, Agawam, Mass.). Unlike other pathogenic fungi, *P. jirovecii* does not bud, and this feature can be used to discriminate between these organisms and other fungi found in the lung that bud, e.g., *Histoplasma capsulatum*. Silver-stained cysts have a distinctive, black, cup-shaped morphology against green-colored host cell architecture. In some staining reactions, cyst wall thickenings appear as a "double comma" morphology. More

often the folds in the wall stain a dark brown to black to produce a crinkled, raisin-like appearance (Fig. 3C). Intracystic daughter forms cannot be seen with this stain, and cysts that are empty (nonviable) appear the same as those with the full contingent of eight spores.

Other stains that complex with components of the cyst wall include periodic acid-Schiff, toluidine blue, cresyl echt violet, and calcofluor white. The reactions to some of the more commonly used stains are described in Table 1. Cresyl echt violet stain produces results similar to those of the toluidine blue O (Fig. 3D) and has the same drawbacks, since a mixture of sulfuric acid and glacial acetic acid is necessary for the step prior to staining with the dye (15).

In contrast to the cyst wall stains, Giemsa and rapid Giemsa-like stains do not stain the cyst wall but instead stain the nuclei of all the various life cycle stages a reddish purple and stain the cytoplasm a light blue (Fig. 3A1–4). The cyst wall excludes the dyes and appears with a circumscribed clear zone surrounding the reddish purple nuclei of the daughter forms within (Fig. 3A1). Originally used for quantitation of rat *P. carinii* organisms (23, 78), the rapid variants of the Giemsa stain are recommended for the diagnosis of PCP by using BALF, induced sputum, or impression imprints because of the low cost, ease, and rapidity of the staining procedure. Commercial kits such as Hema-Quik (Fisher Scientific Co.) produce similar results. The staining procedure requires less than a minute to perform, and all forms of the organism are detected. Since there are approximately 10-fold more trophic forms than cysts, the sensitivity of detection is likely to be increased. This stain also permits the assessment of specimen quality of BALFs by demonstration of host alveolar macrophages, which should be present in a productive sample. In addition, the distinctive Giemsa-stained morphological appearances of other organisms likely to be encountered in the lung environment, such as *Cryptococcus neoformans* or *Toxoplasma gondii,* permit rapid diagnosis of pulmonary infections caused by these pathogens, which may not be detected with other stains. Because background host cells also stain, training and expertise in interpreting cellular elements in the Giemsa-stained preparations are necessary. Laboratories with a lower volume of *P. jirovecii* specimens may prefer to use immunofluorescent staining or one of the other stains described in Table 1.

Direct and indirect fluorescein-conjugated monoclonal anti-*P. jirovecii* antibodies used for immunofluorescent assay are targeted to a family of surface glycoproteins that contain both common and distinct epitopes, within and among *Pneumocystis* species (95). Depending on the monoclonal antibody supplied with the kit, staining may target only the cyst form or all forms of the organism. Since trophic forms are more numerous than cysts, kits using those antibodies directed to all forms of the organism (such as "2G2" and "3F6"; available from DAKO Corp., Carpinteria, Calif., or Chemicon International Inc.) are more sensitive (54). The typical fluorophore conjugated to the antibody or used in an indirect assay is fluorescein isothiocyanate, which produces a brilliant apple green color. The staining reaction shows a diffuse surface pattern distributed over the entire cluster of organisms (Fig. 3B) and often stains the matrix in which the organisms are embedded. Single cysts usually appear with a distinctive rim of fluorescence and duller interior fluorescence. It should be noted that kits using a direct staining procedure may not react with *P. jirovecii* on slides fixed in ethanol (34) and fixation in acetone or vendor recommendations for fixation should be followed.

Papanicolaou's stain, frequently used for cytopathological specimens, stains the clusters of extracellular organisms a pink color, although cysts within a macrophage appear greenish in color (Fig. 3F) (4). Organism architecture is better observed with the Giemsa-like stains. Likewise, Gram's stain produces a negative (pink) reaction with poorly defined organism morphology.

PCR Detection and Other Diagnostic Modalities

Detection of *Pneumocystis* by growth in artificial media or tissue culture is not a diagnostic option since no species of the organism can be continuously cultivated outside the mammalian lung.

Serological assays to detect anti-*P. jirovecii* antibodies are useful for epidemiological studies but not for diagnosis of PCP. Most human beings become seropositive for *P. jirovecii* antibodies early in their childhood, at 2 to 4 years of age (107) and likely come in contact with the organism many times over their lifetimes. In some cases, a rise in antibody titer can be detected in some PCP patients over time; in others, antibody titers can just as frequently drop or remain the same. Likewise, antigen capture assays for *P. jirovecii* antigens have not proven clinically useful.

A number of other laboratory tests have been used for the diagnosis of PCP but do not provide a definitive diagnosis. These include an increased arterial-alveolar gradient; an elevation of serum lactic dehydrogenase levels; and gallium and diethylenetriamine penta-acetic scans (109). The last two tests are not routinely used due to higher costs.

Amplification of *P. jirovecii* DNA is not yet used routinely for the diagnosis of PCP in the clinical laboratory setting. Although more sensitive than conventional methods relying on organism detection by microscopic methods, the presence of a specific *P. jirovecii* PCR product has not been strictly correlated with underlying disease (2, 54, 81). In contrast to conventional methods of detection, PCR-based methods can be more labor-intensive, expensive, and time-consuming. As the clinical laboratory begins to rely more on these amplification techniques or other molecular modalities in the future, it is likely that *P. jirovecii* detection will be included in the battery of infectious disease kits offered by commercial vendors. However, a PCR technique may be considered useful at this time for clinical samples that require detection of early infection or cases in which PCP is suspected but no organisms were detected. Significantly, evidence is accumulating for the emergence of drug resistance in human *P. jirovecii* and PCR can be used for identification of potentially resistant strains of the organism. Although the significance of infections with multiple genotypes of *P. jirovecii* is currently unclear, PCR-based detection systems would also be able to detect PCP caused by single or multiple genotypes.

Detection of the presence of *P. jirovecii* can be accomplished by targeting the large ribosomal subunit of the mitochondrial rRNA (mtLSU) using direct or nested PCR (31, 105). This gene is present in multiple copies per organism and provides the most sensitive target for detection. DNA can be isolated from clinical samples by using commercial kits such as the PhaseLock System (Eppendorf Scientific, Westbury, N.Y.) or a series of products designed for the clinical laboratory by vendors such as Qiagen (Valencia, Calif.). The primers targeting the mtLSU and PCR conditions are listed in Table 2. The expected amplicon size of the first product is approximately 346 bp, and that of the second is 267 bp. If genotyping of the isolates is desired, the PCR amplicon can be sequenced directly or by cloning and subsequent sequencing of the clones. Cloning permits the

assessment of the presence of infections caused by more than a single genotype. Manuals of molecular methods or vendor instructions should be consulted for these procedures. There are 4 genotypes defined by the mtLSU locus (10) and over 60 different genotypes defined using the intertranscribed spacer regions of the nucleus-encoded rRNA locus (57), but such typing is outside the scope of the clinical laboratory at this time.

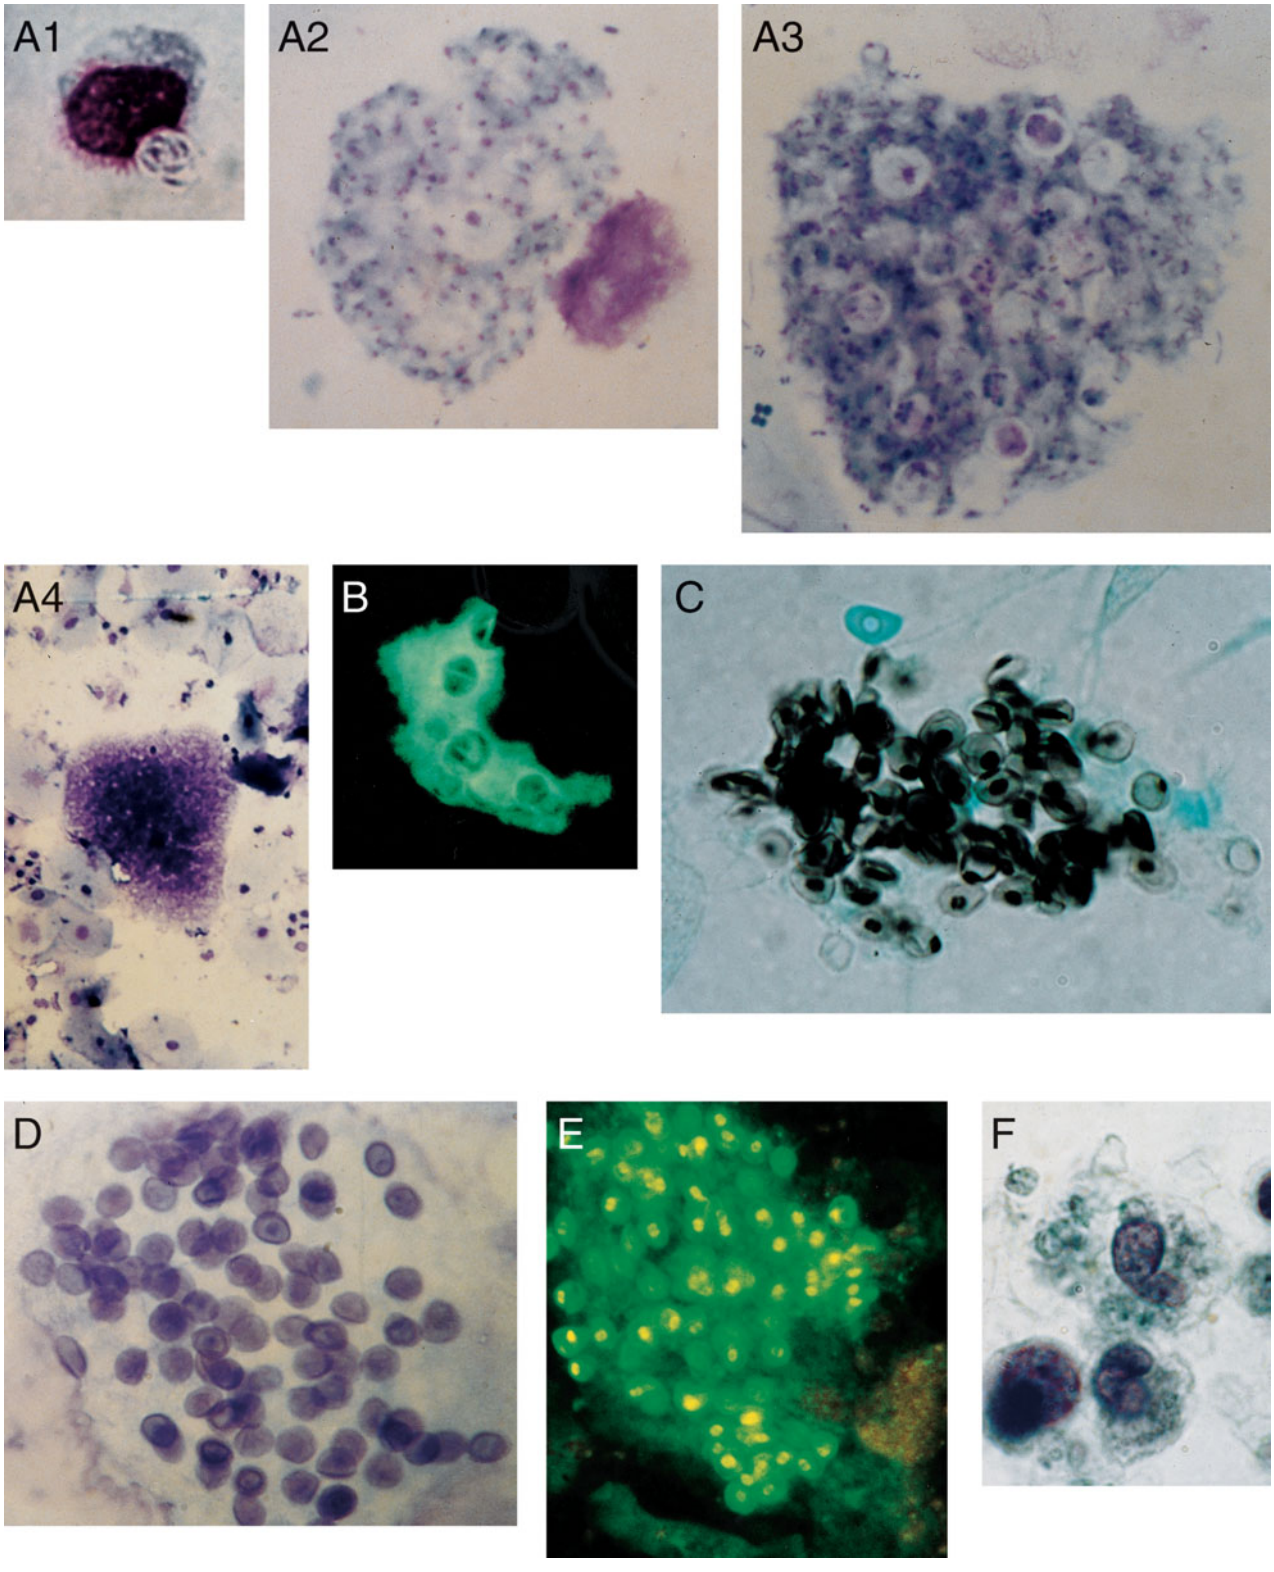

TABLE 2 Suggested primers and conditions for PCR detection of *Pneumocystis*

Gene target	Primer (5′ to 3′ sequence)	Expected product size (bp)	Conditions
MtLSU			
Primary[a]	pAZ102-E (GATGGCTGTTTCCAAGCCCA) pAZ102-H (GTGTACGTTGCAAAGTACTC)	346	94°C for 1 min, 55°C for 1 min, and 72°C for 2 min for 40 cycles; termination, 72°C for 5 min
Nested[b]	pAZ102-X (GTGAAATACAAATCGGACTAGG) pAZ102-Y (TCACTTAATATTAATTGGGGAGC)	267	94°C for 1 min, 55°C for 1 min, and 72°C for 2 min for 35 cycles; termination, 72°C for 5 min
DHPS[c]			
Round 1	F1 (CCTGGTATTAAACCAGTTTTGCC) B_{45} (CAATTTAATAAATTTCTTTCCAAATAGCATC)		94°C for 5 min, 92°C for 30 s, 52°C for 30 s, and 72°C for 1 min for 35 cycles; termination, 72°C for 5 min
Round 2	A_{HUM} (GCGCCTACACATATTATGGCCATTTTAAATC) BN (GGAACTTTCAACTTGGCAACCAC)	300	94°C for 5 min, 92°C for 30 s; 55°C for 30 s, and 72°C for 1 min for 35 cycles; termination, 72°C for 5 min

ANTIMICROBIAL SUSCEPTIBILITIES

Two drugs constitute the mainstay of therapy for acute PCP, trimethoprim-sulfamethoxazole (TMP-SMX) and pentamidine isethionate (109). Secondary treatments such as atovaquone and clindamycin-primaquine have been used for milder forms of the disease, and treatment with corticosteroids has been used to improve the clinical outcome for some patients. PCP remains refractory to most common antifungal and antiprotozoal agents. TMP-SMX is a drug combination that targets the enzymes dihydrofolate reductase (trimethoprim) and dihydropteroate synthase (sulfamethoxazole), both integral steps in the folic acid pathway. Pentamidine is a cationic diamidine that was first used to treat African trypanosomiasis, "sleeping sickness," and later was found to be efficacious as PCP therapy. The mode of action of this drug is not known but may involve suppression of mitochondrial activity (19) or inhibition of topoisomerases (32). These drugs have an overall success rate of 80%, although there is a wide range of effects depending on the study population (110, 111). Neither drug is considered pneumocysticidal, and increasing cases of "breakthrough" PCP have been reported while patients were on prophylaxis with either drug (43). About 11% of those patients on TMP-SMX and 22% of those given pentamidine experienced recrudescence (88). Administration of pentamidine via an aerosolized route delivers the drug efficiently to the areas of infection, but it has been shown to be less effective than other drugs in the treatment of PCP (109). Aerosolized pentamidine administration is typically used for prophylaxis.

Mutations in the DHPS gene of *P. jirovecii* associated with sulfa resistance in other pathogens have been identified in about 50% of the isolates causing PCP in certain geographic areas (10). The presence of the mutations in the DHPS gene

FIGURE 3 Morphology of *Pneumocystis* in clinical samples stained with various stains (magnification, ×1,000 unless stated otherwise). (A) Rapid Giemsa-like (Diff-Quick) stains of induced sputum. (A1) Single mature cyst (8 μm) containing eight fusiform, intracystic bodies with purple nuclei and light blue cytoplasm. Note the clear unstained wall of the cyst at its periphery. The cyst is near an alveolar macrophage. (A2) Cluster of mostly trophic forms (2 to 3 μm) with small reddish purple nuclei and light blue cytoplasm. Boundaries of trophic forms are rarely discernible with this stain. (A3) Thick cluster of *Pneumocystis* containing various developmental forms including precysts with nuclei clustered together; mature cysts with clearly discernible nuclei; and trophic forms overlying each other to produce darker-staining blue cytoplasm. (A4) Thick cluster (magnification, ×250) of overlying *Pneumocystis* stages that appear as a mat of organisms without clearly discernible boundaries. (B) DFA stain of organism cluster from induced sputum. Note apple-green fluorescence distributed over the cluster, with accumulation on a fold in the cyst wall (upper part of cluster). Structures within the cysts are unstained and appear black. (C) Gomori's methenamine silver stain (Grocott) of organisms from BAL fluid. Cyst walls and thickenings (double comma) can be observed. Trophic forms are not stained with silver-based stains. (D) Toluidine blue O stain of *Pneumocystis* in a BAL fluid. Cyst walls are stained purple. The crinkled appearance of the cysts is illustrated with this stain. Note the lack of budding with this and other cyst wall stains. Trophic forms are not stained. (E) Calcofluor white stain of BAL fluid. Cyst walls with internal thickenings (double comma) are highly fluorescent (color varies with barrier filter used). (F) Papanicolaou's stain of pleural fluid. Pneumocystis trophic and cyst forms are phagocytized by the marcrophages. The nuclei of the organisms are dark green, and the cytoplasm is a lighter green. The macrophage nuclei stain dark purple.

of *P. jirovecii* was associated with previous TMP-SMX therapy (66, 72–74, 93), but the impact of the mutations in terms of outcome and response to therapy is not yet clear.

It may become desirable in the future to track the emergence of *P. jirovecii* strains that are resistant to TMP-SMX or to evaluate the potential for therapeutic response. In anticipation of this goal, the primers targeting the regions of the dihydropteroate gene (DHPS) associated with sulfa resistance in other pathogens (50, 56) are shown in Table 2. The nucleotide positions in which the mutations occur are at nucleotides (nt) 165 and 171. Changes at these nucleotide positions result in changes in amino acids. The following are the four genotypes for this target gene (10): genotype 1, nt 165 (A) and nt 171 (C) (resulting in Thr and Pro); genotype 2, nt 165 (G) and nt 171 (C) (resulting in Ala and Pro); genotype 3, nt 165 (A) and nt 171 (T) (resulting in Thr and Ser); and genotype 4, 165 (G) and nt 171 (T) (resulting in Ala and Ser). The last genotype, GT, represents a double mutation in the DHPS gene that has been associated with drug resistance and is emerging as the dominant genotype for *P. jirovecii* isolates in some areas (10). Although atovaquone resistance in PCP has been associated with mutations in the mitochondrial cytochrome b_1 gene (106), resistance to TMP-SMX is much more problematic and identification of mutations in the DHPS gene will likely be the more critical genetic region to evaluate in the clinical setting.

Monitoring of drug efficacy by evaluating organism burdens in clinical specimens, especially BALF, is not practical due to the problems in sampling efficiency. Reasons for the inability to assess organism burdens in response to therapy are that (i) the organisms may colonize discrete regions of the lung not accessible to sputum induction or lavage; (ii) the volume of fluid recovered from an individual patient is variable; (iii) with induced sputum collection, patients vary in their efforts to produce the sample; (iv) microscopic enumeration of trophic and cyst forms may be problematic due to the presence of large clusters that preclude accurate quantitation; and (v) it is not known to what capacity the organisms obtained by induced sputum or BALF reflect the disease state. With the advent of highly sensitive quantitation techniques such as real-time PCR which permits detection of very low template numbers, the problems of accurate quantitation can be overcome. Experimental studies are being conducted to validate the use of real-time PCR for diagnostic purposes (36, 67, 75). However, the same questions of sampling efficiency and predictive ability will remain associated with real-time PCR as well as other issues. Assays targeting genomic sequences will have to be interpreted with caution because they do not provide assessment of organism viability or whether the intact organism is present. A more responsive assay would target quantitation of an mRNA present to determine both diagnosis and viability.

Aspergillus, Fusarium, and Other Opportunistic Moniliaceous Fungi*

PAUL E. VERWEIJ AND MARY E. BRANDT

121

The opportunistic moniliaceous (hyaline or lightly colored) molds constitute a phylogenetically diverse group of common to rare anamorphic (asexual) and teleomorphic (sexual) fungi that typically occur as saprobes in soil, in air, or on plant litter or as facultative plant pathogens. Some of them, especially members of the genus *Aspergillus,* may be recovered from specimens without having any clinical significance. Others are isolated infrequently enough to challenge the diagnostic proficiency of the laboratory, and critical assessment is required to evaluate the significance of their recovery. While several of the genera treated in this chapter include species having either lightly colored or dark (melanized) conidia, the emphasis is on those fungi that grow in tissue in the form of hyaline or lightly colored, septate hyphal elements.

The term "aspergillosis" is used to define infections caused by species of *Aspergillus* (Table 1), but the practice of coining disease names based on the genus of fungus involved is disadvantageous for infections caused by uncommon or rare fungal pathogens. The wide variety of fungi involved makes it difficult to place the organisms into accessible groups, and problems arise when fungus names are changed. To avoid unnecessary name changes for disease names based on the genus of the fungus involved, two major disease groups have been proposed: hyalohyphomycosis and phaeohyphomycosis (4). Although the groups were defined as encompassing similar clinical spectra, they were distinguished by the presence in tissue of septate hyphal filaments without (hyalohyphomycosis) or with (phaeohyphomycosis) pigmentation or melanin in the cell wall. However, some fungi, such as *Scedosporium* species or *Nattrassia mangiferae (Scytalidium dimidiatum),* which form darkly pigmented colonies and conidia in vitro, produce hyaline or lightly pigmented hyphae in tissue. The Masson-Fontana silver stain helps to detect melanin pigmentation of fungal elements in tissue, but the results are not always decisive (see also the discussion in chapter 125). Some fungi with variable pigmentation may stain faintly or inconsistently. In practice, the terms for the disease categories have been used to designate infections caused by fungi that are either moniliaceous or dematiaceous in vitro (see chapter 125). Although it may be useful to have terms for broad categories of mycotic diseases, there are problems in categorizing fungi by color. A subcommittee of the International Society for Human and Animal Mycology has suggested that fungal diseases be named by providing a specific description of the pathology and naming the causative agent, e.g., subcutaneous cyst caused by fungus X (184, 245).

TAXONOMY AND IDENTIFICATION

The opportunistic moniliaceous molds belong to genera of the Ascomycota and Basidiomycota (see chapter 115). Many of these molds propagate asexually, and the sexual stage (teleomorph) is unknown or rarely encountered. Today the relationships between many anamorphs (asexual stages) and their sexual relatives are known through discovery of teleomorphs or are inferred by comparison of nucleic acids. This knowledge is extremely important in understanding fungal relationships and has allowed for the placement of asexual fungi next to their sexual relatives in fungal phylogenetic trees. Rapid developments in this area have led to significant changes in generic and species concepts, particularly among the significant genera *Aspergillus, Penicillium,* and *Fusarium* (74, 176, 185, 228, 255). Although teleomorphs occasionally are isolated in culture, they may be difficult to obtain using routine culture methods. In this chapter, the name of the teleomorph is used for species that are identified mainly by their sexual structures.

Most of the pathogenic molds considered in this chapter are classified in the form-class Hyphomycetes. Identification of Hyphomycetes is based on morphology of the conidia and the mechanisms by which conidia are formed (conidiogenesis; see chapter 115). Three basic tools are necessary for practical observation of these features. (i) An ocular micrometer is essential for determining sizes of conidia or sexual spores when present. Identification of molds often requires comparison with published taxonomic descriptions in which size is often a key criterion for species distinction. (ii) A dissecting microscope with magnification of up to ×60 and basal illumination is useful for the examination of colonies in plates or tubes for the presence of conidia in chains or slimy heads, specialized structures such as Hülle cells, sclerotia, conidiomata, or sexual fruiting bodies forming under the aerial mycelium or embedded in the agar. (iii) Microscopic mounts which allow observation of how a fungus forms its conidia also are necessary. Slide culture preparations are excellent

* This chapter contains information presented in chapter 116 by Lynne Sigler and Paul E. Verweij in the eighth edition of this Manual.

TABLE 1 Classification of *Aspergillus* infection[a]

I. Disease in the otherwise healthy host
  A. Toxicosis or mycotoxicosis
    1. Ingestion of mycotoxins
    2. Ingestion of other metabolites
  B. Allergic manifestations
    1. Allergic asthma
    2. Allergic rhinitis
    3. Allergic sinusitis
    4. Extrinsic allergic alveolitis
    5. Hypersensitivity pneumonitis
    6. Allergic bronchopulmonary aspergillosis
  C. Superficial or noninvasive infections
    1. Cutaneous infection
    2. Otomycosis
    3. Sinusitis
    4. Saprophytic bronchopulmonary aspergillosis
    5. Tracheobronchitis
  D. Invasive infection
    1. Single organ
    2. Multiple organs (disseminated)
II. Infection associated with tissue damage or foreign body
  A. Keratitis and endophthalmitis
  B. Burn wound infection
  C. Osteomyelitis
  D. Prosthetic valve endocarditis
  E. Vascular graft infection
  F. Aspergilloma (fungus ball)
  G. Empyema and pleural aspergillosis
  H. Peritonitis
III. Infection in the compromised host
  A. Primary cutaneous aspergillosis
  B. Sino-orbital infection
  C. Pulmonary aspergillosis
    1. Invasive tracheobronchitis
    2. Chronic necrotizing pulmonary aspergillosis
    3. Acute invasive pulmonary aspergillosis
  D. Central nervous system aspergillosis
  E. Invasive (disseminated) aspergillosis
  F. Gastrointestinal infarction (rare)

[a] Patients infected with other fungi discussed in this chapter may present with similar clinical syndromes, and the fungal structures in tissue may resemble those of *Aspergillus* species.

for many fungi (106), but conidial structures of species of *Aspergillus, Penicillium,* or *Trichoderma* may not be typical in slide culture conditions, and tease or tape mounts are preferred.

Morphologic features of importance for identification of conidial fungi include (i) conidium size, shape, and pattern of septation; (ii) color of conidia and conidiophore, whether light (hyaline or moniliaceous) or dark (dematiaceous); (iii) developmental aspects of conidiogenesis, including the nature of the conidiogenous cell; (iv) mechanism of conidium liberation or dehiscence; and (v) structure of the conidioma (if present). Differences in conidial shape and septation are useful characters for preliminary distinction and have traditionally been used for grouping conidial fungi (known as Saccardo spore groups). Conidia may be nonseptate or may have one or more septa (amerosporae, didymosporae, and phragmosporae, respectively). Some fungi produce both nonseptate and septate conidia, and these conidia are often referred to as micro- and macroconidia. Conidia also vary in shape. Some are long and narrow (scolecosporae), as in *Fusarium* species. Development of a conidium may occur by conversion of an existing cell or several cells (thallic-arthric) or may involve new wall building or blowing out of a portion of the wall (blastic). Conidiogenesis usually occurs at a particular location on a conidiogenous cell. If development occurs at a site that remains fixed and gives rise to more than one conidium, then the site is stable or determinate. If development occurs at new points on the conidiogenous cell (or axis), then the site is unstable or indeterminate. New sites may occur on an axis which lengthens (progressive) or shortens (retrogressive). The conidiogenous cell produces a single conidium or multiple conidia. Sympodial development involves the development of a single conidium at successive sites on a lengthening axis. Conidiogenous cells which are specialized to produce multiple conidia include the phialide and annellide. Conidia are produced successively (serially) and develop in slimy masses or in chains, with the youngest at the base of the chain (basipetal). Although it is sometimes difficult to differentiate between the two types of cells, the annellide elongates and sometimes narrows during the formation of each new conidium, leaving an often imperceptible series of rings or scars on the conidiogenous cell. Scrutiny of the cell by use of an oil immersion objective may be necessary to make this distinction. Conidia may form also in acropetal chains, with the youngest conidium at the tip of the chain. The distinction between acropetal and basipetal chains may be revealed by comparison of the size and wall morphologies of the top and bottom conidia of the chain. The youngest conidium is recognizable by its smaller size, lighter color if the conidia are pigmented, and differences in wall ornamentation if the conidia are roughened. Some conidiogenous cells form multiple conidia simultaneously over the surface of the swollen cell. When mature, conidia detach by fission of a double septum (schizolytic dehiscence) or by sacrifice of a supporting cell (rhexolytic dehiscence), either by fracture of a thin-walled region or by lysis of the supporting cell. Lytic dehiscence typically occurs in the dermatophytes and related fungi.

The presence of different spore states can make identification difficult. Careful examination and sometimes subculture are required to assess whether the spore types represent different states of the same fungus or whether the isolate is contaminated. Molds having more than one independent stage are called pleomorphic (occasionally polymorphic) fungi. Other conidial forms of the same fungus are called synanamorphs. These may be represented by simple yeast stages or by the formation of complex conidiomatal structures such as sporodochia (conidiophores borne crowded on a compact mass of hyphae or a hyphal stroma), synnemata (conidiophores aggregated into a compound stalk), or pycnidia (conidiogenous cells formed inside a round or oval fruiting body). Expression of a synanamorph may be influenced by the agar medium used and may be lost upon repeated subculture.

The number of moniliaceous fungal species that have been reported to cause opportunistic infection in humans and animals is increasing, and it is beyond the scope of this chapter to describe them all. Some reports identify the fungus only to the genus level, while others provide the fungus name but without salient details of its colonial and microscopic features. A continuing and vexing problem is that verification of authenticity of reports cannot be done if the fungus is inadequately described and illustrated and if case isolates are not sent for deposit in culture collections. This

chapter describes in detail the medically important species of the genus *Aspergillus* (Table 2) and provides salient colonial and microscopic characteristics of the more common species of *Fusarium* and other currently recognized moniliaceous opportunists (Tables 3 through 5). Descriptions of species are found in several reference manuals (47, 53, 106, 127, 251).

CLINICAL SIGNIFICANCE

The spectrum of disease caused by moniliaceous molds is diverse, and disease is largely determined by the local and general immunologic and physiologic state of the host and may be symptomatic or asymptomatic. In most instances, the portal of entry for fungal propagules is either through a break in the epidermis or by way of the lungs. Exceptions to this include introduction into the body by means of contaminated surgical instruments, intraocular lenses, prosthetic devices, or other contaminated materials or solutions associated with surgery or routine health care. Individuals whose resistance is lowered as a result of a severe debilitating disease or immunosuppressive therapy typically suffer from invasive pulmonary or paranasal sinus infection, but in some instances, the infecting fungus may spread to surrounding tissues or disseminate to virtually any organ. Fungemia is uncommon except in disseminated *Fusarium* infection. Noninvasive forms of infection also have been noted in debilitated individuals as well as in individuals with apparently normal defense mechanisms. In such cases, the fungus colonizes a preexisting cavity in the lungs such as an ectatic bronchus, a tuberculous cavity, or a lung cyst. Other clinical syndromes usually occurring in immunocompetent individuals include chronic sinusitis, onychomycosis, subcutaneous abscess, keratitis, otomycosis, and allergic manifestations including bronchopulmonary mycosis and sinusitis in atopic patients.

Although the majority of saprobic and plant pathogenic molds are not considered pathogenic and appear unlikely to be able to adapt to or take advantage of risk factors predisposing to opportunistic infection, those capable of growing at or near body temperature must be considered to have latent pathogenic capability. The diversity of fungi capable of colonizing or invading human tissue has increased dramatically in recent years, as reflected by new reports of proven infection. Moreover, certain fungi are isolated often enough to be suspicious for pathogenic potential. Still, there is a need for definitive evidence of infection due to a normally saprobic mold. The laboratory procedure for confirming fungal etiology includes (i) detection in the specimen of hyphal elements which are compatible with the morphology of the isolated mold, (ii) isolation of several colonies of a fungus or isolation of the same fungus from a repeat specimen, (iii) accurate identification of the isolated mold, and (iv) confirmation of the mold's ability to grow at or near body temperature. Species of *Aspergillus, Fusarium,* or *Scedosporium* isolated from all deep tissue or body fluids must be considered potential invasive pathogens. No fungal isolate should be discarded as a contaminant without thorough examination of the clinical specimen. Quality control measures to ensure that isolation media are not contaminated and the inspection of the slant or plate to evaluate where the fungus is growing relative to where the specimen was placed may also be important in evaluating whether an isolate is involved in disease. Close communication between microbiologists and physicians also is essential, especially for rare or unusual opportunists.

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

Clinical specimens from patients with suspected mycosis are to be collected with prudence and transported to the laboratory and processed as soon as possible by using the standard procedures described in chapter 116 of this Manual. Because of the diverse clinical manifestations, various sites may need to be examined for fungal elements. Biopsy material, transtracheal aspirates, and sputum samples collected in the early morning all may be useful specimens for the isolation and detection of hyaline molds, as are infected nails. Swabs taken from mucous membranes and skin lesions are not recommended. Although the reliability in determining whether an isolate is a possible pathogen is increased if cultures of two different specimens yield the same organism, a tissue biopsy is more informative since the significance of culture can be verified by histological examination of the tissue. Blood cultures are of limited use for the diagnosis of invasive aspergillosis (55), but *Fusarium* or *Scedosporium* species may be reliably detected (209). For optimum recovery, the specimen should be inoculated onto several types of media and incubated at 28 to 30°C. The opportunistic molds are variably sensitive to cycloheximide, so media containing this selective agent should be used cautiously. Suspicious isolates, especially of uncommon species, should be tested for their ability to grow at 35 to 37°C.

ASPERGILLUS SPECIES

Taxonomy

The genus *Aspergillus* comprises anamorphic (asexual) species with known or presumed connections to eight different teleomorph (sexual) genera classified in the family Trichocomaceae of the Ascomycota. The family Trichocomaceae also contains teleomorphs of the genera *Penicillium* and *Paecilomyces* (some species) (228). As members of the class Euascomycetes, aspergilli are distantly related to other ascomycetes such as dimorphic fungi, dermatophytes, and *Pseudallescheria* species. Because the large number of species within the genus *Aspergillus* has made identification to the species level difficult for even the experienced microbiologist, the species were placed into groups (211) and, more recently, further subdivided into the subspecies categories of subgenera and sections (53, 114). Peterson's analysis of large-subunit rRNA sequences derived from 215 taxa correlated to a large degree with many of the species originally described by Raper and Fennell (211) but demonstrated a need for taxonomic revision (198). Three main branches on the phylogenetic tree were used to define the subgenera *Aspergillus, Fumigati,* and *Nidulantes,* and sections formerly recognized were either retained or redisposed. A result of this realignment is that the subgenus *Aspergillus* includes both uniserate and biseriate species and species of different colors, whereas in prior treatments these were key characters that separated groupings of species. At this time, the genus *Aspergillus* includes seven subgenera: *Aspergillus, Fumigati, Ornati, Clavati, Nidulantes, Circumdati,* and *Stilbothamnium*. Each subgenus contains several sections, with each section composed of a number of species (115).

In practice, *Aspergillus* species are differentiated mainly on the basis of phenotypic characteristics of the anamorph, but early monographic treatments (211) also included descriptions of the teleomorph. Because this practice was inconsistent with the International Code of Botanical Nomenclature, it caused problems in the nomenclature of some well-known species.

TABLE 2 Characteristics of some medically important *Aspergillus* species grown on identification media[a]

Section[b] and species	Seriation		Colony color	Microscopic features[c]	Comment
	Uniseriate	Biseriate			
Fumigati					
A. fumigatus	+		Dark blue-green to grayish turquoise; slate gray with age; reverse variable	Conidiophore mostly up to 300 μm long and 5–8 μm wide, smooth, uncolored or greenish; vesicle dome shaped, 20–30 μm in diam, phialides on upper half only; head strongly columnar; conidia subglobose to globose, occasionally ellipsoidal, smooth to echinulate, 2–3.5 μm in diam (Fig. 3).	Distinguished by blue-green colonies, growth at 45°C and columnar heads with single layer of phialides. Sterile white fast-growing or glabrous cerebriform slow-growing variants may be confirmed by thermotolerance and DNA sequence. Cosmopolitan airborne mold often found in compost piles, soil of potted plants; most common pathogen.
Neosartorya fischeri (anamorph *A. fischerianus*)	+		White to gray-green; exudate uncolored or pale brown	Conidiophores and conidial heads and conidia as for *A. fumigatus;* cleistothecia globose mostly 150–350 μm; creamy white, ascospores rough walled with two crests, 5–8 μm long; 3 varieties distinguished by ascospore morphologies (Fig. 26).	Conidial characteristics and thermotolerance strongly similar to *A. fumigatus* but colonies usually whiter with fewer conidial heads; rarely reported as a pathogen; some clinical isolates reported as *N. fischeri* have been reidentified as *N. pseudofischeri*.
Flavi					
A. flavus	+	+	Yellow to dark yellowish green	Conidiophore mostly 400–850 μm long and 20 μm wide, roughened; uncolored, vesicle subglobose or globose, 25–45 μm in diam; loosely radiate or splitting into columns in age; conidia globose or ellipsoidal, roughened, 3–6 μm in diam.	Toxigenic[d]; brown to black sclerotia sometimes present; growth usually enhanced at 37°C; heads vary in size and seriation; colony color may be influenced by culture medium additives such as yeast extract; second most common human pathogen.
Nigri					
A. niger		+	Black with white margin and yellow surface mycelium; reverse uncolored or pale yellow.	Conidiophore 400–3,000 μm long and 15–20 μm wide, smooth, uncolored to brownish near tip; vesicle globose, 30–75 μm in diam; radiate, then splitting into columns in age; conidia globose with thick walls, brownish black, roughened, 4–5 μm in diam.	Frequent cause of otomycosis; sometimes associated with intracavitary colonization, especially in diabetics.
Versicolores					
A. versicolor		+	Green to gray-green or tan with patches of pink or yellow; reverse variable and often deep red	Conidiophore 200–400 μm long and 5 μm wide, smooth, uncolored, yellowish, or pale brown; vesicle ovate to elliptical, 9–16 μm in diam, head radiate to loosely columnar; conidia globose, echinulate, 2.5–3 μm in diam; Hülle cells globose (Fig. 27).	Toxigenic; distinguished by slow-growing, greenish-tan or variably colored colonies, and small biseriate vesicles. Conidial heads of *A. sydowii* are similar but colonies are blue-green. Reduced structures resembling penicilli sometimes present.
A. sydowii		+	Blue-green often resembling *Penicillium* spp.	Conidiophore 150–350 μm long and 3–8 μm wide, smooth, thick walled, uncolored or pale brown; vesicle globose or elliptical, 7–13 μm in diam, head radiate; conidia globose, very rough, 2.5–4 μm in diam; reduced structures resembling penicilli common.	Distinguished from *A. versicolor* by slow-growing blue-green colonies; diminutive heads resembling penicilli common.

(Continued on next page)

TABLE 2 Characteristics of some medically important *Aspergillus* species grown on identification media[a] *(Continued)*

Section[b] and species	Seriation		Colony color	Microscopic features[c]	Comment
	Uniseriate	Biseriate			
Terrei					
A. terreus		+	Tan to cinnamon brown, rarely orange-brown, reverse yellow or tan	Conidiophore 100–250 μm long and 4.5–6 μm wide, smooth, uncolored; vesicle dome shaped, 10–16 μm in diam, phialides on upper half; head columnar; conidia globose or subglobose, smooth, 2 μm in diam; solitary single-celled conidia commonly formed sessile on submerged hyphae.	Cinnamon brown colonies, columnar heads and solitary accessory conidia are highly distinctive.
Nidulantes					
Emericella nidulans (anamorph *A. nidulans*)		+	Dark green if mainly conidial; buff to purplish brown if cleistothecial; reverse deep red to purple	Conidiophore 70–150 μm long and 3–6 μm wide, smooth, brown; vesicle hemispherical, 8–12 μm in diam; phialides on upper part, columnar; conidia globose, rough, 3–4 μm in diam; cleistothecia reddish brown, globose, 100–250 μm, Hülle cells globose; ascospores lenticular with two longitudinal crests, ca. 5 μm long, reddish purple (Fig. 4).	Toxigenic; distinguished by reddish brown cleistothecia, abundant Hülle cells, reddish purple ascospores with two crests, short conidiophores and "stout" metulae.
Emericella quadrilineata		+	Olive green to grayish purple, reverse purple	Conidial heads, ascocarps and hülle cells similar to those of *E. nidulans*. Ascospores also similar but have 2 major and 2 minor equatorial crests.	Distinguished from *E. nidulans* by 4 crests on ascospores.
Flavipedes					
A. flavipes		+	White with patches of yellow or pale grayish buff, reverse yellow to golden brown	Conidiophore 150–400 μm long and 4–8 μm wide, smooth to roughened, uncolored to pale brown, vesicle subglobose, 10–20 μm in diam; radiate to loosely columnar; conidia globose, smooth, 2–3 μm in diam; cleistothecia and Hülle cells rarely produced.	Distinguished from *A. terreus* by slower-growing colonies, metulae usually formed over entire vesicle and radiate to loosely columnar heads.
Usti					
A. ustus		+	Brownish gray or olive-gray, reverse yellow, dull reddish or purplish (Fig. 6)	Conidiophore 75–400 μm long and 4–7 μm wide, smooth, becoming brown; vesicle globose or subglobose, 7–16 μm in diam, fertile over upper two-thirds; radiate to loosely columnar; conidia globose, rough, 3–4.5 μm in diam; irregular Hülle cells often present (Fig. 7).	Distinguished by dull gray-green colonies, small vesicles, brown conidiophores, and irregularly shaped Hülle cells when present.
A. deflectus		+	Slow growing, becoming mouse gray with pinkish margins or patches of yellow	Conidiophore 40–125 μm long and 2.5–3.5 μm wide, smooth, reddish brown; vesicle hemispherical, 5–7 μm in diam typically bent at right angle to stipe; phialides on upper surface, columnar; conidia globose, 3–3.5 μm in diam, smooth to roughened; Hülle cells sometimes present.	Distinguished by vesicle bent almost at right angle to stipe; rarely reported as pathogen in humans and dogs.
Aspergillus					
Eurotium spp. Anamorphs *A. glaucus* and other spp.	+		Deep green mixed with bright yellow, reverse uncolored or pale yellow	Conidiophore 200–350 μm long and 7–12 μm wide, smooth, uncolored to pale brown; vesicle globose, 15–30 μm in diam, conidial heads large, radiate; conidia subglobose, echinulate, 5 μm in diam, cleistothecia thin walled,	Formerly called *glaucus* group; osmophilic, reproduction enhanced on high-sugar media; growth poor at 37°C; difficult to distinguish by features of conidial heads, but readily identified by ascospore morphology.

			yellow, globose, 75–150 μm, ascospores smooth or roughened, with furrow and rounded or frilled crests.		*E. repens, E. nuber,* and *E. amstelodami* rarely reported as pathogens. *E. umbrosus* reported as cause of farmer's lung is another name for *E. herbariorum* (anamorph *A. glaucus*).
Restricti					
A. restrictus	+	Dull olive green to brownish green, very slow growing	Conidiophore 80–200 μm long and 4–8 μm wide, smooth or roughened, uncolored; vesicle hemispherical, 8–20 μm in diam, phialides on upper third, head columnar; conidia cylindrical to ellipsoidal, roughened, 4–7 μm long and 3–4 μm wide.		May be confused with *A. fumigatus* but differs by very slow growth on routine media, slightly enhanced growth on high-sugar media, no growth at 37°C, cylindrical conidia developing in long, adherent columns.
Candidi					
A. candidus	+	+ White to cream	Conidiophore mostly 200–500 μm long and 7–10 μm wide, smooth to roughened, uncolored; vesicle globose or subglobose, 17–35 μm in diam, fertile over entire surface; radiate; conidia globose, smooth, 3–4 μm in diam; reddish purple sclerotia sometimes present.		Distinguished from all colored aspergilli by white, slow-growing colonies; from *A. niveus* by larger vesicles, metulae covering entire surface and absence of teleomorph; predominantly biseriate, sometimes uniserate on smaller heads.

[a] Modified from previous versions of this chapter.
[b] Modern concepts have replaced group names with subgenera and sections.
[c] Refer to "*Aspergillus* Taxonomy and Identification" for description of terms.
[d] Only species producing potent toxins are noted as toxigenic, but other species may produce toxins of lesser significance.

Experts in the field have attempted to rectify outstanding problems and have compiled a list of names in current use in the family Trichocomaceae. The list currently includes 184 species of *Aspergillus* and 70 associated teleomorphs (228).

Description of Agents

Aspergillus is a large genus of common environmental fungi containing about 184 species whose members reproduce by producing conidia in dry chains on phialides, cells with a terminal opening through which enteroblastic conidia are produced repetitively. Phialides can be produced directly from the vesicle (uniserate), or from an intermediate series of cells called metulae (biserate). In general, *Aspergillus* colonies usually grow very rapidly, producing powdery white, green, yellowish, brown, or black colonies. They are found worldwide, in soil, water, foods, and other environmental niches. Their dry conidia can be easily dispersed in the air and by birds or insects. Several *Aspergillus* species also produce mycotoxins, which are harmful to humans and animals when ingested (see chapter 127).

About 40 *Aspergillus* species have been implicated in human or animal infection, but 16 of these have been recorded only once (47). Some reports have been discounted because the fungus isolated was not reliably demonstrated to be a pathogen, or because the description clearly represented another fungus or was inadequate for evaluation (255). *Aspergillus fumigatus* still accounts for most cases of aspergillosis, with *A. flavus* and *A. niger* being the next most common pathogenic species worldwide (127). *A. terreus* is increasingly being reported (94, 132, 164), and *A. lentulus* is the newest species recognized as an agent of human disease (15).

Aspergillosis is a general term used to refer to infections caused by members of the genus *Aspergillus*. Invasive pulmonary aspergillosis is the most serious form, occurring in immunocompromised individuals. A classification of *Aspergillus* infections is given in Table 1.

Epidemiology and Transmission

Invasive aspergillosis is most commonly caused by *A. fumigatus* in humans, but other species such as *A. flavus, A. nidulans,* and *A. terreus* have also been implicated in causing invasive infection. In some centers a shift toward *Aspergillus* species other than *A. fumigatus* has been reported, although significant variation between centers exists (138, 164). Conidia of *Aspergillus* species are often found in the ambient air, but large amounts of conidia are present in dust, decomposing organic matter, and soil. Inhalation of conidia may lead to a variety of disease entities ranging from asthma in atopic subjects to invasive infection in patients with severely compromised host defenses. Most invasive infections occur in the lungs, and the incidence of infection largely depends on the risk of the patient population. Typically the incidence of invasive aspergillosis is around 5% of patients with hematological malignancy, especially in acute myeloid leukemia and myelodysplastic syndrome, but may be as high as 15% in patients receiving a hematopoietic stem cell transplant (HSCT) (164).

Although invasive pulmonary aspergillosis is believed to be primarily acquired by inhalation of airborne conidia, there is some evidence that water may play a role in the transmission. *A. fumigatus* has been cultured from hospital water (271) and other sources in the hospital such as showerheads, and strains recovered from water were found to be highly related to those recovered from patients (274). Patients might be exposed to *Aspergillus* conidia during showering by inhaling droplets contaminated with conidia.

TABLE 3 Key features of some opportunistic moniliaceous fungi

Genus	Key features	Etiologic agents	Comments
Acremonium	Colonies slow growing (usually <3 cm in diam in 10 days), often white, cottony, fasciculate (spiky), glabrous or moist and pink or salmon colored. Conidiogenous cells solitary, slender (ca. 2 μm wide), mostly unbranched, awl (needle-shaped) phialides. Conidia one celled, straight or curved, in slimy masses.	*A. alabamense, A. falciforme, A. kiliense, A. potronii, A. recifei, A. curvulum, A. strictum, Acremonium* spp.	Differs from *Fusarium* by slow growth rate, narrower hyphae (mostly <2 μm in width), and more slender and needle-like phialides. Compare *Lecythophora, Phaeoacremonium, Phialemonium.*
Acrophialophora	Colonies fast growing, growth enhanced at 37°C, yellowish white, darkening to grayish brown. Conidiophores brown, seta-like. Conidiogenous cells flask-shaped phialides borne near the tip of conidiophores or on vegetative hyphae. Conidia in long chains, one celled, lemon shaped, smooth or roughened.	*A. fusispora*	Compare *Paecilomyces.* Single report of keratitis.
Aphanoascus	Colonies moderately fast growing, yellowish white, granular; cycloheximide tolerant. A homothallic ascomycete forming globose cleistothecia containing roughened ascospores; associated with a *Chrysosporium* anamorph consisting of terminal one-celled aleurioconidia and alternate arthroconidia.	*A. fulvescens*	Compare *Chrysosporium* and dermatophytes.
Arthrographis	Colonies slow growing, growth enhanced at 37°C, initially yellowish white, and yeast-like, becoming hyphal and tan, cycloheximide tolerant. Conidiophores dendritic (tree-like), bearing lateral branches. Arthroconidia formed by fragmentation of branches or of undifferentiated hyphae.	*A. kalrae*	Compare *Scytalidium hyalinum, Onychocola, Hormographiella.*
Aureobasidium	Colonies wet, pale salmon or pink, usually darkening in age to black. For microscopic features, see chapter description.	*A. pullulans*	Differs from *L. hoffmannii* and *A. strictum* by absence of distinct phialides.
Beauveria	Colonies slow to moderately fast growing, yellowish white. Conidiogenous cells solitary, in whorls or in sporodochia, basally swollen, proliferating sympodially at the tip in a zigzag (geniculate) fashion. Conidia one celled, subglobose.	*B. alba* (also called *Engyodontium album*), *B. bassiana*	Compare *Sporothrix.*
Chaetomium	Colonies fast growing, yellowish green to gray. Conidia absent or formed from phialides. Ascomata perithecia bearing coiled, straight, branched brown or indistinct setae. Ascospores lemon shaped, brown, smooth. Fig. 21.	*C. strumarium, C. atrobrunneum, C. globosum*	*C. strumarium* and *C. atrobrunneum* show enhanced growth at 42°C, but *C. globosum* fails to grow.
Chrysosporium	Colonies slow to moderately fast growing, yellowish white. Conidia single celled smooth to roughened aleurioconidia formed sessile or at the ends or on the sides of unswollen stalks. Arthroconidia sometimes present.	Unnamed species	Reports of infection by unnamed species are difficult to evaluate because the isolates are not described well enough to confirm etiology.
Cylindrocarpon	Colonies fast growing, yellowish white, tan, orange, or purple, felty or cottony. Conidiogenous cells awl-shaped phialides with a single opening, solitary, in branched structures or in sporodochia (conidiophores borne crowded on a compact mass of hyphae). Macroconidia straight or curved, with rounded ends, multicelled; microconidia 1 or 2 celled. Chlamydospores sometimes present.	*Cylindrocarpon destructans, C. cyanescens, C. lichenicola*	Distinguished from *Fusarium* by the more rounded shape of the terminal cells of the macroconidia.

(Continued on next page)

TABLE 3 *(Continued)*

Genus	Key features	Etiologic agents	Comments
Fusarium	About 100 species grouped into sections. Colonies fast growing (>7 cm in diam after 10 days); obverse and reverse colors white, cream to orange, tan, brown, carmine red, reddish brown, pink, purple, or blue to blue-green; texture felty or cottony or sparse and wet looking. Conidiogenous cells awl-shaped phialides with one opening (monophialide) or more than one opening (polyphialide). Phialides solitary, in branched structures or in sporodochia (conidiophores borne crowded on a compact mass of hyphae). Conidia of two types that are common or rare depending on the species. Macroconidia multicelled, with 2 to 5 septa, fusiform or sickle shaped, often with a distinct notched basal cell. Macroconidia produced in the aerial mycelium less typical than those produced in sporodochia. Microconidia oval, globose, ellipsoidal, clavate or reniform (kidney shaped), 1 or 2 celled, and borne in slimy heads or in short chains in the aerial mycelium. Chlamydospores sometimes present; solitary, in chains or in clusters.	*Fusarium solani, F. oxysporum, F. verticillioides (F. moniliforme)* most common (Table 4); *F. anthophilum, F. chlamydosporum, F. dimerum, F. napiforme, F. nygamai, F. proliferatum, F. roseum, F. sacchari* rarely reported.	Differs from *Acremonium* by colonies that are faster growing, broader, more robust hyphae and phialides, and usually by presence of macroconidia; many species toxigenic.
Hormographiella	Colonies fast growing, white, amber to tan, woolly, cycloheximide sensitive. Conidiophores short, bearing short fertile branches. Arthroconidia schizolytic, thin walled, single celled, often adherent around the conidiophore. Sclerotia sometimes present.	*H. aspergillata, H. verticillata*	Differs from *A. kalrae* by cycloheximide sensitivity, fast growth rate.
Lecythophora	Colonies white to salmon, moist or fasciculate (spiky), or tan darkening to black in patches. Conidiogenous cells adelophialides (short, stumpy phialides without a basal septum), as well as awl-shaped phialides. *L. mutabilis* forms brown chlamydospores, while *L. hoffmannii* does not.	*L. hoffmannii, L. mutabilis*	Differs from *Acremonium* by predominance of adelophialides. Hyphal elements in tissue are usually reported as hyaline.
Myceliophthora	Colonies fast growing, thermophilic, cinnamon brown. Conidia pale brown, roughened, single-celled aleurioconidia formed on swollen stalks.	*M. thermophila*	Differs from *Chrysosporium* by swollen stalks.
Onychocola	Colonies restricted, raised, yellowish white to grayish white, cycloheximide tolerant. Conidia 1 or 2 celled cylindrical or swollen arthroconidia forming in adherent chains, detaching by fracture of thin-walled cells. Brown knobby setae often present. Fig. 16.	*O. canadensis*	Differs from *S. hyalinum* and *Hormographiella* by adherent chains, slow growth, and cycloheximide tolerance.
Paecilomyces	About 40 species grouped into two sections. Section *Paecilomyces* includes the thermotolerant *P. variotii* and anamorphs of *Byssochlamys* and *Thermoascus* with fast-growing yellowish brown, buff, white, or orange colonies. Section *Isarioidea* includes *P. lilacinus* and species that are slower growing with white, reddish gray, violet, or brightly colored colonies. Conidiogenous cells phialides formed on verticillately branched conidiophores. Conidia single celled, in chains. Ascospores of *T. crustaceus* are orange brown, rough walled. Fig. 12, 13.	*P. lilacinus, P. variotii* (Table 5), *P. marquandii, P. javanicus, Thermoascus crustaceus*	Differs from *Penicillium* by colonies in colors other than bright green or blue-green, and by the basally swollen phialides that taper toward the neck and that are bent away from the main axis. An isolate of *P. viridis* from human infection was reidentified as *P. variotii*. Compare *Acrophialophora*.

(Continued on next page)

TABLE 3 Key features of some opportunistic moniliaceous fungi *(Continued)*

Genus	Key features	Etiologic agents	Comments
Penicillium	About 200 species divided into 4 subgenera according to conidiophore branching. Colonies moderately fast growing, powdery, green to blue-green, rarely other colors. Conidiophores erect, with 1 to 3 levels of branching. Conidiogenous cells phialides, borne on the stipes or on branches called metula. Conidia globose or ellipsoidal, smooth to roughened, in chains. Sclerotia and ascomata sometimes present. *P. marneffei* distinguished by sparse green aerial and reddish brown vegetative hyphae, red diffusible pigment; compact biverticillate or irregular penicilli on short, roughened conidiophores and growth at 37°C in a yeastlike form. Fig. 8, 9.	*P. marneffei* (true pathogen), *P. brevicompactum, P. chrysogenum, P. citrinum, P. commune, P. decumbens, P. purpurogenum, P. spinulosum,* and unidentified species	Several species may produce red diffusible pigments but fail to convert to yeast-like form. Many species toxigenic.
Phaeoacremonium	Colonies white to tan. Conidiogenous cells solitary unbranched or branched awl-shaped phialides often arising from hyphal strands. Conidia single celled, curved, rarely straight, in slimy masses.	*P. parasiticum*	Accommodates *Phialophora parasitica* and several other species intermediate between *Acremonium* and *Phialophora*.
Phialemonium	Colonies yellowish to green. Conidiogenous cells adelophialides (short, stumpy phialides without a basal septum), as well as awl-shaped phialides.	*P. curvatum, P. obovatum*	Compare *Acremonium* and *Lecythophora.*
Schizophyllum	Colonies fast growing, growth enhanced at 37°C, white, woolly or cottony, cycloheximide sensitive. Conidia absent. Hyphae bearing clamp connections and short, thin pegs or spicules; both may be absent. Clamped isolates usually develop fan-shaped, gilled mushrooms on sporulation media after 3 to 6 weeks. Fig. 24, 25, 31.	*S. commune*	Clinical picture resembles aspergillosis and clampless isolates resemble aspergilli by histopathology. *S. commune* may be the cause of sinusitis attributed to *Myriodontium keratinophilum* and *Chrysosporium* sp.
Scopulariopsis	Colonies white, buff, gray-brown to black. Conidiogenous cells annellides formed on branched conidiophores with 1 or 2 levels of branching. Conidia one celled, globose or ellipsoidal, in chains. *S. brevicaulis* distinguished by buff or tan, granular colonies, thick-walled smooth to coarsely roughened conidia that are truncate at the base and rounded or pointed at the tip and measure 5 to 8 μm wide by 5 to 7 μm long. Ascospores of *Microascus* species are orange, lens or half-moon shaped, and released in a cirrus (a long adherent column) from a short-necked ascocarp. Fig. 20.	*S. brevicaulis, S. candida, S. brumptii, Microascus cinereus, M. cirrosus*	*S. candida* differs from *S. brevicaulis* in having smooth conidia and white colonies. *S. brumptii* differs from *Scedosporium* species by the conidia produced in chains rather than in slimy masses. *Microascus* species differ from *Chaetomium* species by the orange ascospores produced from short-necked ascomata.
Scytalidium	Colonies rapid growing (>8 cm in diam by 7–10 days), yellowish white or black, dense, cottony or woolly, cycloheximide sensitive. Conidia 1- or 2-celled arthroconidia formed by schizolytic fragmentation of branched hyphae varying in width from 2- to 10-μm diam. Hyphae and arthroconidia of *S. hyalinum* are hyaline to pale yellow; those of *S. dimidiatum* are light to dark brown. Pycnidial conidia of *Nattrassia mangiferae* stage are initially hyaline and then develop median brown band.	*S. hyalinum, S. dimidiatum* (synanamorph is known as *Nattrassia mangiferae* or formerly, *Hendersonula toruloidea*)	Isolates reported as *S. lignicola* from human infection have been reidentified as *S. dimidiatum. S. lignicola* differs from *S. dimidiatum* in colonial and microscopic features and should not be considered a synonym as has been suggested in the literature.
Sporothrix	Colonies of *S. cyanescens* moderately fast growing, white to lavender, red diffusible pigment often present; cycloheximide sensitive. Conidiophores solitary, forming conidia sympodially on small denticles on sides or at tips. Primary conidia bear 1 to 3 secondary conidia; brown-pigmented sessile conidia absent.	*S. cyanescens* (also called *Cerinosterus cyanescens*); (*S. schenckii*—see chapter 120)	Affinity of *S. cyanescens* is closer to smuts than to other species of *Cerinosterus*. *S. schenckii* differs in being dimorphic and in forming brown sessile conidia.

TABLE 4 Morphological features of the three commonly isolated *Fusarium* spp.

Characteristic	*F. solani*[a]	*F. oxysporum*	*F. verticillioides* (*F. moniliforme*[b])
Colonies on potato dextrose agar after 4 days at 25°C	3–3.5 μm in diam, creamy white with cream slimy areas, developing blue-green to bluish brown colors, never orange, reverse uncolored, rarely violet	4.5–6.5 cm in diam, creamy white, often with purple or violet tints, sporodochia cream to orange, slimy, reverse uncolored to dark blue or purple	4.5–6.5 μm in diam, white, peach to purple, sporodochia orange, reverse uncolored to dark purple
Phialides	Mono, long, slender, sometimes verticillately branched	Mono, short, stout, mostly unbranched	Mono, long, branched and unbranched
Microconidia	Cylindrical to oval, nonseptate	Oval to kidney shaped, single celled, in heads	Oval to club shaped with flattened base, mostly single celled, in chains[c] or in heads (Fig. 11)
Macroconidia	Mostly three septate (one to five septate), 28–42 by 4–6 μm, slightly curved, rounded at each end or basal cell notched (Fig. 10)	Mostly three (or up to five) septate, moderately curved, 27–60 by 3–4.5 μm, pointed at each end	Present or rare, three to five (or up to seven) septate, sickle shaped to almost straight, 30–60 by 3–4 μm, basal cell foot shaped
Chlamydospores[d]	Present, formed singly and in pairs, commonly produced	Present, formed singly and in pairs, usually abundant	Absent

[a] Molecular studies reveal *F. solani* to be a complex comprising over 50 phylogenetically distinct entities.
[b] *F. verticillioides* is preferred over the name *F. moniliforme*, which has a broader concept.
[c] Best observed on carnation leaf agar or KCL medium (174).
[d] Best observed on carnation leaf agar or in sterile distilled water (176).

Genotyping will help to further understand the significance of waterborne transmission of invasive aspergillosis.

Clinical Significance

Invasive infections caused by *Aspergillus* species are associated with high rates of morbidity and mortality, especially in transplant recipients and patients receiving chemotherapy for hematologic or other malignancies. Invasive aspergillosis now is considered the second most common fungal infection requiring hospitalization in the United States. In patients with positive fungus cultures, *Aspergillus* species are the second most common isolates after *Candida* species, but positive cultures alone may not indicate a pathogenic process (195).

Recovery of *Aspergillus* species from high-risk patients is associated with invasive infection, although the probability of infection depends on the host group. Assessment of the pathologic importance of any species of *Aspergillus* isolated from clinical specimens can be difficult, even with positive radiological or (high-resolution) computed tomography findings, because aspergilli are routinely isolated from respiratory, cutaneous, and other specimens. It is imperative to determine clinical significance by (i) demonstrating hyphae in fresh clinical material, (ii) isolating heavy growth from a single specimen or the same species from multiple specimens, and (iii) demonstrating hyphae in tissue. Fungal culture of at least three serial sputum specimens is recommended whenever fungal infection is suspected. Clinical and radiological correlations help to separate true- from false-positive cultures (88). Consensus definitions have been published by the European Organization for Research and Treatment of Cancer and the Mycoses Study Group in which host factors, clinical signs and symptoms, and mycology results are used to classify patients, i.e., proven, probable, or possible invasive fungal infection (10). For invasive aspergillosis the consensus definitions recognize antigen detection and high-resolution computed tomography as diagnostic tools but do not (yet) recognize nucleic acid detection techniques. The use of the consensus definitions will help to standardize research into performance characteristics of new diagnostic tests and procedures.

Infections may be primary or secondary, and they vary in severity and clinical course (162). The clinical manifestations (Table 1) are largely determined by the local or general immunologic and physiologic state of the host, but various forms of the disease may integrate and overlap (120, 162). The major risk factors for invasive aspergillosis include hematologic malignancy, neutropenia following stem cell or solid-organ transplantation, pulmonary diseases, and glucocorticosteroid or cytotoxic drug therapy (14, 72, 193). Aspergillosis in human immunodeficiency virus (HIV)-infected people is uncommon and occurs largely among severely leukopenic individuals (84, 169). Invasive pulmonary aspergillosis and cerebral aspergillosis are life-threatening complications in patients with advanced AIDS (71, 163, 169, 278). Modification to antiretroviral therapy, combined with antifungal therapy, results in improved survival of some HIV-infected patients (163, 278), but aspergillosis collectively is associated with poor survival (84, 163, 169). Because different species of *Aspergillus* vary in their susceptibility to antifungal agents, every effort must be made to identify the fungus to the species level when isolated from an at-risk patient.

Collection, Transport, and Storage of Specimens

Methods of collection, transport, and storage of specimens are detailed in chapter 116. Invasive pulmonary aspergillosis is very difficult to diagnose and usually requires a combination of clinical, culture, radiographic, and direct antigen findings. Sputum, bronchoalveolar lavage fluid, or other nonsterile lower respiratory tract specimens can be collected for fungus culture, but it must be appreciated that aspergilli isolated from these sites may reflect contamination or colonization (195).

TABLE 5 Morphologic features of selected *Paecilomyces* species[a]

Characteristic	*P. lilacinus*	*P. marquandii*	*P. variotii*
Colonies on potato dextrose agar after 7 days at 25°C	3–3.5 cm in diam, white becoming dull red or reddish gray,[b] cottony, reverse colorless or vinaceous (Fig. 11)	2 cm in diam, violet brown[b] with white margin, cottony, often with radial folds, reverse yellow, slight yellow diffusible pigment	7–8 cm in diameter, yellowish to olive-brown, powdery (Fig. 12)
Thermotolerance	Strongly restricted at 37°C	No growth at 37°C	Reported up to 50°C, but many isolates show no growth above 40°C
Conidiophores	Rough walled, pigmented yellow or purple, metulae densely clustered, bearing whorls of 2–4 phialides (verticillate), rarely synnematous (Fig. 13)	Smooth walled, hyaline, verticillately branched, metulae with 2–4 phialides, often forming loose synnemata	Verticillately or irregularly branched, metulae bearing 2–7 phialides
Phialides	Taper abruptly to narrow neck, about 1 μm wide	Taper abruptly to narrow neck, about 1 μm wide	Phialides robust, tapering gradually to form long neck about 2 μm wide
Conidia	Smooth to rough, ellipsoidal to fusiform, hyaline to vinaceous in mass, 2.5 to 3 by 2 to 2.2 μm	Smooth to slightly rough, ellipsoidal to fusiform, hyaline to purple in mass, 3 to 3.5 by 2 to 2.2 μm	Variable in size and shape, mostly 3.2 to 5 by 2 to 4 μm or up to 15 μm long, ellipsoidal to cylindrical smooth, hyaline to yellow-brown
Solitary conidia	Absent	Present, thin walled, often in submerged mycelium	Terminal or intercalary, brown, thick walled

[a] Modified from previous versions of this chapter.
[b] Color names from reference 118a.

The most convincing evidence of aspergillosis is provided by recovery of organisms from normally sterile sites, such as lung tissue obtained from biopsy, and histopathologic demonstration of hyphal elements in tissue.

Aspergillus can be recovered from cultures of sinus tissue, other tissue biopsy specimens, skin biopsy specimens, heart valves, and appropriate ophthalmologic samples. Although *Aspergillus* endocarditis can occur in the appropriate patient, blood cultures for *Aspergillus* are usually negative. Conversely, positive blood cultures for *Aspergillus* are frequently indicative of contamination, even in a patient population at risk for aspergillosis (246).

Direct Examination

Microscopy

Hyphal elements and the details of hyphal morphology of aspergilli may be observed readily in routine KOH preparations without or with a fluorescent compound such as calcofluor white or Blankophor P or in tissue section with fungal stains such as the Gomori methenamine silver stain. In hematoxylin-and-eosin-stained tissue, viable hyphae are often basophilic to amphophilic, whereas hyphae in macerated or necrotic tissue tend to be eosinophilic (33). The appearance of *Aspergillus* hyphae may vary with the type of infection. In invasive aspergillosis, aspergilli typically are seen as hyaline, septate hyphae that are 3 to 6 μm in diameter, branch dichotomously at acute (45°) angles (Fig. 2), and have smooth parallel walls with no or slight constrictions at the septa (33). In invasive aspergillosis, hyphae proliferate extensively throughout the tissue, often in parallel or radial arrays. Aspergilli colonizing pulmonary cavitary lesions grow as tangled masses of hyphae and in chronic infection may exhibit atypical hyphal features such as swellings measuring up to 12 μm in diameter and/or absence of conspicuous septa. When hyphal elements typical of aspergilli are present in histologic sections, a presumptive diagnosis of invasive fungal infection can be made, but culture or specific immunohistochemical staining is required to identify the pathogen. In particular, hyphae of *Fusarium* or *Scedosporium* species may resemble those of aspergilli both in their propensity to grow in the lumens of blood vessels and in their formation of dichotomously branched hyphae. More promising are the molecular biological techniques that allow species identification using species-specific probes (81).

The presence of typical conidial heads or ascomata in lung cavities or in the ear canal aids in the diagnosis and may allow a presumptive identification of the fungus. In tissue, *A. terreus* displays distinctive aleurioconidia along the lateral walls of hyphae, thus permitting early clinical recognition of this species in histopathologic specimens (270). Especially if *A. niger* is the cause of infection, calcium oxalate crystals also may be found in respiratory specimens (237). Free conidia may resemble structures such as yeast cells or cysts of *Pneumocystis jirovecii* when stained with Gomori methenamine silver stain, which masks the conidium color, but conidia of the aspergilli are often roughened. Hyphae of the zygomycetes are generally broader (up to 15 μm), have nonparallel walls which often appear collapsed and twisted, and are infrequently septate (33).

Antigen Detection

In patients with invasive infection, antigen detection may be helpful in establishing an early diagnosis (134, 158). Monitoring levels of circulating antigens also may be useful for management of such patients, especially those with immunosuppression or underlying hematologic malignancies (147). Several tests for the detection of soluble antigens of *Aspergillus* species in serum, urine, or other body fluids have been developed: radioimmunoassay, enzyme-linked immunosorbent assay (ELISA), biotin-avidin-linked immunosorbent assay, latex agglutination, and immunoblotting have been the most commonly used methods (77, 102, 117, 125, 202, 259, 280). These methods may provide sensitivity sufficient to allow early diagnosis in some cases (126, 263), but few are commercially available. A latex agglutination test, Pastorex Aspergillus (BioRad, Marnes-La-Coquette, France), has been evaluated in several hospital and clinical laboratories (86, 212, 264). Results show that the test lacks sensitivity and that a low level of false-positive results (~6%) occurs for patients with no evidence of invasive disease. The sensitivity of antigen detection was significantly improved with the development of a commercially available ELISA format, Platelia Aspergillus (BioRad), which employs the same monoclonal antibody as the latex kit. Circulating antigen was detected earlier than with the latex kit (265), and several large prospective, autopsy-controlled clinical studies have confirmed the potential of the ELISA to identify patients at high risk for invasive aspergillosis at an early stage of infection (145, 147, 253). In approximately two-thirds of patients, circulating antigen was detected before diagnosis was made by other means (145). However, the main clinical evaluations have taken place in (neutropenic) patients with hematologic malignancy, and studies with other risk groups such as solid-organ transplant recipients indicate less-favorable performance, although the number of studies in solid-organ transplant recipients is limited. Regardless of the test used, success in detecting antigenemia is directly related to the frequency of monitoring of samples (147). Monitoring of antigen titers in patients with hematologic malignancy has shown that the course of the antigen titer corresponds to the response to treatment (147, 263). The antigen galactomannan can be detected in other body fluids of patients with invasive aspergillosis including cerebrospinal fluid (267), urine, and bronchoalveolar lavage fluid (116, 168). Although this application is potentially useful, the assay has thus far been validated only for serum.

In addition to the detection of *Aspergillus* galactomannan, assays that detect (1→3)-β-D-glucan, a characteristic fungal cell wall constituent common to a broad range of fungal pathogens, have been developed (181). Although (1→3)-β-D-glucan itself is not immunogenic, the detection system is based on the activation of a proteolytic coagulation cascade. Circulating (1→3)-β-D-glucan was detected in patients with systemic fungal infections including invasive aspergillosis (104, 194), but clinical experience is at present limited. The positivity of this test, particularly when used in a serial fashion, often precedes the microbiological or clinical diagnosis of invasive fungal infection.

With the increased use of surrogate markers in the management of patients, factors that hamper the use and reliability of these markers have emerged. Most notably, exposure of high-risk patients to mold-active antifungal agents significantly reduces the sensitivity of galactomannan detection (151, 152), a phenomenon that also appears to apply to the detection of circulating fungal DNA (133). In one study the sensitivity of the ELISA was only 20% for patients on antifungal prophylaxis, as opposed to 80% for those not receiving prophylaxis (151). ELISA reactivity was reported with certain beta-lactam antibacterial agents (7), and more recently reactivity of serum was described for patients treated with piperacillin-tazobactam and amoxicillin-clavulanic acid (18, 252, 269). The ELISA reactivity observed in batches of the antibiotics might be due to the use of *Penicillium* fungi for the production of the antibacterial agents. Other exogenous sources for serum reactivity might include bacteria that are present in the microflora of the intestine. The beta-1,5-linked galactofuranosyl chain of the galactomannan molecule, which is the target for the EB-A2 immunoglobulin (IgM) monoclonal antibody used in the ELISA, was found also to be present as a membrane-associated molecule in certain bacteria, most notably the *Bifidobacterium* (159, 160). Since these bacteria are present in the gut of humans and in very high numbers in neonates it was suggested that these bacteria could cause serum reactivity in those patient groups with disruption of the integrity of the intestinal barrier (159).

False-positive reactions of (1→3)-β-D-glucan are known to occur in some patients. These include subjects who had experienced renal failure and who were undergoing hemodialysis with cellulose membranes (108), subjects treated with certain immunoglobulin products (92), and specimens (or subjects) exposed to glucan-containing gauze or related materials (171). This underscores the need to combine serological (1→3)-β-D-glucan monitoring with clinical examination of the patient and other diagnostic procedures, such as high-resolution computed tomography scan, when making a diagnosis.

Nucleic Acid Detection Techniques

The sensitivity and specificity of molecular techniques make them attractive as alternative methods for the early diagnosis of invasive aspergillosis, but they are still experimental. In the absence of a commercial nucleic acid based system, conclusions with respect to the performance and diagnostic value of molecular techniques cannot be drawn since differences between in-house systems are extremely difficult to interpret. The molecular techniques appear to be highly sensitive and specific (56, 279) and can be applied to a broad spectrum of clinical specimens including respiratory samples (168), tissue biopsy specimens (81, 191), and blood (22, 56, 105). PCR-based assays appear to be amenable to the clinical laboratory. Initially, primers were designed to specifically amplify DNA from *Aspergillus* species (279), but alternative approaches have been evaluated in which a broad range of pathogenic fungi can be detected in a first step and identification to the species level can be achieved in a second step (56). The latter approach has great potential since severely immunocompromised patients are at risk for infections due to a broad range of fungal pathogens. Automated systems are increasingly used and adapted for lysis of fungal cells in clinical specimens and recovery of fungal DNA (62). Furthermore, technical advances in postamplification analysis have enabled real-time detection and quantification of the fungal DNA load in blood or tissue samples (TaqMan, LightCycler, and molecular beacons) (42, 142).

Prospective clinical evaluations of PCR-based systems with whole blood show that circulating fungal DNA can be detected early in the course of infection with a very high specificity and a variable sensitivity (56, 79, 131). The release and circulation of fungal DNA appear to be less constant than those of antigens, which results in a high number of negative samples from patients with invasive *Aspergillus* disease. In one study it was calculated that all patients with invasive aspergillosis could be diagnosed by PCR if more than 26 samples were analyzed per risk episode (22).

Isolation

In general, *Aspergillus* species can be recovered easily on routine mycological media and do not possess specific growth requirements. Most identification schemes utilize specific media and incubation conditions for the descriptions of potentially variable characteristics such as colony color and diameter (see below). *Aspergillus* species do not require specific biohazard precautions in the laboratory, although frequently culture materials are handled in a biosafety cabinet to avoid dispersal of the dry spores throughout the environment and cross-contamination of other cultures. The main disadvantages of culture are that it is relatively insensitive and that the culture process requires several days (85).

Identification

Diagnostic features of the more common medically important aspergilli are described in Table 2, and placement of species within sections follows the scheme used by Peterson (198). Species that commonly produce sexual structures (cleistothecia and ascospores; see Fig. 5) are described under their teleomorph names, *Eurotium, Emericella,* and *Neosartorya.* Figure 1 presents a diagrammatic key to several species.

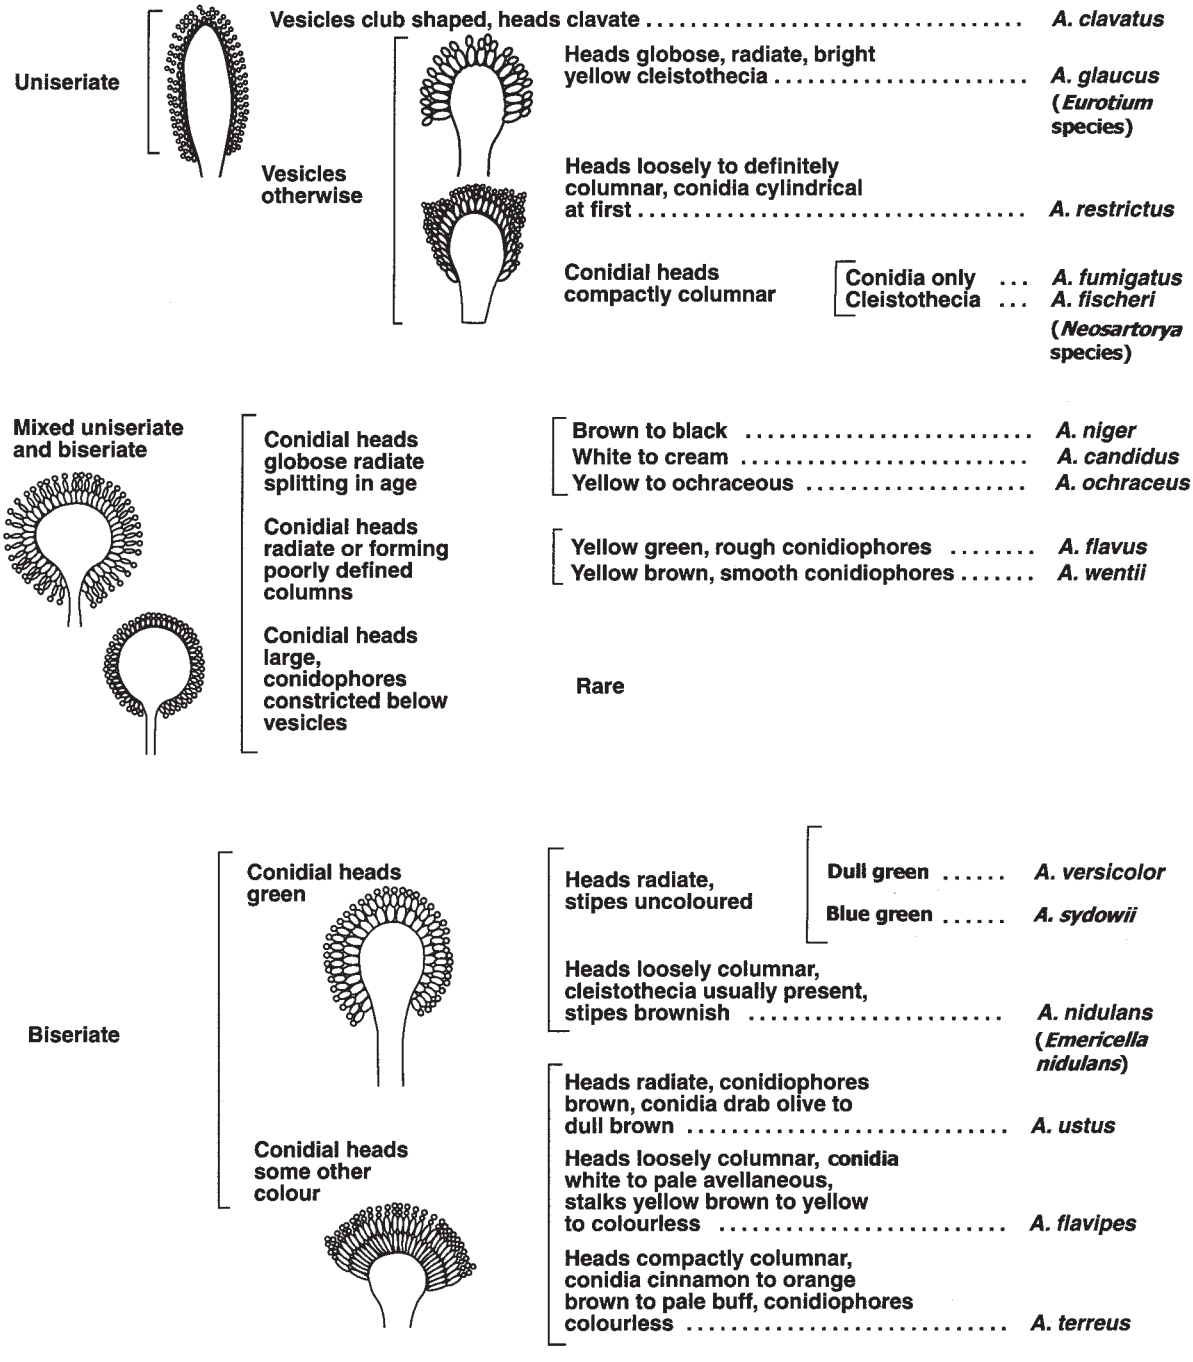

FIGURE 1 Key to representative species of *Aspergillus.* (Reprinted from reference 187 with permission of Cambridge University Press.)

Both macroscopic and microscopic characters are required for identification of *Aspergillus* species. When isolated on media such as Sabouraud dextrose agar (SDA), aspergilli tend to reproduce in the asexual form. Subculture to standard Czapek-Dox, Czapek-Dox with added glucose (20 to 30%), and 2% malt extract agar (211) or on modifications of these media (114) allows comparison of colonial and microscopic features with those given in monographs and taxonomic keys (53, 114, 115, 187, 211, 228). However, standard descriptions are often based on growth after 7 days, and it usually takes longer for development of the teleomorph. Some species are osmophilic and grow poorly on media with low concentrations of sugar. Colony diameters on standard media at 25 and 37°C, obverse and reverse colors, texture, topography, and the presence of exudate droplets or diffusible pigments are recorded after 7 days (53, 114, 187). Isolates not immediately identifiable should be retained longer for possible development of ascomata or other structures that may be helpful in the identification of an isolate.

Important microscopic features include differences in size, shape, color, and wall ornamentation of various structures; shape and size of vesicles; and arrangement of metulae and phialides. An upright stipe or conidiophore arises either directly from the vegetative hyphae or from a specialized hyphal cell called a foot cell, is usually nonseptate, and varies in color, length, and wall ornamentation in different species. The stipe terminates in a swollen cell, called a vesicle (Fig. 1, 5, and 7; see also Fig. 26 and 27), which is globose, subglobose, hemispherical, pyriform (pear shaped), or clavate (club shaped). Either the entire vesicle or the upper portion of it is covered with phialides, which form the conidia. Phialides arise simultaneously directly from the vesicle (uniseriate; Fig. 1; see also Fig. 26), from the intermediate series of cells called metulae (biseriate; Fig. 1; see also Fig. 27), or by a combination of both processes, as occurs in *A. flavus* (Fig. 1). Examination of a colony under a dissecting microscope allows observation of conidial chains to determine whether they are borne in a single column (columnar) or whether the columns are split, with some arising at right angles to the stipe (radiate). The conidia are typically ellipsoidal or globose and vary in size, color, and wall markings depending upon the species. Sclerotia are firm, fruiting-body-like structures composed of swollen hyphal cells but lacking internal spores. Hülle cells are globose or variable in shape and have thick and highly refractive walls (Fig. 5 and 7). They commonly occur immersed in the vegetative mycelium near the center of a colony, where their presence may be indicated by droplets of exudate. Hülle cells are often associated with cleistothecial ascomata such as in *Emericella* species (Fig. 5; Table 2). Cleistothecia have walls composed of enlarged hyphal cells and interiors filled randomly with asci and ascospores. Shape, color, size, and wall features of both ascomata and ascospores are important characters for differentiating teleomorphs of *Aspergillus* species. White, somewhat cottony, nonsporulating variants of aspergilli are isolated occasionally, especially from patients with chronic respiratory infections. *A. fumigatus* should be considered if a sterile white mold grows at 45°C. Variants sometimes appear highly atypical and present with glabrous cerebriform colonies not recognizable as *Aspergillus* (Fig. 3). Extended incubation on malt agar at 37°C can be used to induce sporulation in such isolates.

DNA sequencing can be particularly helpful in the identification of nonsporulating isolates or isolates with atypical morphology. The internal transcribed spacer regions (ITS1 and ITS2) of rRNA have been found to be more discriminatory than the 28S ribosomal subunit (D1-D2 region) for identification of 13 clinically important *Aspergillus* species (83). PCR-based assays utilizing these sequences have also been developed (83).

Typing Systems

Historically, genetic fingerprinting and epidemiological studies have been hampered by the lack of simple, reproducible typing methods. Better knowledge of the genetics of aspergilli and the advent of more user-friendly methods to prepare and manipulate DNA now allow for detailed analyses. Molecular techniques are useful in detection and identification systems and for epidemiological studies, although most techniques have been applied to type *A. fumigatus* strains only. Several genotypic methods can be used to genotype aspergilli including random amplified polymorphic DNA (RAPD) analysis, restriction fragment length polymorphism (RFLP) analysis, repetitive element and/or complex probes with Southern blotting (248), amplified fragment length polymorphism (AFLP) analysis, and microsatellite length polymorphism. However, a major problem with pattern-based techniques, such as RAPD, RFLP, and AFLP analyses, is the low level of concordance between laboratories (17). These drawbacks might be overcome with short tandem repeats, as was recently shown for typing of *A. fumigatus* (51a). Genetic fingerprinting of *A. fumigatus* by RFLP showed an enormous genetic variability among both clinical and environmental strains, indicating that any *A. fumigatus* strain can cause disease in humans (45, 67). Furthermore, the genetic diversity significantly reduces the potential of genotyping of *A. fumigatus* for the purpose of infection control since a considerable number of environmental isolates would have to be genotyped in order to match the patient strain with an environmental strain. For *A. fumigatus,* genotyping might be useful during clusters of infection in order to establish the presence of a common source. Nevertheless, some studies have shown genetic relatedness between environmental strains and patient strains, suggesting that aspergillosis had a nosocomial origin in some cases (45, 48, 66, 136, 137). Similar results have been obtained with RAPD typing patterns (11, 23, 127) and Southern blots probed with rRNA (249) or nonribosomal genomic sequences. Invasive aspergillosis has been linked to a nosocomial origin for *A. fumigatus* (67), *A. flavus* (136), and *A. terreus* (132). By using genotyping, specific niches within the hospital environment could be found, as was the case with *A. terreus,* where genotypes of strains recovered from potted plants in the direct environment of infected patients were identical to patient strains (132).

Serologic Tests

The detection of antibody in serum or other body fluids and reactivity in skin tests is, to some degree, dependent upon the purity, chemical nature, and uniqueness of the antigen preparation used (126). Extracts from the whole mycelium, metabolic products secreted into the medium during the growth of *Aspergillus* spp., purified antigens, and, more recently, recombinantly expressed and purified antigens have all been used in serologic tests and immunoassays. Although such antigen preparations are available commercially, standardized antigens are still not widely available. As reviewed by Kurup and Kumar (126), two of the major reasons for the lack of standardized antigens are that (i) antigen preparations are highly variable and (ii) antigens show various degrees of cross-reactivity. Work is ongoing to address these issues and to find ways to express, purify, and prepare improved antigen preparations (see, e.g., references 99, 162, and 277).

Several serologic tests with disparate sensitivities have been developed to detect circulating antibodies. As noted above, these have proven especially valuable in aiding the

diagnosis of allergic aspergillosis and aspergilloma but are less useful in the diagnosis of acute invasive disease in patients with little or no humoral response. However, antibody detection might be useful as a diagnostic tool for specific host groups such as lung transplant recipients (261) and patients with chronic granulomatous disease (225). It has also been suggested that serology could be used as a means of retrospective diagnosis for patients having undergone immunological reconstitution after an episode of neutropenia (85).

Double immunodiffusion and counterimmunoelectrophoresis remain the most widely used techniques, primarily because they are simple and easy to perform (126, 134), but they lack sensitivity and give no quantitative information on antibody concentrations. Other tests which have achieved some success for diagnosis of aspergillosis include ELISA, biotin-avidin-linked immunosorbent assay, radioimmunoassay, and indirect immunofluorescence (232). Of these, various ELISAs are the most amenable to the clinical laboratory. While in some cases these assays can be highly sensitive, reliable, and versatile, their routine use in many clinical laboratories has been limited by interlaboratory discrepancies in results and by immunological responses leading to false-positive results for some patient groups (126). The reasons for this vary but are primarily due to the ubiquitous nature of aspergilli (leading to high background antibody titers), the lack of ability to mount diagnostic humoral immune responses in immunocompromised patients, cross-reactivities between different fungi and even bacteria, and the selection of *Aspergillus* antigens used (117, 126). Using molecular biological techniques, it is now possible to produce *A. fumigatus* proteins in an expression system that yields large quantities of pure recombinant antigen. These antigens can serve as the basis for the development of ELISA methods to quantify the immune response (134). For example, the presence of antibodies directed against the recombinant protein mitogillin proved to correlate well with clinical disease, especially in patients with aspergilloma, with only 1.3% of healthy volunteers showing detectable antibodies (275). Quantitation of the immunoglobulin isotypes will be of importance to optimize the diagnostic value of the assay and to understand further the humoral response in patients with aspergillosis.

Antimicrobial Susceptibilities

The number of antifungal agents that are licensed to treat patients with invasive aspergillosis has increased. The development of lipid formulations of amphotericin B and the triazole itraconazole have broadened the therapeutic arsenal. Until recently the polyenes were considered to be the "gold standard" for treatment of invasive aspergillosis, but clinical trials have shown the triazole voriconazole to have superior efficacy, prompting many treating physicians to use voriconazole as first-line therapy (82, 192). Other antifungal drugs have been registered for treatment of invasive aspergillosis or are undergoing clinical evaluation, including the echinocandins caspofungin, micafungin, and anidulafungin and the triazole posaconazole.

A reference method for in vitro susceptibility testing of conidium-forming molds has been developed by the Clinical Laboratory Standards Institute (CLSI, formally National Committee for Clinical Laboratory Standards [NCCLS]) (172). With this method the polyenes and azoles are active in vitro. For amphotericin B there is, however, no clear correlation with clinical response because there is a narrow distribution of MICs with no clear resistant phenotype (101). The exception to this is *A. terreus,* which may have MICs as high as 16 μg of amphotericin B per ml and is considered to be resistant to the drug (270). Itraconazole, voriconazole, and posaconazole are active in vitro against *Aspergillus* species, with posaconazole typically showing the lowest MICs (199a). There is a good correlation between high MICs and treatment failure at least in experimental models of invasive aspergillosis (49, 50). Several mutations that correspond with amino acid substitutions and phenotypic resistance of *Aspergillus* against azoles have been identified (60, 157). The frequency of resistance against azoles, however, is low, and resistance appears to be found in patients who receive long-term azole prophylaxis or therapy (44, 274). Testing of the activity of echinocandins against *Aspergillus* is not reliable using the CLSI methodology and reading MIC endpoints. Exposure of *Aspergillus* to caspofungin results in morphologic changes that can be detected only by microscopic examination. Therefore, a microscopic endpoint was suggested, the minimal effective concentration, which enables in vitro testing against this class of antifungal agents (124).

Several commercial kits are available for testing the in vitro activity of antifungal drugs against molds including *Aspergillus*. The E test employs strips that contain a gradient of antifungal drug concentration and shows good correlation with the CLSI reference method (58).

Evaluation, Interpretation, and Reporting of Results

In the laboratory, *Aspergillus* isolates should be identified to the species level when they are recovered from patients at risk for aspergillus disease. Particularly important is *A. terreus,*

FIGURE 2 (row 1, left) Section of lung, stained with hematoxylin and eosin, showing dichotomously branched hyphae of *Aspergillus* in invasive aspergillosis.

FIGURE 9 (row 4, right) Compact biverticillate penicillus of *Penicillium marneffei.*

which is resistant to amphotericin B (270). *A. nidulans* and *A. ustus* (96) have also been reported to be less susceptible to amphotericin B than *A. fumigatus* (118).

On the other hand, *Aspergillus* species recovered from nonsterile specimens in immunocompetent patients may not be causative agents of disease and may not require identification to the species level (195). Decisions regarding workup of these samples should be discussed between microbiologist and clinician.

The diagnosis of invasive aspergillosis remains very difficult, and information obtained by various diagnostic tests and procedures such as clinical symptoms and signs, chest radiograph, high-resolution computed tomography, and, if possible, culture and histology needs to be considered. The conventional approach to the management of patients at risk for invasive aspergillosis is to administer antifungal agents empirically to neutropenic patients who are persistently febrile despite treatment with broad-spectrum antibacterial agents or to those who develop pulmonary infiltrates during antibacterial therapy. The development of tests that detect circulating surrogate markers, such as fungal antigens or DNA, and the use of high-resolution computed tomography allow for alternative approaches to be evaluated. The optimal use of detection of circulating markers appears to be in prospective monitoring of high-risk patients during the period of increased risk, since circulating markers are very early indicators of infection in most patients. Once the marker is detected, patients could undergo a diagnostic workup that includes high-resolution computed tomography of the chest in order to confirm the presence of the infection. The probability of infection is very high for this group, and early antifungal treatment can then be administered selectively. The above strategy proved to be superior to the conventional approach in a decision analysis (236), and a feasibility study indicated that the preemptive treatment strategy might be an alternative to empiric therapy (146).

It should be appreciated that no MIC breakpoints are available for any molds with any antifungal drug. This prevents a straightforward correlation between MIC value and clinical outcome (214). The interpretation of MIC testing of molds remains problematic (215), with the most potential value from testing of *A. fumigatus* isolates against azoles. In general, the most useful information regarding antifungal susceptibility can be obtained from identifying the fungal agent to the species level.

FUSARIUM SPECIES

Taxonomy

Fusarium species are cosmopolitan soil saprobes and facultative plant pathogens that can cause infection or toxicosis in humans and animals (173). Teleomorphs occur in *Gibberella, Haematonectria,* and other genera in the order Hypocreales. Molecular phylogenetic studies have been used to examine species and sections within *Fusarium. F. solani* has been shown to be a complex of at least 55 phylogenetically distinct species which includes medically important isolates grouped among at least 15 different entities not yet completely defined (185, 255). The *F. solani* complex also includes *Acremonium falciforme, Cylindrocarpon lichenicola,* and *Neocosmospora vasinfecta* (47, 185, 256). Several medically important species are included within the 29 species of the *Gibberella fujikuroi* complex: *F. verticillioides, F. proliferatum, F. napiforme, F. nygamai, F. subglutinans,* and *F. sacchari* (176, 255). A synopsis of morphological features defining the *F. solani* complex (Fig. 10), *F. oxysporum,* and *F. verticillioides* (Fig. 11) is presented in Table 4. Relatives of *Fusarium* species, *Cylindrocarpon* species are also cosmopolitan soil- and plant-associated fungi which are recovered occasionally as contaminants from specimens. Rare reports concern keratitis, cutaneous and disseminated infection, and mycetoma (47, 80, 245).

Description of Agent(s)

The most frequent cause of infections in humans is *F. solani,* although other *Fusarium* species have been implicated including *F. oxysporum, F. moniliforme, F. verticillioides, F. proliferatum, F. napiforme, F. nygamai, F. subglutinans,* and *F. sacchari* (176). *F. solani* is a common cause of fungal keratitis (207).

Epidemiology and Transmission

There are numerous toxins and metabolites produced by *Fusarium* species that have been implicated to cause disease in humans, especially associated with the consumption of contaminated food products (see chapter 127). Alimentary toxic aleukia was described in individuals who ate grain contaminated with *F. sporotrichioides* or *F. poae* that produced the trichothecene mycotoxin (100). Besides orally ingested mycotoxins, systemic effects of exposure to inhaled mycotoxins have also been attributed to *Fusarium,* although these effects have been much less characterized (123).

Although invasive infection by *Fusarium* is uncommon, an increased incidence of disseminated infection has been seen in neutropenic patients with hematologic cancer, in recipients of solid-organ transplants, and allogeneic HSCT recipients (127, 154, 173, 209, 226). The incidence of fusariosis among allogeneic HSCT recipients varied between 4.21 to 5.0 cases per 1,000 in human leukocyte antigen (HLA)-matched related transplant recipients and 20.19 cases per 1,000 in HLA-mismatched transplant recipients (177). Among allogeneic HSCT recipients, a trimodal distribution was observed: a first peak before engraftment, a second peak at a median of 62 days after transplantation, and a third peak

FIGURE 17 (row 4, right) Setae (appendages) of *Onychocola canadensis.*

>1 year after transplantation. The actuarial survival was 13% (median, 13 days), with persistent neutropenia (hazard ratio of 5.43) and use of corticosteroids (hazard ratio of 2.18) being the most important factors associated with poor outcome (177, 178).

The portal of entry is unknown in most cases of invasive infection, although inhalation, ingestion, and traumatic inoculation have been suggested (21). In some patients disseminated infection may follow onychomycosis, often associated with cellulitis. The hospital water supply system has also been implicated as a source of infection in immunocompromised patients (6).

Clinical Significance

The spectrum of clinical presentations includes keratitis, onychomycosis, colonization of burned or necrotic skin of wounds or ulcers, sinusitis, and infection of the deeper tissues including mycetoma (see chapter 126), endophthalmitis, peritonitis, endocarditis, osteomyelitis, arthritis, and subcutaneous and brain abscess (106, 127, 173, 179). Cutaneous lesions, fungemia, rhinocerebral involvement, pneumonia, or combinations of these are common clinical findings of disseminated *Fusarium* infection (173, 205, 209, 226), and biopsy of skin lesions may be helpful in establishing a diagnosis. In contrast to the low rate of recovery of *Aspergillus* species in blood cultures in cases of invasive aspergillosis, there is a high rate of recovery (60%) from blood in disseminated *Fusarium* infection (127, 209).

Collection, Transport, and Storage of Specimens

Methods of collection, transport, and storage of specimens are detailed in chapter 116. As in invasive aspergillosis, invasive *Fusarium* infections are difficult to diagnose and usually require a combination of clinical, culture, and radiographic findings. However, unlike *Aspergillus, Fusarium* is cultured more frequently from blood, nails, and skin lesions (21, 167). The recovery from a normally sterile site and microscopic evidence of invasive growth in tissue provide the most convincing evidence of invasive fusariosis.

Direct Examination

Microscopy

In direct examination, the hyphae of *Fusarium* species resemble those of *Aspergillus, Paecilomyces,* or *Scedosporium* species in size (3 to 6 μm in width), septation, branching pattern, and predilection for vascular invasion. The hyphae are irregular in width and may show areas of collapse. Hyphae exhibit both dichotomous branching (i.e., branching at 45°), as is commonly seen in invasive aspergillosis, and branching at right angles (140). Microconidia and rarely macroconidia and budding cells, as well as phialides, may be found in blood vessel lumens or in aerated tissues (140). Immunohistologic methods may help to distinguish between infections caused by some hyaline molds, but cross-reactivity is problematic and serological tests are not in common use (110). Definitive diagnosis requires isolation and identification of the fungus, along with demonstration of fungal elements in tissue.

Antigen Detection

There is no commercial system available for detection of genus-specific or species-specific antigens released by *Fusarium* species in human infection. The diagnostic utility of polyclonal fluorescent-antibody reagents to *F. solani* in tissue sections from patients with invasive fusariosis was evaluated, but extensive cross-staining was observed with sections containing aspergilli, *Paecilomyces lilacinus,* and *Pseudallescheria boydii* (110).

There is one report that suggests that exoantigens from *F. oxysporum* cross-react with the Pastorex Aspergillus antigen latex-agglutination kit (107), but no significant cross-reactivity with *F. solani* and *F. oxysporum* was found with the Platelia Aspergillus assay despite the fact that both kits employ the same monoclonal antibody (258). There are no reports that indicate that sera from patients with invasive fusariosis show reactivity with these antigen detection kits. Antigens prepared from *F. verticillioides* were found to cause borderline cross-reactivity with the Platelia Candida antigen assay (BioRad) (218). This reactivity appeared to be specific for *F. verticillioides* since extracts prepared from *F. solani* and *F. oxysporum* showed no cross-reactivity in vitro.

Circulating (1→3)-β-D-glucan can be detected in the blood of patients with *Fusarium* fungemia and pneumonia (182, 189), although the presence of this marker is not specific for *Fusarium*. The sensitivity for detection of *Fusarium* infection was found to be 100% at a cutoff value of 60 pg/ml, among only three patients with invasive fusariosis (189). The clinical experience of (1→3)-β-D-glucan detection in patients with invasive fusariosis is limited, but the test is of value in patients with suspicion of invasive fungal infection as part of the diagnostic workup.

Nucleic Acid Detection Techniques

Given the difficulty in identification to the species level of *Fusarium* isolates by use of microscopic and macroscopic features, and the expertise required, application of molecular tools in this area seems logical. However, within the field of clinical mycology only a very limited number of studies have been published. In one study, a panfungal and species-specific *F. solani* PCR was designed based on the 18S rRNA gene sequence and applied to ocular specimens from three patients with suspected bacterial or fungal endophthalmitis. Although *F. solani* was detected in spiked specimens, no clinical samples from patients with endophthalmitis due to *Fusarium* were analyzed (98). PCR-based identification was applied to *Fusarium* isolates obtained from patients with onychomycosis (175). The *Fusarium* species identified were the same as those known to cause disseminated fusariosis in immunocompromised patients.

Panfungal PCR systems that detect a wide range of fungi including *Fusarium* have been developed (25). In one study the PCR was positive in blood samples from a patient with an invasive fusariosis and blood cultures positive for *F. solani* (25). As with other opportunistic fungi, molecular methods such as PCR appear to be a valuable tool for the detection and identification of *Fusarium* infections; however, the value of these tools in the management of patients remains to be investigated.

Isolation

In general, *Fusarium* species can be recovered easily on routine mycological media. As with *Aspergillus,* no specific growth requirements and no specific biohazard precautions are required in the laboratory.

Identification

Microscopic features of phialide shape, the number of openings on the phialides (i.e., monophialides or polyphialides), the formation of conidia in heads or chains, micro- and macroconidial shape and septation, the presence and

arrangement of chlamydospores, and colonial features including growth rates, color of colony obverse and reverse, and color of conidial masses are important characters for species identification. However, considerable proficiency is required to identify *Fusarium* species with certainty, and a reference laboratory should be consulted. Alternatively, molecular tools are being developed to help to identify clinical *Fusarium* isolates to the species level (175). Although fusaria grow well on most mycological media, the medium can profoundly influence the colonial topography, color, and conidium development. Synthetic nutrient agar, potato dextrose agar, and tap water agar supplemented with either sterilized carnation leaves or potassium chloride are widely employed (173, 174). Use of a rich medium to maintain isolates can result in cultural degeneration.

Typing Systems

Typing systems that have been applied to *Aspergillus* have also been used to differentiate strains of *Fusarium* (3, 69, 78, 231a), although most experience has been obtained in the field of agricultural research rather than in clinical mycology.

Molecular epidemiological investigations of clinical *F. oxysporum* isolates via multifocus sequence typing and AFLP analyses revealed a geographically widespread clonal lineage comprising >70% of genotyped isolates, including those obtained from different hospitals in the United States (186). These studies have identified the hospital water distribution system as a potential source of nosocomial infection (6). However, the most important mode of transmission is airborne, given the observation that the majority of patients with *Fusarium* are infected on or within 3 days of hospital admission, indicating community rather than nosocomial acquisition (208).

Serologic Tests

Conventional serological tests have been developed and used to measure exposure of specific patient populations to *Fusarium,* most commonly in the setting of occupational exposure or indoor dampness problems (97, 129, 223). In these populations IgG directed against *Fusarium* can be detected. Elevated IgE and IgG antibody levels directed against *F. vasinfectum* were found in a patient with allergic bronchopulmonary mycosis due to *F. vasinfectum* (224). Anti-*Fusarium* antibodies have not been evaluated as a diagnostic tool for patients with invasive fusariosis.

Antimicrobial Susceptibilities

In vitro studies show relatively high MICs for amphotericin B and itraconazole of *F. solani* (MIC_{90}, 4 and >8 μg/ml, respectively) and *F. oxysporum* (MIC_{90}, 1.0 and >8 μg/ml, respectively) (58). Higher MICs of these drugs were obtained with the E test, which showed an agreement of less than 80% for these species with the NCCLS M38-A method. Voriconazole and posaconazole show variable in vitro activity against clinical *Fusarium* isolates. In one series voriconazole was active against *F. solani, F. oxysporum, F. proliferatum,* and *F. moniliforme* (MIC_{90}, 2 μg/ml) but was not fungicidal against most isolates (8, 39). However, in another study both azoles showed no activity (52). The correlation between in vitro activity and clinical outcome remains suboptimal in *Fusarium,* given the clinical responses observed in patients with invasive fusariosis treated with voriconazole (196) and the efficacy of posaconazole in experimental fusariosis (144). The echinocandins show no meaningful activity against *Fusarium* in vitro (9, 200).

SCEDOSPORIUM SPECIES

Taxonomy

Based on analysis of partial sequences of the ß-tubulin and calmodulin genes and the ITS of the rRNA gene, it was demonstrated that *Pseudallescheria boydii* is a species complex (65). The three species *P. angusta, P. ellipsoidea,* and *P. fusoidea,* which are morphologically related to *P. boydii* and which were previously considered synonyms, could be differentiated genetically from *P. boydii.* Strains of *P. ellipsoidea* have caused invasive infections. The species *P. minutispora* and *Scedosporium aurantiacum* are phylogenetically separated from the other species and were proposed as new species, which is supported by morphological features. All the strains included in *S. aurantiacum* species have a clinical origin, while those included in *P. minutispora* are environmental (65).

Description of Agents

Scedosporium species are soil-, manure-, and water-inhabiting molds with virulence and clinical spectra remarkably similar to those of *Aspergillus.* The two species known to cause human and animal infection are *Scedosporium apiospermum* (the anamorph of the ascomycete *Pseudallescheria boydii*) and *S. prolificans.* The similarities between species of *Aspergillus* and *Scedosporium* in both clinical syndromes and appearance in tissue have led to their mention in this chapter, even though species of *Scedosporium* are darkly pigmented in culture.

Epidemiology and Transmission

Scedosporium is a ubiquitous saprophytic mold that is found in soil, stagnant and polluted water, sewage, plants, and decaying vegetation. Disease is caused by inhalation of spores leading to pulmonary or sinus disease or by traumatic inoculation through the skin. The fungus may colonize the respiratory tract in patients with cystic fibrosis (38), but its pathogenicity in this patient group has not been well established. *Scedosporium* is known as the causative agent of mycetoma, a chronic subcutaneous infection characterized by the production of grains (see chapter 126). Invasive infections have been increasingly observed in both immunocompetent and immunocompromised patients. The incidence of infection is typically low but may be underestimated. In organ transplant recipients *Scedosporium* accounted for approximately 25% of non-*Aspergillus* mold infections (90). The most common sites of infection are lung, sinus, skin, bone, and joints. Central nervous system involvement was present in 17 to 30% of patients, depending on the underlying disease of the patient (90). Invasive infections were found to disseminate in 46% of transplant patients, with *S. prolificans* being more likely to cause fungemia than *S. apiospermum* (91, 180).

Clinical Significance

In high-risk patients, culture of *Scedosporium* from lower respiratory tract specimens was found to have a higher positive predictive value for invasive mold infection than recovery of non-*Scedosporium* molds (139). The authors suggested treatment with antifungal agents when this mold was cultured from high-risk patients, given the significance of a positive culture and the high mortality associated with invasive disease. The survival rate of patients with invasive scedosporiosis is low, ranging from 30 to 58% in patients with infection due to *S. apiospermum* (90, 196). The survival rate in patients with *S. prolificans* infection is generally lower (19).

Patients colonized with *Scedosporium* often have risk factors that predispose them to fungal infections (e.g., leukemia, lymphoma, chronic obstructive pulmonary disease, systemic

autoimmune disease that is being treated with immunosuppressants, and AIDS). Disseminated infections with this fungus have been reported in several countries, including the United States, Canada, Australia, Germany, France, and The Netherlands. However, the infection has been reported most frequently in Spain (19), especially in the north.

Collection, Transport, and Storage of Specimens

Methods of collection, transport, and storage of specimens are detailed in chapter 116.

Direct Examination

Microscopy

In tissue sections, the hyphae of *Scedosporium* species are hyaline, septate, branched, and hematoxylinophilic and can be reliably distinguished from hyphae of the aspergilli and other hyaline molds only by direct immunofluorescence. Occasionally, conidia which are pale brown and ovoid or cylindrical are formed, generally in fungus balls or in the sinuses; their presence allows presumptive identification. Culture and serologic analysis are still necessary to establish the diagnosis.

Isolation

S. prolificans and *S. apiospermum* grow well in 2 to 4 days at 37°C in culture media that are specific for fungi, as well as in nonselective media (blood agar and chocolate agar). Their characteristic macroscopic appearance facilitates identification.

Identification

The microscopic morphology of a sporulating culture remains the cornerstone of identification of *Scedosporium*. Identification of significant strains to the species level is required given the consequences for antifungal therapy and outcome. Molecular identification using a standardized DNA sequence approach showed this to be accurate and timely when performed on pure cultures (206).

Typing Systems

Several typing systems have been used to type *Scedosporium* isolates including multilocus enzyme electrophoresis (282), RAPD (46), and inter-simple-sequence-repeat fingerprinting, a technique based on the high degree of polymorphism of the multisatellite genetic markers used (247). These studies show that *S. prolificans* is extremely diverse and that several patients were infected or colonized with more than one genotype(46). High polymorphism was also observed for *S. apiospermum,* but clustering according to geographical origin of strains was not found.

Serologic Tests

There are no systems available to detect (circulating) *Scedosporium* antigen or antibody in human infection.

Antimicrobial Susceptibilities

By using the CLSI reference method (172), *S. apiospermum* was found to be resistant to fluconazole and flucytosine, variably susceptible to amphotericin B, itraconazole, and ketoconazole, and susceptible to miconazole. Voriconazole was as active as miconazole in vitro. However, none of these presently available antifungal agents showed meaningful activity against *S. prolificans* (43). The only drug with activity against *S. prolificans* is the investigational azole albaconazole (29). In vitro MICs of voriconazole corresponded with efficacy of the drug in a guinea pig model of invasive scedosporiosis due to *S. apiospermum* (30). Although the allylamine terbinafine has no meaningful in vitro activity against *Scedosporium* sp. (64), when the drug was combined with azoles, synergistic interaction was observed (156). Several cases have been reported with survival of patients treated with a combination of voriconazole and terbinafine (89). In vitro synergistic interaction against both species was also reported for the combination of amphotericin B and micafungin (281), but there is no clinical experience with this combination.

PENICILLIUM MARNEFFEI

Taxonomy

Like its close relative *Aspergillus,* the genus *Penicillium* comprises anamorphic (asexual) species with connections to the ascomycete family Trichocomaceae (228). About 200 species have been placed into four subgenera according to conidiophore branching (53, 204), but molecular analysis has shown three of these subgenera to be polyphyletic (199). The only true pathogen is *Penicillium marneffei,* a member of the subgenus *Biverticillium* (141). The species is unique among the penicillia in being dimorphic, forming in tissue a unicellular yeastlike organelle that reproduces by planate division (division by fission). The thermally regulated growth has typical features of *Penicillium* at room temperature and as yeast cells (arthroconidium) at body temperature.

Epidemiology and Transmission

P. marneffei infection is an important emerging public health problem, especially among patients infected with HIV in the areas of endemicity in Southeast Asia, with cases being reported from Manipur State, India, Myanmar, Malaysia, southern China, Hong Kong, and Taiwan. Most cases, however, occur in Northern Thailand (41). Within these regions, *P. marneffei* infection is regarded as an AIDS-defining illness, and the severity of the disease depends on the immunological status of the infected individual.

The natural history and mode of transmission of the organism remain unclear. Exposure to soil, especially during the rainy season, has been suggested to be a critical risk factor (35, 54, 150). Even though the fungus was discovered in 1956 in the bamboo rat *(Rhizomys sinensis)* in Vietnam, decaying organic material and soil are most likely its natural habitat. Using multilocus microsatellite typing to characterize this fungus, several isolates from bamboo rats and humans were shown to share identical multilocus genotypes. These data suggest either that transmission of *P. marneffei* may occur from rodents to humans or that rodents and humans are coinfected from common environmental sources (262).

Patients are infected by inhalation of *P. marneffei* conidia. Pulmonary alveolar macrophages are the primary host defense mechanism. The fungus proliferates within phagocytic cells resulting in granulomas in immunocompetent individuals. Among AIDS patients the infection typically develops in individuals with $CD4^+$ cell counts of less than 50 cells/ml. The infection rapidly disseminates, and the yeast can be recovered from blood and bone marrow.

Clinical Significance

P. marneffei has been reported to be the fourth most common cause of disseminated opportunistic infection in patients with AIDS in areas of endemicity (35, 54, 268). Infections

are more common in immunosuppressed than immunocompetent hosts and are usually disseminated, with multiple-organ involvement including the lung, liver, and skin. The fungus can usually be isolated from characteristic skin lesions, which are present in 60% of cases, or from blood or bone marrow (54, 150). Presumptive diagnosis may be made by demonstration of the yeastlike cells of *P. marneffei* in Wright-stained smears from skin lesions or in biopsy specimens from these sites (150).

Collection, Transport, and Storage of Specimens

Methods of collection, transport, and storage of specimens are detailed in chapter 116.

Direct Examination

Microscopy

The yeastlike cells are oval or cylindrical and 3 to 6 μm long and may have a cross wall. Yeast cells of *Histoplasma capsulatum* may appear similar, especially when they are within phagocytes, but they may show evidence of budding rather than division by fission. The yeast may be stained by the methenamine silver or periodic-acid Schiff stains in tissue sections.

Isolation

P. marneffei can easily be cultured from clinical specimens. The fungus grows well on SDA. Culture of bone marrow is the most sensitive (100%) followed by culture of specimens obtained from skin biopsy (90%) and blood culture (76%). Handling and culture of specimens possibly containing *P. marneffei* should be performed with care, avoiding inhalation of conidia from sporulating mold cultures or accidental injection into the skin. Biosafety level 2 practices and facilities are recommended for propagating and manipulating cultures known to contain *P. marneffei*. The main drawback of fungal culture is the long turnaround time and the need for invasive procedures to obtain tissue.

Identification

Members of the genus *Penicillium* are the ubiquitous blue-green molds that are among the most common of all laboratory contaminants and that can be isolated easily from respiratory specimens and body surfaces. Isolates of *P. marneffei* have a distinctive morphology (Table 3; Fig. 8 and 9), with conidiophore-bearing biverticillate penicillia and each penicillus being composed of four to five metulae with smooth-walled conidia. A diffusible red pigment produced in culture is one of the first indications that an isolate may be *P. marneffei.* However, red pigment can also be produced by other *Penicillium* species that are not associated with human infection, including *P. citrinum, P. janthinellum, P. purpurogenum,* and *P. rubrum.*

Yeast-like colonies at 37°C are glabrous and beige and do not produce any red pigment.

Typing Systems

Exact typing systems have been developed to characterize genetic diversity in *P. marneffei* including multilocus microsatellite typing (61). Typing of strains showed clustering into two distinct clades corresponding with isolates obtained from patients living in the eastern parts of the *P. marneffei* range and from the western sector including Thailand and India. Potential geographic isolation of populations was also suggested by other investigators (130). Identical multilocus genotypes were found in isolates from bamboo rats and humans, but the interpretation in relation to the pathogenesis of the infection remains unclear (262).

Serologic Tests

Serologic methods have been developed and are proving to be important in the early diagnosis of infection. A number of studies have aimed at detecting fungal antibodies and/or antigens in the serum and body fluids of infected patients. Culture filtrates from *P. marneffei* cultured in liquid media and anti-*P. marneffei* rabbit sera were incorporated in an immunodiffusion test to detect antibody or antigens, respectively. Other assays included an indirect immunofluorescent-antibody test, using the yeast hyphae or the germinating conidia as antigens (110), a latex agglutination test, and an ELISA (51, 109, 150). Antigens may be detected in urine as well as serum. Specific antibodies against a recombinant cell wall-associated protein (Mp1p) were generated to produce an ELISA-based antibody test. Approximately 80% (14 of 17) of documented penicilliosis HIV^+ patients tested positive for the specific antibody. No false-positive results were found for serum samples from 90 healthy blood donors, 20 patients with typhoid fever, and 55 patients with tuberculosis, indicating a high specificity of the test. Thus, this ELISA-based test for the detection of anti-Mp1p antibody can be of significant value as a diagnostic for penicilliosis (27, 28).

Antimicrobial Susceptibilities

Amphotericin B and itraconazole are commonly used for treating patients with penicilliosis, with amphotericin B for seriously ill patients. *P. marneffei* is highly susceptible in vitro to miconazole, itraconazole, and ketoconazole but less so to fluconazole (257). Newer azoles such as voriconazole also exhibit potent activity (183). The echinocandins are active against *P. marneffei,* but in vitro the drugs are more active against the mycelial forms than the yeast-like forms (170, 183).

OTHER ASCOMYCETES

Taxonomy

Scopulariopsis

The genus *Scopulariopsis* contains both lightly colored and dark species (165), some of which have teleomorphs in the genus *Microascus* (Fig. 20) of the Microascaceae (1, 53, 165) or the genus *Kernia*.

Chaetomium

Analysis of the 18S rRNA gene confirmed the placement of *Chaetomium* in the family Chaetomiaceae under the order Sordariales (135).

Description of Agents

Scopulariopsis

Members of the genus *Scopulariopsis* are common soil fungi and agents of deterioration, especially of cellulosic substrates. Of the 30 species known, only a few are reliably reported from human infections.

Chaetomium

The perithecial ascomycetes *Achaetomium* and *Chaetomium* produce brown lemon-shaped to fusiform ascospores within ascomata that are ornamented with hairs (or setae), especially around the upper part near the opening. Anamorphs

are uncommon. The perithecial hairs of *Achaetomium* species are pale and fine and not very conspicuous, while those of *Chaetomium* species are dark, thicker, spinelike, or elaborately coiled or branched.

Gymnascella

Gymnascella species are onygenalean fungi that produce clusters of ascospores surrounded by yellow or orange filaments, but differentiated ascomata are not formed.

Clinical Significance

Scopulariopsis

Species causing onychomycosis include *S. brevicaulis* (Fig. 29), by far the most important as both pathogen and regular contaminant; *S. candida,* the next most common; and *M. cirrosus, M. cinereus,* and *S. brumptii* (106, 203, 239). Reports of onychomycosis associated with other species have not been validated; *S. koningii* is a synonym of *S. brevicaulis* (1). Like species of *Fusarium* and *Paecilomyces variotii, S. brevicaulis* may colonize necrotic tissue. *Scopulariopsis* species are rarely invasive, and *S. brevicaulis* and *Microascus cinereus* are the most common species reported. Infections include otomycosis, keratitis, prosthetic valve endocarditis, sinusitis, pneumonia, brain abscess, and (sub)cutaneous and bone invasion in immunocompetent and immunosuppressed individuals (13, 47, 122, 149, 161, 201, 231). *S. candida* and *S. acremonium* have been reported from invasive sinusitis, but few details concerning the latter species were provided in the report (57, 121). Brain abscess caused by *S. brumptii* and invasive cutaneous infection caused by *M. cirrosus* have been reported to occur in liver transplant and bone marrow recipients, respectively (122, 190).

Chaetomium

Achaetomium strumarium (reported as *Chaetomium strumarium*) (Fig. 21) and *Chaetomium atrobrunneum* may cause cerebral infection (2), but some reports concerning other *Chaetomium* species in deep infection have not been validated (239, 245). *C. globosum* (see chapter 120) occurs most commonly as a contaminant or as a rare agent of onychomycosis (2, 106, 239).

Gymnascella

Rare reports describe *Gymnascella damkaliensis* as a cause of onychomycosis (106) and *G. hyalinospora* as the cause of invasive pulmonary infection in a leukemic patient (95) (Fig. 22, 23, and 30).

Direct Examination

Microscopy

Histopathologic findings show hyphal morphology indistinguishable from that of species of *Aspergillus, Fusarium,* and *Pseudallescheria* (201).

Isolation

These species grow well on all laboratory media. *Scopulariopsis* species are strongly or moderately resistant to cycloheximide.

Identification

Darkly pigmented *Scopulariopsis* species are difficult to identify. They should be grown on a sporulation medium to promote the development of perithecia (sexual structures) of *Microascus* species. Some species form synnemata (a group of conidiophores united at the base and part of the way up their length) in culture and are classified in the closely related genus *Cephalotrichum* (also known as *Doratomyces*), but none of these has been demonstrated to be a pathogen. The genus *Ascosubramania* was described for a mold with features suggestive of a *Microascus* (74).

The *Chaetomium* species pathogenic to humans can be distinguished by the appearance of the perithecia, setae (undulate hairs), and the mature ascospores (16). Those that have been reported to cause human disease grow well at 35 to 37°C, and those with a predilection for the central nervous system often grow at up to 42 to 45°C.

Gymnascella hyalinum can be identified based on the formation of ascospores within tufts of aerial hyphae on sporulation medium (95). A case isolate and the reference isolate of this species both displayed false-positive results in the Gen-Probe test for *Blastomyces dermatitidis* (95).

Antimicrobial Susceptibilities

Scopulariopsis

Antifungals including amphotericin B and itraconazole have limited in vitro activity against *Scopulariopsis* species, and conflicting results have been reported for voriconazole and terbinafine (64, 250). In vitro, promising interaction was observed between terbinafine and fluconazole, itraconazole,

and voriconazole against isolates of *S. brevicaulis,* although clinical experience with combination therapy is very limited (222).

Chaetomium

Treatment failures of *Chaetomium* infections have been reported when patients were treated with amphotericin B alone or in combination with itraconazole. Voriconazole and the experimental triazoles ravuconazole and albaconazole showed potent activity in vitro with MICs of less than 0.5 μg/ml (235). The echinocandin micafungin was not active in vitro.

SCHIZOPHYLLUM COMMUNE AND OTHER BASIDIOMYCETES

Allergic reactions due to inhalation of mushroom spores (87) and mycetismus due to the ingestion of mushrooms have been frequently reported, but the incidence of human infections by members of the Basidiomycota is rare. *Schizophyllum commune* is recognized as a significant cause of allergy-related sinusitis and pulmonary disease including allergic bronchopulmonary mycosis and bronchial mucoid impaction, a type of hypersensitivity reaction to *S. commune* hyphae (5, 26, 40, 103, 240, 242, 244). *S. commune* has also caused infection of the brain, lungs, and buccal mucosa in both immunocompetent and immunosuppressed patients (103, 217, 220, 239, 240).

Filamentous basidiomycetes, as well as species of smuts which may appear yeastlike (Ustilaginaceae and Tilletiaceae), are commonly isolated from respiratory specimens and sometimes from blood, and their significance can be difficult to evaluate (240). Pathogenicity of members of the genus *Coprinus* (taxonomy currently under revision) has rarely been confirmed by histopathologic evidence of hyphal filaments. *C. cinereus* or its anamorph *Hormographiella aspergillata* have been reported from prosthetic valve endocarditis, fatal lung infections in leukemic patients, and cutaneous lesions (51, 128, 239, 266). Repeated isolation and the presence of filaments in sputum have implicated the thermotolerant *Sporotrichum pruinosum,* the anamorph of *Phanerochaete chrysosporium* (111), a species being investigated for its utility in biodegradation. An isolate reported as *Tilletiopsis minor* from an immunosuppressed patient appears to be *Lecythophora lignicola* (see the discussion of *Acremonium* in "Other Moniliaceous Molds" below) (210, 239).

Direct Examination

Microscopy

Direct microscopy shows septate filamentous organisms, which can be of varying widths. *Schizophyllum commune* in tissue can display histopathologic features suggestive of *Aspergillus*. Septate hyphae with clamp connections can also be demonstrated with some basidiomycete isolates (217).

Antigen Detection

Antibody and antigen tests and *Aspergillus*-specific fluorescent-antibody staining have been recommended as aids in the differential diagnosis, but they are not widely available (217).

Isolation

Filamentous basidiomycetes grow well on routine culture media. The use of the fungicide benomyl at a final concentration of 10 μg/ml in culture media can be useful to distinguish filamentous basidiomycetes, which are tolerant to benomyl, from isolates of ascomycetous origin, which may be sensitive to benomyl (254).

Identification

Hyphae in tissue are narrow (3 to 6 μm wide) or broader (up to 10 μm) and somewhat irregular. The hyphae in tissue or culture may be recognized as belonging to a basidiomycete if clamp connections are present at the septa; if characteristic pegs or spicules are present, the hyphae are typical of *S. commune* (Fig. 25 and 31). However, these structures may be absent, and the hyphae then resemble those of *Aspergillus* species or other molds (5, 240, 244) (Fig. 24). A filamentous basidiomycete can be suspected when a nonsporulating hyaline mold displays growth on benomyl agar, growth at 37°C, and sensitivity to cycloheximide (240). Identification of atypical isolates can be difficult and requires specialized techniques. Vegetative compatibility tests and sequencing of the ITS region of rRNA have been used to confirm the identification of isolates (148, 242, 244).

Antimicrobial Susceptibilities

The largest study to date evaluating the activity of antifungal agents included 44 clinical isolates of filamentous basidiomycetous fungi, including *Schizophyllum commune* ($n = 5$), *Coprinus* species ($n = 8$), *Bjerkandera adusta* ($n = 14$), and sterile, uncharacterized basidiomycetes ($n = 17$). Amphotericin B, itraconazole, voriconazole, and posaconazole showed low MICs, in contrast to fluconazole and flucytosine (70). No statistically significant differences among the genera were noted.

OTHER MONILIACEOUS MOLDS

Features of some opportunistic moniliaceous fungi are described in Table 3.

Ascomycetes: *Acremonium, Lecythophora, Phialemonium,* and *Phaeoacremonium* Species

Fungi belonging to the genera *Acremonium, Lecythophora, Phialemonium,* and *Phaeoacremonium* form single-celled conidia in slimy masses from slender phialides. The genus *Acremonium,* formerly called *Cephalosporium,* includes approximately 100 species associated with soil, insects, sewage, rhizospheres of plants, and other environmental substrates. Teleomorphs, where known, are in the genera *Nectria, Emericellopsis,* and *Thielavia,* which are placed in different ascomycete orders. Teleomorph connections and molecular data provide evidence for some restructuring of the genus along phylogenetic lines (47, 68, 73). Many reports concerning *Acremonium* species involve nail, skin, or eye infections or mycetoma (see also chapter 121) (47, 106, 127, 219). Localized and disseminated infections occur in patients following valve replacement, dialysis, or transplantation or in patients with hematologic or solid-organ malignancies (47, 73, 127, 230, 245, 255, 272). Fungemia is common. In tissue, hyphae of *Acremonium* species resemble those of *Fusarium* in branching pattern, vascular invasion, and propensity to sporulate; budding cells may rarely be seen (140, 230, 272). Recognition of *Acremonium* species in culture is not too difficult, but identification to the species level is very difficult, and many reports of infection are based on unidentified species (73, 255). Species of *Acremonium* grow well on SDA, and some species can tolerate cycloheximide. *A. kiliense,* the most common medically important species, produces cylindrical conidia and solitary hyaline chlamydospores, especially on oatmeal agar. *A. recifei* also produces chlamydospores, but its conidia are sickle shaped or slightly curved. *A. strictum,* a common soil and occasional airborne fungus, forms moist and pale-salmon-colored colonies that resemble those of *Lecythophora hoffmannii;* this fungus can be isolated from blood and can sporulate in tissue (230, 272). The genus *Phaeoacremonium,* including *P. parasiticum* and some other species associated with human infection, is distinguished from *Acremonium* by its brownish pigmented hyphae and conidiophores (see chapter 125). The genera *Lecythophora* and *Phialemonium* differ from *Acremonium* by their formation of short, stumpy phialides without basal septa (called adelophialides) in addition to the more spindle-shaped phialides (63), but these distinctions are not always readily observed. Although *L. hoffmannii* has been implicated as a cause of infection, reports may refer to *Phaeoacremonium* species. An isolate from sinus (153) was examined and determined to be *P. parasiticum* (245), and the pale brown phialides described for another isolate are more suggestive of a *Phaeoacremonium* species (219, 239). *L. mutabilis* differs from *L. hoffmannii* in forming accessory brown chlamydospores on sporulation media. Cases of endocarditis, eye infections, and peritonitis have been reported (47, 148). An isolate reported under the name *Tilletiopsis minor* (210) as causing a subcutaneous cyst may be *L. lignicola* (239). Three species of *Phialemonium* were distinguished originally by conidial shape and colony color (63), but the PCR-RFLP banding patterns showed a close relationship between isolates of *P. curvatum* and *P. dimorphosporum,* and these two species were synonymized (75). *Phialemonium* species have caused fungemia, subcutaneous and disseminated infection, peritonitis, and mycetoma.

Arthrographis, Onychocola, and *Scytalidium* Species

Fungi forming arthroconidia are placed in the genera *Arthrographis, Onychocola,* and *Scytalidium.* The thermotolerant *Arthrographis kalrae* is a rare opportunist recovered from skin, lung, corneal ulcer, and sinus (36, 197, 239, 243). Because initial growth is often yeastlike, an isolate may not be recognized as a pleomorphic mold and may be subjected to tests commonly used for yeast identification (36, 239). *Scytalidium dimidiatum* and its relative *S. hyalinum* are best known as agents of superficial infection (106), causing mainly onychomycosis of the toenails and rarely deep infection (see chapter 120). *Onychocola canadensis* is a cycloheximide-tolerant hyphomycete causing distal subungual onychomycosis or, less commonly, white superficial onychomycosis and infection of the glabrous skin (76, 106, 238, 241) (Fig. 16 and 17). Although *O. canadensis* is an uncommon cause of onychomyosis, more than 60 isolates from nails have now been recorded from New Zealand, Australia, Europe, the United Kingdom, and the United States.

Beauveria, Engyodontium, and *Sporothrix* Species

Beauveria, Engyodontium, and *Sporothrix* species have solitary conidia borne sympodially. *Beauveria bassiana* is a well-known insect pathogen with limited virulence for humans. *B. bassiana* has not been substantiated as the cause of invasive disease in humans (245) but has caused pulmonary infection in a captive alligator. *Engyodontium album* is closely related (47) and was formerly placed in the genus *Beauveria.* These species are uncommonly reported as the cause of keratitis (47, 113, 155) and endocarditis (12). *Sporothrix schenckii* is a well-known dimorphic pathogen described in chapter 125. It forms sessile pigmented conidia in addition to hyaline conidia.

Chrysosporium, Myceliophthora, and *Myriodontium* Species

Members of the genera *Chrysosporium, Myriodontium,* and *Myceliophthora* produce solitary, usually single-celled conidia which are called aleurioconidia because of their lytic method of conidium dehiscence (106). Members of these genera are related to the dermatophytes and the dimorphic pathogens, sharing with them a tolerance of cycloheximide and having teleomorphs in the ascomycete order Onygenales (106, 238).

There are few reports of infection involving *Chrysosporium* species. The thermotolerant *C. zonatum* has caused pneumonia and osteomyelitis in a patient with chronic granulomatous disease as well as noninvasive pulmonary disease in two patients (221) (Fig. 14 and 15). In other reports, the isolated organism was not identified to the species level or described well enough to confirm the etiology (reviewed in references 221, 238, and 245). *Myriodontium keratinophilum* and *Chrysosporium* species have been reported to cause sinusitis, but it seems likely that the fungi involved were misidentified *Schizophyllum commune,* an emerging agent of sinusitis (238, 245). The hyphal spicules of the latter could be confused with the stalks of the former (106). Cutaneous mycosis caused by *Aphanoascus fulvescens,* an ascomycete with a *Chrysosporium* anamorph, has been reliably documented (106, 127). Species of *Chrysosporium* and the similar *Geomyces,* as well as *Myriodontium keratinophilum,* are occasional contaminants of respiratory and cutaneous specimens (106). Members of the genus *Myceliophthora* produce aleurioconidia similar to those of onygenalean fungi, but they have affinities within the order Sordariales. The thermophilic species *M. thermophila* has been reported to cause fatal aortic vasculitis in two patients and was isolated from the brain of a patient who developed a bacterial cerebral abscess after trauma (20, 59, 260).

Metarrhizium and *Trichoderma* Species

Metarrhizium anisopliae is an insect pathogen of wide distribution that was recently documented to cause keratitis, sinusitis, and invasive infection (24, 32, 213). Conidia of *Metarrhizium* are produced from cylindrical phialides borne on verticillately

or irregularly branched conidiophores formed in sporodochia. Conidia are produced in chains that adhere together, in contrast to *Trichoderma* species, which form conidia in slimy heads. *Trichoderma* species are common soil fungi traditionally considered uncommon clinical contaminants. Many species are known, and they are difficult to identify; teleomorphs are in the genus *Hypocrea* (Hypocreales) (112, 229). Case reports attributed to species less well adapted to growth at higher temperatures, such as *T. koningii* and *T. viride,* closely related species which do not grow well above 30°C, require reevaluation (47, 112, 229, 230). *T. longibrachiatum,* which does grow well at 37°C, is probably the most important pathogenic species (166, 216, 234). Morphological criteria for recognition of this species include (i) fast-growing yellowish green colonies with a radius greater than 35 mm at 40°C after 3 days of growth on potato dextrose agar; (ii) a strong yellow diffusing pigment present at 30°C but absent at 40°C; (iii) hyphae sparingly branched and forming phialides that are mostly solitary, longer, and more gradually tapered (cylindrical); and (iv) smooth oblong to ellipsoidal conidia (229) (Fig. 18 and 19). Intercalary phialides and chlamydospores are common (229). Some reports concerning *T. pseudokoningii* may actually refer to *T. citrinoviride,* a thermotolerant species closely related to *T. longibrachiatum* (47).

Paecilomyces Species

Species of *Paecilomyces* occur worldwide as soil saprophytes, insect parasites, and agents of biodeterioration. The two most important medically significant species are *Paecilomyces lilacinus* and *P. variotii.* Their teleomorphs are unknown, but their affinity is within the ascomycete family Trichocomaceae, which also includes *Penicillium* and *Aspergillus* species; some other species have teleomorphs in the genus *Thermoascus* (Thermoascaceae). The colonial and morphologic features of these two species (Fig. 12, 13, and 28) are described in Table 5. *P. marquandii* is included for comparison with *P. lilacinus,* but this and other rarely reported species are not confirmed as agents of infection. Clinical manifestations of both species include cutaneous and subcutaneous infection, pulmonary infection, pyelonephritis, sinusitis, cellulitis, endocarditis, and fungemia in both immunocompetent and immunosuppressed patients (31, 34, 47, 245, 255, 276). Surgery, prosthetic implants, and use of contaminated solutions or lotions are risk factors predisposing to infection since the conidia of both species are relatively resistant to most sterilizing techniques (31, 53, 188), and death may occur in immunosuppressed individuals (93). Most reports of eye infection including keratitis, endophthalmitis, corneal ulcer, and orbital granuloma refer to *P. lilacinus,* but *P. variotii* may also be involved (47, 127, 233). Predisposing factors include use of extended-wear contact lenses, implantation of contaminated intraocular lenses, complications following cataract surgery, and use of topical corticosteroids before onset of clinically apparent keratitis (127, 233). Peritonitis cases caused by *Paecilomyces* species and the homothallic *Thermoascus taitungiacus* have recently been reviewed (119). Fungal elements of *Paecilomyces* in tissue are hyaline, septate, and about 2 to 4 μm wide and have parallel walls or show swellings.

Penicillium Species

Penicillium species other than *P. marneffei* have been implicated in human infection, but the validity of some reports has been questioned (255). Although *Penicillium* species grow over a wide range of temperatures from 5 to 45°C, many species are completely or strongly inhibited at 37°C and thus have low potential for causing human infection (e.g., *P. brevicompactum* and *P. commune*). Even repeated isolation of a *Penicillium* species from patient specimens does not necessarily indicate an etiologic role, unless the isolate is accompanied by typical fungal elements in tissue specimens or smears of lesional exudate. Other factors to consider when assessing the significance of repeated isolation include the isolation of any other fungal species, the patient's possible exposure to airborne conidia, and a diagnosis of bronchiectasis, since conidia may remain viable for prolonged periods without invasion or colonization (127). Nonetheless, several species have been reported to cause peritonitis, urinary tract infection, endocarditis, lung infection, fungemia, and disseminated infection (37, 47, 127, 143). The role of penicillia in allergy and hypersensitivity pneumonitis is well established (87). Identification of penicillia is a complex task, requiring growth of an isolate on several media at different temperatures and careful microscopic examination (53, 204, 227). Czapek yeast extract agar, malt extract agar, and 25% glycerol nitrate agar and incubation at 5, 25, and 37°C are used. The use of SDA alone is not recommended.

Rhizopus, Rhizomucor, Absidia, and Other Agents of Systemic and Subcutaneous Zygomycoses*

MALCOLM D. RICHARDSON AND PIRKKO KOUKILA-KÄHKÖLÄ

122

TAXONOMY

The term zygomycosis embraces both deep and subcutaneous mycoses caused by fungi belonging to various genera of the class Zygomycetes (Table 1), namely, mucormycosis and the entomophthoromycoses, the latter being subdivided into basidiobolomycosis and conidiobolomycosis.

MUCORMYCOSIS

The term mucormycosis is used to refer to uncommon infections due to molds belonging to the order Mucorales. These organisms can cause rhinocerebral, pulmonary, gastrointestinal, cutaneous, or disseminated infection in predisposed individuals, the different clinical forms often being associated with particular underlying conditions.

Fungi belonging to the order Mucorales are distributed into six families (Table 1), all of which can cause cutaneous and deep infections. Species belonging to the family Mucoraceae are isolated more frequently from patients with mucormycosis than those belonging to any other family. Among the Mucoraceae, *Rhizopus oryzae (Rhizopus arrhizus)* is by far the most common cause of infection. Other, less frequently isolated species of the Mucoraceae family that cause a similar spectrum of infections include *Rhizopus microsporus* var. *rhizopodiformis*, *Absidia corymbifera, Apophysomyces elegans, Mucor* species, and *Rhizomucor pusillus*. Increasingly, cases of mucormycosis due to *Cunninghamella* species (in the Cunninghamellaceae family) are being diagnosed.

ENTOMOPHTHOROMYCOSES (SUBCUTANEOUS PHYCOMYCOSIS, SUBACUTE PHYCOMYCOSIS, AND SUBACUTE ZYGOMYCOSIS)

Infection with fungi from the order Entomophthorales (Table 1), namely, *Conidiobolus coronatus, Conidiobolus incongruous,* and *Basidiobolus ranarum*, typically occurs in immunocompetent patients residing in subtropical and tropical climates. Unlike Mucorales, Entomophthorales do not cause angioinvasive disease.

Conidiobolomycosis is a chronic mycosis affecting the subcutaneous tissues. It originates in the nasal sinuses and spreads to the adjacent subcutaneous tissue of the face, causing disfigurement. Basidiobolomycosis is a chronic subcutaneous infection of the trunk and limbs.

The current taxonomy and clinical division of the Entomophthorales has been challenged recently (38). Molecular analyses during the last two decades have shown that orders within the Chytridiomycota and Zygomycota cluster among one another and therefore cannot be considered to be natural taxa (86). Members of the Entomophthorales have been found to fall within two phylogenetically distinct groups, one of which contains *Basidiobolus*, which is related closely to some chytrids, while the remaining entomophthoralean genera, including *Conidiobolus*, form another distinct group that is related closely to other zygomycetes such as the Mucorales (37). A further indication of a close link between *Basidiobolus* and the flagellated Chytridiomycota is the presence of the procentriole, the basal part of a flagellum (52). This evidence has resulted in the creation of the order Basidiobolales, containing the single genus *Basidiobolus*. At present, available data also suggest that the pathogenic agents causing mucormycosis are all members of the Mucorales (Table 1) (95).

The paraphyletic nature of the Entomophthorales, as defined previously, containing both *Basidiobolus* and *Conidiobolus*, offers a partial explanation of the highly different clinical manifestations of basidiobolomycosis and conidiobolomycosis and of the differences in the susceptibilities of the pathogens to antifungal agents. The difficulties with identification of *Conidiobolus* and *Basidiobolus* based on morphological characteristics appear to have been overcome by identification using PCR with taxon-specific primers (94). Based on these developments, one point of view is that the clinical nomenclature should reflect the modern phylogeny and that the term "entomophthoromycosis" should be restricted to mycosis caused by *Conidiobolus* spp. while mycosis caused by *Basidiobolus* spp. should be described as "basidiobolomycosis" (38).

EPIDEMIOLOGY AND TRANSMISSION

The Mucorales are opportunistic fungi capable of causing acute, rapidly developing, and often fulminant infections in the compromised host (4, 35, 68, 72, 73, 83). Major risk factors include ketoacidosis, lymphoma, leukemia, neutropenia,

*This chapter contains information presented in chapter 117 by Malcolm D. Richardson, Pirkko Koukila-Kähkölä, and Gillian S. Shankland in the eighth edition of this Manual.

TABLE 1 Pathogenic Mucorales and Entomophthorales[a]

Order	Family	Genus	Species

corticosteroid or other long-term immunosuppressive therapies, and deferoxamine therapy of dialysis patients with aluminum or iron overload. To date, there have been only a few reported infections associated with AIDS, so AIDS does not appear to be a significant risk factor. Trauma to the skin including severe burns, trauma from intravenous catheters and intravenous drug abuse, and even an insect bite may also result in infection in the immunocompetent host.

The pathogenesis of mucormycosis is unclear, and although undoubtedly exogenous, possible sources of infection have only occasionally been suggested, e.g., adhesive dressings, air conditioning filter units, and food. Cutaneous trauma may be an underestimated event in the initiation of many cases of mucormycosis. However, most infections follow inhalation of spores that have been released into the air, and the lungs and nasal sinuses are common sites of infection. The most common predisposing condition for gastrointestinal infection is severe malnutrition or disruption of the gastrointestinal mucosa.

The nature of the infectious propagule responsible for the establishment of zygomycoses is unproven. Many studies have suggested that sporangiospores are responsible, and others have indicated that small hyphal fragments initiate disease. Since sporangiospores of mucoraceous fungi are both uncommon in air and readily contained by phagocytic cells normally found in pulmonary tissues, it is possible that in some cases, especially where trauma is the associated factor, hyphal fragments are the infectious propagule.

Mucormycosis

Mucormycosis is distributed worldwide. Many different organisms have been implicated, but the most common causes of human infection, listed in order of apparent incidence, are *Rhizopus oryzae* and *Rhizopus microsporus* var. *rhizopodiformis*. Other, less frequent etiological agents for which a major pathogenic role in humans has been established include *Absidia corymbifera, Apophysomyces elegans, Cunninghamella bertholletiae, Mucor* species, *Rhizomucor pusillus,* and *Saksenaea vasiformis*. These molds are ubiquitous and thermotolerant and can be isolated in large numbers from soil or decomposing organic matter, such as fruit and bread. Their spores can be found in the outside air. Nosocomial outbreaks of mucormycosis are not as common as hospital-related *Aspergillus* infections but have been reported to occur in leukemic patients. Nosocomial cutaneous infections with *Rhizopus microsporus* var. *rhizopodiformis* have been traced to contaminated dressings and wooden tongue depressors used as immobilizing splints in a neonatal intensive care unit (53). The major risk factors predisposing individuals to mucormycosis include uncontrolled diabetes mellitus, other forms of metabolic acidosis, burns, and malignant hematological disorders. Treatment is seldom of benefit unless these underlying conditions can be corrected.

Entomophthoromycosis

Conidiobolomycosis occurs mainly in the tropical rain forests of Africa, South and Central America, and Southeast Asia.

Conidiobolus coronatus (Entomophthora coronata) lives as a saprophyte in soil humus and on decomposing plant matter in moist, warm climates. It can also parasitize certain insects. The disease it causes is most common among adult males, particularly those living or working in tropical rain forests. Infection is acquired through inhalation of spores or the introduction of spores into the nasal cavities by soiled hands.

Basidiobolomycosis is encountered chiefly in the tropical regions in East and West Africa, Indonesia, and India. The most widely held view is that *Basidiobolus ranarum* is the sole agent causing the disease and that *Basidiobolus meristosporus* and *Basidiobolus haptosporus* are only synonyms of the former; however, not all authors are of this opinion.

Basidiobolus ranarum has been isolated from the guts of frogs, toads, and lizards that had apparently swallowed infected insects. It has also been isolated from ants and decaying plant matter.

It is still uncertain how the disease is acquired and what is the length of incubation. Inoculation through a thorn prick or an insect bite has been suggested, as has contamination of a wound or other abrasion. The infection is most common in children.

CLINICAL MANIFESTATIONS

Mucormycosis

In most cases, mucormycosis occurs in patients already receiving treatment because of another disease. For precisely this reason, it may not be immediately recognized. The clinical hallmark of mucormycosis is vascular invasion resulting in thrombosis and tissue infarction and necrosis. In most cases, the infection is relentlessly progressive and results in death unless treatment with a combination of surgical debridement and antifungal therapy is initiated promptly.

A number of recent reviews and commentaries underline the increasing prevalence and awareness of these infections (5, 22, 25, 35, 40, 76, 78, 84).

Mucormycosis is an opportunistic infection and is seldom seen in normal persons. Various forms are recognized, each of which is associated with particular underlying conditions. Like the etiologic agents of aspergillosis, the causal organisms of mucormycosis have a predilection for vascular invasion, causing thrombosis and infarction and necrosis of tissue. The anatomical distribution of lesions appears to correlate to a certain degree with defined predisposing conditions, e.g., craniofacial involvement in individuals with diabetic acidosis, pulmonary and disseminated infection in patients with acute leukemia, and gastrointestinal and cutaneous lesions in patients infected following local trauma. Indeed, cutaneous infections have possibly replaced craniofacial and pulmonary disease as the prevalent clinical manifestation of mucormycosis, a change mirrored by the emergence of *Rhizopus microsporus* var. *rhizopodiformis* (known as *Rhizopus rhizopodiformis* in many cases) as a significant pathogen.

Rhinocerebral Mucormycosis

The terms rhinocerebral mucormycosis and craniofacial mucormycosis are used to describe infection which begins in the paranasal sinuses and then spreads to involve the orbit, face, palate, or brain. The terms should be used only when there is documented brain involvement in addition to the involvement of the sinuses alone and in addition to the involvement of both the sinuses and the orbit, respectively. It is not clear whether the paranasal and rhino-orbital forms of mucormycosis are simply rhinocerebral mucormycosis in evolution or whether the extent to which mucormycosis progresses beyond the paranasal sinuses to involve the orbit and brain is dependent on the host response. A number of recent case studies and reviews describe a clinical variety of rhinocerebral mucormycosis termed rhino-orbital-cerebral mucormycosis (5, 27). Nasal endoscopy appears to be useful in diagnosis, tissue debridement, and follow-up with patients.

Rhinocerebral mucormycosis is most commonly seen in acidotic individuals, particularly those with uncontrolled diabetes mellitus, but it also occurs in leukemic patients and organ transplant recipients. It is the most common clinical form of mucormycosis and is often fatal within a week of onset if left untreated. It is assumed that the port of entry of the pathogen is through colonization of the nasal mucosa, allowing the fungus to spread via the paranasal sinuses into the orbit. Involvement of the brain and cavernous sinus occurs by way of the orbital apex (34). Multiple approaches to treatment are required (66, 89). Early clinical and laboratory diagnosis is crucial. If the infection spreads into the palate, a black necrotic lesion is often found. This is an important diagnostic sign, and necrotic lesions may also be found on the nasal mucosa. Nasal septum or palatal perforation is frequent. Drainage of black pus from the eye is an ominous but useful diagnostic sign. From the orbit, infection may spread into the brain, leading to frontal lobe necrosis and abscess formation. These features result from invasion of the fungus through the cribiform plate. The cerebrospinal fluid (CSF) findings are nonspecific. CSF cultures are sterile. The radiological findings are nonspecific but are useful in determining the extent of the infection (59, 79).

Pulmonary Mucormycosis

Pulmonary mucormycosis is seldom diagnosed during life. Mucormycosis may develop in the lungs as a result of aspiration of infectious material or, following inhalation, as a result of hematogenous or lymphatic spread during dissemination. Most cases occur in leukemic patients undergoing remission induction treatment. Pulmonary infiltrates develop, with infarction of focal areas of the lungs. The clinical signs are those of bronchitis, pneumonia, and thrombosis. There is necrosis of the parenchyma, leading to cavitation; the bronchi may be perforated, resulting in hemoptysis. If untreated, hematogenous dissemination to other organs, particularly the brain, will often occur. There are no characteristic symptoms or signs to distinguish mucormycosis from aspergillosis. The infection is fatal within 2 to 3 weeks.

Clinicians are aware that pulmonary mucormycosis is being seen more frequently in patients with cancer (47, 98). However, the clinical manifestation is similar to that of invasive pulmonary aspergillosis. Most cases of pulmonary mucormycosis in these patients appear to develop as breakthrough infections if treatment with antifungal agents effective against *Aspergillus* species is administered. A recent retrospective comparison of cancer patients with pulmonary mucormycosis with similar patients with invasive pulmonary aspergillosis showed that computed tomography imaging could potentially differentiate the two infections, but further validation was required (10).

Cunninghamella bertholletiae is a rare cause of pulmonary mucormycosis. A cluster of invasive pulmonary infections caused by *Cunninghamella bertholletiae* in four immunocompromised patients that occurred during a 2-year period at one center have recently been described (74).

The usefulness of fine-needle aspiration cytology (FNAC) in the diagnosis of lung lesions is well documented. Fungal lesions are among nonneoplastic lesions of the lung for which FNAC has proven to be a useful technique for both immunocompromised and immunocompetent patients. The usefulness of FNAC is highlighted in a number of case reports (2, 18). Various other approaches can be used for the diagnosis of pulmonary mucormycosis, for example, fiberoptic bronchoscopy (24).

Gastrointestinal Mucormycosis

Mucormycosis limited to the gastrointestinal tract is rare (39). It has usually been encountered in malnourished infants or children but also in patients with hematological malignancies (39). Lesions are most common in the stomach, colon, and ileum. It is seldom diagnosed during life. Frequently associated conditions include amebic colitis, pellagra, malnutrition, and kwashiorkor.

The symptoms are varied and depend on the site affected. Nonspecific abdominal pain and hematemesis are typical. Necrotic ulcers develop, and peritonitis follows if intestinal perforation occurs. Intestinal mucormycosis is a fulminant illness ending in death within several weeks due to bowel infarction, sepsis, or hemorrhagic shock.

Cutaneous Mucormycosis

Cutaneous mucormycosis is a particular problem in infected patients with burns in whom spread to underlying tissue is common. The initial signs include fever, swelling, and changes

in the appearance of the burn wound. The development of severe underlying necrosis and infarction in a burn should suggest the diagnosis.

Cutaneous infections account for 16% of all forms of mucormycosis, with an associated mortality of 16%, compared to 67% for rhinocerebral, 83% for pulmonary, and 100% for disseminated infection. The most common causative organism is *Rhizopus* spp., although others such as *Mucor* and *Absidia* are also frequently seen, whereas *Saksenaea vasiformis* and *Apophysomyces elegans* are rare pathogens (9, 45). Cutaneous mucormycosis is less likely to be associated with severe systemic illness than other forms, and local predisposing factors such as burns, trauma, surgery, needle sticks, and others play a major role. The most common sites involved in cutaneous mucormycosis are the lower and upper extremities, followed by the head and neck, and then the abdomen.

Mucormycotic gangrenous cellulitis can follow other forms of trauma to the skin. In diabetic or immunosuppressed patients, cutaneous lesions may arise at an insulin injection site or a catheter insertion site. More massive trauma, such as open fractures or crash injuries, has been present in other patients. Necrotizing cutaneous mucormycosis has occurred in patients who have had contaminated surgical dressings applied to their skin.

A number of infections have been described in a variety of individuals after traumatic injury or near-drowning (30). The most recent examples of mucormycosis in trauma patients are exemplified by survivors of the tsunami in Southeast Asia on 26 December 2004 (1).

Cutaneous lesions resembling ecthyma gangrenosum may develop following hematogenous dissemination of the fungus in immunosuppressed patients. The lesions begin as erythematous, indurated, painful cellulites and then evolve into ulcers covered with a black eschar. Isolated cases of primary cutaneous mucormycosis in a premature neonate (46) and in a patient with acute lymphocytic leukemia (54) have been described previously.

Disseminated Mucormycosis

Disseminated mucormycosis may follow any of the four forms of mucormycosis described so far, but it is usually seen in neutropenic patients with pulmonary infection. Less commonly, dissemination occurs from the gastrointestinal tract or burns or other cutaneous lesions. The most common site of spread is the brain, but metastatic necrotic lesions have also been found in the spleen, heart, and other organs. Mucormycosis can complicate peritoneal dialysis (56, 67).

Disseminated mucormycosis is usually diagnosed after the patient has died of the infection. Occasionally, metastatic cutaneous lesions permit earlier diagnosis.

Cerebral infection following hematogenous dissemination is distinct from the rhinocerebral form of mucormycosis. It results in abscess formation and infarction. Patients present with sudden onset of focal neurological deficits or coma. Investigation of the CSF is unhelpful: protein, glucose, and cell abnormalities are nonspecific, and cultures are sterile. Computed tomography and magnetic resonance imaging scans are useful in locating the lesions.

A number of other diagnostic techniques have been used, including proton magnetic resonance spectroscopy integrated with magnetic resonance imaging (79).

Mucormycosis in AIDS

Mucormycosis in human immunodeficiency virus (HIV) infection is rare. However, it can be the presenting opportunistic infection in AIDS. Predisposing factors for mucormycotic infection in HIV disease include low CD4 count, neutropenia, and active intravenous drug use. Mucormycosis can present in the basal ganglia, the skin, the gastrointestinal tract, or the respiratory tract or may be disseminated.

A total of 31 HIV-positive patients with mucormycosis have been reported (28 of these are reviewed in reference 90). It is presumed that intravenous drug injection was the portal of entry for fungal propagules. The most prevalent clinical presentations of mucormycosis in the intravenous drug-using HIV-positive patients appeared to be cerebral, cutaneoarticular, and renal (accounting for 88% of presentations in total) (26).

Mucormycosis in Hematological Malignancies

The incidence of mucormycosis in patients with hematological malignancies has increased during the last decade, probably due to the more severe and prolonged postchemotherapy neutropenia. The diagnosis is usually made at autopsy, and its incidence in autopsy studies in patients with hematologic malignancies ranges between 0.4 and 0.9%. A number of retrospective studies have been published (61, 64).

In recent years, pulmonary mucormycosis has been reported to occur in patients with leukemia and lymphoma and bone marrow transplant recipients (48, 58, 62).

Voriconazole is increasingly used as prophylaxis in patients with hematological malignancies. A number of reports have linked the prolonged use of this agent to an increase in infections caused by zygomycetes (36, 40, 50, 51, 63, 82, 91, 93).

Mucormycosis in Solid-Organ Transplant Recipients

Mucormycosis is a rare infection in renal transplant recipients; however, mortality is exceedingly high. Risk factors predisposing to this disease include prolonged neutropenia, diabetes, and immunosuppression. Mucormycosis is a rare but highly invasive infection following orthotopic liver transplantation (15, 49, 81). Reports of some 20 cases exist in the literature.

Other Forms of Mucormycosis

Isolated mucormycotic brain lesions have been reported to have occurred in a number of individuals, particularly parenteral drug abusers in whom the typical presentation is localized cerebral lesions. The infection presents as a rapid deterioration in neurological status and can be rapidly fatal (97, 99).

There is a clear association between deferoxamine use (for the treatment of iron overload) and the development of mucormycosis. Most of the reported associated cases have involved rhinocerebral disease (reviewed in reference 83). Deferoxamine is a siderophore derived from *Streptomyces pilosus*. Siderophores are high-affinity iron chelators used by microorganisms to concentrate iron for bioavailability. A number of fungi require iron for growth, and it appears that the fungi responsible for mucormycosis can utilize the iron bound to deferoxamine. The fact that deferoxamine is removed by renal clearance means that its circulation time will be prolonged in patients on dialysis, and this factor may increase the risk for these patients. Infection of bone has also been reported (33).

Differential Diagnosis

Rhinocerebral mucormycosis is a dramatic and distinctive condition, but it can be confused with cavernous sinus thrombosis, bacterial orbital cellulitis, or rhinocerebral aspergillosis or pseudallescheriasis. The clinical manifestations of pulmonary mucormycosis cannot be distinguished from those of gram-negative-bacterial pneumonia, aspergillosis, or infections caused by *Scedosporium* species.

Conidiobolomycosis

Conidiobolus infection generally begins with unilateral involvement of the nasal mucosa. The most common nasal symptom is obstruction, but frequent nosebleeding can occur and is evidence of the development of a nasal polyp in the anterior region of the inferior turbinate. Subcutaneous nodules then develop in the nasal and perinasal regions and may be associated with epidermal lesions.

The spread of the infection is slow but relentless. It is usually confined to the face, and the development of gross facial swelling involving the forehead, periorbital region, and upper lip is very distinctive. As a rule, the lesions are firmly attached to the underlying tissue, although the bone is spared. The skin remains intact. Spread to the lymph nodes has been reported. Even if, in advanced cases, the diagnosis is obvious from the clinical appearance, mycological and histological examinations are essential for its confirmation.

Basidiobolomycosis

The subcutaneous swelling that characterizes basidiobolomycosis is usually localized to the back of the shoulders and to the arms, but it may also be found on the buttocks and thighs. The initial swelling may be rapid or slow in onset, and it is hard and painless. The spread is slow but relentless, and a large mass is formed which is attached to the skin but not the underlying tissue (unlike lesions in *Conidiobolus* infection). This is a disfiguring infection, but the skin covering the lesions does not ulcerate. Lymphatic obstruction may occur and can result in massive lymphedema. There is no functional impairment so long as the joints are not blocked by the volume of the swellings. The underlying bone and joints are not affected by the disease.

Basidiobolomycosis can be diagnosed with confidence on the basis of appearance and the results of the mycological and particularly the histological examinations. Basidiobolomycosis closely resembles soft tissue sarcoma. Mycetoma has the same degree of induration as basidiobolomycosis, but the presence of draining sinuses, fixation to underlying structures, and extension to bone seen with mycetoma make the distinction relatively easy. Bacterial cellulitis is much more acute and painful than that in mucormycosis. All these conditions can be reliably distinguished from mucormycosis by biopsy and culture of the lesion. Immunodiffusion tests have been shown to determine the specific etiology of entomophthoromycosis (41).

Recently, the etiologic role of *Basidiobolus ranarum* in gastrointestinal infections has been increasingly recognized (43). Although the clinical presentation of the subcutaneous disease is quite characteristic (chronic localized subcutaneous infection of the face, trunk, or limbs) and the disease is easy to diagnose, gastrointestinal basidiobolomycosis poses diagnostic difficulties; its clinical presentation is nonspecific, there are no identifiable risk factors, and all age groups appear to be susceptible.

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

Mucormycosis

Because mucormycosis is such an aggressive infection, early diagnosis is essential for successful treatment. It is, however, often difficult to obtain suitable and timely specimens which have been collected correctly.

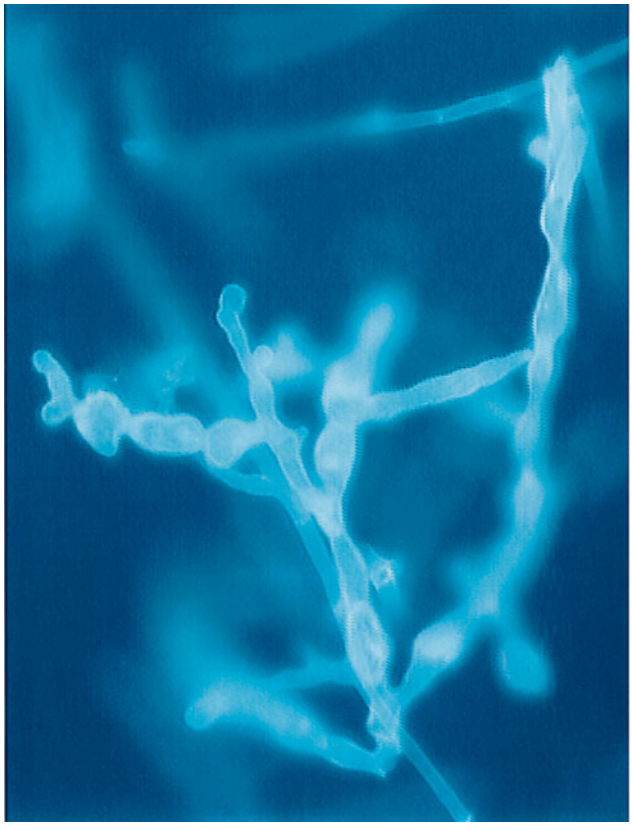
If there is any suspicion of mucormycosis, a diligent search for clues that would help to establish a specific microbiological diagnosis should be initiated without delay. The most useful clue is the presence of a black necrotic eschar either in the nasopharynx or on the palate. This eschar or material sloughing from it may be mistaken for clotted blood. Material from the eschar and underlying tissue should be obtained by biopsy or curettage and transported to the laboratory as quickly as possible for culture and microscopic examination. Other diagnostic approaches are equally effective, for example, fine-needle aspiration (18).

Entomophthoromycosis

Specimens must be taken from the subcutaneous tissue where the infection is seen as nodules which develop into massive, firm, indurated swellings which are freely movable over the underlying muscle but are attached to the skin, which is hyperpigmented but not ulcerated.

DIRECT EXAMINATION

Microscopy



Given the limitations of imaging studies, diagnosing mucormycosis almost always requires histopathological evidence of fungal invasion of the tissues. The urgency of establishing the diagnosis is frequently underappreciated. Delayed diagnosis has been associated with a dramatically worse outcome.

A definitive diagnosis of mucormycosis is best achieved by direct histopathological examination and culture. Biopsy specimens from pulmonary, rhinocerebral, and cutaneous lesions and scrapings of necrotic mucocutaneous lesions are appropriate specimens.

The necrotic material should be gently broken apart and mounted in a few drops of 20% (wt/vol) potassium hydroxide (KOH). Typical wide, nonseptate hyphae with right-angled branching may be seen. Demonstration of mycelial elements in the correct clinical setting constitutes strong evidence for mucormycosis. If the KOH preparation is unrevealing, surgical biopsy or debridement of necrotic material should be performed. Examine any material obtained in KOH and stain with methenamine silver (Grocott's modification; GMS) and hematoxylin and eosin (H&E) (see below). If fungal elements are seen, obtain further biopsy specimens. The rapid progression seen in untreated mucormycosis allows no delays in diagnostic efforts. The sensitivity of these techniques can be enhanced by the use of optical brightners, for example, calcofluor white (Blankophor) (77) (Fig. 1 and 2).

The microscopic demonstration of the presence of Mucorales in clinical material taken from necrotic lesions is more significant than the isolation of these organisms in culture. However, different species cannot be distinguished from one another morphologically. These organisms can be distinguished from other molds, such as *Aspergillus,* due to their characteristic broad, nonseptate filaments with right-angled branching. In contrast to *Aspergillus,* zygomycetes are larger, do not have parallel walls with 45-degree-angle branching, and do not radiate from a single point in tissues. Furthermore, agents of mucormycosis stain poorly with periodic acid-Schiff stain (PAS) but stain well with H&E (Fig. 3). Negative results of microscopic examinations do not eliminate the possibility of mucormycosis even if a portion of necrotic tissue has been examined carefully.

Central nervous system involvement in rhinocerebral mucormycosis may suggest the presence of the etiologic agent in CSF. However, agents of mucormycosis have not been isolated from CSF. In cases of suspected pulmonary mucormycosis, examine biopsy material or material from fine-needle percutaneous aspiration. Sputum culture is rarely helpful.

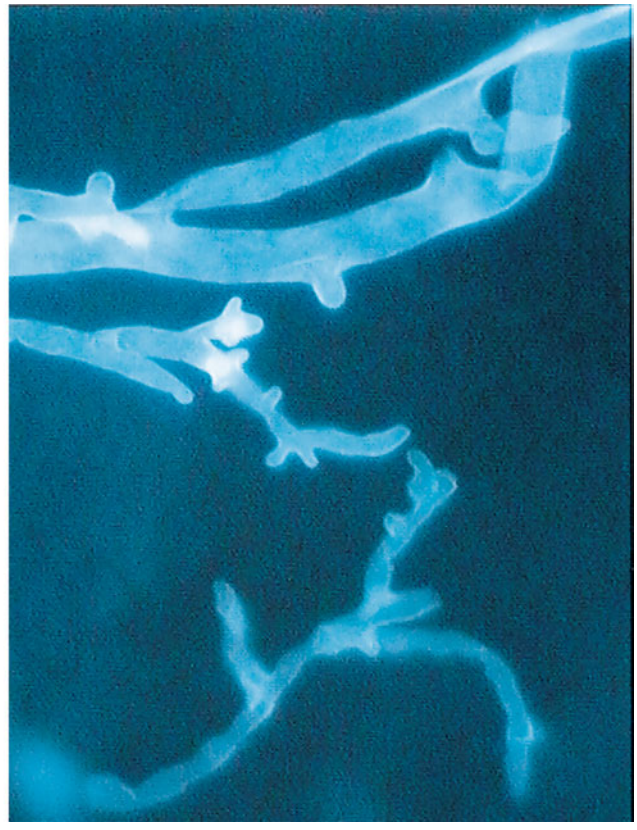


FIGURE 1 (left) Microscopic appearance of *Rhizopus* sp. hyphae in an aspirate from a mandibular gingival abscess stained with calcofluor white.

FIGURE 2 (right) Microscopic appearance of *Absidia corymbifera* hyphae in a thin section of lung tissue stained with calcofluor white.

Metastatic skin lesions, if present, may allow a diagnosis to be made without performing a lung biopsy. In isolated cases, fungal elements have been seen in bronchoalveolar lavage fluid and isolated in culture. Intestinal mucormycosis is usually a rapidly progressive disease ending in death within a few days. In almost all cases, the diagnosis is not suspected until histological examination of gangrenous tissue obtained at surgery or autopsy reveals the fungus. Premortem diagnosis is difficult. In suspected cases, the demonstration of the presence of fungi in gastric aspirates or feces may be useful.

Biopsy specimens or scrapings from oral lesions are most satisfactory for histological examination and culture. Demonstration of the presence of the fungus in tissue is diagnostic of disease (culture is not), but cultures must be set up to determine the specific etiologic agent. Mucoraceous fungi are readily seen by using the H&E stain and GMS, but their detection rate when stained with the conventional specialized fungal stains Gridleys and PAS is uneven and barely adequate. One useful stain is Cresyl Fast Violet, which stains zygomycete walls brick red and other fungi blue or purple.

Hyphal elements of mucoraceous fungi consist of broad, twisted, ribbonlike hyphae, which are variable in width (up to 50 μm) and often devoid of cytoplasm and have collapsed walls. True septa are not usually present, although wrinkles and folds in the cell wall may appear as septa unless the microscope is focused up and down on the apparent boundary. The hyphae are irregularly and haphazardly branched, and a lateral mycelium often grows at nearly 90 degrees. Although hyphae are broad, their widths may vary greatly and the hyphal walls also vary in thickness. The side branches may be much narrower than the main hyphal axis. The mucoraceous fungi can be mistaken for sclerosed capillaries or nematodes, and they may also be confused with empty spherules of *Coccidioides immitis* in regions where this organism is endemic. The small amount of fungus present in tissue sections and the oblique angles at which the sections are cut make the identification of fungus by histological morphology alone difficult. In some tissue areas, hyphae and hyphal fragments may appear to be septate and constricted at prominent septations. Often hyphae may have terminal bulbous swellings and lateral oval to spherical structures.

The pathology does not vary with the site of infection. Gangrene involvement is common. Surfaces show massive hemorrhage with recent emboli, and in older lesions the appearance is puttylike. The tissue reaction is not consistent. In some cases no cellular response is seen, but usually there are various degrees of edema and necrosis with neutrophil accumulations, plasma cells, and some giant cells. The acute reaction shows the diffuse infiltration of polymorphonuclear leukocytes. Eosinophils are not often seen. Tissues often exhibit suppurative reactions but may show granulomatous changes. The characteristic feature is the involvement of the blood vessels, with mucoraceous fungi invading the walls of arteries, causing thrombosis and necrosis of the adjacent tissue. The lumens and walls of blood vessels often contain hyphae, chlamydoconidia, fibrin, and inflammatory cells.

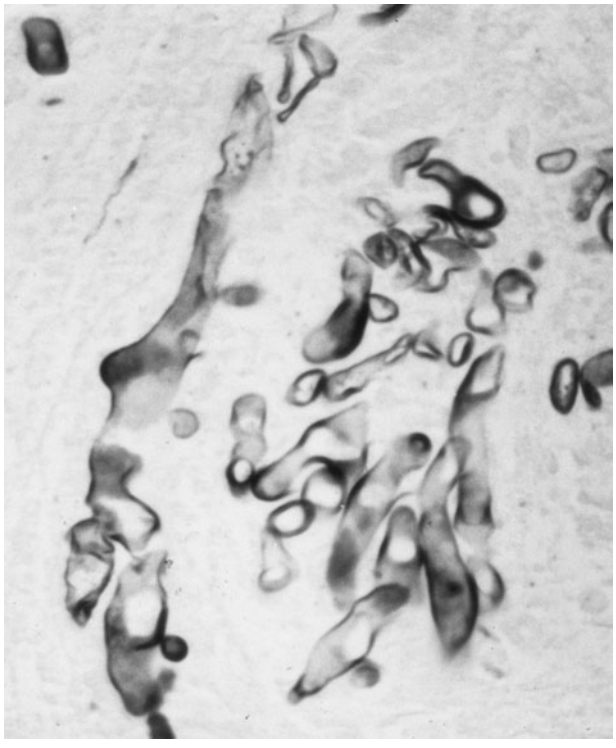

FIGURE 3 Hyphae of *Rhizopus oryzae* in an H&E-stained section of the soft palate from a patient with rhinocerebral mucormycosis. Note the irregular shapes and diameters of the hyphae. Magnification, ×400.

Another pertinent feature is the presence of spherical to ovoid, 15- to 30-μm-diameter, thick-walled, hyaline chlamydospores. Chlamydospores of mucoraceous fungi are PAS and H&E positive but stain either poorly or not at all with GMS. Because of fixation and processing of tissues, the chlamydospore cytoplasm can retract from the plasma membrane, creating an artificial clear space between the condensed cytoplasm and the thick, rigid cell walls. Some chlamydospores stain entirely, and others can appear as empty rings. Chlamydospores are seen in the vicinity of mucoraceous hyphae. Detached chlamydoconidia can resemble the yeast form cells of *Blastomyces dermatitidis* or the immature spherules and arthroconidia of *Coccidioides immitis*. In pulmonary mucormycosis, chlamydospores are most often observed in alveolar spaces, the lumens of bronchioles, and the visceral pleura. In cutaneous mucormycosis, chlamydospores may be seen within necrotic tissue on or near a wound surface.

Invasive mucormycosis is rapidly progressive and is associated with angioinvasion and infarction. In addition to being able to identify the morphological features of zygomycetes in histopathological preparations, it is important to recognize the preferential sites of growth and the host response (21). Medical record and histological, review in a single institution identified 20 patients with mucormycosis. Diagnostic criteria included the presence of typical ribbonlike hyphae and positive culture, a clinical history of invasive mucormycosis, or both. The clinical review in reference 21 is helpful. Fungus ball (15%), rhinocerebral (55%), and pulmonary (30%) disease were the types of diseases represented. The inflammatory responses were predominantly neutrophilic (50%), predominantly granulomatous (5%), pyogranulomatous (25%), or absent (20%). Invasive disease was characterized by prominent infarcts (94%), angioinvasion (100%), and prominent perineural invasion (90%) in biopsy specimens that contained nerves for evaluation. Notably, hyphal septa were always seen (100%), and most branches (95%) varied from 45 to 90 degrees. Furthermore, perineural invasion is a common finding in invasive mucormycosis, as are angioinvasion and infarcts. Therefore, prior to excluding the presence of mucormycosis agents in biopsy specimens suspected to contain zygomycetes, the perineural space should be carefully examined.

Quite often there may be a delay in obtaining fixed and histopathologically stained biopsy sections. One alternative to expedite the work-up is to use frozen sections. The visualization of hyphal elements in frozen sections has been associated with improved outcomes in two recent case series (27, 31).

In cases of conidiobolomycosis, microscopic examination of smears or tissue from the nasal mucosa will reveal broad, nonseptate, thin-walled mycelial filaments. In basidiobolomycosis, direct microscopy will reveal wide, irregular hyphae or fragments thereof with few septa.

In cases of basidiobolomycosis, biopsy specimens will show fibroblastic proliferation and an inflammatory reaction with lymphocytes, plasma cells, histiocytes, eosinophils, and giant cells. Broad, thin-walled hyphae with occasional septa, branched at right angles, are seen. The Splendore-Hoeppli phenemonon may be seen. The histopathological features of basidiobolomycosis are very similar to those of conidiobolomycosis.

Antigen Detection

There are no routinely available antigen detection formats for the diagnosis of mucormycosis.

Nucleic Acid Detection Techniques

Multiplex PCR has been used to identify *Rhizopus* species in paraffin sections and in sera from three mucormycosis patients (55). *Rhizopus oryzae* and *Rhizopus azygosporus* DNA was amplified from clinical material, which correlated with the identification of the isolated strains.

In a case of pulmonary mucormycosis associated with acute lymphocytic leukemia caused by *Cunninghamella bertholletiae,* retrospective analysis of stored serum, sputum, and necrotic lung tissue samples enabled subspecies identification by PCR, direct DNA sequencing of the PCR products, and a homology search with nucleotide basic local alignment search tools (44). A further case of *Cunninghamella bertholletiae* infection diagnosed by panfungal PCR is reported by Rickerts and colleagues (75).

ISOLATION PROCEDURES

Isolation of the causative agents of mucormycosis has been achieved in only a small proportion of cases, but specimens should be sent for culture if the clinician suspects mucormycosis. Direct detection of fungus in tissues is significantly more sensitive than culture. The underlying reason for this is unclear. Typically, even if a large amount of tissue is removed at surgery, a relatively small piece is submitted for fungal culture. Infections may be quite localized and may not be detected in all portions of the specimen submitted for analysis. Infarcted areas and areas into which there has been extensive bleeding are the best choices of sites for culture. To maximize the recovery of zygomycetes from tissue, the material should be cut up into small fragments and inoculated onto Sabouraud dextrose agar.

Because the Mucorales are common contaminants, isolation of these organisms from sputum, aspirated material from the sinuses, or bronchial washings must be interpreted with

caution. However, if the patient is diabetic or immunosuppressed, the isolation should not be ignored. Isolation of the causal agents of disease has been achieved in a small proportion of cases. Sputum culture is highly unreliable. In two case series, sputum and bronchoalveolar lavage fluid cultures were negative in 18 of 19 cases of biopsy-proven pulmonary mucormycosis (71, 88). The agents of mucormycosis can be grown on most laboratory media, but glucose-peptone agar (glucose, 4%; mycological peptone, 1%; agar, 2%) or 4% malt extract agar (malt extract, 4%; agar, 2%) is recommended because typical morphology can be demonstrated. Media containing cycloheximide should not be used because cycloheximide inhibits the growth of these fungi. Small portions of biopsy material should be point inoculated onto glucose-peptone agar. Cultures of swabs from the nose or palate are usually negative and are not recommended. Cultures should be incubated at room temperature and 37°C. Tissue material should not be homogenized, as this procedure will kill viable hyphal elements of mucoraceous fungi. Refrigeration may also reduce the viability of some of these agents.

In suspected cases of entomophthoromycosis, tissue obtained by biopsy or curettage should be cultured on Sabouraud dextrose agar. Positive cultures are difficult to obtain, and the pathological material must be inoculated onto the largest possible number of mycological media plates to ensure culture growth if the organism is present in the tissues; the plates should be incubated at between 25 and 35°C. Identifiable colonies should be obtained in less than 1 week.

IDENTIFICATION

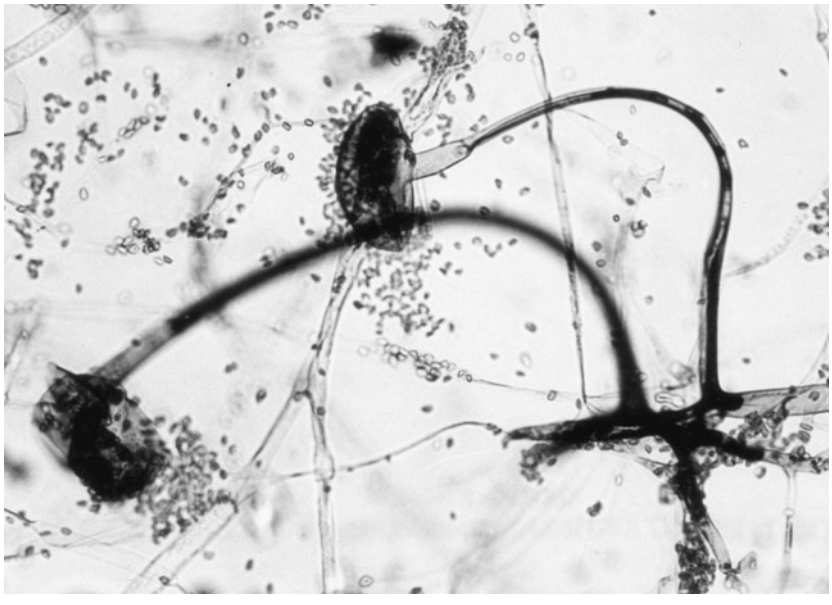
General Description of Fungi Most Likely Isolated and Basis of Identification

Identification of most zygomycetes is based primarily on the morphology of the sporangia, i.e., the arrangement and number of sporangiospores and the shape, color, and presence or absence of columellae and apophyses, as well as the arrangement of the sporangiophores and the presence or absence of rhizoids. Growth temperature studies can also be especially helpful in identifying and differentiating members of the genera *Rhizopus, Rhizomucor,* and *Absidia.* The Mucorales are characterized by the production of nonseptate hyphae. However, occasional septa are formed in older cultures. Some genera produce rhizoids, rootlike anchors (Fig. 4) which are connected by hyphae called stolons. The Mucorales reproduce asexually by producing spores in sporangia which are borne on sporangiophores. The sporangiophores of some genera swell where they meets the sporangium, forming the structure called an apophysis (Fig. 5 and 6). Typically, a sporangium is a globose swelling at the apex of a sporangiophore. The sporangium contains a central, variously shaped collumella which is separated from the spore-containing sac by a membrane. The cytoplasm of the sporangium is cleaved into hundreds of sporangiospores during maturation (Fig. 5 and 6). In addition, some genera of Mucorales produce small, several-spored sporangia called sporangioles. Finally, a few genera, for example, *Cunninghamella,* produce sporangia which contain a single spore; these are called conidia. Sexual reproduction in the Mucorales is characterized by the formation of zygospores. However, detection of the presence of zygospores is not a part of a routine laboratory identification scheme.

Several excellent monographs and book chapters on the taxonomy and detailed identification of zygomycete fungi have been published (17, 72, 86). The interested worker is referred to these sources for information to complement those features highlighted here and for data on routine isolates not corresponding to the descriptions below. World Wide Web sites and CD-ROM resources include http://www.doctorfungus.org and Organism Central (Lippincott Williams and Wilkins, Philadelphia, Pa.) and the CD-ROM version of *Atlas of Clinical Fungi,* 2nd ed. (http://www.cbs.knaw.nl) (17).

Description of Causal Agents

The descriptions given below of the causal agents of zygomycoses are based almost entirely on their asexual characteristics.



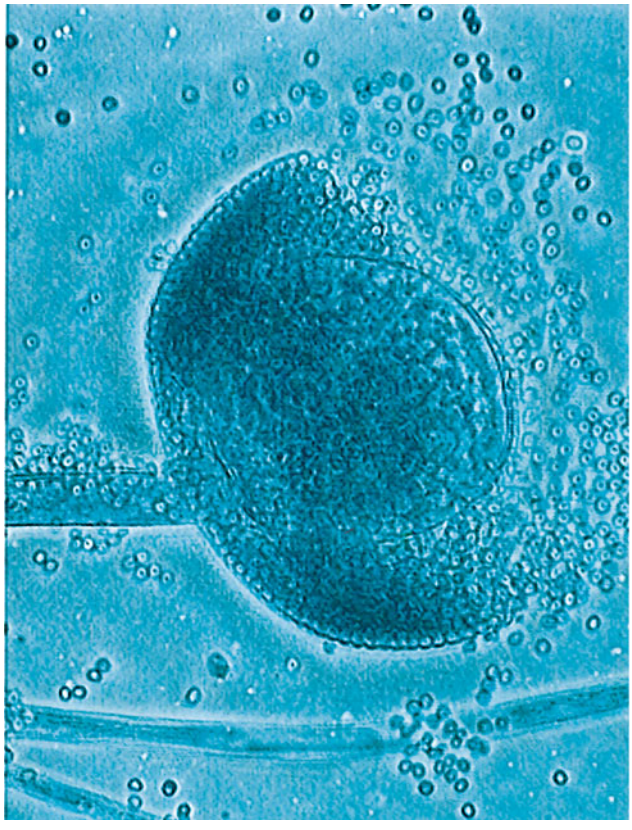


FIGURE 4 *Rhizopus oryzae* (NCPF 2634). Note the simple sporangiophores borne singly opposite rhizoids. Some sporangia have collapsed, and the sporangial wall has dissolved. Magnification, ×400.

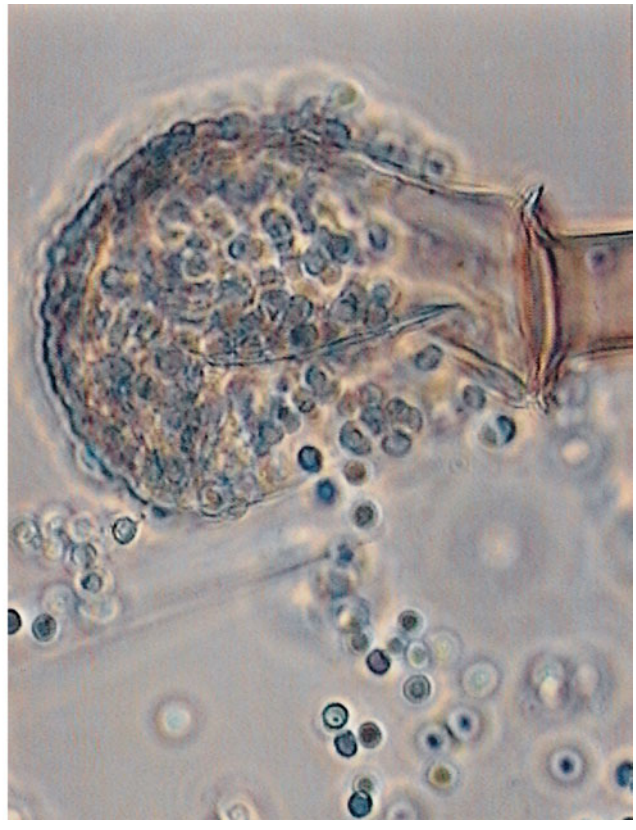

FIGURE 5 (left) Microscopic appearance of sporangium of *Rhizopus* species.

FIGURE 6 (right) Microscopic appearance of sporangium of *Rhizopus oryzae*.

The differentiation of these fungi to the species level is difficult, but a scheme of identification based on a combination of their asexual morphology and biochemical characteristics has made it more feasible for the clinical laboratory. The descriptions given below are based on the colony appearances and microscopic morphologies of individual isolates (some deposited in the National Culture Collection of Pathogenic Fungi, Mycology Reference Laboratory, Public Health Laboratory, Bristol, United Kingdom) cultured on 4% malt agar as a primary isolation medium and subcultured on glucose-peptone agar without the addition of cycloheximide. The maximum incubation temperature is indicated, assuming that primary isolation plates for clinical specimens from suspected cases of fungal infection are routinely incubated at a range of temperatures, e.g., 28, 37, and 45°C.

Rhizopus oryzae

Found in soil, decaying fruit and vegetables, animal feces, and old bread, *Rhizopus oryzae* is the most prevalent agent of mucormycosis.

Colony Morphology

Rhizopus oryzae grows as a rapidly growing, white, cottony colony at 28°C, filling a 9-cm-diameter petri dish within 2 to 3 days and reaching up to about 8 mm in height. The fungus will grow at temperatures of up to 45°C if routine primary isolation plates are incubated at this temperature. Colonies tend to collapse, becoming brownish gray to blackish gray, depending on the amount of sporulation. Growth is inhibited by cycloheximide.

Microscopic Morphology

The single most useful characteristic in identifying members of the genus *Rhizopus* is the presence of simple sporangiophores borne singly or in groups opposite rhizoids (Fig. 4). With *Rhizopus oryzae,* broad, nonseptate hyphae are seen. Sporangiophores are seen and are up to 3,500 μm in length and 18 μm wide, smooth walled, nonseptate, and simple with a single axis or branched, arising from stolons opposite brownish rhizoids, usually in groups of three or more.

Grayish black sporangia are globose, often with a flattened base, powdery in appearance, and up to 200 μm in diameter. Columellae are ellipsoidal on a truncate base, mouse gray in color, and up to 130 μm in length. Sporangiospores vary in shape and size, having a rhomboidal, lemon shape, with ridges on the surface.

Rhizopus microsporus var. *rhizopodiformis*

The second most common species associated with mucormycosis, causing nearly 15% of all culturally proven cases of the disease in humans, is *Rhizopus microsporus* var. *rhizopodiformis*, which is isolated mainly from cutaneous lesions (reviewed in references 19 and 53).

Colony Morphology

Colonies range from gray to dark grayish brown.

Microscopic Morphology

Rhizoids are hyaline to subhyaline. Sporangiophores are shorter (maximum length, 1,000 μm) than those of *Rhizopus oryzae* and are produced singly or in groups of up to four (Fig. 7). Sporangia average 100 μm in diameter. Columellae

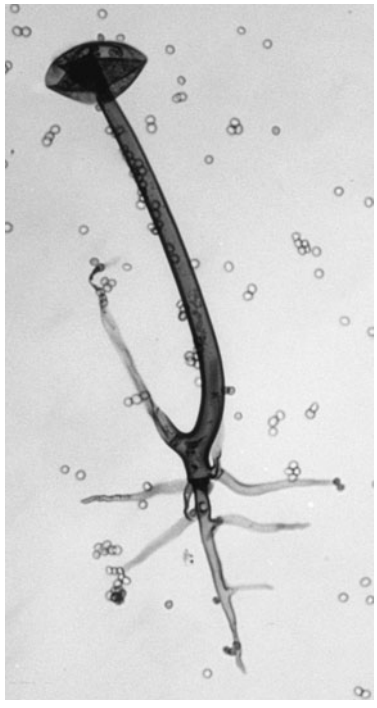

FIGURE 7 *Rhizopus microsporus* var. *rhizopodiformis* (NCPF 2955). Note the short sporangiophore compared with that of *Rhizopus oryzae* and the branched rhizoids. Magnification, ×400.

are pyriform or somewhat elongated, with distinct angular apophyses. Sporangiospores (4 to 6 μm) are uniform in size and spherical or slightly elongated, with fairly striated surfaces. The fungus is thermotolerant, growing well at up to 50°C.

Rhizopus microsporus var. *microsporus*

Rhizopus microsporus var. *microsporus* is an emerging pathogen and has been reliably identified in two patients with cutaneous infections for whom amputation of the affected area was required (96).

Colony Morphology

Rhizopus microsporus var. *microsporus* may be distinguished from other pathogenic variants of the microsporus group by growth at 46°C but not at 50°C.

Microscopic Morphology

The sporangiophores of *Rhizopus microsporus* var. *microsporus* are angular to broadly ellipsoidal, striated, and up to 6.5 μm in length.

Rhizomucor pusillus

Rhizomucor pusillus is found in decaying fruits and vegetables and in the soil. Very few reports of human disease caused by this organism have been published. *Rhizomucor pusillus* has been isolated in cases of pulmonary, rhinofacial, and disseminated infection in immunocompromised patients and also in occasional cases of cutaneous infections and endocarditis. This fungus can also cause mycotic abortion in cows, horses, and pigs.

Colony Morphology

Colonies are rapidly growing and appear white at first, turning dark smoke gray or brown as sporulation occurs. The colony texture is floccose to woolly. Growth is inhibited by cycloheximide. The maximum growth temperature of 54 to 58°C is a useful distinguishing feature.

Microscopic Morphology

Rhizomucor pusillus forms broad, sparsely septate, hyaline hyphae. Sporangiophores are mainly monopodially branched and anchored to the substratum by short rhizoids (Fig. 8). Sporangia are globose and dark brown and measure up to 100 μm in diameter. *Rhizomucor* differs from *Rhizopus* by forming sporangia without apophyses. Columellae are subglobose to pyriform. The sporangium wall dissolves to leave a collar around the sporangiophore. Globose to subglobose, hyaline sporangiospores are released (3 to 5 μm in diameter).

Absidia corymbifera

Absidia corymbifera is an infrequent agent of mucormycosis in humans (19, 65). It is found worldwide in soil, compost, and decaying vegetation. Documented cases of *Absidia corymbifera* infection include a case of meningitis in an immunocompetent patient that followed a penetrating head injury (65), a case of cutaneous infection in an immunocompetent patient, and cases of infection in AIDS patients and, more recently, in patients with hematological malignancies (62). Infection is most probably acquired by inhalation of sporangiospores. *Absidia corymbifera* is the only human pathogenic species of the genus *Absidia* and is also an agent of bovine mycotic abortions.

Colony Morphology

Absidia forms rapidly growing colonies that quickly fill the petri dish. It grows well at 25 to 45°C, and some isolates can grow at 50°C. The very high colonies are light gray to grayish brown. The reverse side is colorless to very slightly yellow to buff with age. The colony may originate from stolons between

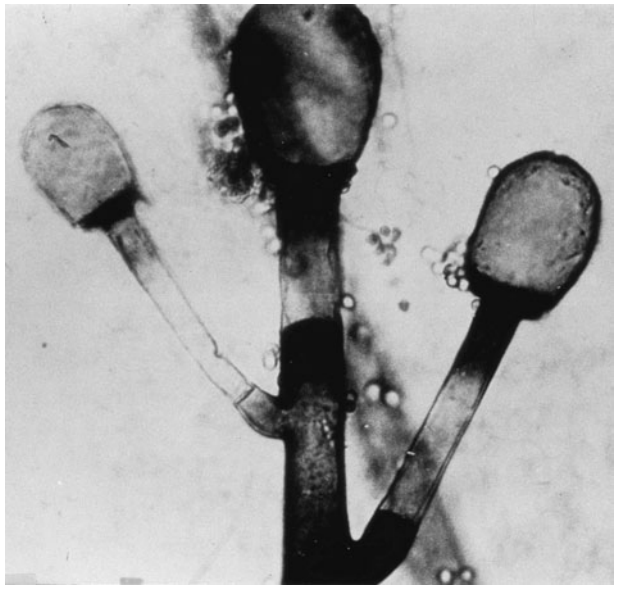

FIGURE 8 *Rhizomucor pusillus*. Note the monopodially branched sporangiophores, pyriform columellae, and small sporangiospores. A collarette can be seen around the sporangiophore. Magnification, ×262. (Reprinted with permission of Kaminski's Teaching Slides on Medical Mycology, Adelaide Children's Hospital, Adelaide, Australia.)

rhizoids or from finely branched aerial hyphae. *Absidia corymbifera* does not grow in the presence of cycloheximide.

Microscopic Morphology

Absidia corymbifera forms broad (often 10-μm or more), sparsely septate hyphae with stolons and internodal rhizoids. Sporangiophores are hyaline to light gray and branched simply or in a corymbiform pattern. Sporangia are pyriform, 100 to 150 μm in diameter, and hyaline when young, but they become grayish brown to greenish beige. A swollen apophysis is seen at the point where the sporangiophore merges with the sporangium (Fig. 9). Columellae are hemispherical to short-ovoidal. Sporangiospores have a greenish yellow tinge and are variable in shape and size, with dimensions ranging from 3.2 to 3.9 by 3.1 to 3.5 μm to those of a long, ellipsoidal shape, 4.1 to 4.9 by 2.3 to 2.9 μm.

Cunninghamella bertholletiae

In the genus *Cunninghamella,* only the species *Cunninghamella bertholletiae* has been verified as a human pathogen. *Cunninghamella bertholletiae* is widely distributed in decaying vegetation and animal matter and in the soil and has been recovered from cheese and Brazil nuts. Infection is acquired by inhalation of conidia. Mating reactions have been very important in classifying the species of *Cunninghamella.*

Cunninghamella spp., in the class Zygomycetes and the order Mucorales, are unusual opportunistic pathogens that have been identified with increased frequency in immunocompromised patients. Infections with this group of organisms have been seen most frequently in patients with hematologic malignancies. Thirty or so cases of invasive *Cunninghamella* infection have been reported in the literature (reviewed by Darrisaw and colleagues in reference 14; for recent case reports, see references 7, 60, 69). A series of cases highlight the ineffectiveness of prophylaxis and the difficulties of treatment (74).

Colony Morphology

Cunninghamella bertholletiae is rapidly growing, filling a petri dish within 2 to 3 days. Colonies are white at first, becoming dark gray and powdery with development. The reverse side is colorless to buff. Primary isolates will grow at temperatures of up to 42°C. This organism is sensitive to cycloheximide.

Microscopic Morphology

The sporangiophores of *Cunninghamella bertholletiae* are up to 20 μm wide and are straight with verticillate or single branches (Fig. 10). Terminal vesicles are subglobose to pyriform, with the terminal ones up to 40 μm and the lateral ones 10 to 30 μm in diameter. Sporangiola are globose (7 to 11 μm in diameter) or ellipsoidal (9 to 13 by 6 to10 μm), verrucose or echinulate, and hyaline when single but brownish in mass (Fig. 10). *Cunninghamella bertholletiae* grows optimally between 25 and 30°C, and the maximum temperature tolerated is 50°C.

FIGURE 9 *Absidia corymbifera*. Note the relatively fine sporangiophore, pyriform sporangium, hemispherical columella, and long, conical apophysis. Sporangiospores vary in shape from globose to long ellipsoidal. Magnification, ×400. (Reprinted with permission of Kaminski's Teaching Slides on Medical Mycology, Adelaide Children's Hospital, Adelaide, Australia.)

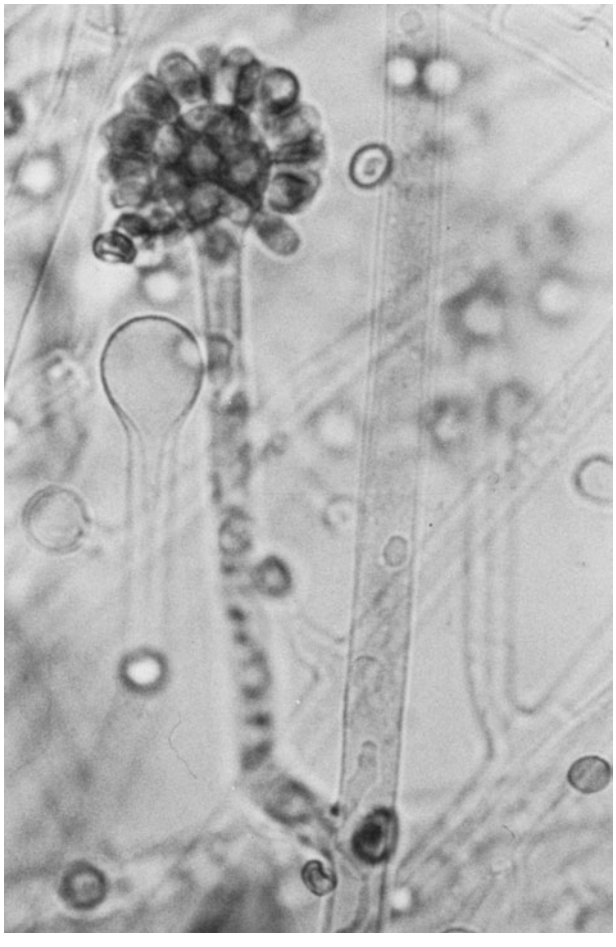

FIGURE 10 *Cunninghamella bertholletiae*. Note the single sporangiophore branching off a main hyphal trunk and subglobose to pyriform vesicle bearing ellipsoidal sporangiola. Magnification, ×400. (Reprinted with permission of Kaminski's Teaching Slides on Medical Mycology, Adelaide Children's Hospital, Adelaide, Australia.)

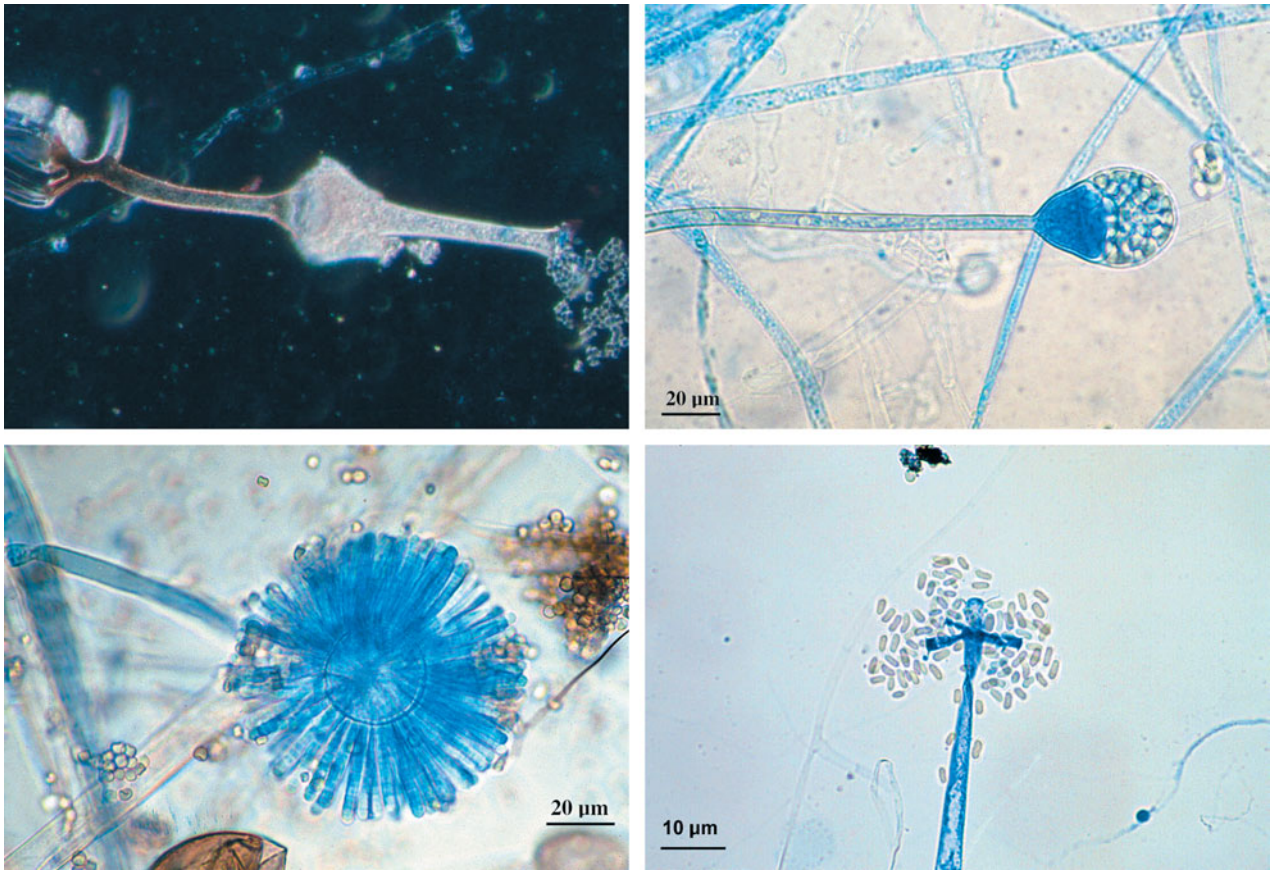

FIGURE 11 (top left) *Saksenaea vasiformis* isolated from a tsunami patient. Note the flask-shaped sporangium with a distinct, globose columella and small, smooth, elongated sporangiospores.

FIGURE 12 (top right) Young sporangium of *Apophysomyces elegans* showing distinct funnel-shaped apophyses and a conspicuous pigmented subapical thickening below the apophysis. (Reprinted with permission of Kaminski's Teaching Slides on Medical Mycology, Adelaide Children's Hospital, Adelaide, Australia.)

FIGURE 13 (bottom left) Microscopic morphology of *Syncephalastrum racemosum* showing a terminal vesicle, fingerlike merosporangia, and sporangiospores. (Reprinted with permission of Kaminski's Teaching Slides on Medical Mycology, Adelaide Children's Hospital, Adelaide, Australia.)

FIGURE 14 (bottom right) Microscopic morphology of *Mortierella wolfii* showing a typical erect, delicate sporangiophore, wide at its base, with a compact cluster of acrotonous (terminal) branches. On dehiscence of the sporangia, a conspicuous collarette is usually present. Columellae are generally lacking, and sporangiospores are single-celled, short cylinders with a double membrane. (Reprinted with permission of Kaminski's Teaching Slides on Medical Mycology, Adelaide Children's Hospital, Adelaide, Australia.)

Saksenaea vasiformis

Saksenaea vasiformis is widespread in tropical soils and is a known agent of subcutaneous zygomycosis (8). At least 21 cases of invasive infection have been reported, occurring in both immunocompromised and immunocompetent individuals. Many of these cases have been reviewed by Holland (32). Disseminated infection is rapidly fatal. *Saksenaea vasiformis* is a rare cause of rhinocerebral mucormycosis.

Colony Morphology

The colonies of *Saksenaea vasiformis* are rapidly growing and appear downy white with no reverse pigment.

Microscopic Morphology

Saksenaea vasiformis forms broad, nonseptate hyphae and flask-shaped sporangia (Fig. 11) with a distinct spherical venter (that portion of a phialide that lies between the base of the phialide and the conidiogenous locus) and long necks arising singly or in pairs from dichotomously branched, darkly pigmented rhizoids. The collumellae are prominent and dome shaped. Small, oblong sporangiospores, 1 to 2 by 3 to 4 μm in size, are discharged through the necks of the sporangia following the dissolution of an apical mucilaginous plug.

Laboratory identification may be difficult or delayed because of the mold's failure to sporulate on primary isolation media or upon subsequent subculture onto potato

dextrose agar. Sporulation may be stimulated by the use of nutrient-deficient media, such as cornmeal-glucose-sucrose-yeast extract agar.

Saksenaea vasiformis usually grows easily on routine mycological media, but it often fails to sporulate on those media. It usually produces sporangia when it is grown on nutrition-deficient media, such as inoculated agar blocks containing hyphal growth on sterile distilled water with sterilized yeast extract solution added to it, Czapek's agar, and 1 to 1.5% agar in saline. In most reported cases, sporulation was successfully induced by using the sterile distilled water method, although this method may fail occasionally, and on rare occasions, sporulation may occur on routine media, such as Sabouraud dextrose agar and cornmeal agar. In our experience gained from the isolation of *Saksenaea* from Finnish tsunami patients, subculture on Sabouraud glucose agar induced sporulation.

Refer to the review by Holland for additional details on the laboratory diagnosis of *Saksenaea vasiformis* infection (32).

Mucor Species

Mucor species are infrequently the causative agents of mucormycosis. The genus contains 49 recognized species, many of which have a widespread occurrence and are of considerable importance. However, few species have been recovered in well-documented cases of mucormycosis, and infections due to members of this genus are rare.

Identification of *Mucor* species beyond the genus level is difficult because the pathogenic species lack distinctive characteristics. However, molecular typing has been described previously (70). Emerging pathogens within the *Mucor* group are *Mucor circinelloides* and *Mucor ramosissimus*. Very few cases of human disease have been associated with *Mucor circinelloides* and have, to date, been limited to cutaneous infections. Similarly, very few cases of human disease caused by *Mucor ramosissimus* have been reported in the literature; such cases are possibly underreported owing to inaccurate or incomplete identification. *Mucor ramosissimus* has been associated with peritoneal dialysis-associated peritonitis, septic arthritis, and mucocutaneous and rhinocerebral disease.

Colony Morphology

Mucor species are rapidly growing organisms. Colonies are white and cottony at first but become gray to brown as sporulation occurs. *Mucor* species are inhibited by the concentration of cycloheximide usually incorporated into routine isolation media. Most species grow poorly, if at all, at 37°C.

Microscopic Morphology

The genus *Mucor* can be differentiated from *Absidia, Rhizopus,* and *Rhizomucor* by the absence of stolons and rhizoids. Species of *Mucor* produce simple or sympodially branching sporangiophores from nonseptate hyphae. There is no swelling where the sporangiophore and the sporangium merge. The gray-brown sporangia themselves are globose and contain globose to ellipsoidal sporangiospores.

Apophysomyces elegans

Originally described after detection in specimens from India, *Apophysomyces elegans* was found in soil samples from a mango orchard, and subsequently, 27 definite cases of mucormycosis caused by this fungus have been described, resulting from traumatic implantation, contamination of burns, or disseminated infection (8, 9, 20, 32). *Apophysomyces* species closely resemble *Absidia* species in their morphology.

Colony Morphology

Apophysomyces elegans grows rapidly. Colonies are white initially, becoming creamy white to buff with age and downy, with no reverse pigment. The fungus grows well at temperatures of up to 42°C. The growth of *Apophysomyces elegans* is not inhibited by cycloheximide.

Microscopic Morphology

Apophysomyces elegans does not sporulate on routine mycological media; it forms only broad, nonseptate hyphae. Water culture containing 10% yeast extract is required to induce sporulation. Characteristic identifying features include sporangiophores arising singly from aerial hyphal segments. Thin-walled, hyaline, light grayish brown rhizoids are produced opposite sporangiophores. A foot cell (resembling that seen in *Aspergillus* species) is present at the union of the sporangiophore with the surrounding hyphae. Sporangia are pyriform in shape (20 to 50 μm in diameter) with prominent funnel- or wine glass-shaped apophyses and hemispherical columellae produced singly at the tips of sporangiophores (Fig. 12). Sporangiospores are smooth, mostly oblong (5.4 to 8.0 by 4.0 to 5.7 μm), occasionally globose, and light brown.

Basidiobolus ranarum

Colony Morphology

Colonies are moderately fast growing at 30°C and are flat, yellowish gray, and glabrous, becoming radially folded and covered by a fine, powdery, white surface mycelium. Satellite colonies are often formed by germinating conidia ejected from the primary colony.

Microscopic Morphology

Large, vegetative hyphae (8 to 20 μm in diameter) forming round, smooth, thick-walled zygospores (20 to 50 μm in diameter) that have two closely appressed beaklike appendages are characteristic. Two types of asexual spores are formed: primary and secondary. Primary spores are globose, one celled, and solitary and are forcibly discharged from a sporophore. The sporophore has a distinct swollen area just below the spore that actively participates in the discharge of the spore. Secondary spores are clavate and one celled and are passively released from a sporophore. These sporophores are not swollen at their bases. The apex of the passively released spore has a knoblike adhesive tip. These spores may function as sporangia, producing several sporangiospores. See reference 6 for additional details.

Conidiobolus coronatus

Colony Morphology

Colonies of *Conidiobolus coronatus* grow rapidly and are flat, cream colored, and glabrous and become radially folded and covered by a fine, powdery, white surface mycelium and conidiophores. The lid of the petri dish soon becomes covered with conidia, which are forcibly discharged by the conidiophores. The color of the colony may become tan to brown with age.

Microscopic Morphology

Conidiophores are simple, forming solitary, terminal conidia which are spherical, 10 to 25 μm in diameter, and single celled and have a prominent papilla. Conidia may also produce hairlike appendages called villae. Conidia germinate to produce either (i) single or multiple hyphal tubes that may also become conidiophores which bear secondary conidia or

(ii) multiple short conidiophores, each bearing a small secondary conidium.

Rare Causes of Mucormycosis

Rare causes of mucormycosis include *Cokeromyces recurvatus, Syncephalastrum racemosum* (Fig. 13), *Mortierella* species (Fig. 14), and *Actinomucor elegans* (6, 16).

TYPING SYSTEMS

The phenotype-based identification methods routinely used for the identification of zygomycetes require expertise. Isolates are identified by recognition of colonial morphology and microscopic reproductive structures. A number of molecular methods for identification of pathogenic fungi have been validated for use in clinical settings (87). Many of these methods have focused on sequence diversity of the internal transcribed spacer regions (ITS1 and ITS2). Voigt et al. (94) used 18S and 28S sequences and the actin and EF-1alfa genes (95) to describe the phylogeny of medically important zygomycetes. More recently, it has been suggested that DNA sequence analysis of multiple loci should be useful for rapidly identifying medically important molds. Rakeman et al. (70) generated a phenotypically validated database of 118 diagnostic alleles from 210 fungal strains which included four isolates of *Rhizopus oryzae* and various *Mucor* species. Sequence analysis permitted identification of all species tested. The MicroSeq D2 large-subunit ribosomal DNA sequencing kit (Applied Biosystems, Foster City, Calif.) has become commercially available for the identification of filamentous fungi. In an extensive study, this system correctly identified only 67.5% of over 200 clinical isolates identified by using standard morphological criteria (28). Of the 17 zygomycetes identified in this series, only 6 were correctly identified by using this molecular assay. It is noteworthy that this system misidentified all of the *Absidia, Rhizopus, Cunninghamella,* and *Apophysomyces* isolates and some of the *Mucor* isolates.

Molecular methods have been applied to determine the genetic variability of *Rhizomucor* species. In one study, 23 *Rhizomucor* isolates were characterized by random amplified polymorphic DNA-PCR with 10-bp oligonucleotide primers (92). These data were used for numerical analyses to obtain information on the intraspecies genetic polymorphism of *Rhizomucor* species. The extents of genetic variability in *Rhizomucor pusillus* and *Rhizomucor miehei* isolates were found to differ; the latter revealed less intraspecies polymorphism. The different levels of genotypic diversity suggest a correlation with the different forms of mating behavior of these species. *Rhizomucor tauricus* displayed amplification patterns similar to those of the investigated *Rhizomucor pusillus* strains.

A recent study by Nagao and colleagues reported a multiplex PCR designed to identify five *Rhizopus* species, namely, *Rhizopus oryzae, Rhizopus microsporus* (var. *microsporus* and var. *rhizopodiformis*), *Rhizopus azygosporus, Rhizopus stolonifera,* and *Rhizopus schipperae* (55). Strains of *Apophysomyces elegans* isolated from patients in northern India were assigned to groups based on microsatellite and PCR fingerprinting (9).

ANTIFUNGAL SUSCEPTIBILITIES

There are four factors that are critical for treating mucormycosis: rapid diagnosis, reversal of underlying predisposing factors, appropriate surgical debridement of infected tissue, and appropriate antifungal therapy. Guidelines for the management of zygomycoses can be found in Richardson and Warnock (73), Spellberg et al. (84), and numerous case reports (3, 23, 29, 62).

A number of new antifungal compounds are under development, including voriconazole, posaconazole, ravuconazole, and the echinocandins. Voriconazole has fungistatic activity against many yeasts and filamentous fungi but minimal activity against zygomycetes. Caspofungin is an echinocandin and has been licensed for the salvage treatment of confirmed cases of invasive aspergillosis and the treatment of invasive candidiasis and for empiric treatment of febrile neutropenic patients. In vitro antifungal susceptibility data suggest that caspofungin has little activity against zygomycetes. The investigational drug posaconazole appears to be active against various species of zygomycetes. A distinct advantage of posaconazole is that for the first time there is an oral treatment for zygomycoses (36, 42).

Treatment of conidiobolomycosis is difficult, but patients often respond to oral itraconazole, ketoconazole, or saturated potassium iodide. Treatment should be continued for at least 1 month after the lesions have cleared. The therapy of choice for basidiobolomycosis remains saturated potassium iodide solution.

Most of the information available in the literature about the susceptibility profiles of the zygomycetes is based on the methods detailed in the NCCLS (now the Clinical and Laboratory Standards Institute [CLSI]) document M38-A, which was published as the accepted standard in 2002 (57) and reviewed by Greenberg et al. (25).

The CLSI standard recommends the use of a broth microdilution assay for antifungal susceptibilities, with *Rhizopus arrhizus (Rhizopus oryzae)* being the only zygomycete addressed specifically. Interpretative breakpoints have not been published at this time, and the CLSI protocol states that the clinical relevance of testing of this group of fungal pathogens remains uncertain. The number of reports on antifungal susceptibility tests of zygomycetes is limited, with only a few publications describing testing of 35 or more isolates (11, 12, 13, 85).

The sensitivity of *Cunninghamella bertholletiae* to amphotericin B determined by using the CLSI standard has been described by Carey et al. (7). The MIC for the isolate was 4 μg/ml. The other reported MICs for *Cunninghamella bertholletiae* range from 1 to 100 μg/ml. Although the available data represent only a few patients, it is interesting to note that the patients who survived had isolates for which MICs were 1 to 2 μg/ml.

Sun and colleagues (85) compared the activity of posaconazole with those of amphotericin B, itraconazole, voriconazole, and fluconazole against 37 clinical isolates of zygomycetes, namely, *Mucor* species, *Rhizopus* species, isolates of *Absidia corymbifera*, *Cunninghamella* species, isolates of *Apophysomyces elegans*, and isolates of *Cokeromyces recurvatus* and *Saksenaea vasiformis*. The MICs of posaconazole at which 50 and 90% of the isolates were inhibited (MIC_{50} and MIC_{90}) were 0.25 and 4 μg/ml, respectively. Posaconazole was significantly more active than voriconazole and fluconazole and slightly more active than itraconazole.

By using the CLSI broth dilution method, amphotericin B and posaconazole have been found to be the most effective drugs against the zygomycetes in vitro (11, 12, 13). The MIC_{50} of amphotericin B for all isolates was 0.125 μg/ml. The MIC_{50} of posaconazole was 0.25 μg/ml. Voriconazole demonstrated a MIC of 2 μg/ml or greater, with an overall MIC_{50} of 32 μg/ml. Zygomycetes are variably susceptible to itraconazole and to terbinafine (11).

The CLSI method has more recently been applied to an extended range of zygomycetes (80). In summary, the in vitro susceptibilities of 15 strains of six genera of zygomycetes, including *Rhizopus oryzae* (*Rhizopus arrhizus*), *Rhizopus stolonifer*, *Mucor circinelloides* (three strains), *Absidia corymbifera* (three strains), *Rhizomucor pusillus* (three strains), *Cunninghamella bertholletiae* (two strains), and *Syncephalastrum racemosum* (two strains), to nine antifungal agents were determined by the CLSI M38-A broth microdilution method. Geometric means of the MICs were as follows: amphotericin B, 0.07 μg/ml (range, 0.03 to 0.5 μg/ml); nystatin, 0.83 μg/ml (range, 0.25 to 4 μg/ml); itraconazole, 0.59 μg/ml (range, 0.03 to >8 μg/ml); voriconazole, 6.50 μg/ml (range, 2 to >8 μg/ml); ciclopiroxolamine, 1.59 μg/ml (range, 0.5 to 4 μg/ml); and amorolfine, 9.19 μg/ml (range, 1 to >16 μg/ml). All strains were resistant to 5-flucytosine, fluconazole (MIC, >64 μg/ml), and caspofungin (MIC, >16 μg/ml).

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

The microscopic demonstration of the presence of Mucorales in clinical material taken from necrotic lesions or in sputum or bronchoalveolar lavage fluid is more significant than the isolation of these fungi in culture. These organisms can be distinguished from other molds, such as *Aspergillus* species, by their characteristic broad, nonseptate hyphae with right-angled branching.

Isolation in culture is required for specific identification of the Mucorales. Despite the predilection of these organisms for angioinvasion and hematogenous dissemination, blood cultures in all forms of mucormycosis are always negative. Nasal, palatal, and sputum cultures are seldom helpful. Because the Mucorales are common contaminants, isolation of these organisms from material obtained from a necrotic lesion or from sputum or bronchoalveolar lavage fluid must be interpreted with caution. However, if the patient is diabetic or immunosuppressed, the isolation should not be ignored and treatment should be initiated immediately.

Histoplasma, Blastomyces, Coccidioides, and Other Dimorphic Fungi Causing Systemic Mycoses*

MARY E. BRANDT AND DAVID W. WARNOCK

123

TAXONOMY

The dimorphic fungi causing systemic disease belong to the class Euascomycetes, order Onygenales. This contains three families of medical importance, the Onygenaceae (dimorphic pathogens), the Arthrodermataceae (dermatophytes), and the Gymnoascaceae (agents of onychomycosis and dermatomycosis). The Onygenales share several general characteristics: their sexual stages (teleomorphs) form rudimentary asci surrounded by a network of hyphae, which may have complex appendages; and their asexual (anamorph) species generally possess one of two forms, either unicellular aleurioconidia or arthroconidia in chains of alternately viable and nonviable cells.

The family Onygenaceae was originally defined on the basis of morphological characteristics of the teleomorphs and of the conidia of these organisms. The teleomorph genus *Ajellomyces* contains three species, *A. dermatitidis, A. capsulatus,* and *A. crescens,* the anamorphs of which are placed in the genera *Blastomyces, Histoplasma,* and *Emmonsia,* respectively (60). The teleomorphs of *Coccidioides* and *Paracoccidioides* have not been discovered, although genetic data suggest that *Coccidioides* is recombining in nature (12).

Molecular phylogenetic studies have indicated that species of the Onygenales are divided into several clades (descendants of a common ancestor). The family name Ajellomycetaceae has recently been proposed for one of these clades (72), which includes *Emmonsia crescens* and *E. parva, H. capsulatum, P. brasiliensis, B. dermatitidis,* and *Lacazia loboi,* the agent of lacaziosis (34, 60). A second clade, which retains the family name Onygenaceae, includes the pathogen *Coccidioides immitis* with, among others, species of *Aphanoascus, Chrysosporium, Nannizziopsis,* and *Uncinocarpus* (72). The Onygenaceae and Ajellomycetaceae are well separated from the other families, Gymnoascaceae and Arthrodermataceae. In all these phylogenetic trees, pathogenic organisms are interspersed with nonpathogenic relatives. This suggests that the capacity to infect humans has arisen numerous times during the evolution of the Onygenales (8).

This chapter covers the families Onygenaceae and Ajellomycetaceae, which include the classical dimorphic fungi *B. dermatitidis, H. capsulatum, P. braziliensis,* and *C. immitis* as well as *Emmonsia* species and nonpathogenic species of *Chrysosporium, Uncinocarpus,* and other related genera. It should be noted that, because the three species with *Ajellomyces* teleomorphs appear in the same clade, an argument has been made that all the anamorphs should be placed in the same genus. At this time, this proposal has not been implemented, in part due to the widespread usage of the anamorph names.

Histoplasma capsulatum

Historically, *H. capsulatum* was divided into three varieties: *H. capsulatum* var. *capsulatum,* a human pathogen found in North and South America; var. *duboisii,* a human pathogen found in Africa; and var. *farciminosum,* a pathogen of horses and mules found in parts of northern Africa and the Middle East. Recent phylogenetic studies have defined at least eight clades within *H. capsulatum:* North American class 1, North American class 2, Latin American group A, Latin American group B, Australian, Netherlands (Indonesian), Eurasian, and African clades (40). Seven of these eight clades comprise genetically distinct geographical populations that can be regarded as phylogenetic species. The single exception, the Eurasian clade, originated from within the Latin American group A clade. *H. capsulatum* var. *farciminosum* was placed within the Eurasian clade. In addition to the seven phylogenetic species, another seven lineages represented by single isolates from Latin America were identified (40). These may represent additional phylogenetic species.

At this time, African histoplasmosis, as defined by var. *duboisii,* is considered a distinct entity, but this view has been called into question by the finding of one var. *capsulatum* isolate from South Africa that was placed in the African (var. *duboisii*-containing) clade (40). This extends the results of earlier studies which had shown that var. *duboisii* had mitochondrial DNA restriction patterns identical to those of var. *capsulatum* strains (73).

Blastomyces dermatitidis

The genus *Blastomyces* is represented by the single species *B. dermatitidis*. Phylogenetic data show that, within the single branch occupied by the anamorphs of the three dimorphic *Ajellomyces* species, *B. dermatitidis* is most closely related to the genus *Emmonsia*. Isolates of *E. parva* are closer to *B. dermatitidis* than they are to *E. crescens*. The recognition

* This chapter contains information presented in chapter 118 by Thomas J. Walsh, Davise H. Larone, Wiley A. Schell, and Thomas G. Mitchell in the eighth edition of this Manual.

of this close relationship between *Blastomyces* and *Emmonsia* has suggested that they be consolidated into one genus. However, this proposal has not been implemented.

Coccidioides Species

Phylogenetic studies have led to the recognition of two species within the genus. The species name *C. immitis* is now restricted to isolates from California, while the new name *C. posadasii* has been proposed for all other isolates belonging to this genus (23). Zimmerman et al. (85) first divided *C. immitis* into two groups, named group I (non-CA) and group II (CA), after comparing restriction fragment length polymorphisms (RFLPs) within total genomic DNA. The genealogies of five nuclear genes were later used to confirm that *C. immitis* consists of two taxa, non-CA (Arizona, Texas, Mexico, and Argentina) and CA (California) (43). These two taxa did not interbreed, although genetic recombination had occurred between individuals within each of the two groups. Later, a more extensive population sample, including isolates from Venezuela, Mexico, and Brazil, was studied using a set of nine microsatellite markers (23). This study showed that two major clades could be distinguished. These clades, now named *C. posadasii* and *C. immitis,* respectively, correspond to the previous group I (non-CA) and group II (CA).

Paracoccidioides brasiliensis

This species has no known teleomorph, but sequence data suggest that, if one is found, it will be in the genus *Ajellomyces*. On phylogenetic trees showing the family Onygenaceae, Peterson and Sigler (60) and Bialek et al. (2), using internal transcribed spacer (ITS) and 18S sequences, respectively, were able to place this genus between *E. crescens* on one side and *E. parva* and *B. dermatitidis* on the other. Comparison of 18S and chitin synthetase sequences has indicated that *P. brasiliensis* is related to the uncultivable pathogen *Lacazia loboi,* the agent of lacaziosis (34). However, these sequences demonstrated sufficient differences that *L. loboi* was kept as an independent genus (34).

Emmonsia Species

The genus *Emmonsia* currently includes three species: *E. crescens, Emmonsia parva,* and *E. pasteuriana* (29, 60). The last organism has thus far been recovered from only a single case of disseminated cutaneous infection in an AIDS patient (29). *E. crescens* is known to form a sexual stage in the genus *Ajellomyces,* but *E. parva* has no known teleomorph.

DESCRIPTION OF AGENTS

Histoplasma capsulatum

H. capsulatum is a thermally dimorphic fungus, displaying a filamentous mold form in the environment and in culture at temperatures below 35°C and a yeast phase in tissue and at temperatures above 35°C. The mold phase may contain two types of conidia (Fig. 1). Macroconidia are thick-walled, with a diameter of 8 to 15 μm, and display characteristic tubercles or projections on their surfaces. Microconidia, smooth-walled with a diameter of 2 to 4 μm, are the infectious particles. The yeast phase develops as small oval budding cells with a diameter of 2 to 4 μm, often within macrophages (Fig. 2 and 3). The yeast cell found in African histoplasmosis is thick-walled and larger at 8 to 15 μm.

H. capsulatum is found in soils throughout the world. It grows best in soils with a high nitrogen content, particularly those enriched with bird or bat guano. Birds do not become colonized or infected with *H. capsulatum* (due to their high body temperatures), and their droppings are primarily a nutrient source. Soil samples from sites where birds have roosted have been found to remain contaminated for at least 10 years after the roost has been cleared.

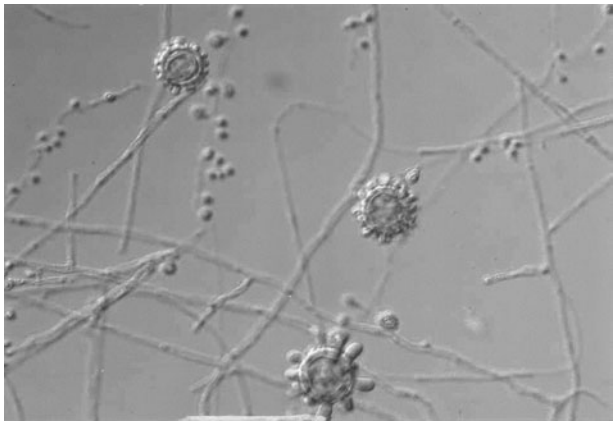

FIGURE 1 Mycelial phase of *H. capsulatum* showing tuberculate macroconidia and microconidia. Lactophenol cotton blue stain. Magnification, ×244.

Histoplasmosis is the most common endemic mycosis in North America, but it is also found throughout Central and South America. In the United States, the disease is most prevalent in states surrounding the Mississippi and Ohio Rivers, but foci of endemicity exist throughout the eastern half of the continent. Other regions of endemicity include parts of Africa, Australia, and eastern Asia, in particular India and Malaysia.

Blastomyces dermatitidis

B. dermatitidis is thermally dimorphic, converting from the mold phase to the yeast phase under appropriate conditions of temperature and nutrition. At room temperature, a floccose white mold can be recovered (Fig. 4). The microconidia are oval or pyriform (pear shaped), with a diameter of 2 to 10 μm; no macroconidia are produced. Large round thick-walled yeast cells, 5 to 15 μm in diameter, with broad-based budding daughter cells, are found in tissue and on appropriate media at 37°C (Fig. 5). Yeast cells may occur inside or outside macrophages.

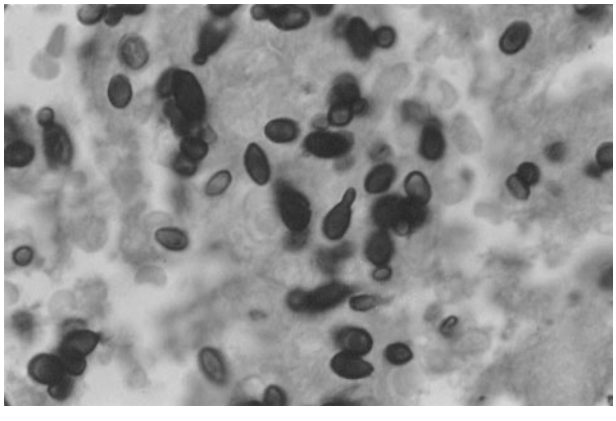

FIGURE 2 GMS stain showing blastoconidia of *H. capsulatum*. Magnification, ×285.

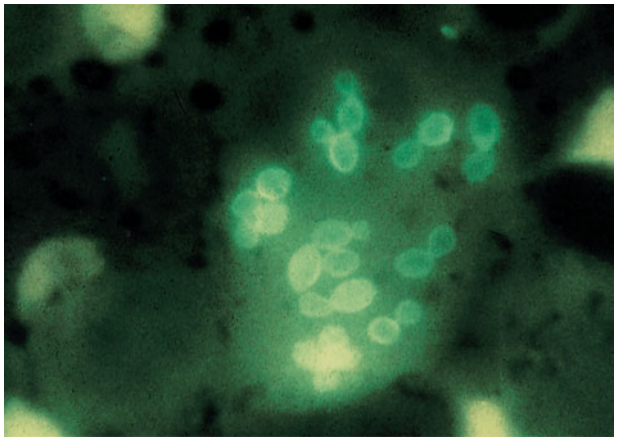

FIGURE 3 Calcofluor white wet mount of sputum showing blastoconidia of *H. capsulatum*. Magnification, ×475. (American Society of Clinical Pathology.)

The natural habitat of *B. dermatitidis* is the soil. It appears to survive best in moist acidic soils that contain a high nitrogen and organic content. Higher soil temperatures and recent rainfall facilitate growth of the fungus.

The largest number of cases of blastomycosis has been reported from North America, but the disease is also endemic in Africa and parts of Central and South America. In the United States, the organism is most commonly found in states surrounding the Mississippi and Ohio Rivers; in Canada, the disease occurs in the provinces that border the Great Lakes.

Coccidioides Species

In the environment and in culture at room temperature, the fungus exists as a mold producing septate hyphae and arthroconidia that usually develop in alternate hyphal cells (Fig. 6). As the arthroconidia mature, the alternating disjunctor cells undergo lytic degradation, releasing the barrel-shaped arthroconidia, approximately 2 to 5 μm, which are the infectious particles. Inside the host and on special media, the arthroconidia transform into a structure called a spherule. A spherule is a large (up to 120 μm in diameter),

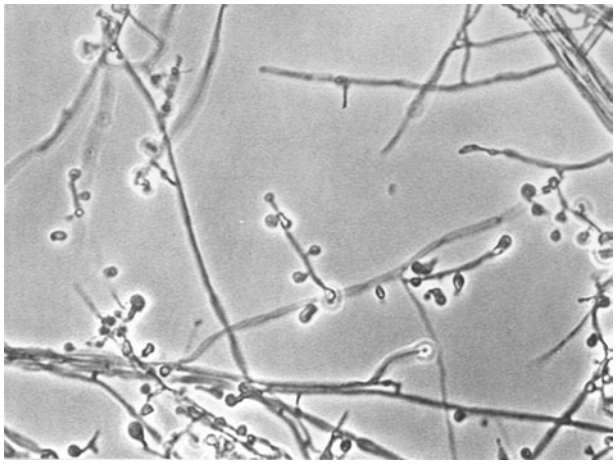

FIGURE 4 Mycelial phase of *B. dermatitidis*. Magnification, ×240.

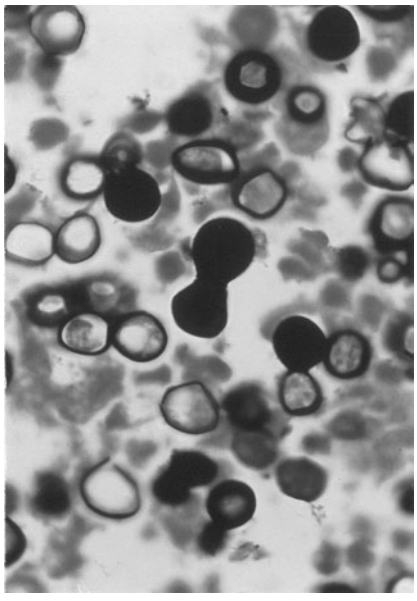

FIGURE 5 Blastoconidia of *B. dermatitidis*. GMS stain. Magnification, ×285.

thick-walled spherical structure containing many internal endospores, each approximately 2 to 4 μm, which can be released if the spherule ruptures (Fig. 7). Each endospore can develop into a spherule as well, continuing the process within the host.

Coccidioides is a soil-inhabiting fungus with a restricted geographical distribution. It is confined to regions of the Western Hemisphere that correspond to the lower Sonoran desert life zone. In the United States, the region of endemicity includes central and southern California, southern Arizona, southern New Mexico, part of Utah, and western Texas. The region of endemicity extends southwards into the desert regions of northern Mexico and parts of Central and South America.

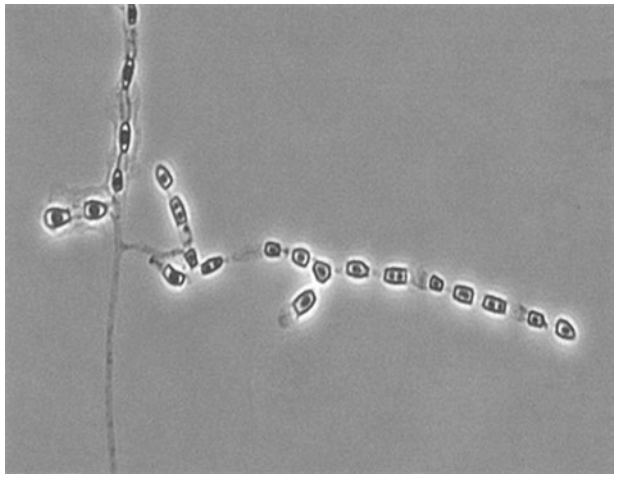

FIGURE 6 Mycelial phase of *Coccidioides immitis* showing alternating arthroconidia. Lactofuchsin stain. Magnification, ×248.

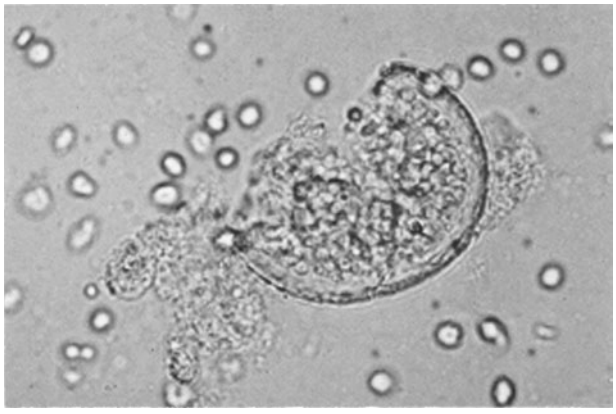

FIGURE 7 KOH preparation of pus from a lesion showing *Coccidioides* spherule and endospores. Magnification, ×285. (Reprinted from S. Verghese, D. Arjundas, K. C. Krishnakumar, P. Padmaja, D. Elizabeth, A. A. Padhye, and D. W. Warnock, *Med. Mycol.* **40:**307–309, 2002, with permission.)

Paracoccidioides brasiliensis

This organism is a thermally dimorphic fungus. At room temperature, *P. brasiliensis* grows as a mold. Growth requires a lengthy incubation of up to 30 days. Isolates incubated on rich media produce thin septate hyphae with sparse terminal and intercalary chlamydospores, but no conidia. Under conditions of nutritional deprivation, some isolates produce conidia, which vary in structure from arthroconidia to microconidia of less than 5 μm. Conidia transform into yeast cells under appropriate nutritional conditions and at a temperature of approximately 37°C. Yeast cells are mostly oval and characteristically display a mother cell surrounded by multiple buds, referred to as a "pilot's wheel" appearance (Fig. 8).

Although *P. brasiliensis* has been isolated from soil, understanding of its precise environmental habitat remains limited. The region of endemicity extends from Mexico to Argentina, but the disease is more prevalent in South America than Central America. The greatest number of reported cases has come from Brazil, Venezuela, and Colombia. The disease is most frequently acquired in regions classified as subtropical upland rain forests, such as the Amazon river basin in Brazil.

Emmonsia Species

In the environment and in culture at room temperature, *Emmonsia* species exist as a mold that produces small, single-celled conidia (about 4 μm) on the sides of the hyphae or on short side branches. Inside the host, the conidia of *E. crescens* and *E. parva* transform into structures termed adiaspores, which resemble the spherules of *Coccidioides* species (Fig. 9). Although adiaspores enlarge to become enormous, thick-walled structures, no endospores are produced and the spores eventually die. Adiaspores can also be generated in vitro using rich media. *E. crescens* and *E. parva* are largely indistinguishable: the former produces large (20- to 140-μm) multinucleate adiaspores at 37°C, whereas the latter produces smaller (8- to 20-μm) adiaspores at 40°C. *E. pasteuriana* does not produce adiaspores in tissue; rather, at 37°C on rich media it produces structures that resemble budding yeast cells.

The natural habitat of *Emmonsia* species is the soil. Infection has occurred in numerous species of burrowing mammals. Human cases are rare but have been reported from North, Central, and South America, as well as from several European and Asian countries.

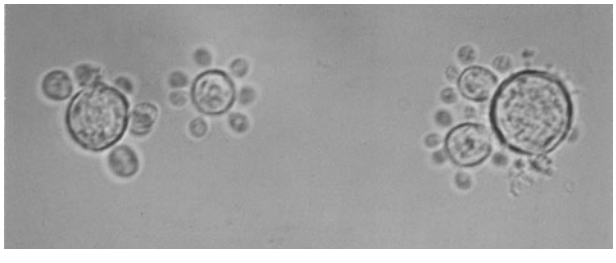

FIGURE 8 Wet mount showing blastoconidia of *P. brasiliensis*. Magnification, ~×290.

EPIDEMIOLOGY AND TRANSMISSION

Histoplasmosis

Inhalation of microconidia of *H. capsulatum* is the usual mode of infection in humans. The incubation period is 1 to 3 weeks. In cases of reinfection, the incubation period appears to be shorter (4 to 7 days after exposure). Histoplasmosis is not contagious, but there have been occasional reports of transmission from an organ donor to a recipient (45).

The major risk factor for infection is environmental exposure. The risk depends on several factors including the nature of the environmental site, the activities performed, and the duration and degree of dust or soil exposure. Longer and more intense exposures usually result in more severe pulmonary disease. Most reported outbreaks have been associated with exposures to sites contaminated with *H. capsulatum* or have followed activities that disturbed accumulations of bird or bat guano.

Persons with underlying illnesses are at increased risk for some forms of histoplasmosis. Disseminated infection is more common among individuals with underlying cell-mediated immunological defects, including those with human immunodeficiency virus (HIV) infection, and transplant recipients. Immunocompromised persons with histoplasmosis have a higher mortality rate than those who are not immunosuppressed.

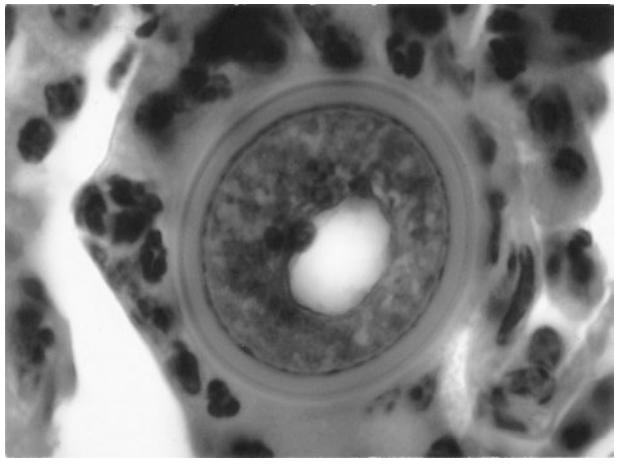

FIGURE 9 *E. parva* adiaspore in mouse tissue. PAS stain. Magnification, ~×280.

Blastomycosis

Inhalation of conidia is the usual mode of infection leading to blastomycosis. The incubation period has been estimated to be 4 to 6 weeks. Blastomycosis is not contagious.

Outbreaks have been associated with occupational and recreational activities, often along streams or rivers, and have resulted from exposures to moist soil enriched with decaying vegetation. Apart from outbreaks, blastomycosis is more commonly seen in adults than children. More men than women are affected. The disease often occurs in individuals with an outdoor occupation or recreational interest.

B. dermatitidis is uncommon as an opportunistic pathogen, but it causes more aggressive disease in persons with underlying cell-mediated immunological defects, such as those with HIV infection and transplant recipients. Immunocompromised persons with blastomycosis have a higher mortality rate than those who are not immunosuppressed.

Coccidioidomycosis

Inhalation of arthroconidia is the usual mode of infection leading to coccidioidomycosis in humans. The incubation period is 1 to 3 weeks. In contrast to what is observed with histoplasmosis, once individuals have recovered from *Coccidioides* infection, they are usually immune to reinfection. The infection is not contagious, but occasional person-to-person spread has occurred via contaminated fomites (20) or by transmission from an organ donor to a recipient (83).

The major risk factor for infection is environmental exposure. The risk depends on a number of factors including the nature of the environmental site, the activities performed, and the duration and degree of dust or soil exposure. Infection has been associated with ground-disturbing activities, such as building construction, landscaping, farming, archaeological excavation, and numerous recreational pursuits. Natural events that result in the generation of dust clouds, such as earthquakes and windstorms, have been associated with an increased risk of infection and have resulted in large outbreaks.

Disseminated infection is more common among those of black, Asian, or Filipino race and among pregnant women in the third trimester. Individuals with underlying cell-mediated immunological defects, such as those with AIDS and those receiving immunosuppressive medications, are also at increased risk of disease dissemination.

Paracoccidioidomycosis

Inhalation of conidia is the usual mode of infection leading to paracoccidioidomycosis in humans. The incubation period is unknown, but it is clear that the fungus can remain dormant for very long periods in the lymph nodes following asymptomatic primary infection.

Paracoccidioidomycosis is rare in children, accounting for around 5% of all reported cases. More than 90% of cases of symptomatic disease occur in men, most of whom have outdoor occupations: estrogen-mediated inhibition of the mold-to-yeast transformation could help to account for this (61). In recent years there has been an increase in the number of cases involving immunocompromised patients, including persons with HIV infection.

Adiaspiromycosis

Inhalation of conidia is the usual mode of infection leading to adiaspiromycosis in animals and humans. The incubation period is unknown. No risk factors have been identified.

CLINICAL SIGNIFICANCE

Histoplasmosis

There is a wide spectrum of clinical manifestations of histoplasmosis, ranging from a transient pulmonary infection which subsides without treatment to chronic pulmonary infection or to more widespread disseminated disease. Many healthy individuals develop no symptoms when exposed to *H. capsulatum* in a setting of endemicity. Higher levels of exposure result in an acute symptomatic and often severe flu-like illness. The symptoms, which include fever, chills, headache, nonproductive cough, myalgia, pleuritic chest pain, loss of appetite, and fatigue, usually disappear within a few weeks. The most severe and rarest form of this disease is disseminated histoplasmosis. The clinical manifestations range from an acute illness that is fatal within a few weeks if left untreated (often seen in infants, persons with AIDS, and solid-organ transplant recipients) to an indolent, chronic illness that can affect a wide range of sites.

Hepatic infection is common in nonimmunosuppressed individuals with disseminated histoplasmosis, and adrenal gland destruction is a frequent problem. Mucosal ulcers are found in over 60% of these patients. The mouth and throat are often affected, but lesions also occur on the lip, nose, and other sites. Central nervous system (CNS) disease occurs in 5 to 20% of patients, presenting as chronic meningitis or focal brain lesions. In persons with AIDS, disseminated histoplasmosis is usually associated with low CD4 T-lymphocyte counts and presents with nonspecific symptoms, such as fever and weight loss. Mucosal lesions are uncommon, but multiple cutaneous lesions may be present. CNS involvement occurs in 10 to 20% of cases.

African Histoplasmosis

The clinical manifestations of *H. capsulatum* var. *duboisii* infection (African histoplasmosis) differ from those of var. *capsulatum* infection. The illness is indolent at the onset, and the predominant sites affected are the skin and bones. Those with more widespread infection involving the liver, spleen, and other organs have a febrile wasting illness that is fatal within weeks or months if left untreated. Multiple cutaneous lesions often develop on the face and trunk. These often enlarge and ulcerate. Osteomyelitis occurs in about 30% of patients. The infection may spread into contiguous joints, causing arthritis, or into adjacent soft tissue, causing a purulent subcutaneous abscess.

Blastomycosis

There is a wide spectrum of clinical manifestations of blastomycosis, ranging from a transient pulmonary infection which subsides without treatment to chronic pulmonary infection or to more widespread disseminated disease. Acute pulmonary blastomycosis usually presents as a nonspecific influenza-like illness, similar to that seen with histoplasmosis or coccidioidomycosis. Most otherwise healthy persons recover after 2 to 12 weeks of symptoms, but some return months later with infection of other sites. Other patients with acute blastomycosis fail to recover and develop chronic pulmonary disease or disseminated infection.

The skin and bones are the most common sites of extrapulmonary disease. The skin is involved in more than 70% of cases, the lesions presenting either as raised verrucous lesions with irregular borders or as ulcers. The latter can also appear on the mucosa of the nose, mouth, and throat. Osteomyelitis occurs in about 30% of patients with disseminated infection,

the spine, ribs and long bones being the most common sites of involvement. Arthritis occurs in about 10% of patients. Meningitis is rare, except in immunocompromised individuals. Other organs, such as the male genitourinary tract, adrenal glands, thyroid, liver, spleen, and gastrointestinal tract, are sometimes involved.

Coccidioidomycosis

There is a wide clinical spectrum of manifestations of coccidioidomycosis, ranging from a transient pulmonary infection which resolves without treatment to chronic pulmonary infection or to more widespread disseminated disease. About 40% of newly infected persons develop an acute symptomatic and often severe flu-like illness. Higher rates of symptomatic infection (50 to 100%) have often been reported during outbreaks. The symptoms include fever, headache, chills, nonproductive cough, myalgia, and pleuritic chest pain. Up to 50% of patients develop a mild, diffuse erythematous or maculopapular rash, covering the trunk and limbs, within the first few days of the onset of symptoms. More dramatic and persistent is the rash of erythema nodosum or erythema multiforme, which occurs in about 5% of infected persons but is more common in women. Most otherwise healthy persons will recover without treatment, their symptoms disappearing in a few weeks.

Fewer than 1% of infected individuals develop disseminated coccidioidomycosis. This is a progressive disease that usually develops within 3 to 12 months of the initial infection, although it can occur much later, following reactivation of a quiescent infection in an immunosuppressed individual. The clinical manifestations range from a fulminant illness that is fatal within a few weeks if left untreated to an indolent chronic disease that persists for months or years. One or more sites may be involved, but the skin, soft tissue, bones, joints, and meninges are most commonly affected. Cutaneous and subcutaneous lesions are common. Osteomyelitis occurs in about 40% of patients, with the spine, ribs, cranial bones, and ends of the long bones being the most common sites. The disease may spread into contiguous joints, causing arthritis, or into adjacent soft tissue, causing subcutaneous abscess formation. Meningitis is the most serious complication of coccidioidomycosis, occurring in 30 to 50% of patients with disseminated disease. Without treatment, it is almost always fatal.

Paracoccidioidomycosis

The lungs are the usual initial site of *P. brasiliensis* infection, but the organism then spreads through the lymphatics to the regional lymph nodes. In most cases the primary infection is asymptomatic. However, children and adolescents sometimes present with an acute disseminated form of infection in which superficial and/or visceral lymph node enlargement is the major manifestation. This presentation is also seen in immunocompromised patients. It has a poor prognosis.

Most adults with paracoccidioidomycosis present with chronic progressive infection. In 80% of cases the disease involves the lungs. In some, it spreads to involve the mucosa, skin, and other organs. The disease is slowly progressive and may take months or even years to become established. Ulcerative mucocutaneous lesions of the face, mouth, and nose are the most obvious presenting sign. Other sites of infection include the small or large intestine, liver and spleen, adrenal glands, bones and joints, CNS, and male genitourinary tract.

Adiaspiromycosis

In most cases, adiaspiromycosis is a self-limited, localized pulmonary infection with few or no symptoms. Because the adiaspores enlarge but do not reproduce, symptoms and clinical signs appear to depend upon the number of conidia inhaled. Some patients have presented with nonproductive cough, dyspnea, and fever. A few cases of fatal, multifocal pulmonary disease have been reported.

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

Clinical Specimens

Methods of collection, transport, and storage of specimens are detailed in chapter 116. Tissue samples should be obtained when appropriate and should be divided and submitted for microbiological and histopathological examination. If possible, special tissue stains should be requested, such as the Grocott-Gomori methenamine silver (GMS) and periodic acid-Schiff (PAS) stains. Since colonization with the dimorphic fungal pathogens does not occur, their microscopic detection and/or isolation in culture is consistent with a firm diagnosis.

Histoplasma capsulatum

H. capsulatum can be isolated from sputum or bronchoalveolar lavage fluid specimens in 60 to 85% of cases of chronic pulmonary histoplasmosis if multiple specimens are tested (77). In disseminated disease, useful specimens for culture include blood, urine, lymph node, and bone marrow samples. Bone marrow cultures are positive in over 75% of cases. Blood cultures collected with the Isolator lysis-centrifugation system (Wampole Laboratories, Princeton, N.J.) or Bactec Mycolytic bottles (BD Diagnostic Systems, Franklin Lakes, N.J.) show the greatest sensitivity. Biopsy specimens of oral, cutaneous, and gastrointestinal lesions, adrenal glands, or liver and spleen have also provided a diagnosis. *Histoplasma* meningitis is difficult to diagnose, cerebrospinal fluid (CSF) cultures being positive in no more than two-thirds of cases. The best results are obtained when large volumes of CSF (10 to 20 ml) are cultured on multiple occasions.

Blastomyces dermatitidis

Sputum samples, bronchoalveolar lavage fluid, or lung biopsy specimens may be submitted for isolation of *B. dermatitidis*. Skin biopsy specimens are useful in the diagnosis of cutaneous disease. Collection of urine after prostatic massage may be helpful in the diagnosis of genitourinary blastomycosis.

Coccidioides Species

In addition to lower respiratory tract samples, material for microscopy and culture can be collected from suppurative cutaneous and soft tissue lesions for isolation of *Coccidioides* species. Organisms can be recovered only infrequently from CSF, and usually only after culture of large volumes (10 to 20 ml).

Paracoccidioides brasiliensis

In addition to lower respiratory samples, material can be collected from oral or pharyngeal lesions, cutaneous lesions, lymph nodes, adrenal glands, and the gastrointestinal tract for detection of *P. brasiliensis.*

Emmonsia Species

Sputum and bronchoalveolar lavage fluids are seldom culture positive in patients with disease caused by *Emmonsia* species. The diagnosis is usually based on histopathologic demonstration of adiaspores in lung tissue.

DIRECT EXAMINATION

Microscopy

Direct microscopic examination of clinical materials may provide a rapid presumptive diagnosis of a systemic fungal infection. However, it is important to appreciate that tissue form cells of *H. capsulatum* and *B. dermatitidis* can appear similar to each other, as well as to yeast cells of various *Candida* species, *Cryptococcus neoformans* and *Penicillium marneffei,* and endospores of *C. immitis*. It is often helpful to stain fresh, wet preparations of sputum, bronchoalveolar lavage fluid, CSF, urine, pus, or other material with calcofluor white, a fluorescent compound that binds to the fungal cell wall.

Histoplasma capsulatum

Giemsa and Wright's stains can be used to detect yeast cells of *H. capsulatum* in blood or bone marrow smears. These cells can also be seen in tissue sections stained with GMS or PAS, but usually not with hematoxylin and eosin (H&E). Detection of the small (2- to 4-μm) oval budding yeasts allows a presumptive diagnosis of histoplasmosis. Organisms can be found within macrophages or free in the tissues. It is unusual to find yeasts on cytological examination of sputum or other respiratory tract fluids. The thick-walled, narrow-based budding yeast cells of *H. capsulatum* var. *duboisii,* approximately 10 to 15 μm in diameter, are about fourfold larger than those of *H. capsulatum* var. *capsulatum* in tissue sections.

Blastomyces dermatitidis

Direct calcofluor white or KOH mounts or Gram stains of sputum, tissues, and exudates will often permit the detection of the large round yeast cells of *B. dermatitidis*. The broad-based buds often attain the same size as the parent cells before becoming detached. Histopathologic examination using PAS or GMS stains also can be of value.

Coccidioides Species

Tissue sections should be stained with PAS, GMS, or H&E to permit the detection of the characteristic large, thick-walled spherules of *Coccidioides* species. Microscopic examination of wet preparations of sputum, bronchoalveolar lavage fluid, pus, etc., treated with KOH is also helpful but less sensitive. *Prototheca wickerhamii* may resemble small spherules, and *Rhinosporidium seeberi* may simulate larger ones.

Paracoccidioides brasiliensis

The characteristic yeast cells with multiple buds of *P. brasiliensis* can often be found on direct microscopic examination of sputum, bronchoalveolar lavage fluid, pus from draining lymph nodes, or tissue biopsy specimens. Staining of wet preparations with lactophenol cotton blue, methylene blue, Gram's stain, or calcofluor white can be helpful. Tissue sections can be stained with PAS, GMS, or H&E.

Emmonsia Species

Tissue sections stained with PAS or GMS are most helpful in demonstrating the characteristic adiaspores of *Emmonsia* species in lung tissue. It is important to appreciate that in the chronic stage, the organism may collapse and thus form various shapes that may resemble other fungi, helminths, or pollen grains. Adiaspores must also be distinguished from the spherules of *Coccidioides*. Adiaspores do not contain endospores.

Antigen Detection

Histoplasma capsulatum

The *Histoplasma* polysaccharide antigen (HPA) test is a microtitration plate-based double-antibody sandwich enzyme immunoassay (EIA) to detect antigenuria and antigenemia in cases of disseminated histoplasmosis (18). This test is also useful in the early diagnosis of acute pulmonary histoplasmosis (82). No kits or reagents are commercially available for purchase, but this test is performed on a fee-for-service basis by MiraVista Diagnostics (Indianapolis, Ind.; http://www.miravistalabs.com).

Ten milliliters of urine, 5 ml of serum, or 1 ml of CSF is the preferred volume for testing, although a minimum volume of 0.5 ml of any specimen is required for a single test. To obtain maximum test sensitivity, it is recommended that both serum and urine specimens be tested in parallel. Treatment success or failure may be assessed by collecting specimens at least 14 days after starting treatment and testing the newly acquired samples in parallel with the last specimen that was positive before initiation of treatment.

Blastomyces dermatitidis

The *Blastomyces* antigen test is a microtitration plate-based double-antibody sandwich EIA to detect antigenuria and antigenemia in disseminated blastomycosis (19). No kits or reagents are commercially available for purchase, but this test is performed on a fee-for-service basis by MiraVista Diagnostics (http://www.miravistalabs.com). The sample requirements are the same as those for the HPA test.

Coccidioides Species

Galgiani et al. (24) reported the detection of circulating antigen in sera from 35 patients with coccidioidomycosis, 33 of whom had no detectable antibodies to *C. immitis* at that time. Antigen was detected most frequently in sera obtained within the first month of the onset of symptoms. At present, coccidioidomycosis antigen testing is not available as a routine diagnostic test.

Paracoccidioides brasiliensis

Mendez-Giannini et al. (53) demonstrated that a 43-kDa glycoprotein antigen of *P. brasiliensis* could be detected in the sera of patients with both the acute and chronic forms of paracoccidioidomycosis. Later, Gomez et al. (25) described an inhibition enzyme-linked immunosorbent assay (ELISA), which utilized a monoclonal antibody directed against an 87-kDa heat shock protein antigen of *P. brasiliensis*. Several reports have described the detection of *P. brasiliensis* antigen in urine, CSF, and bronchoalveolar fluid samples (47, 65). Others have noted that antigen levels in serum diminished or even disappeared during successful treatment (26, 48). At present, paracoccidioidomycosis antigen testing is not available as a routine diagnostic test.

Emmonsia Species

No serologic tests exist at this time for the diagnosis of adiaspiromycosis in humans.

Nucleic Acid Detection in Clinical Materials

No commercially available systems exist for the detection of fungal nucleic acid in clinical materials. However, several methods are currently under investigation. Conserved regions of the rRNA genes have been used as targets in a number of PCR-based detection assays. It is important to appreciate that amplification of conserved genes can result

in products derived both from pathogenic fungi and from genetically related nonpathogenic fungal species. These nonspecific nucleic acids could arise from colonization of the original sample with saprophytic organisms, from contamination during sample collection, or from contamination of PCR reagents with fungal DNA. It is very important that the identity of amplicons detected using conserved genes be verified by direct sequencing (7, 54). In more recent studies, genes specific for the fungus of interest are now being chosen as PCR targets, thus eliminating this specificity problem.

Histoplasmosis

Several publications have described the use of PCR to detect *H. capsulatum* DNA in fixed paraffin-embedded tissue samples (64, 67, 71), in blood or tissue samples (9), and in clinical materials from three patients with histoplasmosis (49). Imhof et al. (37) used a real-time PCR to detect *H. capsulatum* DNA in a culture-positive bone marrow sample; the amplicon was then sequenced to verify the specificity of the product. Bialek et al. designed a nested PCR that targeted the gene coding for a unique 100-kDa protein of *H. capsulatum* (4). This assay was also used to detect *H. capsulatum* DNA in several clinical samples from a patient with disseminated histoplasmosis (63).

Blastomycosis

A nested-PCR assay targeting the WI-1 gene has been described for the detection of *B. dermatitidis* DNA in paraffin-embedded tissue (5). The PCR amplified DNA from 8 of 13 tissue samples in which yeast cells were detected by microscopy, and all products were homologous to the WI-1 gene on direct sequencing.

Coccidioidomycosis

A PCR assay using *Coccidioides*-specific primers derived from the ITS region of rRNA was used to amplify DNA from sera of mice infected with *C. posadasii* and from sera of seropositive patients (39). In another study, a PCR directed at the antigen 2/proline-rich antigen gene was used to detect *C. posadasii* DNA in three human paraffin-embedded tissue samples that were microscopically positive for spherules (6).

Paracoccidioidomycosis

A nested-PCR assay targeting the immunogenic *gp43* gene was evaluated for the detection of *P. brasiliensis* DNA in lung homogenates from infected and uninfected mice (3).

ISOLATION PROCEDURES

Biosafety

Laboratory-associated infections with *Coccidioides* species, *H. capsulatum,* and *B. dermatitidis* have occurred in healthy immunocompetent individuals after exposure to airborne conidia (74). These can be released from contaminated soil samples as well as from sporulating mold phase cultures of the organisms. Even the mere lifting of a culture plate lid is often sufficient to cause the release of large numbers of conidia into the air. Should a sporulating culture be dropped, millions of conidia will be dispersed. It is also important to note that local infections including granuloma formation have been reported following accidental percutaneous inoculation during injection of laboratory animals, or while performing autopsies of humans with histoplasmosis, coccidioidomycosis, or blastomycosis. No cases of laboratory-acquired *P. brasiliensis* infection have been reported.

All procedures involving the manipulation of sporulating cultures of *Coccidioides* species and *H. capsulatum* and for processing soil or other environmental materials known or likely to contain these organisms should be performed inside a class II biological safety cabinet under conditions of biosafety level 3 containment. Biosafety level 2 practices and facilities are recommended for handling and processing clinical specimens and animal tissues (62). Hyaline (colorless) molds of unknown identity should always be examined and manipulated inside a class II biosafety cabinet. Such molds should never be handled on an open laboratory bench.

Biosecurity

In the United States, both species of *Coccidioides* are classified as select agents. The select agent regulations (42 C.F.R. Part 73, 7 C.F.R. Part 331, and 9 C.F.R. Part 121) govern the possession, use, and transfer of these agents. Any entity in the United States that possesses, uses, or transfers isolates that are known to be *Coccidioides* species must have a certificate of registration issued by the Secretary of the Department of Health and Human Services (DHHS). Isolates that are known to be *Coccidioides* may be transferred only between registered laboratories. In addition, individuals may not handle or possess isolates that are known to be *Coccidioides* species unless they have been approved by DHHS based on a security risk assessment from the U.S. Attorney General. Clinical or diagnostic laboratories that possess, use, or transfer an isolate suspected to be *Coccidioides* that is contained in a specimen presented for diagnosis, verification, or confirmation are exempt from these requirements. These exempt laboratories must destroy or transfer the isolate within seven calendar days of identification of the agent. The exempt laboratory, as well as the registered laboratory, must submit a completed APHIS/CDC Form 4 within seven calendar days of identification, specifying the final status of the isolate. Application forms, Form 4, and a copy of the regulations can be found at http://www.cdc.gov/od/sap.

Culture for Mold Phase

In general, the organisms discussed in this chapter can be readily cultivated in the mold phase on general fungal media such as Sabouraud dextrose agar or potato dextrose agar incubated at 25°C. Incubation at 37°C is also helpful to recover the yeast phase of dimorphic organisms. Media containing antibiotics such as chloramphenicol or gentamicin should be used when culturing clinical materials, such as sputum, that may be contaminated with bacteria. Media containing cycloheximide are useful to inhibit saprophytic fungi and to provide a useful differential tool in identification. Many unrelated saprophytic soil fungi fail to grow on media containing cycloheximide, fail to grow altogether at 37°C, or fail to convert to the yeast phase at 37°C. Screw-capped slants are preferable to plates for culturing dimorphic fungi. If plates are used, they should be sealed so that mold spores cannot escape into the ambient air. Seals that are permeable to air such as Shrink Seals (Scientific Device Laboratory, Des Plaines, Ill.) are useful for this purpose. In general, colonies develop within 3 to 7 days, but some strains of *H. capsulatum* may require incubation for as much as 4 to 6 weeks.

Culture for Yeast Phase

H. capsulatum, B. dermatitidis, and *P. brasiliensis* can be recovered in the yeast phase by using appropriate media incubated at 37°C. *Coccidioides* species do not have a yeast phase. *E. parva* and *E. crescens* produce adiaspores at elevated temperatures.

Histoplasma capsulatum

The yeast phase of *H. capsulatum* can be recovered using rich media such as brain heart infusion agar (BHI) or BHI with blood (BHIB). Plates or slants should be incubated at 37°C under aerobic conditions for at least 4 weeks.

Blastomyces dermatitidis

The yeast phase of *B. dermatitidis* can be recovered using rich media such as BHI, BHIB, Pine's medium, or Kelley's agar, incubated at 37°C under aerobic conditions. Yeasts are usually visible within 1 week, but media should be held for at least 4 weeks before being discarded.

Paracoccidioides brasiliensis

The yeast phase can be recovered using media such as BHI, Pine's medium, or Kelley's agar, incubated at 37°C. The organism grows slowly, and plates or slants should be held for at least 4 weeks.

Emmonsia Species

E. parva and *E. crescens* produce adiaspores in vitro when cultivated on phytone yeast extract agar, BHI, or BHIB at 37 to 40°C depending on the species. *E. pasteuriana* produces yeast-like cells after culture on BHI at 37°C for approximately 10 days.

IDENTIFICATION

In general, these organisms are identified by their characteristic morphologic features, by conversion to the yeast phase, and/or by DNA probe testing. Slide cultures should not be performed for suspected dimorphic isolates due to the possibility of laboratory infection from accidental inhalation of infectious conidia.

Histoplasma capsulatum

The mold phase of *H. capsulatum* can be recovered after incubation at 25°C. The colony is initially white or buff-brown. Both types may be isolated from the same patient, and eventually the brown type may convert to the white type. The brown type generally produces more of the characteristic tuberculate macroconidia than the white type. On subculture, only about 30% of macroconidia show tubercles. Microconidia are abundant in fresh isolates of *H. capsulatum*. After multiple subcultures, the production of both macroconidia and microconidia may be diminished. The presence of both macroconidia and microconidia is not required for identification of *H. capsulatum,* as authentic *H. capsulatum* isolates that fail to produce either macroconidia or microconidia have been recognized. Macroconidia but no microconidia can also be seen in the saprophytic fungus *Sepedonium,* as well as in the related fungus *Renispora flavissima*. Authentic *H. capsulatum* isolates can be recognized by their thermal dimorphism, as well as by their growth on inhibitory mold agar.

Once the characteristic morphology has been recognized, mold phase *H. capsulatum* isolates can be confirmed by conversion to the yeast phase. The isolate is transferred to BHI or BHIB agar and incubated at 37°C for at least 7 to 10 days. Hyphal cells may form buds directly or develop enlarged, transitional cells that subsequently begin to bud. The microconidia may also convert to budding yeast cells. Complete conversion rarely is achieved, and multiple transfers to fresh BHI or BHIB medium may be required. The colony will develop a white, smooth, yeast-like appearance, and microscopic examination will reveal oval, budding yeasts approximately 1 to 3 by 3 to 5 μm. The cells have a narrower base of attachment between the bud and parent cell than do those of *B. dermatitidis*.

The Gen-Probe AccuProbe test (GenProbe, San Diego, Calif.) can also be used to confirm isolates as *H. capsulatum.* This test requires actively growing cultures: mold phase cells not more than 4 weeks of age or yeast cells no older than 1 week. Isolates can be taken from solid media or broth cultures. A portion of the isolate or the broth culture is added to lysis and hybridization buffers in a tube containing glass beads. After sonication and denaturation steps, the mixture is incubated with the acridinium ester-labeled *H. capsulatum* hybridization probe, which binds to *H. capsulatum* rRNA if the latter is present in the sample. Following a short incubation to degrade unbound probe, formation of specific DNA-RNA hybrids is quantitated in relative light units by using a luminometer. Extracts that display relative light unit values greater than 50,000 are considered positive.

The GenProbe test has largely replaced exoantigen testing for identification of *H. capsulatum*. Several studies have shown that the GenProbe method is sensitive and specific for identification of *H. capsulatum* (31, 35, 56, 68), although false-positive results can be obtained when isolates that are genetically related to the Ajellomycetaceae are tested (10).

The colonial morphology of *H. capsulatum* var. *duboisii* is indistinguishable from that of non-African isolates of *H. capsulatum*. Isolates of *H. capsulatum* var. *duboisii* also display positive results in the GenProbe test for *Histoplasma capsulatum* (56). Histopathologic examination of tissue forms is essential to distinguish the two varieties.

Blastomyces dermatitidis

At 25 to 30°C, isolates of *B. dermatitidis* produce a variety of forms ranging from a fluffy white colony that is visible within 2 to 3 days to a glabrous, tan, nonconidiating colony that grows more slowly. Microscopic examination shows microconidia that are oval or pyriform, usually smooth-walled, and formed on short lateral or terminal branches along the hyphae. *B. dermatitidis* also grows readily on inhibitory media containing cycloheximide. Conidia of the hyaline hyphomycete *Scedosporium apiospermum,* of some *Chrysosporium* species, and of the dermatophyte *Trichophyton rubrum* are morphologically similar and can be mistaken for *B. dermatitidis*. These species either fail to grow at 37°C (some *Chrysosporium* species) or grow as mold when incubated at 37°C *(S. apiospermum* and *T. rubrum)*.

The identification can be confirmed by conversion to the yeast phase. Generally, isolates of *B. dermatitidis* convert readily to the yeast phase on BHI, BHIB, or Pine's or Kelley's medium incubated at 37°C. Yeast cells are hyaline, smooth- and thick-walled, generally 8 to 15 μm in diameter, with the bud connected to the parent cell by a broad base of up to 4 to 5 μm in diameter. Conversion can be accomplished in 2 to 3 days, although occasional isolates may take several weeks.

Identification can also be confirmed using the GenProbe AccuProbe reagent for *B. dermatitidis*. False-positive *Blastomyces dermatitidis* Gen-Probe results were obtained with *P. brasiliensis* (57), so care must be taken to distinguish these organisms. An isolate of *Gymnascella hyalinospora* also cross-reacted with the *B. dermatitidis* probe (38).

Coccidioides Species

At 25 to 30°C, isolates of *Coccidioides* species display considerable variation in colonial morphology. Colonies can range from moist, glabrous, and grayish to abundant, floccose, and white. Colonies may become tan with age. Microscopic

examination shows hyphae that are thin and septate, with fertile (spore-producing) hyphae usually arising at right angles. Arthroconidia are hyaline, one celled, short, cylindrical to barrel shaped, moderately thick walled, smooth walled, and 2 to 8 by 3 to 5 μm. Arthroconidia alternate with thin-walled empty disjunctor cells. At maturity, the disjunctor cells undergo lytic degradation, releasing the arthroconidia. After this fragmentation, the arthroconidia may display frill-like remains of the disjunctor cells on each end. Isolates of *Coccidioides* grow well on inhibitory mold agar containing cycloheximide, which helps to distinguish this organism from similar soil saprophytes such as *Malbranchea* species. It is also important to distinguish true alternate arthroconidia from aging mycelia that, due to cytoplasmic shrinkage, display an appearance that can be misinterpreted as arthroconidia formation. True arthroconidia eventually fragment and disperse; aging mycelia do not. The two species of *Coccidioides* cannot be readily distinguished morphologically, although some strains of *C. posadasii* display slower growth on media containing high salt concentrations.

When incubated at 37°C, no yeast form is produced. The organism can produce spherules in vitro by using appropriate media and increased CO_2 tension incubated at 37 to 40°C, but this is rarely performed with routine clinical isolates.

The GenProbe AccuProbe for *Coccidioides* may be used for confirmation of unknown isolates as *Coccidioides* species. This test is generally sensitive and specific, although pretreatment of isolates with formaldehyde leads to false-negative results (30). The GenProbe test does not distinguish between the two species of *Coccidioides*.

Paracoccidioides brasiliensis

When incubated at 25 to 30°C, *P. brasiliensis* isolates display slow growth and produce a variety of forms ranging from a glabrous, leathery, brownish, flat colony with a few tufts of aerial mycelium to a wrinkled, folded, floccose to velvety, and white to beige form. The colonies are very similar in appearance to those of *B. dermatitidis*. Most strains grow for long periods of time without the production of conidia. Microscopic examination shows intercalary chlamydospores and coiled hyphae. Sporulation can be enhanced on yeast extract agar, and some isolates may produce pyriform conidia and arthroconidia.

When cultures are transferred to 37°C on rich media such as BHI or Pine's or Kelley's agar, colonies are generally folded (cerebriform) in appearance. Mycelial elements may be seen mixed with yeast cells. Conversion to the yeast phase also is quite slow. Yeasts are 2 to 30 μm in diameter and are oval or irregular in shape, displaying the characteristic "pilot's wheel" appearance of multiple thin-necked round buds developing around the parent cell. The walls are thinner than those of *B. dermatitidis* yeast cells, and the buds are not broad based.

Identification is usually confirmed by demonstrating thermal dimorphism. There is no commercial DNA probe test for *P. brasiliensis*. The GenProbe test for *B. dermatitidis* cross-reacts with *P. brasiliensis* (57), so care must be taken when employing this test with isolates that may actually be *P. brasiliensis*. Slow-growing, nonsporing isolates are more characteristic of *P. brasiliensis* than of *B. dermatitidis*.

Emmonsia Species

At 25°C, *Emmonsia* species grow as glabrous (waxy), colorless colonies, which produce yellowish white aerial mycelia in time. Some display pale orange to grayish orange aerial mycelia. The colonies often have areas that alternate between tufted mycelium and a glabrous consistency. Reverse pigmentation is pale gray to grayish brown. On microscopic examination, the hyphae are septate and branching. Sporulation is enhanced on potato dextrose or Pablum cereal agar. Numerous conidia are produced either directly from the sides of the hyphae or on short stalks that branch at right angles from the hyphae. Each stalk bears a single terminal conidium. Sometimes the swollen end may bear one to three secondary spine-like pegs, which in turn form a secondary conidium in a flower-like arrangement (66). The conidia are round, oval, or pyriform and measure 2 to 4 μm by 3 to 5 μm. The conidial wall is smooth but may roughen with age. *E. parva* and *E. crescens* are indistinguishable in morphology and appearance at 25°C.

E. crescens displays no hyphal growth at 37°C and forms larger adiaspores (20 to 140 μm in diameter) on BHI or phytone yeast extract agar at this temperature. *E. parva* produces hyphae at 37°C and produces smaller adiapores (8 to 20 μm in diameter) at 40°C. *E. pasteuriana* displays features at 25°C that are similar to those of *E. crescens* and *E. parva*. At 37°C on BHIB, this species produces yeast-like cells that are oval or lemon shaped, budding on a narrow base, and 2 to 4 μm. The colonies are creamy and smooth. This species does not produce adiaspores in vitro or in vivo (29).

TYPING SYSTEMS

In general, typing systems have been used to show geographic differences among isolates and cryptic species. In some genera, diversity among isolates collected from a single geographic area can be shown.

Histoplasma capsulatum

Isolates can be divided into at least eight clades as described earlier (40). This typing system can be used to place an unknown isolate into one of these major worldwide geographic groupings. In earlier studies, types based on variation in mitochondrial DNA or on the yeast phase-specific nuclear gene *yps-3* were shown to be consistent for U.S. isolates from persons without AIDS. Central American isolates and U.S. isolates from AIDS patients have a different *yps-3* genotype and several different mitochondrial DNA subtypes (reviewed in reference 69). Carter et al. (14) analyzed 30 isolates from Indianapolis, Ind., using a set of 11 biallelic markers, and found that every isolate had a distinct multilocus genotype. Taylor et al. (70) investigated the genetic polymorphisms of *H. capsulatum* isolates recovered from infected bats captured in Mexico by using random amplified polymorphic DNA (RAPD) PCR. The pattern of DNA polymorphisms appeared to reflect the geographic areas from which the bats originated. A major relatedness between bat and human isolates was shown, in contrast to blackbird isolates.

Blastomyces dermatitidis

RFLPs in mitochondrial DNA were used to type 19 isolates of *B. dermatitidis* from Little Rock, Ark. (84), dividing these isolates into three classes. When these isolates were typed in an RAPD assay with arbitrary primers, the classes could be further subdivided. Significant genetic diversity was observed. In another study, 55 isolates from the United States, India, and Africa were divided into three major groups based on RFLP analysis. These groups were further divided using RAPD fingerprinting into 5, 15, and 12 types, respectively, that correlated with the geographic origin of the isolate (51). Interestingly, these studies showed that soil isolates collected from an outbreak of blastomycosis in Eagle

River, Wis., were not responsible for the majority of cases of disease in that outbreak.

Coccidioides Species

Two major clades, corresponding to the two species *C. immitis* and *C. posadasii,* were defined when an extensive population sample, including isolates from Venezuela, Mexico, and Brazil, was studied using a set of nine microsatellite markers (23). Typing of isolates to *C. immitis* (California) or *C. posadasii* (non-California) species can be accomplished by examining any of 17 sites fixed for alternate alleles (43).

Paracoccidioides brasiliensis

The first genetic study of this organism compared ITS 1 and ITS 2 DNA sequences from armadillo and human clinical isolates (33) and suggested the existence of two genetic groups within this species. In a later study, microsatellite sequences were compared as markers to discriminate among a set of *P. brasiliensis* human isolates causing either chronic or acute disease (55). These authors did not observe any clustering of isolates associated with either acute or chronic disease.

Emmonsia Species

Based on ITS sequences, isolates of *E. crescens* fall into two phylogenetic groups, North American and Eurasian, depending on the continents from which the isolates were obtained (60). Isolates of *E. parva* separate into two groups as well, one group isolated from the North American prairies and the second group from the desert southwest of the United States or from Italy.

SEROLOGIC TESTS

Histoplasmosis

Serologic tests have an important role in the rapid diagnosis of several forms of *H. capsulatum* infection but are most useful for persons with chronic pulmonary or disseminated histoplasmosis (46). Of the different methods that have been developed, the immunodiffusion (ID), complement fixation (CF), and latex agglutination (LA) tests are the most popular. The principal antigen used in these tests is histoplasmin, a soluble filtrate of mycelial-phase broth cultures. Histoplasmin contains two glycoprotein components of particular interest: the H antigen, against which antibodies are formed during the acute phase of histoplasmosis, and the M antigen, against which antibodies are produced during all phases of the disease. In contrast to the other components of histoplasmin, such as the C antigen, which is a heat-stable galactomannan polysaccharide that is cross-reactive with *B. dermatitidis* and *C. immitis*, both the H and M antigens were once thought to be specific proteins for the detection of anti-*H. capsulatum* antibodies. The M antigen, however, was found to be a catalase that was not specific unless used in a deglycosylated form (32). The H antigen has been identified as a β-glucosidase (15).

The ID test is a qualitative method that detects precipitins to the H and M glycoprotein antigens of *H. capsulatum* present in histoplasmin. Both serum and CSF can be used. Patients with negative serum reactions during the acute phase of infection should have additional samples taken 3 to 4 weeks later. ID test kits and reagents are available from Gibson Laboratories (Lexington, Ky.), Immuno-Mycologics, Inc. (Norman, Okla.), and Meridian Diagnostics (Cincinnati, Ohio). Commercial kits include mycelial-phase culture filtrates containing *H. capsulatum* H and M antigens, positive control sera containing antibodies against both H and M antigens, and ID plates. Positive control sera must be included each time the test is performed and must react with both the H and M antigens. The ID test is a useful screening procedure or adjunct to the CF test. It is more specific but less sensitive than the CF test.

The CF test is a quantitative procedure in which two antigens are employed: histoplasmin and a suspension of intact merthiolate-killed *H. capsulatum* yeast phase cells. The latter is more sensitive (~80% versus ~20%) but less specific (~90% versus ~99%) than histoplasmin. Serum, peritoneal fluid, or CSF can be used in the CF test. Patients with negative serum reactions during the acute phase of infection should have additional samples taken 3 to 4 weeks later. No commercial kits are available, but antigens, antisera, and other reagents can be purchased from several commercial sources (Immuno-Mycologics, Inc., and Meridian Diagnostics). Negative control sera and positive control sera from human histoplasmosis cases demonstrating a CF titer of 1:32 or greater with the homologous antigen should be tested each time the CF test is performed.

An LA test, using histoplasmin as antigen, is commercially available (LA-Histo Antibody system; Immuno-Mycologics, Inc.). This semiquantitative test detects immunoglobulin M (IgM) antibodies and is used primarily for the presumptive diagnosis of acute histoplasmosis. It is less helpful for the detection of chronic infection.

Blastomycosis

The most useful serologic test is ID, but CF and ELISA procedures have also been developed and evaluated. Substantial improvement in the performances of these tests has been achieved by the use of a purified surface antigen of *B. dermatitidis,* termed the A antigen (36) or WI-1 antigen (42). Both are released from the yeast phase of *B. dermatitidis* by autolysis and can be recovered from culture filtrates. Immunological comparison of the two antigens has shown that they are very similar, but WI-1 is a 120-kDa protein that is not glycosylated whereas the A antigen is a 135-kDa glycosylated protein.

The ID test is a qualitative method that detects precipitins to the A antigen of *B. dermatitidis*. Patients with negative serum reactions during the acute phase of infection should have additional samples taken 3 to 4 weeks later. ID test kits and reagents are available from Gibson Laboratories, Immuno-Mycologics, Inc., and Meridian Diagnostics. Commercial kits include purified *B. dermatitidis* A antigen, positive control serum containing antibodies against A antigen, and ID plates. The positive control serum must be included each time the test is performed and must react with the homologous reference antigen to form the A precipitin line.

Coccidioidomycosis

Despite the fact that sensitive procedures, such as ELISA, have been developed, the ID and CF tests remain the most reliable methods for the serologic diagnosis of coccidioidomycosis (46). The principal antigen used in these tests is coccidioidin, a soluble filtrate of mycelial-phase broth cultures.

The simultaneous use of heated and unheated coccidioidin antigens permits the ID test to be employed to detect either IgM or IgG antibodies on a single plate. The immunodiffusion tube precipitin (IDTP) test utilizes heated coccidioidin as antigen, detects IgM, and gives results comparable to those obtained with the classical tube precipitin test. It is most useful for diagnosing recent infection.

The immunodiffusion complement fixation (IDCF) test utilizes unheated coccidioidin, detects IgG antibodies, and gives results comparable to those of the CF method (see below). It is less sensitive but more specific than the CF test (59). Commercial kits are available (Gibson Laboratories, Immuno-Mycologics, Inc., and Meridian Diagnostics) and include unheated and heat-treated coccidioidin antigens, positive control sera containing IgM or IgG antibodies, and ID plates. The sensitivity of the IDTP and IDCF tests can be improved by 10-fold concentration of serum prior to testing. Positive control sera must be included each time the test is performed and must react with the homologous reference antigen to form a precipitin line. The ID test is useful for initial screening of specimens and can be followed by other tests if positive.

The CF test is a sensitive quantitative method in which unheated coccidioidin is used to detect IgG antibodies. The major disadvantage of CF is that it is a laborious and time-consuming procedure that requires experienced personnel for optimum performance. No commercial kits are available, but reagents for in-house use can be obtained from several commercial sources (Immuno-Mycologics, Inc., and Meridian Diagnostics). Negative control serum and a positive control serum from a human case of coccidioidomycosis (with a titer of ≥1:32) should be included each time the test is performed. Anticomplementary activity in serum samples can occur and may be resolved by subsequent ID testing. In addition to serum, the CF test can be performed on CSF, pleural, and joint fluid samples.

A qualitative LA test, using heat-treated coccidioidin as antigen, is available from several commercial sources (LA-Cocci Antibody system; Immuno-Mycologics, Inc., and Coccidioides Latex Agglutination system; Meridian Bioscience, Inc.). This test is simple and rapid to perform. It detects IgM antibodies and is more sensitive than the IDTP test in detecting early infection. However, it has a false-positive rate of 5 to 10% and the results should be confirmed using the IDTP and/or CF methods. It is not recommended for screening CSF specimens because false-positive reactions can occur (58).

The Premier *Coccidioides* EIA (Meridian Bioscience, Inc.) is a qualitative test for detection of IgM and IgG antibodies in serum or CSF specimens. The antigen used in this test is a mixture of purified TP and CF antigens. Published evaluations suggest that this test has a sensitivity of >95% and a specificity of ~95% (41, 50). However, false-positive reactions have been obtained with some sera from patients with blastomycosis. EIA results should be confirmed by the IDTP and IDCF tests.

Paracoccidioidomycosis

The most popular serologic methods are ID and CF, but other tests, such as ELISA, have also been employed. The principal antigens used in these tests are derived from culture filtrates of mycelial or yeast phase broth cultures of *P. brasiliensis*. The major diagnostic antigen found in these preparations is a 43-kDa glycoprotein. Cell wall antigens have proved less useful than culture filtrate antigens, largely because they are dominated by cross-reactive galactomannan (11).

The ID test is a qualitative method that can be performed on a fee-for-service basis by Cerodex Laboratories, Inc., Washington, Okla. Commercial mycelial-form culture filtrate antigen can be obtained for in-house use from Immuno-Mycologics, Inc. No commercial kits are available for this test. The CF test is performed with *P. brasiliensis* yeast-form culture filtrate antigen. No commercial kits or reagents are available.

Adiaspiromycosis

No serologic tests are available for the diagnosis of adiaspiromycosis.

ANTIMICROBIAL SUSCEPTIBILITIES

Established treatment options for *H. capsulatum, B. dermatitidis, Coccidioides* species, and *P. brasiliensis* include amphotericin B, ketoconazole, itraconazole, and fluconazole, although no comparative trials of these agents have been performed. Table 1 lists the in vitro susceptibilities of these molds to established and investigational antifungal agents as reported in studies that were performed in accordance with Clinical and Laboratory Standards Institute (formerly National Committee for Clinical Laboratory Standards) document M38-A guidelines. Of note, *H. capsulatum* has been reported to become resistant to fluconazole during treatment, and this has accounted for failure in some patients (81).

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

Histoplasmosis

The definitive diagnosis of histoplasmosis can be accomplished by direct microscopic detection of *H. capsulatum* in clinical specimens or its isolation in culture. However, isolation and identification may take 2 to 4 weeks.

Antigen detection complements other diagnostic methods for histoplasmosis and is particularly useful for immunocompromised patients with more extensive disease, often providing a rapid diagnosis before positive cultures can be identified. HPA has been detected in serum, urine, CSF, and bronchoalveolar lavage fluid specimens obtained from individuals with disseminated histoplasmosis. Antigen levels are higher in urine than in serum. For patients with AIDS and disseminated histoplasmosis, sensitivity is 95% in urine and 86% in serum (82). Specificity is about 98%.

Antigen levels in the urine and serum decline with effective treatment, becoming undetectable in most patients (80). Failure of antigen concentrations to fall during treatment suggests therapeutic failure. For patients who have responded to treatment and in whom antigen levels have previously fallen, an increase in antigen in the urine or serum is suggestive of relapse (79). Antigen has been detected in the CSF of patients with meningitis caused by *Histoplasma*.

The LA test for *Histoplasma* antibodies is most useful for the diagnosis of acute infection, positive results being obtained within 2 to 3 weeks after exposure. An LA titer of 1:16 is presumptive evidence of infection, and a titer of ≥1:32 is considered strong presumptive evidence of active or recent infection (46). Because false-positive reactions can occur, the results should be confirmed by the ID test. Low-titer results from single specimens should be interpreted with caution. In such cases, the test should be performed on another specimen collected 4 to 6 weeks later.

In the ID test, precipitins to the M antigen of *H. capsulatum* are the first to appear (4 to 8 weeks after exposure) and can be detected in up to 75% of persons with acute histoplasmosis. However, they can also be found in nearly all individuals with chronic pulmonary infection, as well as in those who have undergone a recent skin test with histoplasmin. Precipitins to the H antigen are specific for active disease

TABLE 1 In vitro susceptibilities of dimorphic fungi to antifungal agents

Fungus	Antifungal agent	MIC range (μg/ml)	MIC_{90} range (μg/ml)	Reference(s)
B. dermatitidis	Amphotericin B	≤0.03–1	0.5	21, 44, 52
	Fluconazole	1–64	NR[a]	52
	Itraconazole	≤0.03–1	0.125	21, 44, 52
	Posaconazole	≤0.03–0.06	NR	22
	Voriconazole	≤0.03–16	0.25	21, 44, 52
	Anidulafungin	2–8	NR	22
	Caspofungin	0.5–8	NR	22
Coccidioides spp.	Amphotericin B	0.125–2	0.5–1	27, 44, 52
	Fluconazole	2–64	64	27, 52
	Itraconazole	0.125–2	1	44, 52
	Posaconazole	0.25–1	1	28
	Voriconazole	≤0.03–0.5	0.25	44, 52
	Caspofungin	8–64	32	27
H. capsulatum	Amphotericin B	≤0.03–2	0.25	21, 44, 52
	Fluconazole	≤0.125–64	NR	52
	Itraconazole	≤0.03–8	0.06	21, 44, 52
	Posaconazole	≤0.03–0.06	NR	22
	Voriconazole	≤0.03–2	0.25	21, 44, 52
	Anidulafungin	2–4	NR	22
	Caspofungin	0.5–4	NR	22
P. brasiliensis	Amphotericin B	0.125–4	NR	52
	Fluconazole	≤0.125–64	NR	52
	Itraconazole	≤0.03–1	NR	52
	Voriconazole	≤0.03–2	NR	52

[a] NR, not reported.

but occur in fewer than 20% of cases (76). They usually disappear within the first 6 months of infection and are seldom, if ever, found in the absence of M precipitins. The presence of precipitins to both H and M antigens is highly suggestive of active histoplasmosis, regardless of other serologic test results.

The CF test is useful in the diagnosis of acute, chronic, disseminated, and meningeal forms of histoplasmosis. In acute infections, antibodies to the yeast antigen are the first to appear (about 4 weeks after exposure) and the last to disappear after resolution of the infection. Antibodies to histoplasmin appear later and reach lower titers than those observed for the yeast antigen. In contrast, histoplasmin titers are usually higher in persons with chronic histoplasmosis. CF test results can be difficult to interpret because cross-reactions can occur with sera from persons with blastomycosis, coccidioidomycosis, and other fungal infections. In such instances, titers usually range between 1:8 and 1:32 and occur mainly against the yeast-form antigen. However, many serum samples from culture-confirmed cases of disseminated histoplasmosis give titers in the same range. CF titers of 1:8 or greater with either antigen are considered presumptive evidence of histoplasmosis. Titers above 1:32 or rising titers in serial samples offer stronger evidence of infection.

Titers of CF antibodies to *H. capsulatum* decrease following resolution of the infection but increase in individuals with chronic progressive disease. However, clinical and microbiological findings should also be considered in assessing the patient's prognosis or making treatment decisions. In some patients, positive CF titers decline slowly and persist long after the disease has been cured. The significance of persistently elevated or fluctuating CF titers is unclear, as is the effect of antifungal treatment on antibody clearance (78).

Serologic tests are particularly useful for patients with *Histoplasma* meningitis. The detection of precipitins to H and M antigens in CSF specimens is sufficient to make a diagnosis in the appropriate clinical setting and often is the only positive diagnostic test (75).

Blastomycosis

Although microscopic examination and culture remain the most sensitive means of establishing the diagnosis of blastomycosis, serologic tests can also provide useful information. A positive reaction in an ID test using the A antigen of *B. dermatitidis* is specific and diagnostic for blastomycosis (46). However, a negative ID test does not rule out the diagnosis because the sensitivity of this method has been reported to range from ~30% for cases of localized infection to ~90% for cases of disseminated blastomycosis. In established cases of the disease, a decline in the number or the disappearance of precipitin lines is evidence of a favorable prognosis.

With urine specimens, the *Blastomyces* antigen test has been reported to have a sensitivity of 89% for disseminated infection and 100% for pulmonary disease (19). However, cross-reactive antigens occurred in urine samples from all patients with paracoccidioidomycosis and 96% of patients with histoplasmosis (19).

Coccidioidomycosis

Although the definitive laboratory diagnosis of coccidioidomycosis depends on microscopic examination and

culture, serologic tests are of proven usefulness in diagnosis and management. A positive IDTP test result is indicative of acute coccidioidomycosis. IDTP-reactive IgM antibodies can be detected in up to 75% of cases within 1 week of symptom onset, and ~90% are positive within 3 weeks. Although infrequent, a positive IDTP test result with CSF is indicative of acute meningitis. In cases where the IDTP test is negative but the CF test is positive, patients should be investigated for microbiologic or histopathologic evidence of histoplasmosis or blastomycosis. In addition, further sera should be obtained at 3-week intervals and examined by CF and ID tests for coccidioidomycosis, histoplasmosis, and blastomycosis. False-positive IDTP reactions have been reported to occur in 15% of sera obtained from cystic fibrosis patients in the absence of a positive culture for *C. immitis* (17).

A positive IDCF test result is presumptive evidence of recent or chronic infection. IDCF-reactive IgG antibodies can usually be detected within 2 to 6 weeks after onset of symptoms. Although the IDCF test is generally not performed as a quantitative test, it can be used in this manner after serial dilution of patient serum to obtain an endpoint titer. Titers obtained using the quantitative IDCF test are not identical to titers obtained from the CF test, but the observed trends are comparable.

The LA test is more sensitive than the IDTP test in detecting acute infection, but it is less specific. For this reason, a positive test result with undiluted serum should be confirmed by the ID and/or CF tests.

The CF test does not become positive until about 4 to 12 weeks after infection, but CF antibodies persist for long periods in individuals with chronic pulmonary or disseminated coccidioidomycosis. Testing of serial specimens to detect rising or falling titers can reveal the progression or regression of illness and the response to antifungal treatment. A CF titer to coccidioidin at any dilution should be considered presumptive evidence of coccidioidomycosis. In most instances, the titer is proportional to the extent of the infection, and failure of the CF titer to fall during treatment of disseminated coccidioidomycosis is an ominous sign (59). Titers of 1:2 or 1:4 are usually indicative of early, residual, or meningeal disease; however, similar titers are sometimes found in individuals without coccidioidomycosis. The parallel use of the IDCF and the CF tests can help to confirm or refute the diagnosis. CF titers of >1:16 should lead to a careful assessment of the patient for possible spread of the disease beyond the respiratory tract. More than 60% of patients with disseminated coccidioidomycosis have CF titers of >1:32. However, false-negative results can occur for immunocompromised individuals, such as persons with AIDS (1). Patients with clinical presentations consistent with coccidioidomycosis and whose sera give negative or low CF titers should be retested at 3- to 4-week intervals.

The detection of CF antibodies in the CSF is usually diagnostic of coccidioidal meningitis and remains the single most useful test for diagnosis of that infection. However, ~5% of CSF specimens from patients with coccidioidal meningitis are negative in the CF test.

Paracoccidioidomycosis

The definitive diagnosis of paracoccidioidomycosis depends on microscopic examination and culture. However, isolation and identification of *P. brasiliensis* from clinical specimens may take up to 4 weeks.

Serologic tests are useful for the rapid presumptive diagnosis of paracoccidioidomycosis, particularly in cases of disseminated infection. The ID test with yeast-form culture filtrate antigen is highly specific and is positive in 65 to 100% of cases of acute or chronic pulmonary infection or of disseminated paracoccidioidomycosis (13). The CF test with yeast-form culture filtrate antigen is less specific than the ID test, and cross-reactions can occur with cases of histoplasmosis (16). However, CF titers of ≥1:8 are considered presumptive evidence of paracoccidioidomycosis. Low CF titers are usually associated with localized infection, while higher titers are found for patients with multifocal disease (14, 19). Falling CF titers are often predictive of successful treatment, and high or fluctuating CF titers are suggestive of a poor prognosis (13, 16). Some reports, however, have indicated that ID and CF results do not correlate well with the clinical status of the patient (26, 48).

Adiaspiromycosis

The definitive diagnosis of adiaspiromycosis can be accomplished by direct microscopic detection of *Emmonsia* species in clinical specimens or their isolation in culture.

Trichophyton, Microsporum, Epidermophyton, and Agents of Superficial Mycoses

RICHARD C. SUMMERBELL, IRENE WEITZMAN, AND ARVIND A. PADHYE

124

TAXONOMY

The etiologic agents of dermatophytosis are classified, along with some nonpathogenic relatives, in three anamorphic genera: *Trichophyton, Microsporum,* and *Epidermophyton*. Those dermatophytes capable of reproducing sexually, i.e., producing ascomata with asci and ascospores, are classified in the teleomorphic genus *Arthroderma* (113) in the family Arthrodermataceae of the order Onygenales (21), phylum Ascomycota. The recorded connections between teleomorphic (sexual) and anamorphic (asexual) states of the dermatophytes as well as the dermatophytoids (i.e., the soil-borne *Trichophyton* and *Microsporum* species that are best not called "dermatophytes" [Greek for "skin plants"] because they are not pathogenic [3, 105]) are given in Table 1.

Recent phylogenetic studies have tended to support the ongoing classification of dermatophytes in the three traditional anamorph genera mentioned above. Some normally nonpathogenic, geophilic dermatophytoids currently placed in *Trichophyton,* e.g., *T. ajelloi* and *T. terrestre,* appear to belong to a distinct clade in most phylogenies based on the ribosomal internal transcribed spacer (ITS) region sequences, but the degree of bootstrap support for this clade does not support its distinction as a separate genus (15, 33, 34). Further study of this matter with additional genes is necessary.

As part of the ongoing molecular revolution in biology, fungal taxonomy is ever more strongly influenced by our greatly increased understanding of population genetics (16). Dermatophytes show two population genetics patterns differing among species having "population hosts" (43) in different zoological families, orders, or classes (101, 102). (A population host, which is the normal epidemiologic reservoir of the species, is distinguished from "occasional host" species that may acquire infection but that do not support ongoing populations; for example, *Microsporum canis* has mostly feline population hosts, and while humans are frequently infected by feline carriers, the species is seldom directly transmitted from human to human, making our species only an occasional host.) Some dermatophyte species, including pathogens with population hosts in the rodent, rabbit, pig, dog, and cat families, are potentially sexual, with sexual reproduction occurring only off the host, i.e., on hair or other keratinous debris in contact with the ground. Other species, particularly those with human, ungulate, equine, or avian population hosts, have no access to a soil-based location suitable for sexual reproduction and host reinfection; not surprisingly, these species are found on investigation to be asexual and clonal. They consist, in all known cases, of genetically highly uniform isolates (36, 72, 83) sharing, where known, a single mating type factor (101, 107). Most appear to have evolved from a single strain of a sexual ancestral species that was able to make the rare, successful switch to ongoing contagious infection of a new animal host. A few epidemiological and phenotypic characters in the clonal species appear to have undergone accelerated evolution due to strong selection for increased compatibility with the new host. This process has tended to produce differences allowing relatively easy laboratory identification of these species. At the same time, the basic cellular housekeeping genes investigated in phylogenetic taxonomic studies have evolved at a normal rate and thus strongly tend to resemble forms seen in ancestral species complexes or in sibling species. This has led to considerable recent confusion about species concepts. Long-recognized dermatophyte species such as *Trichophyton equinum* and *Microsporum gallinae* that have distinct epidemiologies and that are easily identified in the routine diagnostic laboratory have nonetheless been suggested not to be distinct species as traditionally conceived (33, 35), since their ITS and some other sequences are strongly similar to those of related species (e.g., *Trichophyton tonsurans* and *Arthroderma grubyi,* respectively, for the examples mentioned). The ITS sequences of the dermatophytes proposed for synonymy, however, generally show a small number of consistent sequence polymorphisms when compared with sequences of the species with which synonymy has been proposed. This suggests that further genetic study will tend to support the species in question as recently diverged but nonetheless separate lineages. The present chapter takes a relatively cautious approach to the ongoing debates in this area (118), synonymizing traditionally recognized species primarily when there is unequivocal, multigene molecular evidence that they are not supported at the species level. Notwithstanding recent literature, in no case is a clonal species of a given mating type (such as the horse dermatophyte *T. equinum,* + mating type) recognized as synonymous with a phenotypically and epidemiologically distinct species evolutionarily derived from the opposite ancestral mating type (such as the human tinea capitis agent *T. tonsurans,* – mating type), since such a difference in mating types confirms independent evolutionary origin from a common ancestor. The list of recognized species is in Table 1.

TABLE 1 Important characteristics of clinically isolated dermatophytes and dermatophytoids[a]

Dermatophyte species (teleomorph name[s] if formation of sexual state is known)	Growth	Macromorphology	Micromorphology	BCPMSG medium pH results (for 7–10 days)	Urea test (7 days, broth)	Hair perforation	Other comments
Epidermophyton floccosum[b]	Moderately rapid	Flat, slightly granular at first, soon developing white puffs of degeneration; sandy to olive-brown (Fig. 18e); reverse pale to yellowish	Macroconidia abundant, club shaped with broadly rounded apex, usually with fewer than 6 cells (Fig. 12); no microconidia formed; many chlamydospores in primary isolates	Alkaline	Pos	Neg	Invades skin and nails, rarely hair; no microconidia
Microsporum spp.							
M. audouinii[c]	Moderately rapid	Flat to velvety, thin, pale salmon to pale brownish reverse	Rare, deformed macroconidia, often with beak, constricted midregion, and at least trace granulation (Fig. 13); drop-shaped microconidia and aerial arthroconidia may be present; pectinate branching, apiculate terminal chlamydospores often seen	No pH change or alkaline	Neg	Neg	Poor growth and no or brownish pigment on polished rice medium; usually connected with patient or index patient in or recently from Africa; only children typically infected
M. canis[b] *(Arthroderma otae)*	Rapid	Flat to velvety, thin, pale to yellow (Fig. 18g), with yellow (rarely pale) reverse	Macroconidia thick walled, roughened and beaked (Fig. 14); microconidia drop shaped	No pH change; macroconidia often abundant	Pos	Pos	Good growth and yellow pigment on polished rice medium; human infection usually from cat or dog; *M. canis* "distortum" phenotype has macroconidia distorted, bizarrely shaped; "*M. equinum*" phenotype from horses has few, short macroconidia
M. cookei[c] *(A. cajetani)*	Moderately rapid	Granular to velvety; reverse wine red	Macroconidia rough, thick walled with cellular compartments rather than true cross walls (Fig. 15); microconidia drop shaped	No pH change	Pos	Pos	Probably nonpathogenic; existing case reports poorly substantiated

(Continued on next page)

TABLE 1 Important characteristics of clinically isolated dermatophytes and dermatophytoids[a] *(Continued)*

Dermatophyte species (teleomorph name[s] if formation of sexual state is known)	Growth	Macromorphology	Micromorphology	BCPMSG medium pH results (for 7–10 days)	Urea test (7 days, broth)	Hair perforation	Other comments
M. ferrugineum[d]	Slow	Flat or folded, waxy to slightly velvety; surface and reverse yellow, rusty or pale	No conidia, coarse, straight "bamboo" hyphae with prominent septa may be present	No pH change	Neg	Neg	Yellow colony on Lowenstein-Jensen medium (compare *T. soudanense*); geographically restricted to parts of Africa, Asia, and Eastern Europe
M. gallinae[d]	Moderately rapid	Flat to velvety; surface white tinged with pink; reverse red; red pigment diffuses into agar	Macroconidia smooth to slightly rough, often bent and with thickest cells near the apex, sometimes slightly rough; microconidia drop shaped	No data	Neg	Neg	Rare; human infection usually from chicken. Species may be an asexual phenotype within *A. grubyi* according to Gräser et al. (33)
M. gypseum complex[b] (*A. gypseum*, *A. incurvatum*, *A. fulvum*)	Rapid	Granular, sandy in color, or occasionally light cinnamon or rosy buff; reverse usually pale to brownish	Macroconidia abundant, thin walled, fusoid (tapered at both ends), roughened, with up to 6 septa (Fig. 16); microconidia drop shaped, mostly formed along sparsely branched hyphae (a feature only noted if *M. racemosum* is queried)	No pH change	Pos	Pos	Human infection usually from soil contact
M. nanum[c] (*A. obtusum*)	Moderately rapid	Powdery, sandy in color; reverse often reddish brown	Macroconidia rough, usually only 1–3 cells long, egg shaped to ellipsoidal	No data	Pos	Pos	Human infection usually from pig; now rare
M. persicolor[c] (*A. persicolor*)	Rapid	Powdery, sandy in color; reverse pale to yellowish, sometimes with rosy tones	Macroconidia fusoid (tapered on both ends), often absent or smooth walled on Sabouraud agar but usually common and rough walled on Sabouraud with added salt (3 or 5% NaCl) (Fig. 17); microconidia formed on pedicels (must be checked within 5 days)	No pH change	Pos	Pos	Usually poor growth at 37°C in vitro; rose to wine red reverse on sugar-free media, e.g., glucose-free Sabouraud agar; human infection usually from soil (fomites from voles)

M. praecox[c]	Rapid	Powdery, sandy in color, reverse yellow	As *M. gypseum*	No pH change	Pos	Neg	Uncommon
M. racemosum[d] (*A. racemosum*)	Rapid	Powdery, sandy in color, reverse red	Macroconidia as *M. gypseum;* microconidia mostly formed in densely branched formations structured like grape clusters (racemes)	No pH change	Pos	Pos	Rare
M. vanbreuseghemii[d] (*A. grubyi*)	Rapid	Powdery, pinkish or buff; pale to yellow reverse	Macroconidia rough, thick walled, cylindrical, often more than 8 cells long, with cellular compartments rather than true cross walls	No data	Pos	Pos	Rare; anamorph may be conspecific with phenotypically and epidemiologically different *M. gallinae* according to Gräser et al. (33)
Trichophyton spp.							
T. ajelloi[c] (*A. uncinatum*)	Moderately rapid	Powdery, rich tan to medium orange-brown in color; reverse pale, brownish or with purple-black pigment	Macroconidia smooth, thick walled, cylindrical, often more than 7 cells long, with cellular compartments rather than true cross walls (Fig. 5)	No data	Pos	Pos	Nonpathogenic in humans
T. concentricum[d]	Slow	Folded, honey brown to reddish brown, glabrous or slightly velvety colony	No conidia	No data	Pos or neg	Neg	Only from indigenous Asian, Austronesian/Melanesian, or indigenous Central and South American people with distinct tinea imbricata infection
T. equinum[c]	Moderately rapid	Flat to velvety colony with cream-colored surface and yellow to red-brown reverse	Macroconidia uncommon, cylindrical to club shaped, smooth; microconidia abundant, on small pedicels (examine before 5 days)	Alkaline	Pos	Usually neg, sometimes pos	Human infection usually from horse; has a nicotinic acid requirement except in autotrophic variant from Australia and New Zealand
T. erinacei hedgehog form[c] (*A. benhamiae*)	Rapid	Granular to powdery, yellow-cream to buff surface, yellow reverse	Macroconidia uncommon, club shaped, smooth; microconidia nearly spherical, abundant, mostly produced in dense tufts; spiral appendages present	Alkaline	Neg (European/ New Zealand form); pos (African form)	Pos	Human infection usually from hedgehog or its fomites; therefore, mostly restricted to regions with wild hedgehogs or to pet hedgehog owners
T. megninii[c]	Moderately rapid	Cottony, with white down sometimes suffused with rosy pigment; reverse red to red-brown	Macroconidia seldom seen, pencil shaped; microconidia drop shaped	Alkaline	Pos or weak pos	Neg	Region of endemicity in Portugal and nearby areas; requires histidine; considered a subtype of *T. rubrum* by Gräser et al. (33)

(Continued on next page)

TABLE 1 Important characteristics of clinically isolated dermatophytes and dermatophytoids[a] *(Continued)*

Dermatophyte species (teleomorph name[s] if formation of sexual state is known)	Growth	Macromorphology	Micromorphology	BCPMSG medium pH results (for 7–10 days)	Urea test (7 days, broth)	Hair perforation	Other comments
T. mentagrophytes complex (zoophilic)[b] inclusive of *T. mentagrophytes* sensu stricto (= the former *T. mentagrophytes* var. *quinckeanum*) plus animal-adapted forms of *T. interdigitale* and the *Trichophyton* anamorph of *A. benhamiae* (*A. vanbreuseghemii*, *A. benhamiae*)	Rapid	Granular to powdery, yellow-cream to buff surface (Fig. 18b), pale to red-brown reverse	Macroconidia uncommon, club shaped, smooth; microconidia nearly spherical, abundant, mostly produced in dense tufts; spiral appendages present	Alkaline (rarely weak)	Pos	Pos	Human infection usually from rodent or rabbit. Macroconidia induced on SGA + 3 or 5% sodium chloride (Fig. 6)
T. mentagrophytes complex (anthropophilic)[b] inclusive of human-adapted forms of *T. interdigitale* and possibly of the *Trichophyton* anamorph of *A. benhamiae* (*A. vanbreuseghemii*, *A. benhamiae*)	Rapid	Powdery to cottony, yellow-cream to buff or white surface, pale to red-brown reverse	Macroconidia uncommon, club shaped, smooth; microconidia nearly spherical or drop shaped, abundant, produced mainly in dense tufts when round and on sparsely branched hyphae when drop shaped; spiral appendages present but rare in very cottony isolates	Alkaline	Pos	Pos	Macroconidia often induced on SGA + 3 or 5% sodium chloride
T. mentagrophytes ("nodular" variant[c] formerly called *T. krajdenii*, now known to be a distinct morph of *T. interdigitale*)	Moderately slow	Cottony, cream to white surface often with yellow marginal zone (Fig. 18a), intense yellow reverse	Macroconidia rare, microconidia usually drop shaped, sometimes also round; coiled, yellow "nodular bodies" and yellow pigment granules present in submerged mycelium; spiral appendages seldom seen	Alkaline	Pos	Pos	Although usually very different in morphology, this variant so far is not genetically distinguishable from other anthropophilic isolates of *T. interdigitale*
T. rubrum[b] (cosmopolitan variant)	Moderately slow	Cottony to velvety, white to reddish surface (Fig. 18c), typically wine red reverse (Fig. 18d) but yellow variants occasional; red	Macroconidia seldom seen, pencil shaped (Fig. 8); microconidia drop shaped, abundant, scanty or not formed;	No pH change (alkalinity after 14 days)	Neg (rarely weak)	Neg	Melanoid variants secreting brown pigment rarely seen

		color poorly formed in presence of common bacterial contamination	lateral hyphal projections often present				
T. rubrum (Afro-Asiatic variant[c] formerly called *T. raubitschekii, T. fluviomuniense,* or, when microconidia absent, *T. kanei*)	Moderately slow	Powdery to low velvety, cream to deep red; reverse wine red	Macroconidia abundant (Fig. 7), club shaped, sometimes with "rat-tail" extension; microconidia drop shaped to round; many chlamydospores in primary isolates	No pH change (alkalinity after 14 days)	Pos	Neg	Although usually very different in morphology, this variant so far is genetically distinguished from typical *T. rubrum* only at microsatellite markers. It is often from upper body infection (tinea corporis, tinea cruris)
T. schoenleinii[d]	Slow	Convoluted, slightly velvety whitish colony	No conidia seen; "favic chandeliers" or "nailhead hyphae" present	Alkaline	Variable	Neg	Very rare; associated with clinically recognizable "favus" lesions; now extirpated except in rural central Asia, rural Africa
T. simii[c] *(A. simii)*	Rapid	Granular to powdery, yellow-cream to buff surface, pale to red-brown reverse	Macroconidia abundant, often with some cells swollen as chlamydospores; microconidia drop shaped	Alkaline	Pos	Pos	Endemic to India and Africa; similar to zoophilic *T. mentagrophytes* but macroconidial number and shape are atypical; reference distinction is by mating or molecular study
T. soudanense[c]	Moderately slow	Flat, bright yellow to (less commonly) wine red colony with radial striations and starlike margin; uncommonly cottony; reverse yellow to wine red	Macroconidia not seen, microconidia drop shaped, scarce or absent; reflexive hyphal branches in radial striations	Alkaline, with small zone of clearing	Usually neg, occasionally pos	Neg	Endemic to sub-Saharan Africa but widely disseminated in cosmopolitan parts of Europe and Americas.Dark colony on Lowenstein-Jensen medium (compare *M. ferrugineum*); may or may not grow on growth factor test media, considered a subtype of *T. rubrum* by Ohst et al. (77)
T. terrestre complex[c] *(A. lenticulare, A. quadrifidum, A. insingulare)*	Moderately rapid	Powdery white to cream or pinkish surface; pale or rarely yellow to red reverse	Macroconidia numerous, mostly small (5 or fewer cells) intergrading with large club-shaped micro-conidia in a continuous series (Fig. 9), so that 3-, 2-, and 1-celled conidia are present	Alkaline	Pos	Pos	No growth at 37°C in vitro; nonpathogenic

(Continued on next page)

TABLE 1 Important characteristics of clinically isolated dermatophytes and dermatophytoids[a] *(Continued)*

Dermatophyte species (teleomorph name[s] if formation of sexual state is known)	Growth	Macromorphology	Micromorphology	BCPMSG medium pH results (for 7–10 days)	Urea test (7 days, broth)	Hair perforation	Other comments
T. tonsurans[b]	Moderately slow	Powdery to velvety, white to yellowish or red-brown surface; reverse chestnut, red-brown (Fig. 18f), and/or sulfur yellow, rarely pale	Macroconidia uncommon, small pencil or club shaped; microconidia abundant (Fig. 10), often on broad "match-stick" pedicels; "balloon forms" and "filiform branches" may be seen	Alkaline, sometimes weak	Pos	Usually neg, sometimes pos	Stimulated by thiamine; a form producing only macroconidia has been described
T. vanbreuseghemii[d] *(A. gertleri)*	Moderately slow	Buff colony, leathery, finely grainy; reverse whitish or pale yellow	Abundant macroconidia with cells of uneven length, tending to fragment into single cells; microconidia small, boxy	No data	Pos	Pos	Geophilic; very rare in clinical laboratory
T. verrucosum[b]	Slow	Convoluted, slightly velvety, whitish or less commonly tan to ochraceous colony	Macroconidia seldom seen, with "rat-tail extension"; microconidia round to drop shaped; chains of symmetrical chlamydospores seen on milk solids media at 37°C (Fig. 11)	Alkaline (may be weak) with broad zone of clearing	Neg	Neg	Human infection usually from cattle; growth stimulated at 37°C
T. violaceum[c]	Slow	Glabrous (bald-looking), smooth or convoluted colony; purple-red, sometimes with white sectors; some East African isolates purely whitish	Macroconidia seldom seen; microconidia drop shaped, formed mostly on thiamine medium or on sporulation media; chains of asymmetrical chlamydospores seen on milk solids media at 37°C	No pH change or weak alkaline with small to broad zone of clearing (always broad after 14 days)	Pos or weak	Neg	Endemic to North Africa and Middle East but widely disseminated in cosmopolitan parts of Europe, Americas, and South Africa

[a] Abbreviations: Pos, positive; Neg, negative.
[b] Common.
[c] Uncommon but likely to be seen by large laboratories in the Americas and Europe.
[d] Unlikely to be seen except in regions of endemicity, proficiency test, or soil isolation experiment.

EPIDEMIOLOGY AND TRANSMISSION

Dermatophytes are keratinophilic fungi that are capable of invading the keratinous tissues of living animals. They are grouped into three categories based on host preference and natural habitat (Table 2) (2). Anthropophilic species almost exclusively infect humans; animals are rarely infected. Geophilic species are soil-associated organisms, and soil per se or soil-borne keratinous debris (e.g., shed hairs or molted feathers) is a source of infection for humans as well as other animals. Zoophilic species are essentially pathogens of nonhuman mammals or, rarely, birds; however, animal-to-human transmission is not uncommon. Understanding this ecological classification for case isolates may be helpful in determining the source of infection; e.g., human infections caused by *Microsporum canis* are often the result of contact between susceptible children and newly acquired or stray kittens (64). Clinical species identification of dermatophytes assists in controlling infections that may have a family pet or other domesticated animal as an ongoing source of inoculum.

Some dermatophytes, e.g., *Trichophyton rubrum,* are cosmopolitan, whereas others, e.g., *Trichophyton concentricum,* are geographically limited (87). *T. concentricum* is found only in the Pacific Islands and regions in Southeast Asia and Central and South America.

Anthropophilic fungi are usually transmitted either directly through close human contact or indirectly through sharing of clothes, combs, brushes, towels, bedsheets, etc. Tinea capitis is highly contagious and may spread rapidly within a family, institution, or school. Transmission of tinea cruris is associated with shared clothing, towels, and sanitary facilities. The transmission of tinea pedis and tinea unguium often involves communal showers, baths, or other aquatic facilities but may depend on both environmental and host factors (91, 115). Acquisition of chronic *T. rubrum* tinea pedis has been suggested to require a dominant autosomal susceptibility gene (121).

Infections with geophilic dermatophytes involve transmission of soil-borne inoculum to humans or other mammals. Outbreaks originating from infected soil with secondary human-to-human transmission have been reported (5). Infections by zoophilic species result from animal-to-human contact (cats, dogs, cattle, laboratory animals, etc.) or from indirect transmission involving fomites. The fungi may then be transmitted among humans to a limited extent, especially in institutions (96).

[a] Normally nonpathogenic, soil-associated dermatophytoids such as *T. terrestre* and *M. cookei* are not included in this table.

CLINICAL SIGNIFICANCE

The dermatophytoses (tinea or ringworm) generally manifest as infections of the keratinized tissues (hair, nails, skin, etc.) of humans, other mammals, and birds. Cutaneous infections resembling dermatophytoses may be caused by yeasts or by unrelated filamentous fungi that are normally saprobes or plant pathogens; these infections are referred to as opportunistic dermatomycoses (115).

Dermatophytes are among the very few fungal species that cause contagious, directly host-to-host-transmissible diseases of humans and animals. The transmission of these fungi is usually carried out by arthroconidia that have formed in or on infected host tissue. These conidia may be spread by direct skin-to-skin contact or via fomites containing free arthroconidia, shed skin scales, or hairs. Typical fomites include such divergent materials as hats, shoes, shower room floors, bedding, clothing of nursing staff in chronic care institutes, and farm fenceposts used by animals for scratching. Tissue invasion is normally cutaneous; dermatophytes are usually unable to penetrate deeper tissues as a result of nonspecific inhibitory factors in serum (60), inhibition of fungal keratinases (24), and other immunological barriers (76, 116), including a Th1 reaction mediated in part by $CD4^+$ lymphocytes (61). Dermatophytes tend to grow in an annular fashion on most affected skin regions, producing a "ringworm" infection form with a more or less raised and erythematous active area at the periphery and a relatively scurfy inactive zone at the center of established lesions. The organism can often be isolated only from the active, peripheral ring. Infection may range from mild to severe, partly as a consequence of the reaction of the host to the metabolic products of the fungus. Also important in determining the severity of infection are the virulence of the infecting strain, the anatomic location of the infection, the status of the host's immune system, and local environmental factors. Occasionally, especially in immunocompromised patients, subcutaneous tissue may be invaded, e.g., in Majocchi's granuloma, kerion, mycetoma-like processes (11, 117), or, more rarely, a generalized systemic infection (8). A *T. rubrum* infection suggestive of cutaneous blastomycosis has been reported in an immunocompromised patient (97).

In synopsis, the principal current risk factors for common forms of dermatophytosis are age (youth for tinea capitis or advanced age for onychomycosis), family history of chronic dermatophytosis, participation in athletics featuring extensive body contact (e.g., wrestling or judo) or foot maceration (e.g., marathon running), barefoot use of communal aquatic facilities (showers and swimming areas), exchange of headgear and footwear or inadequately cleaned bedding, contact with feral domestic animals (especially street kittens) or animals recently supplied by en masse breeding operations

(especially cats, guinea pigs, rabbits, laboratory rats, and cattle), inhabitation of rodent-infested dwellings, and, especially for children in developing countries, contact with livestock suffering from untreated dermatophytosis and contact with barbering instruments that have not been effectively disinfected (1, 7, 19, 42, 48, 62, 66, 89, 116, 121).

Anatomic Specificity

Infections caused by dermatophytes are named according to the anatomic location involved, e.g., tinea barbae (beard and moustache), tinea capitis (scalp, eyebrows, and eyelashes), tinea corporis (face, trunk, and major limbs), tinea cruris (groin, perineal, and perianal areas), tinea pedis (soles and toe webs), tinea manuum (palms), and tinea unguium (nails). Different dermatophyte species may produce clinically identical lesions; conversely, a single species may infect many anatomic sites.

Tinea barbae, usually caused by zoophilic fungi, e.g., *Trichophyton verrucosum* and granular, zoophilic forms of the *T. mentagrophytes* complex, is typically highly inflamed and may present as acute pustular folliculitis that can progress to suppurative boggy lesions (kerion). A less severe form that appears as dry, erythematous, scaly lesions also occurs. Tinea capitis may vary from highly erythematous, patchy, scaly areas with dull gray hair stumps to highly inflamed lesions with folliculitis, kerion formation, alopecia, and scarring. *Trichophyton tonsurans* and *M. canis* are the most common agents (87). Favus (tinea favosa), usually caused by *Trichophyton schoenleinii* but also potentially caused by *Trichophyton violaceum* or *Microsporum gypseum,* is a now very rare chronic infection of the scalp and glabrous skin characterized by the formation of cup-shaped crusts (scutula) resembling honeycombs. Tinea corporis, which can be caused by any dermatophyte but is often associated with zoophiles, classically manifests as circular, erythematous lesions with scaly, raised, active, and often vesicular borders. Chronic lesions on the trunk and extremities usually are caused by *T. rubrum,* in particular by Afro-Asiatic forms of this fungus (formerly often called *Trichophyton raubitschekii*). Tinea cruris ("jock itch"), usually caused by *T. rubrum* or *Epidermophyton floccosum,* typically appears as scaly, erythematous to tawny brown, bilateral and asymmetric lesions extending down to the inner thigh and exhibiting a sharply marginated border frequently studded with small vesicles. Tinea pedis varies in appearance: the most common manifestation is maceration, peeling, itching, and painful fissuring between the fourth and fifth toes, but an acute inflammatory condition with vesicles and pustules can also occur, as can a hyperkeratotic chronic infection of the sole ("moccasin foot"). Members of the *T. mentagrophytes* complex frequently cause the more inflammatory type of infections, whereas *T. rubrum* usually causes the more chronic type. Infection of the sole by human-adapted forms of *Trichophyton interdigitale,* one of the members of the *T. mentagrophytes* complex, can be recognized by the formation of bullous vesicles in the thin skin of the plantar arch and along the sides of the feet and heel adjacent to the thick plantar stratum corneum (120). Tinea unguium, or nail infection by dermatophytes, is a subcategory of the more general phenomenon of onychomycosis, fungal nail infection. It is most often caused by *T. rubrum* and usually appears as thickened, deformed, friable, discolored nails with accumulated subungual debris. This type of presentation results from invasion of the underside of the distal nail and is therefore termed "distal-subungual onychomycosis." A less common infection type usually caused by *T. interdigitale* typically manifests, especially in its earlier stages, as "superficial white onychomycosis," i.e., white patches in the superficial portions of the nail. "Proximal-subungual tinea unguium" may also occur. This infection, in which the nail is subungually infected beginning near its point of origin in the area of the lunula, is usually caused by *T. rubrum* and often signals immunosuppression, e.g., AIDS (22).

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

Preliminary Patient Examination

In areas where tinea capitis caused by *Microsporum canis* is common, patients may be examined with a Wood's lamp (filtered UV light with a wavelength of 365 nm) in a darkened room for the presence of bright green fluorescent hairs. These are ideal for collection as laboratory specimens, although in some cases diagnosis may be done by Wood's light alone. The fluorescent hairs, considered "Wood's light positive," typically show a small-arthroconidial, ectothrix type of hair invasion in direct microscopy. Apart from *M. canis, M. audouinii* and *M. ferrugineum* also cause this type of fluorescent ectothrix infection. Hairs infected with *T. schoenleinii* may show a dull green color (89). The Wood's lamp can also be used to differentiate between dermatophytosis and nonfungal skin conditions that may be similar clinically, e.g., erythrasma. In erythrasma, the skin fluoresces orange to coral red, whereas in dermatophytosis, the skin is not fluorescent.

Sampling Preparations and Practice

Sufficient clinical material should be collected for both direct microscopic examination and culture. Whenever feasible, an aseptic technique should be used to minimize contamination. The following equipment should be available for the collection and transport of specimens: forceps for epilating hairs, sterile no. 15 scalpel blades or sharp curette, sterile nail clippers, scissors, sterile gauze squares, 70% alcohol for disinfection, sterile water for cleansing painful areas, and clean pill packets or clean paper envelopes to contain and transport the clinical specimens such as hairs, skin scrapings, or nail clippings. Black photographic paper or strong black paper may be used for collecting and better visualizing scrapings. After collection, the paper is folded, tightly taped in the corners, and placed in an envelope for transport. Closed tubes are not recommended for specimens, since they retain moisture, which may result in an overgrowth of bacterial as well as fungal contaminants. Disposable sterilized brushes have been recommended for collection of specimens from the scalp or from the fur of animals (68). If histopathological processing is done, the nail plate may be placed in a 4% formaldehyde solution (98). Culture media (detailed below) may be inoculated directly on collection.

Hairs from the scalp should be epilated with sterile forceps. If the specimen is Wood's light positive, epilate only fluorescent hairs. Nonfluorescent hairs, especially those infected with endothrix fungi such as *T. tonsurans,* may need to be dug out with the tip of a sterile scalpel blade because the hairs often break off at the scalp level and are thus difficult to grasp with a forceps. Rubbing with a sterile moistened swab has been successful with pediatric patients (47). In the rare event that favus is seen, the scutulum at the mouth of the hair follicle is suitable for culture and microscopic examination. In lower-body dermatophytoses, lesions with defined borders should be preliminarily disinfected with alcohol or cleansed with sterile water, and then active

border areas should be scraped with a scalpel to collect epidermal scales. If borders are not visible to indicate the area of maximal fungal activity, as in tinea manuum, the preliminarily cleansed infected area can be broadly scraped in order to obtain specimen from a variety of areas that may imperceptibly differ in current fungal activity. In vesicular tinea pedis, the tops of the vesicles can be removed with sterile scissors for direct examination and culture. Culture of the vesicle fluid is not recommended.

Nails should be disinfected with alcohol gauze squares. The most desirable material for culture in typical subungual onychomycosis is the waxy subungual debris, which contains the fungal elements. The highest proportion of viable elements for culturing is often found close to the juncture of the nail bed. In order to remove contaminating saprobic fungi and bacteria, the crumbly debris directly underneath the nail near the tips is removed with the scalpel before material is collected for culture. Some investigators clip the nail short first and perform this scraping away of contaminated material on the clipping. If the dorsal nail plate is diseased (superficial white onychomycosis), scrape and discard the outer surface before the underlying material is removed for culture. In rare cases with a presentation consistent with *Trichophyton soudanense* endonyx nail infection (110), in which the internal strata of the nail plate are milky white but the upper and lower nail surfaces appear relatively unaffected, clippings may be taken or the milky area may be exposed and scraped.

Any specimen needing to be transported, or for any other reason not processed immediately, should be retained in the paper packets described above. Closed tubes are not recommended for specimens since they may retain moisture and may result in an overgrowth of contaminants. Dermatophytes in dry specimens of skin, hair, and nails may be stored for years in viable condition, provided the material is not subjected to temperature extremes.

LABORATORY TESTING OF SPECIMENS

Direct Microscopic Examination

Direct microscopic examination of skin, hair, and nails is the most rapid method of determining fungal etiology and is traditionally accomplished by examining the clinical material in 10% potassium hydroxide (KOH) (freely interchangeable with the cheaper sodium hydroxide [NaOH]) (59, 90). Another common procedure is to use 25% potassium or sodium hydroxide mixed with 5% glycerin to impede desiccation (59). Addition of fluorescent brighteners such as calcofluor white may significantly increase accuracy, especially if the staff are not highly experienced in visual detection of fungal elements (86). In nails, histopathology based on staining nail biopsy material with periodic acid-Schiff (PAS) stain has been shown to have potential for generating results more accurate than those afforded by hydroxide-based direct microscopy (63). The suggestion, however, that the biopsy-PAS method can also replace culturing (63) is unsound, because this technique does not permit reliable distinction of dermatophytes from other nail-invading species (103).

Nail clippings should be aseptically cut into smaller fragments and, where possible, pounded with a heavy object inside their collection packet in order to release friable, flaky material containing the greatest amount of dermatophyte inoculum. Skin or nail scrapings, nail fragments, or hair roots are placed in 1 or 2 drops of one of the above-mentioned KOH or NaOH solutions on a clean glass slide. A coverslip is placed on top, and the preparation is heated gently (short of boiling) by being passed rapidly over a Bunsen burner three or four times, and then it is allowed to sit at room temperature for a few minutes for clearing. The exact time needed depends on the concentration of hydroxide used, the thickness of specimen fragments, and the exact amount of heat imparted by contact with flame. Clearing is evident to the naked eye as a pronounced decrease in the opacity of the scraping. Alternatively, a slide warmer set at 51 to 54°C may be used to heat the slides for 1 h (59). Laboratories using a 10% KOH or NaOH solution for skin may find that nail scrapings may require a stronger alkali solution (up to 25% KOH or NaOH). Demonstration of fungal elements may be facilitated by use of glucan-binding fluorescent brighteners such as calcofluor white (90) or Congo red (59). These require use of a fluorescent microscope set up to visualize the specific fluorescence obtained. Calcofluor white is added directly to the KOH drop on the slide as an approximately equal drop of 0.1% solution (69). All preparations should be examined under low power and confirmed under high power.

Skin and nails infected by dermatophytes may reveal one or more of the following: hyaline hyphal fragments; septate, often branched hyphae; and chains of arthroconidia (Fig. 1).

The appearance of infected hairs depends on the invading dermatophyte species. Hyphae invade the hairs, and arthroconidia are formed by fragmentation of these hyphae. The appearance and locations of the arthroconidia may suggest the infecting genera or species (Table 3), as may the sizes (89). Three main types of colonizations (ectothrix, endothrix, and favic) are observed by direct microscopic examination. The terms "ectothrix" and "endothrix" refer to the location of the arthroconidia in relation to the hair shaft (ecto- and endo- meaning outside and inside, respectively), while favic refers to the distinctive infection caused by *T. schoenleinii,* a fungus that is now extremely rare except in some parts of central Asia and the African Sahel**.**

In ectothrix colonization, arthroconidia appear as a mosaic sheath around the hair or as chains on the surface of the hair shaft (Fig. 2). In *M. canis, M. audouinii,* and *M. ferrugineum* infections, colonized hairs fluoresce green under Wood's lamp; other ectothrix infections (Table 3) are nonfluorescent. Endothrix hair invasion is observed as chains of arthroconidia filling the insides of shortened hair stubs (Fig. 3). Hairs are

Wood's lamp negative. In favic hairs, hyphae, air bubbles, or tunnels and fat droplets are observed within the hair (Fig. 4). These hairs are dull green under the Wood's lamp. In general, infected hairs from all infection types show hyphae within the hair shaft at some time during the course of infection, usually during the early stages.

Isolation Procedures

Scrapings, hairs, and other materials collected as outlined above for direct examination are plated on selected isolation media and incubated at 32°C for optimal growth; temperatures between 24 and 32°C are also acceptable if the total incubation time is suitably adjusted to compensate for the slower outgrowth expected at lower temperatures. Generally from 5 to 15 skin or nail fragments are planted per plate or tube used for isolation, and these fragments are separated so that antibiotic-resistant mold or bacterial contaminants from one piece cannot overgrow the others. Hairs are also well separated. Cultures on primary isolation medium are routinely incubated at 25 to 30°C and examined weekly for up to 4 weeks.

The most common medium used for the isolation of dermatophytes is Sabouraud glucose agar (SGA) (original formulation with 4% glucose or Emmons' modification with 2% glucose), amended with chloramphenicol and cycloheximide to inhibit bacterial and saprobic fungal contamination. This type of medium is available commercially as, for example, Mycobiotic agar (BD Diagnostic Systems, Sparks, Md.; Remel, Lenexa, Kans.), Mycosel (BD), or Dermasel Selective Supplement (Oxoid, Basingstoke, Hampshire, United Kingdom; note that Remel is currently the U.S. distributor for Oxoid). An alternative medium promoting more rapid conidiation and colony pigmentation development is potato flakes agar amended with cycloheximide and chloramphenicol (Hardy Diagnostics, Santa Maria, Calif.; also available as Rapid Sporulation Medium, Bacti-Lab, Mountain View, Calif.). For the isolation of cycloheximide-susceptible fungi that cause clinical infections resembling dermatophytosis, any of the SGA with chloramphenicol (Remel, BD), inhibitory mold agar (BD, Remel), or Littman oxgall agar (BD) may be recommended (90). Inhibitory mold agar and Littman oxgall agar have

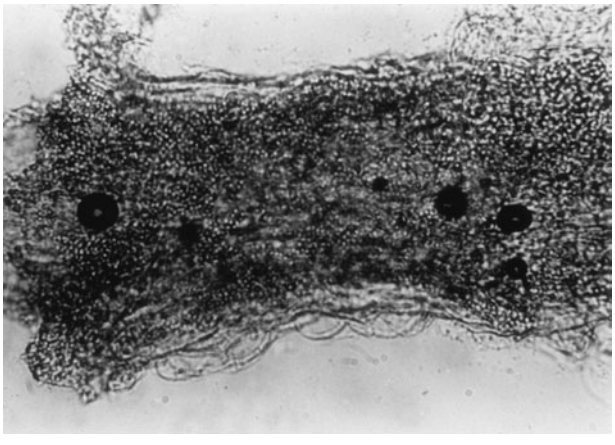

FIGURE 2 *M. audouinii,* ectothrix type of hair invasion. Magnification, ×400.

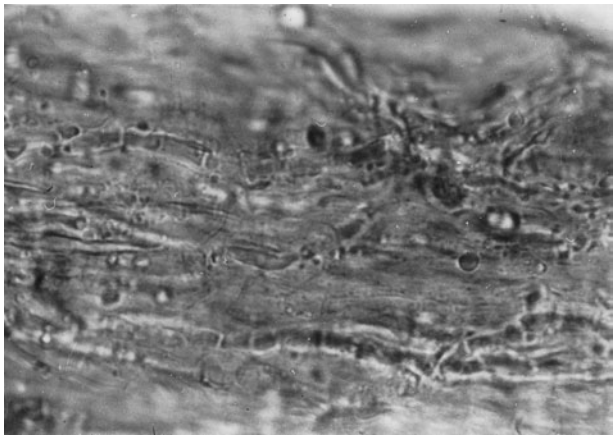

FIGURE 4 Hair infected by *T. schoenleinii* from a patient with favus. Magnification, ×1,000.

the advantage of restricting contaminant colony diameters. For all media, the addition of gentamicin is recommended for specimens heavily contaminated by bacteria (108). SGA with cycloheximide, chloramphenicol, and gentamicin (CCG) is routinely used as an isolation medium in some laboratories (59).

Additional and alternative media may be used in special circumstances. For example, vitamin-free Casamino acids (BD)-erythritol-albumin agar medium plus CCG may be used for filament-positive skin and nail specimens, especially from body sites where *Candida* overgrowth may be a problem (e.g., groin or fingernails). This medium (currently not commercially available to our knowledge) prevents the common suppression of dermatophyte outgrowth by heavy inoculum of *Candida albicans, C. parapsilosis,* and related biotin-requiring yeasts (28). Dermatophyte species with vitamin requirements (very uncommon in these types of cases) may grow poorly on it, and it is always used in combination with a cycloheximide-containing SGA.

Another primary isolation medium that may be used is dermatophyte test medium (DTM; available commercially from BD and Remel). This selective medium screens for the presence of dermatophytes in heavily contaminated material (nails, etc.). The growth of dermatophytes causes a rise in pH, thus changing the phenol red indicator from yellow to red (109). The use of DTM should be combined with morphological study, since dermatophytoids such as *Trichophyton terrestre,* as well as various *Chrysosporium* species and other nondermatophytic fungi, can grow and turn the medium red (59, 70, 93). Rapid sporulation medium (Bacti-Lab), mentioned above (amended potato flakes agar), contains a pH indicator that works on a similar principle but turns from yellow to blue-green, leaving the red reverse pigment of typical *T. rubrum* visible (6). DTM may uncommonly give false-negative results with some *Microsporum* isolates (73).

Nucleic Acid-Based Direct Detection Techniques

Numerous techniques have been published for directly detecting dermatophyte DNA in tissue, but as yet none is established as a routine diagnostic procedure. This is due mainly to the relatively high cost-effectiveness of traditional procedures. However, in terms of accuracy, traditional procedures are by no means optimal; in onychomycosis, for example, they disclose at best circa 85% of true-positive cases from the initial patient specimen, and this percentage is much lower in many laboratories (103). This has given strong incentive for molecular development. A combination of amplifications with ribosomal PCR primer pairs TR1/TR2 and N5/N6, followed by HaeIII restriction enzyme digestions, was shown to amplify dermatophytes and nondermatophytes from infected nails and distinguish dermatophytes as a group from other fungi (10). Dermatophyte species could not be consistently identified based on the patterns seen. Similar results were also seen in a study that followed up the same procedures with LightCycler melting curves for the N5/N6 amplicon, which offered greater resolution than several other amplicons tested (46). In a deep dermatophytosis case in which all conventional tests had given negative results, *Trichophyton rubrum* was identified by means of a nested-PCR study directed to amplifying a portion of the ITS region from paraffin-embedded sections (74). Some additional studies dealing with direct amplification of dermatophyte materials are discussed by Gutzmer et al. (46). It is beyond the scope of the present chapter to extensively review studies that are preliminary in terms of implemented diagnostic procedure. Some molecular culture identification methods for dermatophytes are mentioned below under "Identification."

IDENTIFICATION

At present, the great majority of dermatophytes are identified phenotypically. Identification is often based on (i) colony characteristics in pure culture on SGA and (ii) microscopic morphology. These criteria alone, however, may be insufficient, since colonial appearance may vary or be similar for different species. Characteristic pigmentation may fail to appear, and isolates, especially *Trichophyton* spp., may not sporulate. Special media may be required to stimulate pigment production; it may be necessary to use sporulation and physiologic tests in conjunction with morphology to identify the species correctly. Various molecular identification mechanisms have also been described (discussed below) but are seldom practically applicable except in high-level reference laboratories. The majority of isolates are easily identified when visual examination is combined with any needed testing for characteristic growth factor requirements; the consequence of this is that phenotypic studies remain the least expensive option for routine identification.

Colony Characteristics

In observing gross colony morphology, note the color of the surface and the reverse of the colony, the texture of the surface (powdery, granular, woolly, cottony, velvety, or glabrous), the topography (elevation, folding, margins, etc.), and the rate of growth.

Microscopic Morphology

Microscopic morphology, especially the appearance and arrangement of the conidia (macroconidia or microconidia) and other structures, may be determined by teased mounts or slide culture preparations mounted in lactophenol cotton blue (LCB), in lactophenol aniline blue (phenol, an ingredient of LCB and lactophenol aniline blue, is listed as a hazardous chemical; therefore, solutions containing phenol should be prepared, stored, and used in an approved chemical safety cabinet), in lacto-fuchsin (59), or in more permanent mounting fluids (112). Sometimes a special medium such as cornmeal or cornmeal-glucose agar, potato-glucose agar, SGA plus 3 to 5% NaCl (56, 58), pablum cereal agar (59), rapid sporulation medium (6), or lactrimel agar (14, 53) may be required to stimulate sporulation.

Physiological Tests

In Vitro Hair Perforation Test

The in vitro hair perforation test distinguishes between atypical isolates of the *T. mentagrophytes* complex and *T. rubrum* (4). It may also be used to assist in making other distinctions such as *M. canis* versus *Microsporum audouinii* and *Microsporum praecox* versus *M. gypseum* (81). Hairs exposed to *T. mentagrophytes, M. canis,* and *M. gypseum* show wedge-shaped perforations perpendicular to the hair shaft (a positive test result), whereas *T. rubrum, M. audouinii,* and *M. praecox* do not form these perforating structures.

Place short strands of human hair (ideally hair from a child under 18 months old) in petri dishes, and autoclave the dishes at 121°C for 10 min; add 25 ml of sterile distilled water and 2 or 3 drops of 10% sterilized yeast extract. Inoculate these plates with several fragments of the test fungus that has been grown on SGA; incubate the plates at

25°C, and examine them at regular intervals over a period of 21 days. Hairs may be examined microscopically for perforations by removing a few segments and placing them in a drop of LCB mounting fluid. Gently heating the mounts aids in the detection of the fungus. A positive control test should always be run with a known perforating species; *M. canis* is recommended. Some hair samples may prove unsuitable for unknown reasons, e.g., possible prior contact with shampoos containing antifungal inhibitors.

Special Nutritional Requirements

Nutritional tests aid in the routine identification of *Trichophyton* species that seldom produce conidia or that resemble each other morphologically (30). Certain species have distinctive nutritional requirements, whereas others do not. The method employs a Casamino acids basal medium that is vitamin free (*Trichophyton* agar 1 [T1]) and to which various vitamins are added, i.e., inositol (T2), thiamine + inositol (T3), thiamine (T4), and nicotinic acid (T5). In addition, the series includes an ammonium nitrate basal medium (T6) to which histidine is added (T7). These media are available commercially in dehydrated form from BD Biosciences and in prepared form from Remel. A small fragment (about the size of the head of a pin) from the culture to be tested is placed on the surface of the basal medium (controls) and the media containing the vitamin and amino acid additives. Care must be taken to avoid transferring agar from the fungal inoculum to the nutritional media. Cultures are incubated at room temperature (or 37°C if *T. verrucosum* is suspected) and read after 7 and 14 days. The amount of growth is graded from 0 to 4+. Commonly observed reactions are summarized in Table 4.

Urea Hydrolysis

The ability to hydrolyze urea provides additional data to aid in distinguishing the typical, cosmopolitan form of *T. rubrum* (urease negative) from members of the *T. mentagrophytes* complex (typically urease positive) and from the urease-positive Afro-Asiatic or "granular" form of *T. rubrum,* formerly often called *T. raubitschekii* (92, 95). Christensen urea agar and broth may both be used; the broth appears to be the more sensitive of these alternatives (57). After the urea medium is inoculated, it is incubated at 25 to 30°C up to 7 days. The tubes should be examined every 2 to 3 days for the color change from orange or pale pink to purple-red that indicates the presence of urease, a positive test result. Negative and positive controls should always be done with new batches of these media. See Table 1.

Growth on BCPMSG

BCP-milk solids-glucose medium (BCPMSG) is available commercially as Dermatophyte Milk Agar (Hardy). The type of growth (profuse versus restricted) and a change in the pH indicator (BCP) indicating alkalinity are especially useful for distinguishing *T. rubrum* from the *T. mentagrophytes* complex and *T. mentagrophytes* from *Microsporum persicolor* (58, 59, 106). *T. rubrum* shows restricted growth and produces no alkaline reaction on BCPMSG, whereas members of the *T. mentagrophytes* complex typically show profuse growth and an alkaline reaction. Although *M. persicolor* shows profuse growth, it does not result in an alkaline reaction. Other tests for distinguishing *T. mentagrophytes* and allies from *M. persicolor* are described elsewhere (78).

Cultures to be tested are inoculated onto slants of BCPMSG and examined for pH change and growth characteristics at the end of a 7-day incubation at 25°C. A color change from pale blue to violet-purple indicates an alkaline reaction.

Growth on Polished Rice Grains

Unlike most dermatophytes, *M. audouinii* grows poorly on rice grains and produces a brownish discoloration of the rice (18, 59). This is a useful test for differentiating this species from *M. canis* and from other dermatophytes that typically grow and sporulate on rice grains. It may be especially useful in areas where *M. audouinii* is still endemic, e.g., sub-Saharan

TABLE 4 Dermatophyte nutritional response as elucidated by *Trichophyton* agars[a]

Species	Response by vitamin tests					Response by amino acid tests	
	1 Vitamin free	2 Inositol	3 Thiamine + inositol	4 Thiamine	5 Nicotinic acid	6 Amino acid free	7 Histidine

[a] Only the growth responses for organisms with growth factor requirements and the selected organisms that must be most closely compared with them are included in this table. The numbers in the table body indicate the relative degree of growth according to traditional 1+ to 4+ visually approximated scale: 0, no growth; 1, slight growth, strongly nutrient-deprived colony morphology (very sparse, subsurface colonial growth only or colony diameter strongly reduced compared to Sabouraud agar control); 2, partially stimulated growth, but still significantly suppressed compared to that of the control; 4, growth comparable to that of the control (the table includes no 3+ reactions); v, variable; blank spaces in the table indicate growth responses that are not customarily examined but that are insignificantly different from control growth responses on Sabouraud agar.

Africa, or where immigrants or travellers from such areas are reintroducing it.

The medium is prepared in 12-ml flasks by mixing 1 part raw unfortified rice grains and 3 parts water (18) or 8.0 g of rice grains and 125 ml of distilled water. Autoclave at 15 lb/in^2 for 15 min. Inoculate the surface of the rice, and incubate the sample for 2 weeks at 25 to 30°C.

Temperature Tolerance and Temperature Enhancement

Tests for temperature tolerance and enhancement are useful for distinguishing the *T. mentagrophytes* complex from *Trichophyton terrestre* (79), *T. mentagrophytes* from *M. persicolor* (58), *T. verrucosum* from *T. schoenleinii* (89), and *Trichophyton soudanense* from *M. ferrugineum* (114). At 37°C, members of the *T. mentagrophytes* complex show good growth, whereas *T. terrestre* does not grow and *M. persicolor* generally grows poorly or not at all (a single atypical isolate with good growth has been observed); growth of *T. verrucosum* and *T. soudanense* is enhanced, but that of *T. schoenleinii* and *M. ferrugineum* is not.

Inoculate two slants of SGA with equivalent fragments of the culture. Incubate one slant at room temperature (25 to 30°C) and one at 37°C. Compare the growths at the two temperatures when mature colonies appear at room temperature. Appropriate controls are recommended and should be compared first.

Molecular Identification Techniques

Numerous methods for rapid nucleic acid-based distinction of dermatophyte species have been described in recent years (51). Methods used in recent studies have largely been based on arbitrarily primed PCR (34, 67) or restriction fragment length polymorphisms generated from PCR products (13). An oligonucleotide probe for *T. rubrum* has been designed (27). Recently, several additional techniques have been shown to have promise, in particular a rather complex amplification of the DNA topoisomerase II gene followed by nested PCR and restriction fragment digestion (54, 55). Repetitive-sequence-based PCR performed via the patented DiversiLab system (Spectral Genomics, Houston, Tex.) has also shown promise but has so far been tested only on a reduced set of species (82). It is currently unclear whether any techniques based on electrophoretic banding patterns of amplicons or restriction fragments will be able to compete with routine diagnostic sequencing of the ITS region (84) or with forthcoming oligonucleotide-based array and bead technologies (104).

DESCRIPTION OF ETIOLOGIC AGENTS

Characteristic features of dermatophyte species are presented in Table 1. The table also includes data on some similar but rarely or never pathogenic *Microsporum* and *Trichophyton* species that must be distinguished from pathogenic species.

Two types of conidia may be produced on the aerial mycelium of the dermatophytes: large multicellular, smooth or rough, thin- or thick-walled macroconidia and smaller unicellular, smooth-walled microconidia. The three genera are classically grouped according to the presence or absence of these two types of conidia and the appearance of the surface of the macroconidia, i.e., rough versus smooth. However, these conceptual distinctions must be mapped onto a reality in which, when atypical isolates are taken into account, a morphologic continuum is found based on overlapping characteristics (80). For this reason, it is often more convenient to identify isolates directly at the species level than it is to try to identify them at the genus level first. Identification of species is based on the microscopic appearance and arrangement of the conidia (Fig. 5 through 17), colonial morphology on SGA (Fig. 18), and physiological tests (Table 5).

FIGURE 5 Smooth-walled macroconidia of *Trichophyton ajelloi.* Magnification, ×400.

Trichophyton Species

Macroconidia have smooth, thin to thick walls, are variable in shape (clavate, fusiform to cylindrical), vary in number of septa (1 to 12) and in size (8 to 86 by 4 to 14 μm), and are borne singly or in clusters. Microconidia, which are usually present and more numerous than macroconidia, may be globose, pyriform, or clavate and are borne singly along the sides of hyphae or in grapelike clusters. Though species in this genus generally produce microconidia more readily than macroconidia, two lineages producing macroconidia but lacking microconidia have been described: (i) "*Trichophyton kanei*" (100), now known to be a variant of the Afro-Asiatic genotype of *T. rubrum*, and (ii) a variant all-macroconidial form of *T. tonsurans* (80). Fresh isolates of the dermatophytoid *T. ajelloi* may also produce many macroconidia and few

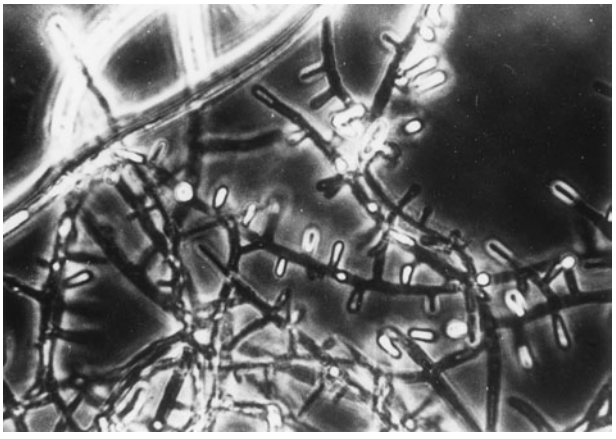

FIGURE 9 Clavate macroconidium, microconidia, and intermediate conidia of *Trichophyton terrestre*. Phase contrast; magnification, ×400.

or no microconidia. Some species such as *T. schoenleinii* rarely produce conidia of any kind in culture, and nonsporulating isolates of normally conidial species, especially *T. rubrum,* may also be encountered.

Microsporum Species

Microsporum species produce macroconidia and microconidia that may be rare or numerous, depending on the species and the substrate. The distinguishing characteristic is the macroconidium, which is typically rough walled (varying from minutely to strongly roughened). Macroconidia also vary in shape (obovate, fusiform to cylindrofusiform), number of septa (1 to 15), size (6 to 160 by 6 to 25 μm), and width of the cell wall. Microconidia are pyriform or clavate and usually are arranged singly along the sides of the hyphae. *Microsporum* species invade skin, hair, and, rarely, nails. Biological (teleomorphic) species within the *M. gypseum* complex can be provisionally recognized on the basis of colonial and microscopic features on Takashio's medium (25), but these species are best distinguished by mating or molecular testing.

Epidermophyton floccosum

In *E. floccosum,* microconidia are lacking; only smooth-walled, broadly clavate macroconidia are produced. They have one to six septa, are 20 to 40 μm long by 7 to 12 μm wide, and are borne singly or in clusters of two or three. *E. floccosum* is currently the only recognized *Epidermophyton* species; the former *E. stockdaleae* is now considered a synonym of *Trichophyton ajelloi* (33).

STRAIN TYPING SYSTEMS

Dermatophyte strains within anthropophilic species tend to be very closely related, making epidemiological analysis difficult, but strains of *T. rubrum* have been distinguished by polymorphisms in the numbers of subrepeat elements in the ribosomal nontranscribed spacer region (45, 50, 85, 119). Similar techniques can also be applied to distinguish *Trichophyton interdigitale* and *T. tonsurans* isolates (29, 45, 71). In addition, the Afro-Asiatic lineage of *T. rubrum* can be distinguished from the now-cosmopolitan epidemic *T. rubrum* form by means of a microsatellite marker designated T1 (77).

FIGURE 13 Macroconidia of *Microsporum audouinii* on SGA with 3% NaCl. Magnification, ×400.

ANTIMICROBIAL SUSCEPTIBILITIES

Dermatophytes can in principle be tested for susceptibility to antifungal drugs by using the general NCCLS (now CLSI) M38-A standard for molds (75). A trial has shown that this methodology can be applied with good inter- and intralaboratory reproducibility to the commonly used drugs ciclopirox, fluconazole, griseofulvin, itraconazole, posaconazole, terbinafine, and voriconazole (31). Treatment failures in dermatophytoses, however, are almost always due to factors other than drug resistance (44), and potentially burdensome requests for dermatophyte susceptibility testing should be closely screened for scientific and clinical appropriateness.

EVALUATION, INTERPRETING, AND REPORTING OF LABORATORY RESULTS

For nonimmunocompromised patients, positive direct microscopy compatible with dermatophytosis is conventionally interpreted as presumptively indicating this condition in hair and in skin specimens other than those from nails, soles, and palms. The positive microscopic report itself conveys this information; it should be issued within two working days of specimen receipt. With soles and palms, persons who have lived in tropical areas or who are of south Asian heritage may have dermatophytosis-like *Scytalidium* infections, which are similar to dermatophytoses both clinically and in direct microscopy (59); no presumptive diagnosis can be inferred until the culture result is available. The direct microscopic result, however, is still reported immediately. For patients without risk factors for *Scytalidium,* qualified physicians may make presumptive diagnoses of dermatophytosis for sole and palm skin as for other skin sites. In onychomycosis, over 35 different mold species may be involved in producing conditions clinically and microscopically resembling tinea unguium (59), particularly in geriatric patients. Microscopic results are still reported promptly, but culture results are of high interest. At the same time, outgrowth of known onychomycosis-causing nondermatophytes may or may not be significant, excepting the nail-infecting *Scytalidium* species, which are always considered significant when grown. The complexities of accurately reporting nondermatophytes from nail specimens are beyond the scope of this

chapter but are discussed in light of the first-ever rigorous validation studies on this topic by Summerbell et al. (103).

Isolation of a dermatophyte culture from lesional skin, hair, or nails is interpreted as diagnostic whether or not fungal elements are seen in the initial direct microscopy examination. Note that dermatophytoids such as *Microsporum cookei* and *Trichophyton terrestre* are presumed to be contaminants until proven otherwise; they are, however, reported along with the comment "normally nonpathogenic" when grown. These fungi have been the subjects of numerous false and questionable case reports in the literature, and there may be some confusion about their status. If such a fungus were to infect human epidermis, the "gold standard" for scientifically evidencing the case would be three successive, consistent repeat isolations of the fungus from the lesion in specimens collected on different days, plus demonstration of compatible fungal elements in direct microscopy of the affected tissue. No inferential diagnoses from lower-quality evidence should be accepted as conclusive, even if the patient is said to have been successfully treated. A common dermatophyte such as *T. rubrum* that failed to grow out in initial culture(s) is very likely to be the actual etiologic agent in such cases (103). In onychomycosis in particular, true causal dermatophytes have only at best a circa 75% chance of being grown from the initial specimen taken from any given patient; another circa 15% can be recovered from a second specimen, while circa 10% can be detected only by doing three or more serial specimens, something very seldom done in practice (103). Cycloheximide-tolerant dermatophytoids that grow (in any quantity whatsoever) from single, otherwise unproductive specimens should not be assumed to be causal simply because they share a genus name with dermatophyte species.

FIGURE 16 Macroconidia of *Microsporum gypseum*. Magnification, ×400.

SUPERFICIAL MYCOSES

In the superficial mycoses, the causative fungi colonize the cornified layers of the epidermis or the suprafollicular portion of the hair. There is little tissue damage, and cellular response from the host generally is lacking. The diseases are largely cosmetic in impact, involving changes in the pigmentation of the skin (tinea versicolor or tinea nigra) or formation of nodules along the distal hair shaft (black piedra and white piedra).

In contrast to agents of the dermatophytoses, the etiologic agents are diverse and unrelated.

Tinea Versicolor (Pityriasis Versicolor)

Tinea versicolor is an infection of the stratum corneum caused by a group of closely similar lipophilic yeast species of the *Malassezia furfur* complex. Members of this complex infecting human skin were often treated in former times as a single species but were then shown by molecular, physiological, and serotyping studies to be separate (39). The complex includes *M. furfur* (synonyms, *Pityrosporum furfur* and *P. ovale* pro parte), *M. sympodialis, M. globosa* (probable synonym, *Pityrosporum orbiculare*), *M. restricta, M. slooffiae, M. obtusa, M. dermatis, M. japonica,* and *M. yamatoensis* (39, 99). Some additional species have been reported from animals. In routine clinical reporting, referring to these organisms as members of the *M. furfur* complex is normally sufficient. *Malassezia pachydermatis,* which causes animal ear infections and occasional human iatrogenic fungemias, is not considered a member of the *M. furfur* complex and, if reported, is reported under its individual species name. It is

easily distinguished from *M. furfur* complex members by its ability to grow on ordinary laboratory media such as Sabouraud agar (see comments on *Malassezia* culture below). It is insignificant when grown from human skin except if investigations of catheter-related problems are involved.

Tinea versicolor lesions appear as scaly, discrete or concrescent, hypopigmented or hyperpigmented (fawn, yellow-brown, brown, or red) patches chiefly on the neck, torso, and limbs. The infection is largely cosmetic, becoming apparent when the skin fails to tan normally. The disease has a worldwide distribution: in tropical climates 30 to 35% of the population may be affected, while incidence in areas of temperate climate is much lower, with only 1.0 to 4.0% of the population affected. *M. furfur* and related yeasts are found on the normal skin and elicit disease only under conditions, local or systemic, that favor the overgrowth of the organism.

The *M. furfur* complex has been associated with folliculitis (9), obstructive dacryocystitis (88), systemic infections in patients receiving intralipid therapy (23), and seborrheic dermatitis, especially in patients with AIDS (37). Excellent reviews are available on human infections caused by *Malassezia* spp. and on the characteristics of the genus (12, 41, 94). Additional information is also found in chapter 119 of this Manual.

Direct Examination

The fungi are observed readily when scrapings are mounted in 10% KOH plus ink (17), 25% NaOH plus 5% glycerin, calcofluor white, or Kane's formulation (glycerol, 10 ml; Tween 80, 10 ml; phenol, 2.5 g; methylene blue, 1.0 g; distilled water, 480 ml). In cases where skin scrapings from unspecified body sites are examined, Kane's formulation has the advantage of vividly staining both fungi and the differential-diagnostic organisms causing erythrasma and pitted keratolysis. (These two bacterial infections, often confused with superficial mycosis, are mainly from intertriginous sites and foot soles, respectively.) Tinea versicolor is signaled in microscopy by the presence of "spaghetti and meatballs," i.e., short, septate, occasionally branching filaments 2.5 to 4 μm in diameter and of variable lengths intermingled with clusters of small, unicellular, oval or round budding yeast cells (Fig. 19). The yeasts show the presence of a collarette between mother and daughter cells (budding is phialidic and unipolar) and average 4 μm (up to 8 μm) in size.

Isolation and Culture

Culture is not essential for identification unless the findings of direct microscopic examination are atypical, or unless full species identification is desired for research purposes. Also, *M. furfur* complex members are part of the normal flora of the skin and positive culture does not indicate infection. The species require exogenous lipid and do not grow on routine mycology media. If culture is desired, scrapings may be inoculated on Leeming-Notman medium, which uses whole milk as a major lipid source (65), on Dixon agar (20), or on modified Dixon agar, consisting of malt extract (3.6%), Mycological Peptone (Oxoid) (0.6%), desiccated ox bile (Bile Salts, Oxoid) (2%), Tween 40 (1%), glycerol (0.2%), oleic acid (0.2%), and agar (1.2%). Growth of the yeasts is slow; colonies are cream colored, glossy or rough, and raised (Fig. 20), later becoming dull, dry, and tan to brownish. Only budding yeast cells generally appear in culture (Fig. 21).

Tinea Nigra

Tinea nigra is characterized by the appearance, primarily on the palms of the hands and less commonly on the dorsa of the feet, of flat, sharply marginated, brownish black, nonscaly macules that may resemble melanoma (94).

The disease, almost always caused by *Hortaea werneckii* (= *Phaeoannellomyces werneckii*, = *Exophiala werneckii*, = *Cladosporium werneckii*), is most common in tropical areas (88) but has been contracted occasionally in coastal areas in and near the southeastern United States (94, 111). Cases diagnosed outside the area of endemicity have mostly resulted from travel to the American tropics or the Caribbean islands (88). *H. werneckii* is related to the ascomycetous order Dothideales (49).

Direct Microscopic Examination

Microscopic examination of skin scrapings in KOH or NaOH reveals numerous light brown, frequently branching septate filaments 1.5 to 5 μm in diameter (Fig. 18h); short, sinuous filaments; and budding cells, some septate.

Isolation

On SGA with or without antibiotics *H. werneckii* grows slowly and usually appears within 2 to 3 weeks as moist, shiny olive to greenish black yeast-like colonies. The yeast-like cells are usually two-celled when reproductive and, instead of budding, produce new yeast cells from thick (up to 2 μm in diameter) distinctly annellated (multiply ringed as if wearing several bracelets) pegs. After 7 or more days, colonies may develop a fringe of thick, dark, conspicuously septate hyphae that also bear annellated fertile structures. These produce conidia that are indistinguishable from young yeast cells. The micromorphology of *H. werneckii* is described in more detail in chapter 125.

Black Piedra

Black piedra is a fungal infection of the scalp hair, less commonly of the beard or moustache, and rarely of axillary or pubic hairs. The disease is characterized by the presence of discrete, hard, gritty, dark brown to black nodules adhering firmly to the hair shaft (Fig. 22). It is found mostly in tropical regions in Africa, Asia, and Central and South America. Humans as well as other primates are infected (32, 88, 94).

The etiologic agent in humans is *Piedraia hortae*, an ascomycete (order Dothideales) forming nodules that serve as ascostromata containing locules that harbor the asci and ascospores.

Direct Microscopic Examination

Hair fragments containing one or more black nodules are placed in 25% KOH or NaOH with 5% glycerol. The preparation is heated gently and carefully squashed so as not to break the coverslip, as the nodules are very hard. A squashed preparation of a mature nodule should reveal compact masses of dark, septate hyphae and round to oval asci containing two to eight hyaline, aseptate banana-shaped (fusiform) ascospores that bear one or more appendages. The preparation should first be observed under low-power objective to reveal the dark mass of compacted hyphae around the surface of the hair and then examined under the high-power objective to observe the asci and ascospores.

Isolation, Culture, and Identification

When ascospores are seen in direct specimen microscopy, culture is unnecessary. Otherwise, SGA with chloramphenicol and SGA with chloramphenicol and cycloheximide may be used for isolation. Some reports have indicated that cycloheximide may be inhibitory; however, others have used

TABLE 5 Sequence of procedures for phenotypic identification of dermatophytes in pure culture[a]

1. Examine colony at day 7 and, if necessary, day 14 for colors of surface and reverse, topography, texture, and rate of growth. Proceed to step 2.
2. Prepare tease mounts and search for identifying microscopic morphology, especially presence, appearance, and arrangement of macroconidia and microconidia (consult Fig. 5 to 18 and Table 1). If the results are inconclusive, proceed to step 3.
3. Prepare slide cultures or transparent tape mounts and examine for characteristic morphology as indicated above if tease mounts do not provide sufficient information. Consider special media if sporulation is absent (potato glucose agar, lactrimel, BCPMSG, SGA with 3–5% NaCl). At the same time, proceed to step 4.
4. Perform as many of the following physiologic and other special tests as necessary for identification.
   a. Urease (ensure culture is bacteria-free!).
   b. Nutritional requirements if a *Trichophyton* is suspected.
   c. Growth on rice grains if an unusual *Microsporum* sp. is suspected.
   d. Elevated temperature response (37°C on SGA or, if *T. verrucosum* is suspected, BCPMSG).
   e. Special differentiation media: e.g., BCPMSG to distinguish *T. mentagrophytes* complex from *T. rubrum* and *M. persicolor;* Lowenstein-Jensen or BCPMSG to distinguish *T. soudanense* from *M. ferrugineum;* SGA + 3–5% NaCl to distinguish *T. mentagrophytes* complex from *M. persicolor* and atypical *T. rubrum;* DTM to distinguish nonsporulating dermatophytes from most other nonsporulating hyaline fungi.
   f. In vitro hair perforation test.
   g. Molecular or mating studies (to be performed in reference laboratories).

[a] It may be necessary to incubate cultures on brain heart infusion agar or BCPMSG to ensure absence of antibiotic-resistant bacterial contamination before proceeding to step 4. Procedures are adapted from Weitzman and colleagues (115) and Kane et al. (59).

this antibiotic successfully. SGA amended with chloramphenicol alone may be used for successful isolation.

Colonies are very slow growing, appear dark brown to black, are glabrous at first, and later are covered with short dark brown-to-black aerial mycelium. They tend to be heaped in the center, with a flat periphery. Some colonies produce a reddish brown diffusible pigment on the agar. Microscopic examination reveals only highly septate dark hyphae and swollen intercalary cells. Conidia and ascospores are usually not found on routine mycological media.

White Piedra

White piedra is a fungal infection of the hair shaft characterized by the presence of soft white, yellowish, beige, or greenish nodules found chiefly on facial, axillary, or genital hairs (Fig. 23) and less commonly on scalp, eyebrows, and eyelashes. Nodules may be discrete or more often coalescent, forming an irregular transparent sheath.

The infection occurs sporadically in North America and Europe and more commonly in South America, Africa, and

(b) *Trichophyton mentagrophytes* complex: granular, zoophilic type *Trichophyton interdigitale* (mating tester strain of *Arthroderma vanbreuseghemii*), 14 days. (c) *Trichophyton rubrum*, SGA, 10 days, surface showing cottony white mycelium. (d) *Trichophyton rubrum,* SGA, 10 days, reverse showing typical red pigment. (e) *Trichophyton tonsurans,* SGA, 14 days, surface showing low velvety texture, mixed white and brownish mycelium. (f) *Trichophyton tonsurans,* SGA, 14 days, reverse showing mixture of mahogany red-brown and sulfur yellow coloration. (g) *Microsporum canis,* SGA, 10 days, relatively flat colony showing pale striate margin and yellowish pigment near colony center. (h) Brown filaments of *Hortaea werneckii* in NaOH mount of scraping from tinea nigra. Magnifications, ×400.

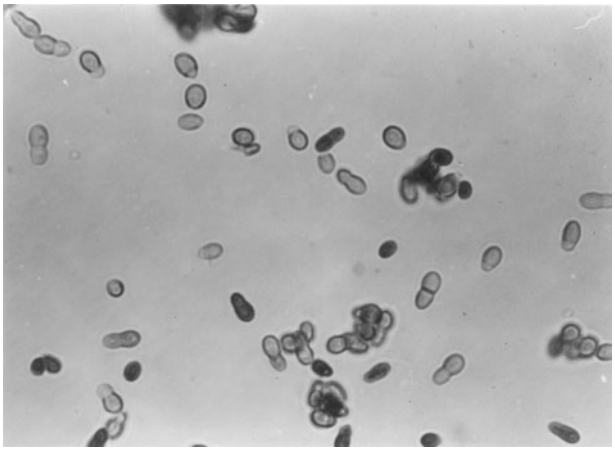

FIGURE 21 Microscopic appearance of *Malassezia furfur* yeast cells on Littman oxgall overlaid with olive oil. Magnification, ×400.

the Orient (88). Although white piedra is an uncommon infection, genital white piedra is occasionally but regularly seen in certain populations (52, 94).

Microscopic examination of hairs containing the adherent nodules mounted in 10% KOH or 25% NaOH–5% glycerin and squashed under a coverslip reveals intertwined hyaline septate hyphae, hyphae breaking up into oval or rectangular arthroconidia 2 to 4 μm in diameter (Fig. 24), occasional blastoconidia, and bacteria that may surround the nodule as a zooglea.

The isolates were formerly described as *Trichosporon beigelii* or *T. cutaneum* but are now correctly identified in most cases as *Trichosporon ovoides* (which causes scalp hair white piedra), *T. inkin* (which causes most cases of pubic white piedra), and *T. asahii* (26, 40). As with the *M. furfur* complex, these species form a complex of difficult-to-identify species whose distinction, except in demonstrated cases of piedra, is not known to have strong clinical implications in dermatologic mycology. They are also very common skin contaminants. Ordinarily, they may be reported from skin, hair, and nails of nonneutropenic patients simply as members of the genus *Trichosporon,* based on the production of budding yeast cells and of arthroconidia and a positive urease test, unless a research level identification of a proven etiologic agent is attempted. The causal agents of white piedra may be readily isolated on SGA with chloramphenicol or other isolation media containing antibacterial antibiotics. The isolation medium should not contain cycloheximide, since this drug is inhibitory to some of the species. Growth is rapid, yielding white to cream-colored colonies that exhibit a variety of colonial morphologies depending on the species. A description of the genus and characteristics of the species involved in white piedra are given in papers by Guého et al. (38, 40). More information about *Trichosporon* is found in chapter 119 of this Manual.

Bipolaris, Exophiala, Scedosporium, Sporothrix, and Other Dematiaceous Fungi*

G. SYBREN DE HOOG AND ROXANA G. VITALE

125

The melanization of vegetative cells, conidia, or both, which results in colony coloration that ranges from olive or gray to black, is caused by the deposition of dihydroxynaphthalene melanin in cell walls. This property occurs commonly among species classified in very different parts of the fungal kingdom. The amount of melanin expressed in host tissue may be very small. The use of the Fontana-Masson stain (127, 134) for demonstrating the presence of melanin is therefore recommended as a routine to distinguish fungi with melanized hyphae from, e.g., *Aspergillus*. This does not apply for *Scedosporium* and *Sporothrix*, which are not melanized but are able to produce melanized conidia in vitro. *Sporothrix* has a characteristic yeast form in tissue; the recognition of *Scedosporium* (causing "hyalohyphomycosis") rests upon other methods than histopathology.

The genera discussed in this chapter belong to the ascomycetous orders Chaetothyriales, Calosphaeriales, Dothideales, Microascales, Ophiostomatales, Pleosporales, and Sordariales (Table 1). It is often incorrectly believed that all these fungi are ubiquitous and cosmopolitan on living and dead plant material and infect humans and animals occasionally. But depending on their phylogenetic position, very divergent degrees of predisposition for infection of vertebrate hosts are noted (48). While members of Pleosporales and Dothideales, such as *Alternaria, Aureobasidium, Bipolaris,* and *Curvularia*, are indeed ubiquitous saprobes, members of Chaetothyriales (*Exophiala* and relatives) can be characterized as microextremophiles, living on special microhabitats such as toxic compounds (186). In this review the genera are therefore treated according to their ordinal relationships.

The term "dematiaceous" applies to fungi with black hyphae in general (69, 70), but it has been recommended in medical mycology to reserve this term for the rapidly growing members of Pleosporales only (48), as these are very different from, for example, Chaetothyriales in all respects. Also the term "phaeoid" indicates brown hyphae (177); "phaeohyphomycoses" is an umbrella term for any fungus present in tissue with brownish yeastlike cells, pseudohyphae, or hyphae or a combination of these forms. The term "black yeasts and relatives" is preferably used to indicate members of Chaetothyriales and Dothideales only (48). The "black yeasts" are not a formal taxonomic group, but the term is applied to a wide range of unrelated ascomycetous and basidiomycetous fungi that are able to produce budding cells at some stage in their life cycle.

Pleoanamorphism is particularly striking in members of the black yeasts and in the genus *Scedosporium.* These fungi are frequently seen in the clinical laboratory to produce more than one asexual form of propagation, so-called "anamorphs," which may bear separate names. For example, the preponderant morphology of *Scedosporium apiospermum* consists of solitary annellated conidiogenous cells, but an additional, synnematous anamorph, known as *Graphium fructicola,* may be exhibited. When a single fungus produces more than one anamorph, the term "synanamorph" is used to designate any of the concurrently existing forms. In addition, some isolates of *S. apiospermum* have the ability to produce a sexual form ("teleomorph"), characterized by the formation of fruiting bodies with meiotic ascospores. In each organism only a single teleomorph can be produced. The fungus involving all its forms of propagation is preferably referred to by its teleomorph name, which is in the present example *Pseudallescheria boydii*.

Among the specific disease entities in the melanized fungi is chromoblastomycosis, a cutaneous disease with often extended acanthosis and in which the fungus is present as muriform cells. Sporotrichosis characteristically develops with nodular abscesses along the lymphatic system, while mycetoma is a subcutaneous infection in which the fungus is present in the form of grains that are expelled from the host through sinuses. When darkened hyphae are present in tissue, the umbrella term "phaeohyphomycosis" is frequently used, but this is confusing because the melanized fungi may not be black or may not be hyphal in tissue.

TAXONOMY

Calosphaeriales

Recently some melanized phialidic fungi were segregated from *Phialophora* on molecular grounds, and they now constitute small islands of clinical significance in the order Calosphaeriales that otherwise contains plant-associated molds. A close relationship to teleomorph genera such as *Togninia* and *Pleurostoma* was revealed (235). Infections are mostly of traumatic nature and are considered to originate directly from the woody plant material of the fungal habitat.

*This chapter contains information presented in chapter 120 by Wiley A. Schell, Ira F. Salkin, and Michael R. McGinnis in the eighth edition of this Manual.

Phaeoacremonium

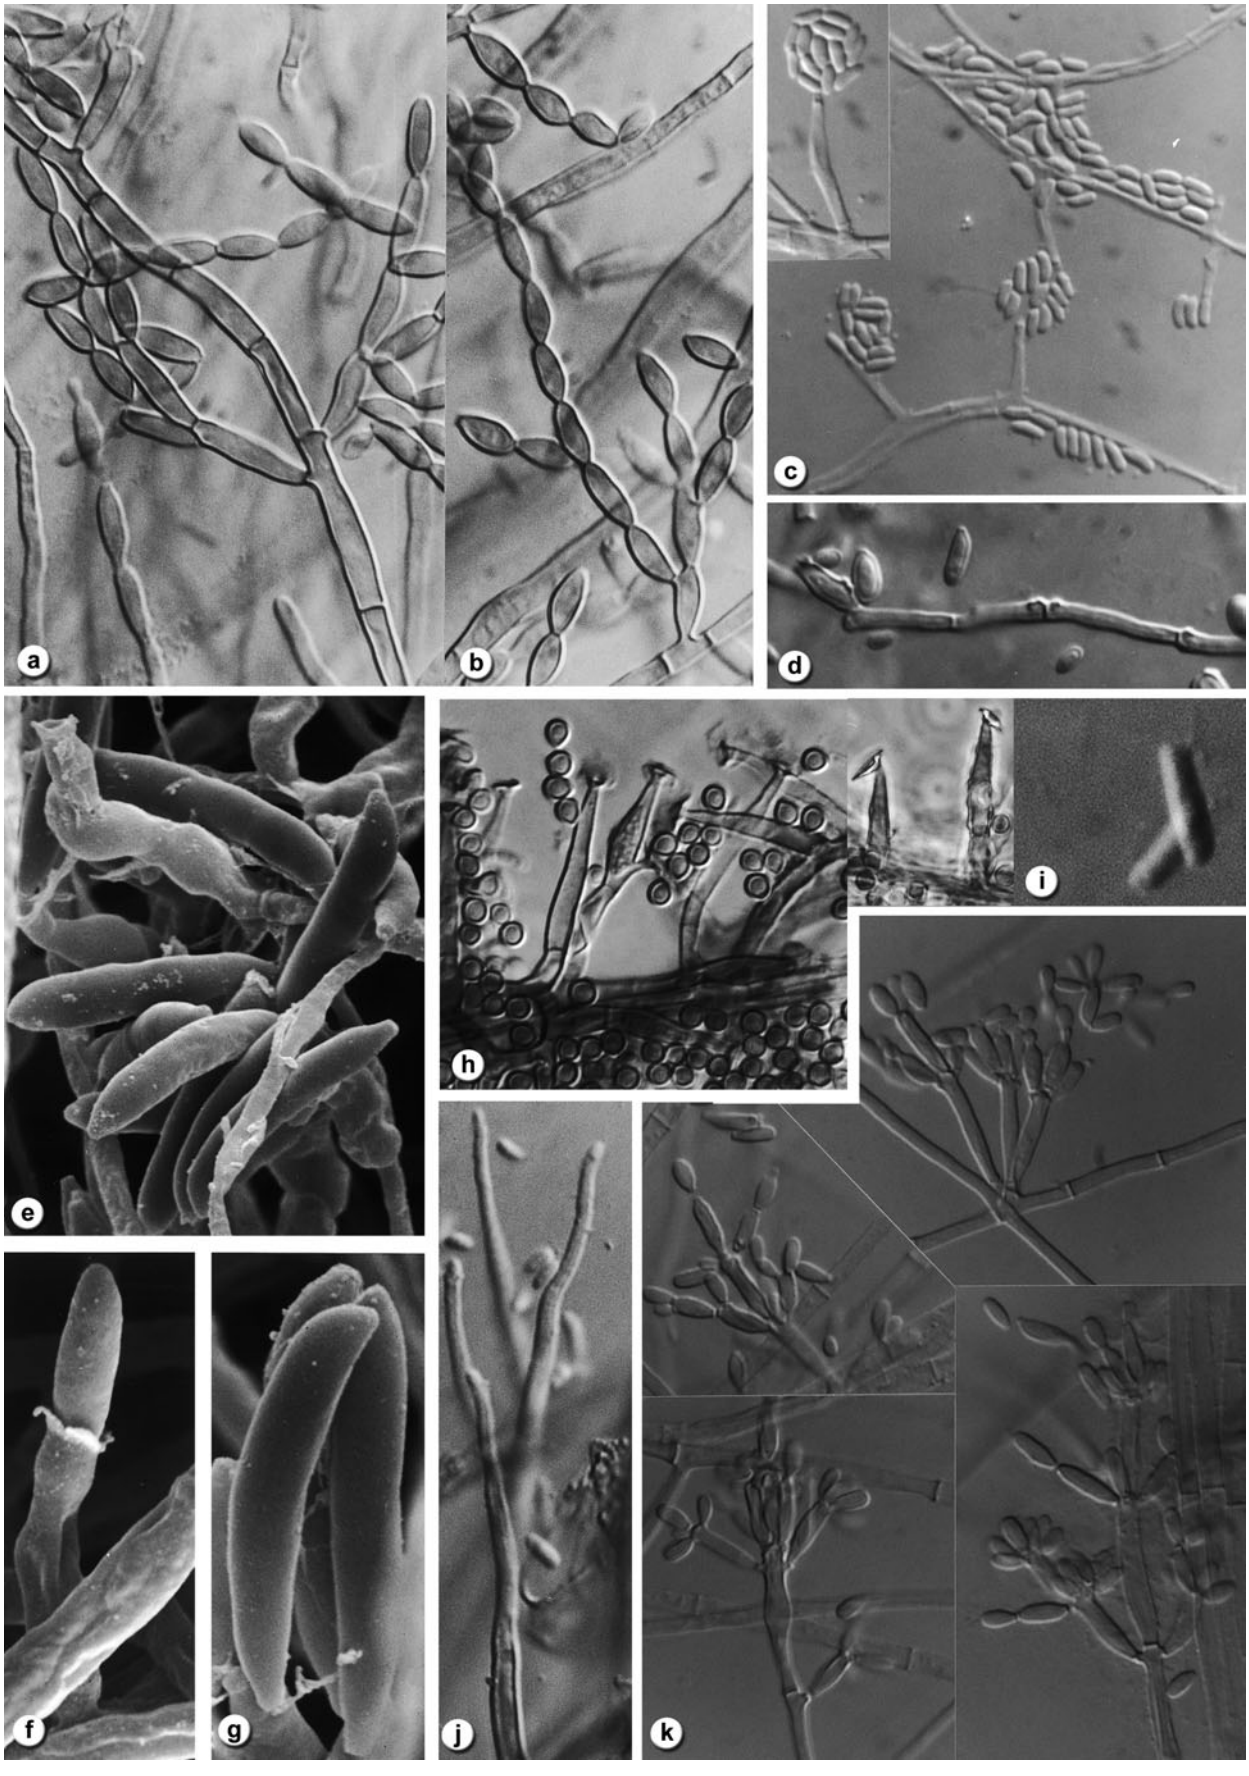
Phaeoacremonium (44) is morphologically characterized by slender, tubular, and often tapering or inflated, brown phialides. Hyaline, slimy conidia are produced through inconspicuous collarettes. Six species have been described, three of which are known from opportunistic infection in humans. *Phaeoacremonium parasiticum* (Fig. 1) is a well-documented agent of phaeohyphomycosis (75) and mycetoma (110, 201), while deep and disseminated infections occur in debilitated patients (104). *P. inflatipes* was implicated in a mycetoma (5) and in a phaeohyphomycosis (173). *P. rubrigenum* caused subcutaneous infection in an immunosuppressed patient (152).

Phialemonium

The genus *Phialemonium* is only poorly melanized, and its phylogenetic position is unknown. Colonies are white, with some strains having a diffusible yellow-green pigment or a faint vinaceous hue (84, 128). Reported cases of infection by *P. curvatum* involve subcutaneous cysts, disseminated infection, endocarditis, peritonitis, and fungemia (84, 97, 128, 207). Proia et al. (187) reported several cases of infection after hemodialysis, some of which were fatal.

Pleurostomophora

This is a genus of mainly wood-inhabiting fungi (235). Hyphae are dark and bear pale, tapering phialides that may be single or aggregated in dense brushes; hyaline, slimy conidia are produced through small or large collarettes. *Pleurostomophora repens*, until recently known as *Phialophora repens*, was occasionally reported from subcutaneous infections in humans (105, 160). *Pleurostomophora richardsiae* (Fig. 1) (syn. *Phialophora richardsiae*) is a soft-rot fungus on wood (242); human infections caused by this species involve mostly subcutaneous cysts in which the fungus is encapsulated by a collagen layer (98), occasionally with bone involvement (232). Most patients have some underlying disorder such as diabetes (184) or immunodepression (119).



Chaetothyriales

This rather small order is clinically highly relevant, because about one-half of the species known to date are able to cause infections in humans. Infections vary from traumatic inoculations into otherwise healthy individuals and largely asymptomatic colonization of cavities to a wide range of opportunistic disorders and systemic, mainly cerebral or disseminated disease. The deep clinical syndromes are mostly fatal if untreated and frequently occur in patients with no known immune disorder. The Chaetothyriales contain some of the most dangerous fungi known to date, which should be handled with great care. The natural ecology of most species is practically unknown. A remarkable tendency is observed in growth with xenobiotics, such as creosote-treated utility poles (242), xylene (42), or toluene (186).

Among the traumatic infectious syndromes is chromoblastomycosis, with a small number of potential etiologic agents, all of which are members of Chaetothyriales. The disorder occurs in otherwise healthy patients and is characterized by chronic, cutaneous to subcutaneous lesions, frequently with marked hyperplasia. Typically, spherical and mostly cruciately septate muriform (sclerotic) bodies are present within infected tissue. The bodies in tissue are a hallmark of chromoblastomycosis. Three fungal species account for virtually all cases of chromoblastomycosis: *Cladophialophora carrionii, Fonsecaea pedrosoi,* and *Phialophora verrucosa*.

Another disease entity that is largely confined to Chaetothyriales is primary cerebral infection in immunocompromised or immunocompetent individuals, i.e., cerebritis in which the first symptoms of disease are of neurological nature. Hyphal elements that show melanization either directly or after Fontana-Masson staining are observed in abscesses in the brain parenchyma. The portal of entry may be the lung, but frequently symptoms are confined to the brain. Six fungal species account for most nontraumatic brain infections: *Cladophialophora bantiana* (Fig. 1), *C. modesta, Exophiala dermatitidis, Fonsecaea monophora, Ochroconis gallopava,* and *Ramichloridium mackenziei*.

Occasionally systemic dissemination is observed in patients with or without proven immune disorder; these infections are fatal after a chronic course if untreated. Secondary cutaneous lesions often lead to marked eruptions with high morbidity. The disorder has been observed repeatedly with *Cladophialophora devriesii, Exophiala dermatitidis,* and *E. spinifera*.

Cladophialophora

Catenate, dry conidia and the absence of differentiated conidiophores characterize *Cladophialophora*. This genus contains eight species, seven of which are nearly exclusively known from humans and other warm-blooded animals. *C. bantiana* is a neurotropic mold that has caused numerous cases of cerebral phaeohyphomycosis (63, 111, 123, 192), in about one-third of the cases in otherwise healthy individuals. If untreated, the infections are fatal within 1 to 6 months. The species is recognizable by very long, coherent, poorly branched conidial chains and by an ability to grow at 40°C. It has a characteristic 558-bp intron at position 1768 of the small subunit ribosomal operon (87). *C. devriesii, C. modesta,* and *C. arxii* are known from scattered cases of chronic, fatal deep or disseminated mycoses (92, 156, 163, 230). *C. emmonsii,* with branched conidial chains and a maximum growth temperature of 38°C, has thus far been seen only in cutaneous infections (176). *C. carrionii,* with small conidia in profusely branched chains, is a common agent of chromoblastomycosis in arid climates (72, 140). The disease is probably acquired via traumatic inoculation of cactus spines (255). *Cladophialophora boppii* is a rare agent of mild cutaneous infections (22).

Cyphellophora

This is a rare group of infective agents characterized by slender, curved, mostly 1-3-septate conidia. Cultures are evenly melanized and show limited expansion growth; budding cells are absent. Conidia are produced from poorly developed collarettes alongside the hyphae. *C. laciniata* (Fig. 1), also known under the generic name *Pseudomicrodochium,* and *C. pluriseptata* are occasionally isolated from human skin and nails (60, 61), rarely from other body sites (3, 226), but their etiology has not unambiguously been proven.

Exophiala

Exophiala (including *Wangiella*) is the main genus of clinically relevant black yeasts. Strains show high degrees of morphological diversity. Most isolates initially grow in a yeast form that is succeeded by a hyphal anamorph. As a result, colonies are moist and slimy at first, becoming velvety to woolly with age. The process of conidium production is annellidic, from narrow, inconspicuous scars or extensions. Occasionally a very slow growing, meristematic morphology ("*Sarcinomyces*") is preponderant. Fresh isolates or strains cultivated on nutritionally deficient media frequently produce catenate conidia (53) and may produce scattered or compacted phialides with huge collarettes (54). The species are uncommon in the environment and occupy hitherto-unrevealed microhabitats. Some thermotolerant species seem to be associated with environmental xenobiotics (42) or occur in animal feces (G. S. de Hoog and M. Sudhadham, unpublished data); others are found on slightly osmotic surfaces such as fruit (150). Psychrophilic species that cause infections in cold-blooded vertebrates are frequent in water, either ocean water (136, 137), municipal drinking water (95), or hospital water (185). The most frequently identified species, *E. jeanselmei,* has recently been subdivided into a number of taxa on molecular grounds (56, 236). *E. oligosperma* is a common etiologic agent of subcutaneous infections in immunosuppressed, elderly, diabetic, or otherwise debilitated individuals (56, 212, 224). The two species with capsule-like extracellular polysaccharides around yeast cells, *E. spinifera* and *E. dermatitidis* (Fig. 1) (251), have the highest virulence to humans. The rare infections by *E. spinifera* can be localized, but in about one-half of the cases fatal, disseminated mycoses are observed in adolescents (reviewed by de Hoog et al. [52]). The species can be recognized by the presence of large, stiff conidiophores. Recently a similar species with reduced conidiogenous cells, *E. attenuata,* was described (236). *Exophiala (Wangiella) dermatitidis* is the most commonly encountered species in clinical settings, causing infections of cutaneous and subcutaneous tissue (108) in mostly immunocompromised patients; recurrent continuous ambulatory peritoneal dialysis-related infections are also seen (239). It regularly occurs asymptomatically in the lungs of patients with cystic fibrosis (102, 114), as well as in the stool of patients with diarrhea (50). A striking number of fatal, neurotropic infections have been described in young, healthy individuals, all in Asia (35, 107, 153). In the indoor environment the fungus has a focus in Turkish steam baths (150). *E. dermatitidis* is recognizable morphologically by "phialides without collarettes," which are wide, scar-like, very short annellated zones. In addition, growth at 40°C and the inability to assimilate nitrate are characteristic (172). The related species *E. phaeomuriformis* differs by having a growth maximum at 38°C (151).

Fonsecaea

The two species known in the genus *Fonsecaea,* characterized by conidia produced in chains of maximally four, are both human pathogens. In culture *Fonsecaea* species are mostly monomorphic but may produce additional phialides with collarettes releasing balls of one-celled conidia. No budding cells are produced on routine media. *Fonsecaea pedrosoi* (Fig. 1; including the mutant *F. compacta*) is one of the etiologic agents of human chromoblastomycosis (13, 161, 219). The second species, *F. monophora* (47), has a more diverse clinical spectrum which includes brain infections (170, 225). The etiologic agents in cases of phaeohyphomycosis published under the name *F. pedrosoi* (17, 166) should therefore be reconsidered.

Ochroconis

The phylogenetic position of the genus *Ochroconis* is unclear. All species have rust brown to olivaceous colonies and produce 1-3-septate conidia from small, open denticles inserted in low numbers on sympodial cells. *O. gallopava* (Fig. 2) is an etiologic agent of neurotropic infections in immunocompromised humans, and it is the cause of epizootic encephalitis in flocks of turkeys and chickens (112, 145, 215). It has hyaline, clavate conidia and grows well at 40°C. Other, nonthermotolerant species have been observed to cause disseminated infections in cold-blooded animals such as fish (205).

Phialophora

When phialides are the only form of propagation in chaetothyrialean fungi, the generic name *Phialophora* is applied. Dematiaceous phialidic fungi belonging to other orders are now classified in genera such as *Cadophora, Phaeoacremonium,* and *Pleurostomophora* (83, 235). No budding cells are produced in *Phialophora. P. verrucosa,* with darkened, funnel-shaped collarettes (Fig. 2), is a leading cause of chromoblastomycosis in tropical climatic zones (81, 233). Occasionally, opportunistic infections were reported, including

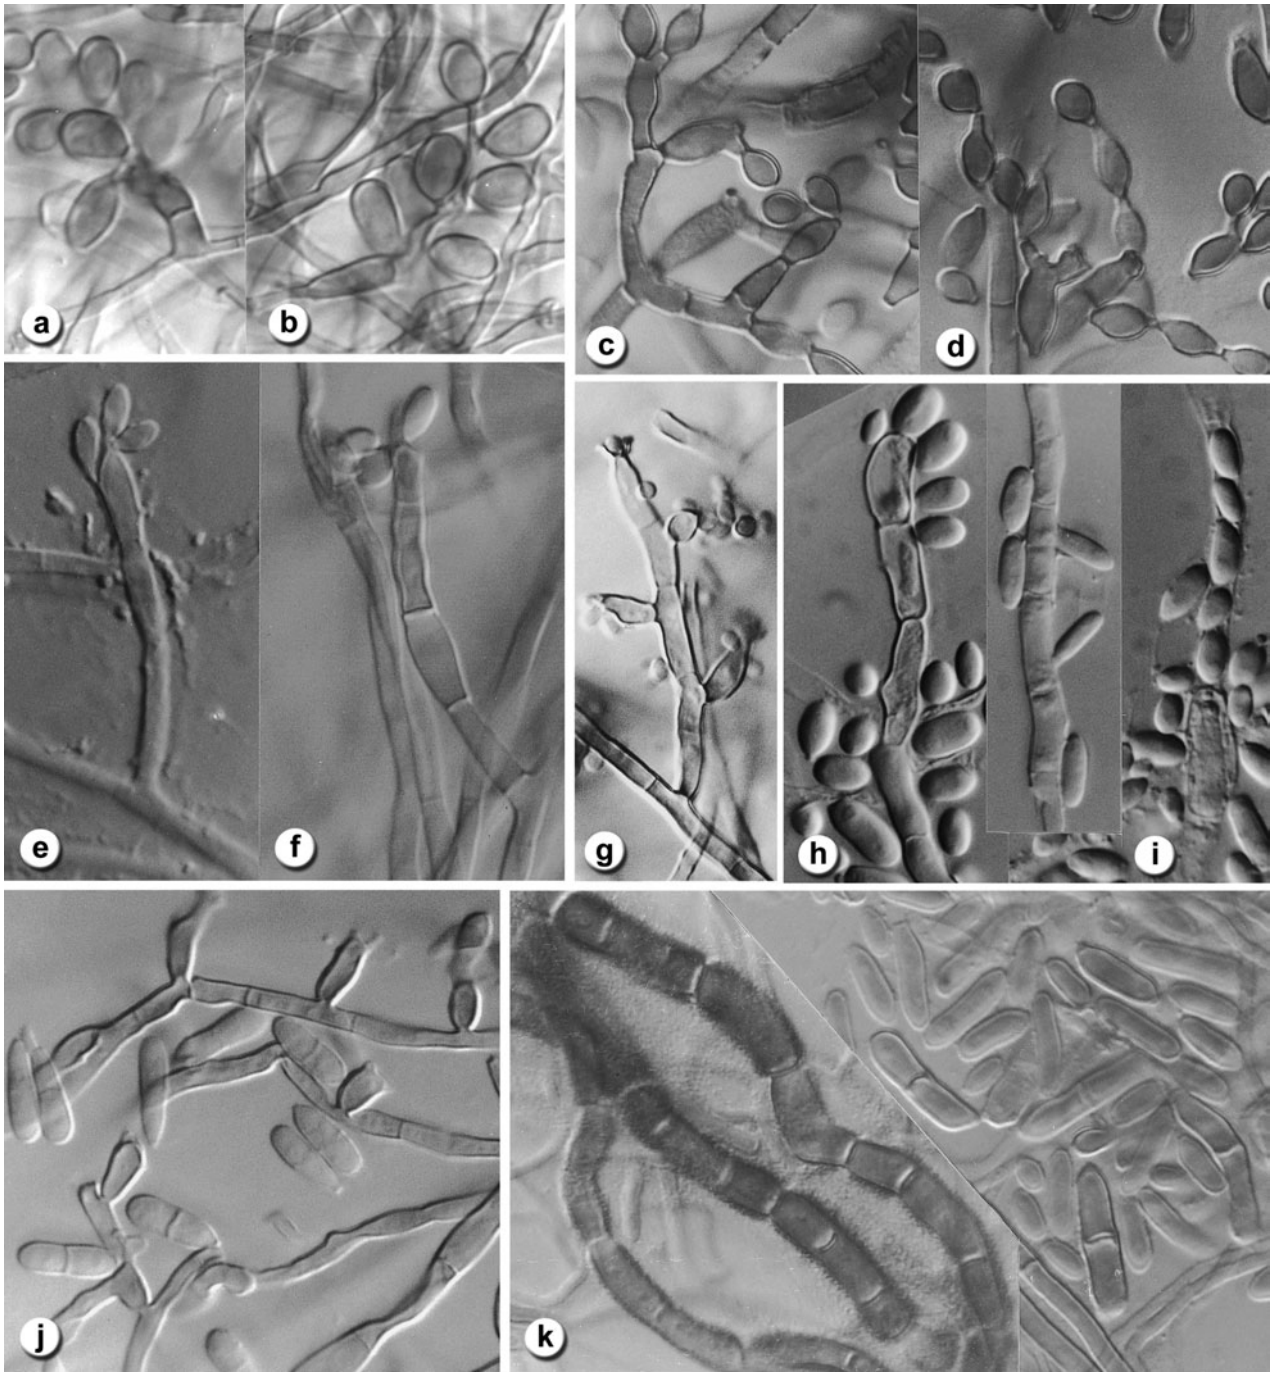

FIGURE 2 (a and b) *Ramichloridium mackenziei;* (c and d) *Cladosporium cladosporioides;* (e and f) *Rhinocladiella aquaspersa;* (g) *Phialophora verrucosa;* (h and i) *Aureobasidium pullulans;* (j) *Ochroconis gallopavum;* (k) *Hormonema dematioides*. Reproduced from de Hoog et al. (48).

endocarditis, keratitis, and osteomyelitis (65, 231). It is possible that some of these infections are attributable to *P. americana,* which differs mainly by having vase-shaped collarettes (57). Given their close molecular similarity, there is no consensus as to whether *P. verrucosa* and *P. americana* constitute two species or one (57, 214, 246). *P. europaea,* with very short collarettes (51), is fairly commonly involved in mild skin and nail infections, but due to its slow growth it is frequently overlooked.

Ramichloridium

Ramichloridium is morphologically characterized by stout, mostly erect conidiophores bearing noncatenate conidia on denticles. *Ramichloridium mackenziei* (Fig. 2) is a remarkable fungus because it is exclusively known from fatal brain infections in the Middle East or from immigrants from that region (29, 122, 227). Several patients had no known immune disorder; the environmental niche of the species is unknown.

The species is morphologically similar to *R. obovoideum,* an organism described as occurring on leaf litter and long thought to be conspecific, but on the basis of rRNA gene data it is distantly related, not even belonging to the same order (G. S. de Hoog, unpublished data).

Rhinocladiella

The genus *Rhinocladiella* has less conspicuously differentiated conidiophores, the sympodial conidia being produced from a loosely branched system. In addition to the sympodial anamorph, annellidic and phialidic cells can be observed. *Rhinocladiella aquaspersa* (Fig. 2) is a rare agent of chromoblastomycosis in South America (11, 182, 206, 216). *R. atrovirens* has been reported to cause cerebral phaeohyphomycosis in an AIDS patient (59) and mycetoma of the foot (167), but because *R. atrovirens* in a modern, molecular circumscription is limited to isolates growing on conifer wood in Northern countries, these cases probably concerned the sibling species *R. similis* (56).

Dothideales

The order Dothideales comprises numerous saprobes which thrive well under conditions of decreased water activity, such as on sugary leaf surfaces, rock, glass, and moist medical devices. Many are extremotolerant and are found in Antarctic or Mediterranean rock (209, 222) or in hypersaline ponds (254) and have the ability of morphological transition to a tolerant, meristematic ecotype consisting of clumps of amorphous, thick-walled, highly melanized cells. *Cladosporium* species are very common airborne laboratory contaminants.

Aureobasidium and *Hormonema*

The genus *Aureobasidium* contains a single, ubiquitous, and highly polymorphic species, *A. pullulans* (Fig. 2). It has a yeast phase that colonizes moist surfaces of, for example, insufficiently sterilized instruments or prosthetic devices. It can maintain by converting to a meristematic morphology, i.e., it forms isodiametrically expanding cells that become subdivided in all directions and may eventually fall apart into small cell clumps. Colonies in vitro are often pink due to the preponderance of wide, hyaline, oligokaryotic hyphae bearing synchronously produced conidia and containing scattered endoconidia. *Aureobasidium* is often confused with *Hormonema* (Fig. 2), which, however, produces conidia in a basipetal succession (58). In addition, the internal transcribed spacer (ITS) rRNA gene sequences of the two species are clearly different (252). *A. pullulans* has been implicated as an opportunistic agent of mycoses in humans and other animals, having been isolated from peritonitis and disseminated infection (31, 38, 79, 80, 106, 117, 191, 202). Cutaneous phaeohyphomycosis and peritonitis have been reported as caused by *H. dematioides* (40, 213).

Cladosporium

Species of *Cladosporium,* especially *C. cladosporioides* (Fig. 2) and *C. sphaerospermum*, are extremely common contaminants in the clinical laboratory. They are also associated with allergic disease in the indoor environment. Some (sub)cutaneous (100, 142, 180, 199, 234) and even deep (124, 134) infections have been reported, but there remains some doubt about the pathogenic role of the *Cladosporium* isolates.

Hortaea

Members of the genus *Hortaea* have rather wide hyphae which become profusely septate during growth of the fungus, and they have annellidic conidiogenesis from broad scars. Two species are recognized to date, which have a predilection for acidic (109) and salty (254) environments, respectively, and do not show any pathogenicity for humans. The halophilic species, *H. werneckii* (Fig. 3), lives in evaporation ponds at the subtropical seashore and can adhere to human hands when these are exceptionally salty (95), causing a syndrome in the dead keratin layers known as tinea nigra (210). Therapy is by the application of keratin-dissolving agents.

Lasiodiplodia

Lasiodiplodia is a coelomycete genus characterized by spherical fruiting bodies filled with asexual conidia. The conidia initially are ellipsoidal and hyaline but gradually become brown and develop a median septum at maturation. *L. theobromae* (Fig. 3) is occasionally encountered as a cause of keratitis following injury to the cornea (190). Rare cases of subcutaneous infection have also been reported (148).

Nattrassia

N. mangiferae is a pycnidial fungus. Inside multilocular fruiting bodies hyaline, ellipsoidal conidia develop, which in part become brownish and 1-2-septate. In culture usually only a rapidly growing, jet black, hairy anamorph with dark arthroconidia (*Scytalidium dimidiatum;* Fig. 3) is seen; the pycnidia are produced only after 2 months of growth on a moistened plant leaf. Melaninless mutants (195), which also show reduced conidiation, were until recently referred to as *Scytalidium hyalinum*. The fungus is a common plant pathogen in the tropics, is regularly involved in syndromes very similar to dermatophytosis on skin and nails (68, 141, 164, 253), is rarely involved in subcutaneous tissue (194, 218), and has caused endophthalmitis (6). Deep infections are very rare in immunocompromised patients (19).

Microascales

The order Microascales comprises *Scopulariopsis,* with its *Microascus* teleomorphs, but also *Scedosporium,* linked to *Pseudallescheria* and *Petriella* teleomorphs. *Scopulariopsis* has dry, airborne conidia and is commonly involved in superficial infections, although some *Microascus* species were found to be involved in deep infections (131, 147). In contrast, *Scedosporium* has sticky conidia and the species cause subcutaneous infections, while deep and disseminated infections are noted in immunosuppressed or otherwise debilitated patients.

Scedosporium/Pseudallescheria

Scedosporium comprises three clinically relevant species (89). The genus is characterized by hyaline, Fontana-Masson-negative hyphae from which slimy, pale brown conidia are produced in basipetal succession from inconspicuous annellides (66). *S. prolificans*, with flask-shaped conidiogenous cells, is monomorphic; the complete life cycle of *S. apiospermum* (Fig. 3), with cylindrical conidiogenous cells, comprises a *Graphium fructicola* synanamorph and a *Pseudallescheria boydii* teleomorph (Fig. 3). The latter fungus has become one of the most frequently misidentified organisms in medical mycology, largely due to the differential abundance of each of the phenotypes of *P. boydii*. This has led to a large number of new introductions in totally unrelated genera (48). The most recent synonym is *Polycytella hominis* (28), a near-sterile phenotype that was found to cover degenerate *P. boydii* strains lacking annellidic conidia (23).

Scedosporium apiospermum was discovered in 1889 as an agent of human otitis (217). The reported clinical spectrum of the fungus has changed over time, from prevalently chronic mycetoma in otherwise healthy patients between 1911 and 1980 to systemic opportunistic infection after 1980 (96). Systemic infections after solid organ transplant are relatively frequent (85, 143); occasionally infections are noted with the

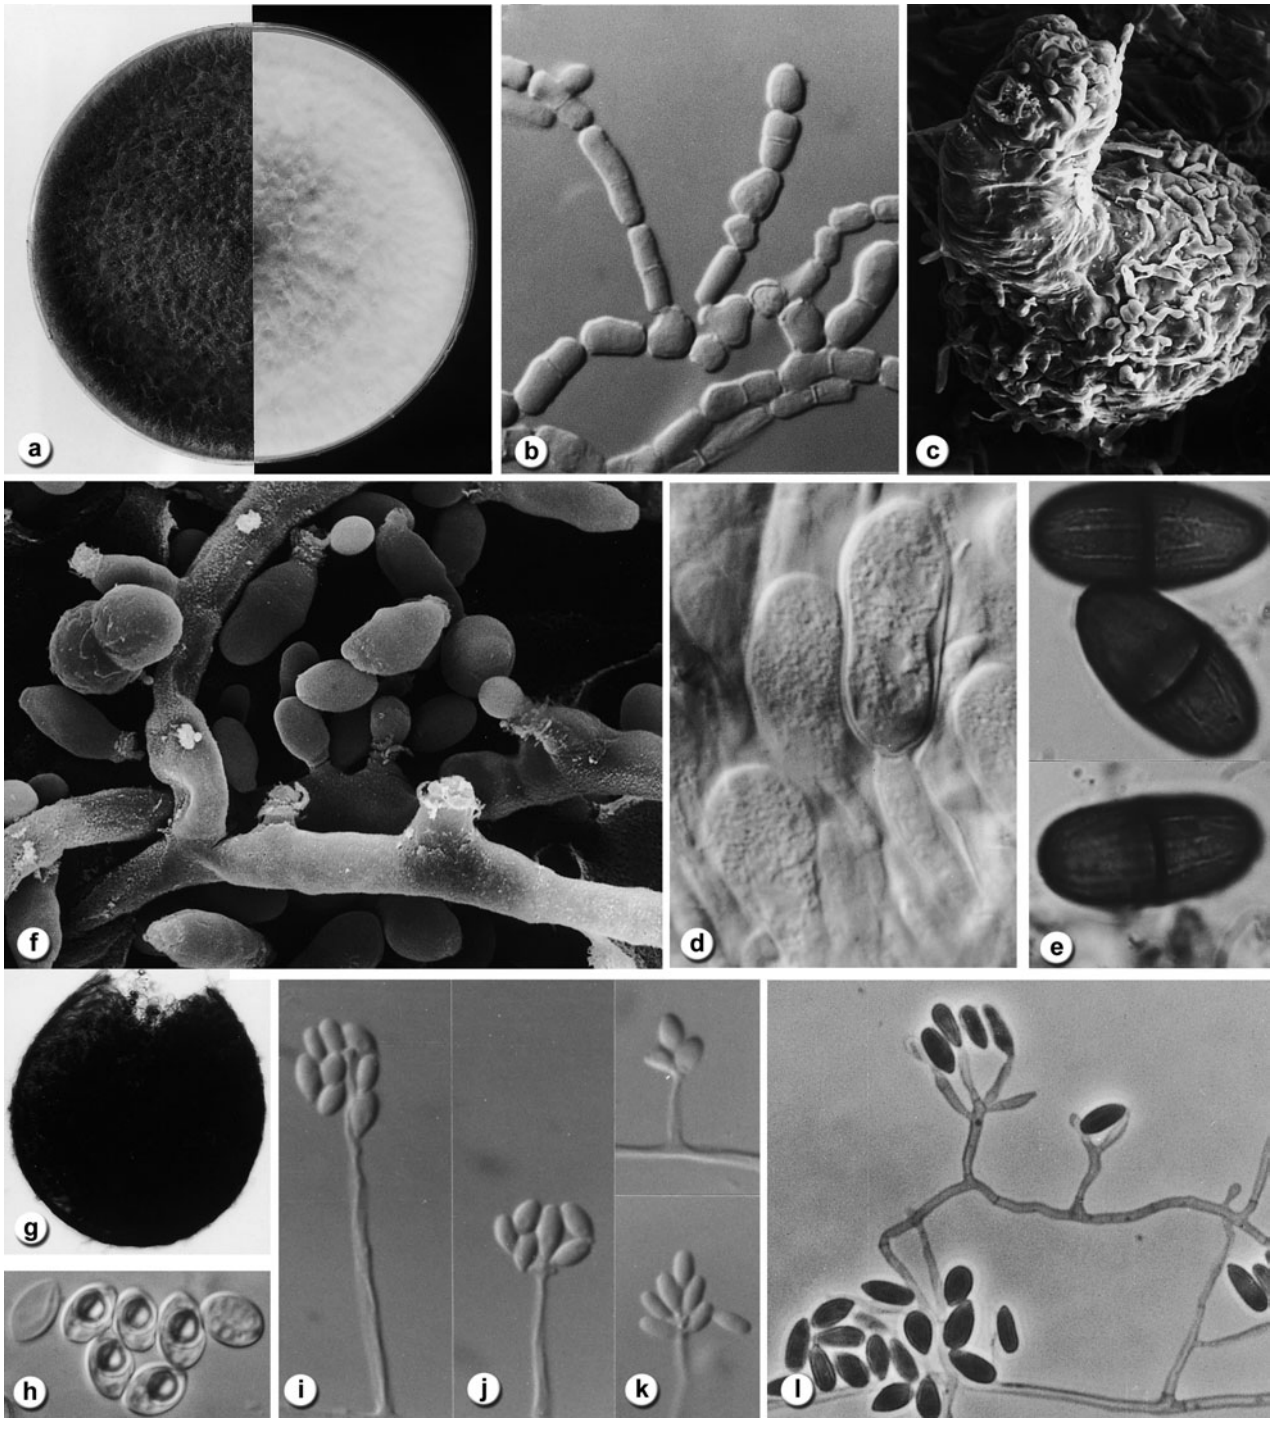

FIGURE 3 (a and b) *Scytalidium* synanamorph of *Nattrassia mangiferae;* (c to e) *Lasiodiplodia theobromae;* (f) *Hortaea werneckii;* (g and h) *Pseudallescheria boydii;* (i to l) *Scedosporium* anamorph of *Pseudallescheria boydii*. Reproduced from de Hoog et al. (48).

application of invasive devices (118, 211). Osteomyelitis (15) and arthritis (91) are frequent. Fisher et al. (76) were the first to describe the near-drowning syndrome by *S. apiospermum*, which characteristically leads to delayed, potentially fatal brain infection after the patient has recovered from the primary effects of aspiration of polluted water. The species' neurotropism was stressed by Berenguer et al. (20). In severely compromised patients, cerebral dissemination may take place from local foci (113). Although Creitz and Harris (43) had already noted the occurrence of *P. boydii* as a colonizer of the lungs of patients with pulmonary disorders and numerous cases have been reported since then (196), its consistent occurrence in patients with cystic fibrosis has only recently received proper attention (37).

Despite its rather frequent occurrence in clinical settings, the history of the second species, *Scedosporium prolificans*, is

remarkably short (96). The first clinical cases were described by Malloch and Salkin (144) after disseminated infections in immunocompromised hosts. Since then, numerous strains have been recovered, mostly from clinical cases with major immunosuppression, and since no older reports of cases in immunocompetent patients are known, the species is a truly emerging opportunist (20). The species has been reported from bone and soft tissue infections (203, 244, 245) as well as from (secondary) cutaneous infection, fungemia, and endocarditis (24, 32, 90). The fungus may disseminate to visceral organs in immunocompromised individuals (7, 20, 169, 183). A nosocomial outbreak has been described (99).

Ophiostomatales

Ophiostomatales is a large order of plant-pathogenic fungi. Most are blue-stain fungi in wood and live in association with bark beetles. Only a single species has a clinical potential. The main teleomorph genus is *Ophiostoma*.

Sporothrix

Sporotrichosis, caused by *Sporothrix schenckii,* is a cutaneous-to-subcutaneous chronic infection that can undergo lymphatic spread. Musculoskeletal involvement and disseminated infection are relatively rare, as are the nasal and pulmonary infections that may arise from inhalation of conidia (34, 39, 93). Most infections originate from traumatic implantation of the fungus. Some disseminated cases were observed in AIDS patients (21, 64). In addition, infections have been described to be transmitted by animals (8, 204). In sporotrichosis, the narrow-based yeast cells in tissue are characteristic, but their numbers are usually very small and may easily be missed upon microscopy. Gomori methenamine silver or periodic acid-Schiff staining is therefore recommended; Fontana-Masson staining is negative.

Hyphae of *S. schenckii* are colorless and bear a cluster of thin denticles with hyaline, tear-shaped conidia at their tips. Additional spherical conidia may or may not be present; this is the only melanized part of the fungus. Strains lacking these brown conidia have been shown to be avirulent in mice (62). The mold can be transformed in vitro to a stable yeast at 37°C on enriched media such as chocolate agar or brain heart infusion agar. Occasional isolates are difficult to convert and may require multiple subcultures and extended incubation. Transition is observed in environmental as well as clinical isolates.

Three isolates of *S. schenckii* var. *luriei* have been reported (2, 4, 175). The appearance of this variety differs from that of *S. schenckii* var. *schenckii* by large, often septate budding cells. Its separation is supported by rRNA ITS sequence data (G. S. de Hoog and R. C. Summerbell, unpublished data).

Pleosporales

Most members of the order Pleosporales have rapidly expanding, hairy colonies, which show optimal conidium production on media poor in nutrients, such as potato carrot agar. The large conidia are then mostly visible with the aid of a stereomicroscope. Very rarely, however, preponderantly meristematic cultures are produced, which show limited expansion growth and produce amorphous clumps of black cells as the only form of conidiation, reported in the literature as *Phaeosclera* and *Botryomyces*.

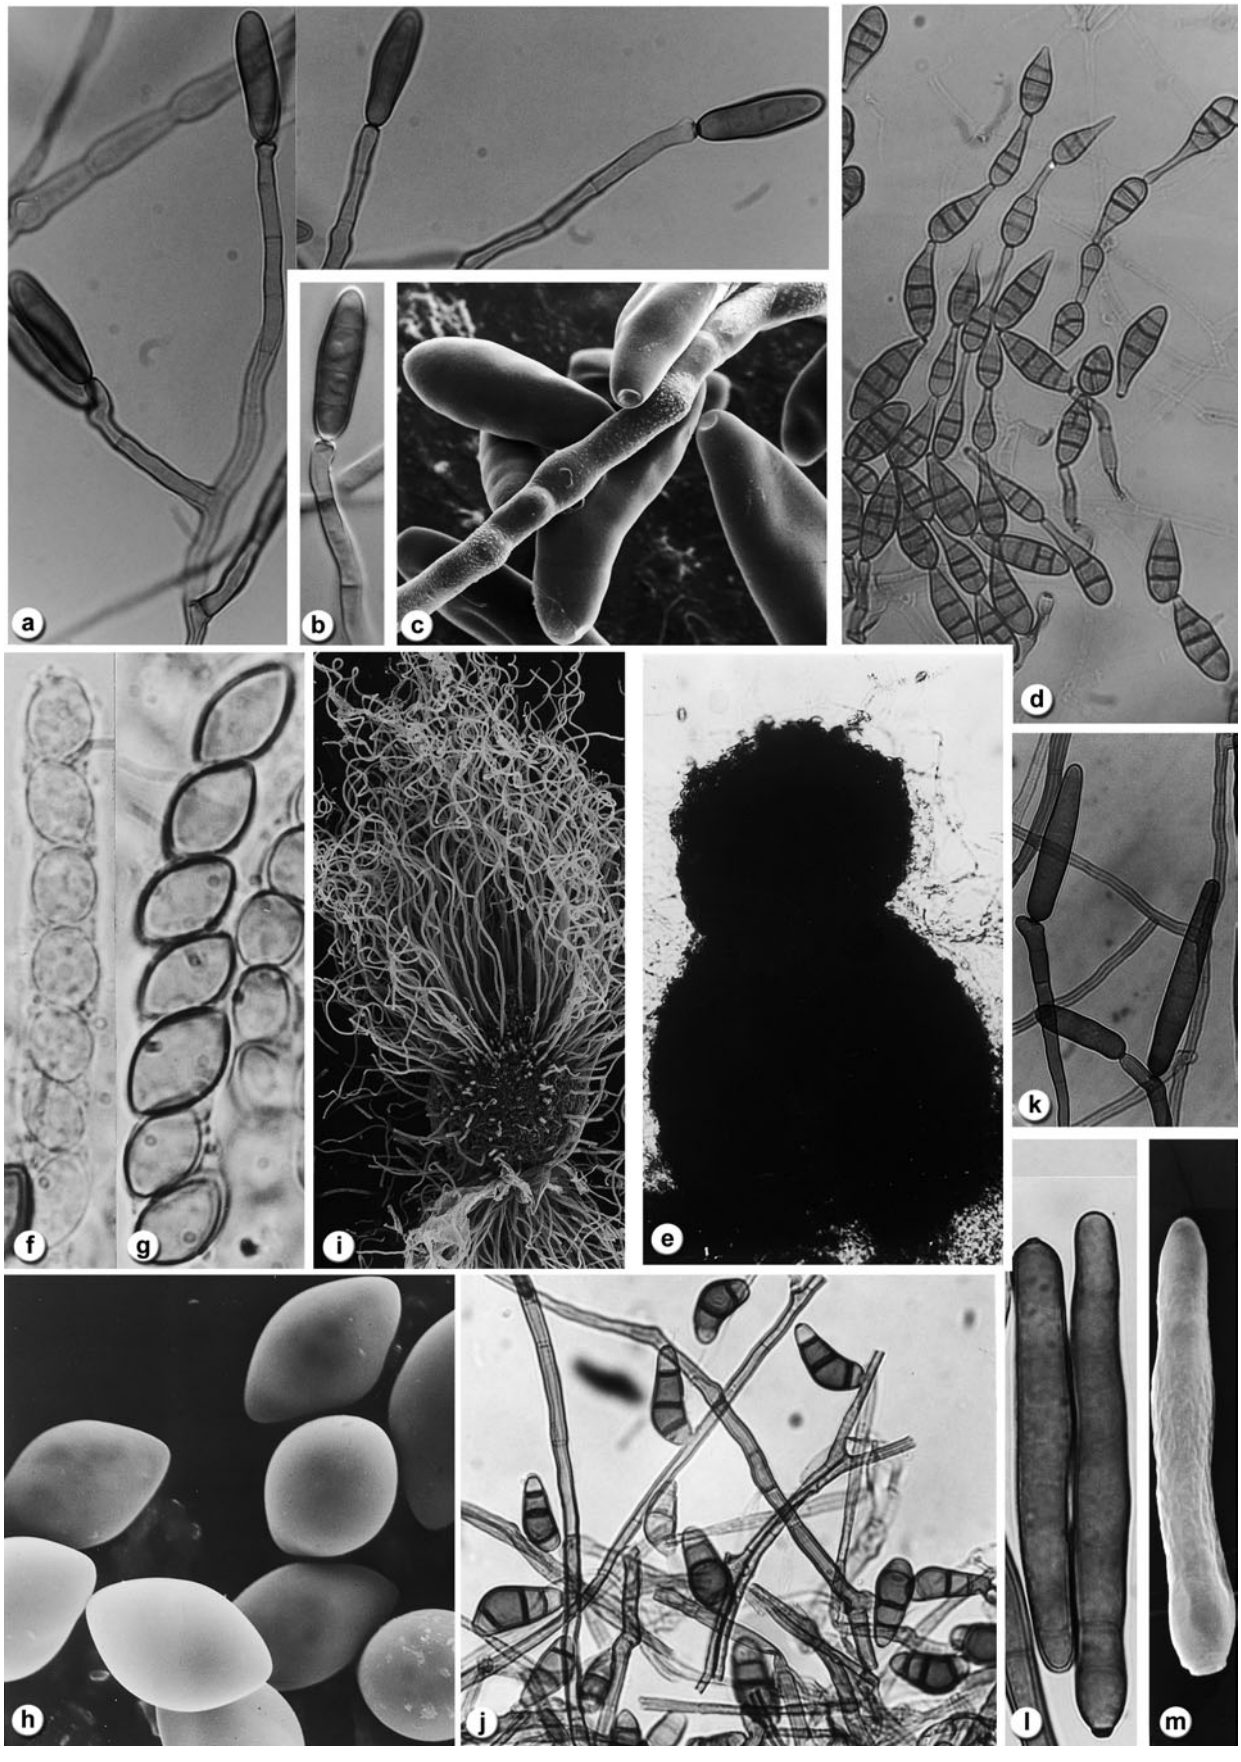
Conidia are generally produced on septate, dark brown, erect conidiophores. They consist of several compartments. Different types of septation, characterizing the genera, are observed. True septa are found in those conidia where outer wall and septum are continuous; such conidia are euseptate (in *Alternaria* and *Curvularia*). False septa are observed in those conidia where only the inner wall layers are involved in septation and the outer wall forms a sac-like structure around the individual cells; such conidia are distoseptate (in *Bipolaris* and *Exserohilum*).

Members of the Pleosporales are mainly plant pathogens with a restricted host range. The few saprobic members in each of the genera mentioned are occasionally observed in human disease. Two main clinical entities are recognized, namely, cutaneous infections in immunosuppressed patients *(Alternaria)* and allergic sinusitis with occasional cerebral involvement in otherwise healthy individuals *(Bipolaris, Curvularia,* and *Exserohilum)*.

Alternaria

Species of *Alternaria* are fairly frequent agents of mainly cutaneous infections in patients on long-term steroid usage, tacrolimus, or other immunosuppressive agents (88, 181, 238, 243), cases of sinusitis being rare. Nearly all cases were caused by *Alternaria infectoria* (139, 200) and *A. alternata* (Fig. 4) (155), the two main saprobic species of the genus (49). Infections attributed to the host-specific plant pathogen *A. dianthicola* (162) have not been confirmed by molecular methods. Infections attributed to *A. chlamydospora* (16, 221) probably concerned meristematic segregants of *A. alternata*. *A. longipes* (86) is a host-specific pathovar of *A. alternata* on tobacco, with identical diagnostic features. Several cutaneous infections have been attributed to *Alternaria tenuissima* (33, 197, 198), which is only doubtfully separate from *A. alternata* (49).

Since clinical strains are very likely to belong to only two species of *Alternaria*, isolates are easily identified down to the species level. Available criteria comprise characteristics of growth, sporulation, and morphology and very large differences in rRNA gene ITS, which can be displayed by sequencing or by restriction fragment length polymorphism (49). *Alternaria infectoria* in tissue may present with hyaline yeast cells rather than melanized hyphae. Cultures of *A. infectoria*, in contrast to those of *A. alternata*, frequently exhibit creamish patches and show reduced sporulation. Conidia of *A. infectoria* bear long apical beaks which serve as secondary conidiophores.



Bipolaris

Preponderant species of the *Bipolaris* genus are *Bipolaris australiensis, B. hawaiiensis* (Fig. 4), and *B. spicifera,* which are infrequently involved in allergic sinusitis (77, 138, 157, 179). Cerebral complication takes place, which is rapidly fatal if untreated (82, 250). Simmons et al. (220) reported such a case caused by the single member of the genus *Dissitimurus*, which probably concerned a degenerate strain of *Bipolaris hawaiiensis* (55).

Curvularia

Most species of this genus are easily recognizable on the basis of conidial characteristics (69, 70). Saprobic members of *Curvularia,* particularly *C. geniculata* and *C. lunata* (Fig. 4),

FIGURE 4 (a to c) *Bipolaris hawaiiensis;* (d) *Alternaria alternata;* (e to h) *Achaetomium strumarium;* (i) *Chaetomium globosum;* (j) *Curvularia lunata;* (k to m) *Exserohilum rostratum*. Reproduced from de Hoog et al. (48).

have been identified as potential agents of fungal sinusitis, in humans as well as in cattle (18, 193). Cerebral involvement may occur (135), which may be fatal if untreated. A wide spectrum of opportunistic infections is noted, including endocarditis, pulmonary infection, cerebral infection, and subcutaneous phaeohyphomycosis (26, 67, 74, 120, 132, 193, 247).

Exserohilum

Exserohilum (5, 157) is characterized by very long, distoseptate conidia with a distinct, protruding hilum at the basal scar. Three species have been recognized as opportunistic agents (*E. longirostratum, E. mcginnisii,* and *E. rostratum*; Fig. 4), but given their close molecular similarities the possibility is not excluded that these are morphological variants of a single species (48). Prevalent etiology is sinusitis with eventual brain involvement (14). Exceptionally, phaeohyphomycosis of the skin, subcutaneous tissue, and cornea has been documented (10, 115, 149, 157, 171).

Sordariales

Sordariales is a large and diverse order of ascomycetes. *Madurella mycetomatis* was recently proven to be a further member of Sordariales (46); this species is treated in chapter 126.

Chaetomium

Chaetomium species are very common saprobic decomposers of all sorts of organic materials. The few human infections, particularly those caused by *C. globosum,* may involve blood, lung, and brain in both healthy and immunocompromised patients (Fig. 4) (9, 101, 223, 229, 248). Cutaneous infections are extremely rare (223). The related species *Achaetomium strumarium* (Fig. 4) has been reported from cerebral infections in several patients (1). *Chaetomium* species have sexual fruiting bodies containing brown, one-celled ascospores produced in deliquescent asci. The fruiting bodies are covered with often elaborately branched and ornamented hairs. Anamorphs are not produced.

CLINICAL SIGNIFICANCE

Disorders caused by the fungi described in this chapter are mainly localized and occur in otherwise healthy hosts. The infections arise mostly after traumatic inoculation of contaminated material from the environment, or, less frequently, e.g., in the case of sinusitis, otitis, or growth in the mucous lungs of patients with cystic fibrosis, asymptomatic or mildly symptomatic colonization of cavities is observed. They are typical opportunists, infections increasing in severity in individuals with impaired innate immunity and metabolic diseases such as diabetes. The infections also arise in patients with severe immunological disorders such as neutropenic patients, solid organ transplantation recipients, or patients undergoing long-term corticosteroid therapy. Some species of Chaetothyriales are able to cause deep or disseminated infections in hosts with no known immune disorder. Such infections may take, if untreated, a chronic, fatal course after a destructive disease process. The frequency of all infections described above is relatively to extremely low, but given the potential severe course of the disease, as well as the sometimes very high degrees of resistance to antifungal drugs, attentiveness to these fungi is mandatory. *Sporothrix* (order Ophiostomatales) is the only agent of infection that increases in severity with defects of acquired cellular immunity, such as AIDS.

IDENTIFICATION

Direct Microscopic Examination

There are numerous procedures for treating the specimen to enhance fungal detection, including treatment with potassium hydroxide or calcofluor white and Giemsa, Wright, or Gram stains. Histopathology procedures using periodic acid-Schiff, hematoxylin and eosin, or methenamine silver enhance observation. Fontana-Masson staining is useful to detect melanization in cells that appear hyaline with light microscopy. Below some characteristic features are summarized.

Skin Infections

Pigmented hyphal fragments, occasionally melanized yeast-like cells, are visible in infected skin tissue.

Subcutaneous Infections

Mycetoma, a chronic subcutaneous infection, is characterized by the formation of large aggregates of fungal elements in the form of grains. The grains are black when *Exophiala* is the etiologic agent but white in the case of *Pseudallescheria*. Occasionally the infection is encapsulated by a collagen layer. Otherwise, the prevalent form is hyphal, less commonly yeast-like. Hyphae and yeasts are generally melanized, but frequently melanization is observed only after specific staining.

Sporotrichosis

In sporotrichosis, hyaline yeast-like cells are present in low frequency, bearing slender daughter cells at very narrow bases.

Chromoblastomycosis

The hallmark of chromoblastomycosis disease is the presence of muriform cells, which are swollen, spherical, dark brown cells which often develop a septum and may finally become cruciately septate. The skin usually is verrucose and through acanthosis may develop cauliflower-like tumors.

Sinusitis

In sinusitis, the sinuses are occluded by amorphous fungus balls.

Cerebral Infection

In cases of cerebral infection, the hyphae are often poorly colored and scantily branched. In advanced cases abscesses are formed.

Disseminated Infection

Pigmented or poorly colored fungal elements such as hyphae or yeast-like cells can be observed in cases of disseminated infection.

Isolation Procedures

The use of nutritionally minimal media such as 2% water agar, moistened sterile wooden sticks, or moistened filter paper stimulates the formation of conidia. In the case of infection due to more than one agent, the strain with limited expansion growth may pass unnoticed. Therefore, a loopful of cells suspended in 0.1% Tween and streaked onto a fresh culture plate is useful to select an individual colony for identification. Slide culture preparations (157) using potato dextrose agar or cornmeal dextrose agar, to be handled only within a biological safety cabinet, are ideal for determining conidiogenesis. For morphological features of the fungi treated in this chapter, the reader is referred to de Hoog et al. (48).

Nucleic Acid Detection Techniques

Molecular identification of most species is currently performed by sequencing of ribosomal genes and comparison with dedicated databases. Care should be taken when GenBank is used for the purpose of identification in less-known fungal groups, because over 10% of the sequences may be incorrect (49). Sequences should be evaluated not only from a technical point of view but also nomenclaturally, i.e., by comparison with ex-type strains.

When using ribosomal genes, the phylogenetic position of taxa can be established by sequencing the nuclear small subunit rRNA gene. This gene is mostly invariant between closely related species. In most fungal groups, species diagnostics is possible with ITS sequences. But application of this technique as a "gold standard" for melanized fungi is still in dispute. In some genera, such as *Alternaria*, the numerous species described on the basis of morphology prove to be invariant with ITS. In this case the question as to whether ITS shows insufficient polymorphism or whether simply too many species have been introduced remains pending. In contrast, ITS-based species distinction with black yeasts provides satisfactory results.

Serologic Tests

Serologic tests can detect the presence of antibodies or antigens. A latex agglutination test is commercially available (Immuno-Mycologics Inc., Norman, Okla.) for detecting antibodies against *S. schenckii*, particularly in disseminated cases, but despite a study (27) reporting sensitivity and specificity of 90 to 94% and 95 to 100%, respectively, the test has not been used widely. However, the detection of antibodies was demonstrated to be useful in the diagnosis of central nervous system sporotrichosis in several patients when culture-based diagnosis had failed (208). The remaining serologic tests consist of fluorescent-antibody conjugates for differential staining of histologic sections (125) and the exoantigen test for identification of cultures (126, 178). None of these reagents are commercially available.

ANTIMICROBIAL SUSCEPTIBILITIES AND RECOMMENDED TREATMENTS

In this section an overview of in vitro susceptibility testing and current therapies for the fungi described above is given (Table 2). The optimal therapy for infections caused by black fungi is controversial. Generally, surgical excision, antifungal monotherapy, or application of drug combinations has been used, but prolonged treatment is needed because relapses often occur.

The main etiological agents of chromoblastomycosis are *Cladophialophora carrionii, Fonsecaea pedrosoi, F. monophora,* and *Phialophora verrucosa.* Clinical trials for the treatment of the disease have not been performed. Patients with small lesions mostly respond better than those with progressive disease. Good results were obtained with topical heat. Cryosurgery has been recommended, but subsequent administration of antifungal agents is necessary. The use of terbinafine and itraconazole alone or combined with flucytosine seems to be the best option for treatment. The use of the new triazoles, voriconazole and posaconazole, might be promising since low in vitro MIC values were observed, but their effectiveness for treatment of chromoblastomycosis remains to be determined (71, 146, 188).

(Sub)cutaneous phaeohyphomycoses are caused by a diversity of black fungi belonging to unrelated genera such as *Alternaria, Aureobasidium, Bipolaris, Curvularia, Exophiala, Phaeoacremonium,* and *Phialemonium* (Fig. 1) (36, 97, 104, 110, 128, 174, 249). In vitro test results have shown that itraconazole, voriconazole, and terbinafine were active for these groups of fungi (121, 236, 237, 241, 249). Itraconazole is used as well as amphotericin B alone or in combination with flucytosine (241, 249).

For *Exophiala* species, the use of itraconazole alone or in combination with flucytosine has been reported to be effective and the new triazole, posaconazole, was shown to be active (36, 168), whereas the use of ketoconazole or miconazole appeared to be inadequate (129). The in vitro data for *Exophiala* species have demonstrated low MIC values for itraconazole, voriconazole, and terbinafine (236, 237).

The primary neurotropic dematiaceous fungi with a pronounced predilection for the central nervous system include *Cladophialophora bantiana, Exophiala dermatitidis, Ochroconis gallopava,* and *Ramichloridium mackenziei.* In vitro data have shown that amphotericin B, itraconazole, voriconazole, and terbinafine are active against *C. bantiana* and *O. gallopava* (121, 158). For treatment the following drugs have been used successfully: amphotericin B, liposomal amphotericin B, and the combination of itraconazole or voriconazole with

TABLE 2 Summary of diseases and generally applied treatments

Disease	Etiologic agents	Recommended treatments[a]	Reference(s)
Chromoblastomycosis	*Cladophialophora carrionii, Fonsecaea pedrosoi, F. monophora, Phialophora verrucosa*	TBF, ITZ, 5FC + TBF or ITZ, cryosurgery	73, 188
Subcutaneous mycosis	*Alternaria* spp., *Aureobasidium pullulans*, *Bipolaris* spp., *Curvularia* spp., *Exophiala* spp., *Phaeoacremonium parasiticum*, *Rhinocladiella similis, Phialemonium* spp.	ITZ, AMB + 5FC, ITZ + 5FC, PCZ, surgical excision	36, 168, 241
Cerebral mycosis	*Cladophialophora bantiana, Ochroconis gallopava, Ramichloridium mackenziei*	ITZ, AMB + 5FC, L-AMB, surgical excision, new triazoles (investigational)	192, 241
Sinusitis	*Bipolaris* spp., *Exserohilum* spp.	AMB, ITZ, surgical curettage, corticosteroids (allergic sinusitis)	25
Scedosporiosis	*Scedosporium apiospermum, S. prolificans*	VCZ + TBF, L-AMB, ABZ (investigational)	94
Sporotrichosis	*Sporothrix schenckii*	ITZ, TBF, AMB, VCZ, PCZ (investigational), potassium iodide solution, thermotherapy	188

[a] Abbreviations: AMB, amphotericin B; 5FC, 5-fluorocytosine; ITZ, itraconazole; L-AMB, liposomal amphotericin B; PCZ, posaconazole; TBF, terbinafine; VCZ, voriconazole.

amphotericin B. Ketoconazole, miconazole, or fluconazole is not recommended. In addition, surgical excision of the lesion has proven useful (78, 192).

Pleosporalean agents of sinusitis mostly are *Bipolaris, Curvularia,* or *Exserohilum*. For these infections, surgical curettage and initial treatment with amphotericin B is advised. Itraconazole should be given after surgery in order to prevent recurrence of the infection and has also led to improvement in patients who failed to respond to amphotericin B. Allergic sinusitis may require the administration of corticosteroids after surgery (25, 241).

In vitro data on *Scedosporium apiospermum, S. prolificans,* and *Sporothrix schenckii* have shown that amphotericin B was more active than itraconazole or voriconazole (121). Lymphocutaneous sporotrichosis can be treated effectively with orally administered itraconazole and potassium iodide solution. Thermotherapy is also useful. For sporotrichosis, itraconazole, amphotericin B, or the new triazoles are applicable, although the last require more investigation (189). *Scedosporium* infections are difficult to treat because these pathogens are often resistant to amphotericin B and several azoles, and thus, the therapeutic strategies are limited. The mortality rate among transplant recipients with scedosporiosis was reported to be 58%, and voriconazole was associated with a trend towards better survival than that obtained with amphotericin B (116). Voriconazole or itraconazole combined with terbinafine was reported to be synergistic in vitro, despite high MIC values for the drugs alone (94, 159). A successful outcome was observed in an orthopedic infection due to *S. prolificans* in a nonimmunocompromised host following treatment with the combination of voriconazole plus terbinafine, without radical surgery (94). The combination of new triazoles and amphotericin B at high doses seems to be better than monotherapy. Nevertheless, reversal of predisposing factors such as neutropenia remains essential (240). Cytokines and immunomodulation may be applicable, as was reported previously (241). One of the latest drugs, albaconazole, was evaluated in an immunocompetent rabbit model of systemic infection due to *Scedosporium prolificans* and showed promising efficacy exceeding that of amphotericin B at a dose of 50 mg/kg of body weight (30).

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

More than 100 species of melanized fungi have caused infection in humans and animals, and many of these are relatively rare as etiologic agents. As a result, few clinicians are familiar with these fungi and they are frequently overlooked. Infections caused by dematiaceous fungi are being diagnosed increasingly among healthy as well as compromised patients. Concurrently, the expanding diversity of etiology within this group of fungi is becoming apparent.

Determining whether a particular dematiaceous fungus is involved in a disease process can be difficult because most of these fungi occasionally are recovered as contaminants from clinical specimens. Repeated recovery of a suspected etiologic agent is significant, while sequence identity of clinical material and the isolate is highly supportive. Isolation of a dematiaceous fungus from a normally sterile body site should not be dismissed as contamination, particularly if colonies are numerous or more than one culture vessel shows growth. The isolation from a nonsterile pulmonary specimen, such as skin, sputum, or bronchial lavage fluid, of well-documented opportunists from genera such as *Cladophialophora, Fonsecaea, Ochroconis,* or *Scedosporium,* which are not seen as contaminants, also is highly indicative.

Fungi Causing Eumycotic Mycetoma

G. SYBREN DE HOOG, ABDALLA O. A. AHMED, MICHAEL R. McGINNIS, AND ARVIND A. PADHYE

126

TAXONOMY

All fungi known to cause eumycetomata are supposed to belong to the division Ascomycota, although for many species no ascigerous state is known (23). Ordinal relationships are then hypothesized on the basis of ribosomal small subunit DNA sequences (21) (Table 1; see also listing per order below). The etiologic agents described in this chapter are species that are isolated most commonly from human or lower-animal mycetomata.

DESCRIPTION OF AGENTS

Curvularia geniculata (Pleosporales)

The common saprobe *Curvularia geniculata* (Fig. 2) has occasionally been reported as an etiologic agent of mycetoma in dogs in the United States (13). Its grains are black to dark brown, firm, and 0.5 to 1.0 mm or more in size. In tissue sections, grains are spherical, ovoid, or irregularly shaped and are often surrounded by a zone of epithelioid cells. The periphery of the grain is a dense, interwoven mass of dematiaceous mycelium and thick-walled, chlamydospore-like cells embedded in a cement-like substance. The interior of the grains is vacuolar and consists of a loose network of septate, hyphal filaments.

In culture, *C. geniculata* develops a rapidly growing, floccose to downy, olive-gray to black colony. Microscopically, the melanized, septate hyphae bear solitary, geniculate conidiogenous cells. The conidia are without protruding hila. They are smooth walled, predominantly five-celled, curved, with the swollen median cell pale to dark brown, in contrast to the lighter end cells.

Curvularia lunata (Pleosporales)

The ubiquitous saprobe *Curvularia lunata* (Fig. 3) has exceptionally been described as an etiologic agent of mycetoma in humans in Senegal and Sudan (51, 82). Its grains resemble those of *C. geniculata* in their morphologic characteristics. In culture, *C. lunata* produces geniculate conidiophores that are sympodial in their development. Conidia are without protruding hila. They are smooth and predominantly four-celled, with the penultimate cell being pale to dark brown.

Exophiala jeanselmei (Chaetothyriales)

E. jeanselmei (Fig. 4) has been reported as an agent of eumycetoma in India (86, 87), Malaysia, Thailand (71), Argentina (66), and the United States (67), but only a few cases (46, 65) have been confirmed by molecular data (25). In host tissue, *E. jeanselmei* produces dark sclerotia that are brown to black, irregular in shape, and fragile. Detached portions or fragments of the sclerotia often are found within giant cells. When extruded through fistulae, the grains often look like worms (vermiform) because of their elongated shapes and irregular surfaces. In tissue sections, they appear as hollow structures or as sinuous bands that are vermiform. The external surface is composed of brown, thick-walled hyphae and thick-walled chlamydospore-like cells. The grains are cement free. Within the hollow grains, smaller, degenerated hyphal fragments with leukocytes and giant cells may be seen.

Initially, the colonies of *E. jeanselmei* may be yeast-like and black, gradually spreading, becoming raised or dome shaped, with limited expansion growth. After 2 weeks on Sabouraud dextrose agar (SDA), the colonies are covered with short aerial hyphae and appear olive-gray with an olive-black reverse. Microscopically, annellidic, rocket-shaped conidiogenous cells are inserted at right angles on undifferentiated hyphae. The septate mycelium is sometimes toruloid, branched, and pale brown. The conidia, which aggregate in masses at the tips of annellides, tend to slide down the conidiophore or along the hyphae. The smooth conidia are exogenous, nonseptate, subspherical, and ellipsoidal to cylindrical, measuring 1.5 to 2.8 μm.

Recently Guillot et al. (35) reported a canine mycetoma caused by a related fungus, *Cladophialophora bantiana* (Chaetothyriales), a species that in humans causes nearly exclusively brain infections (41).

Fusarium falciforme (Hypocreales)

Fusarium falciforme (85) (Fig. 1), previously known as *Acremonium falciforme,* is occasionally found as a cause of mycetoma in the United States (38, 60). It was also reported as the cause of an opportunistic infection in a renal transplant recipient (30). The grains of *F. falciforme* are white to pale yellow, soft, and 0.2 to 0.5 mm in diameter. They are composed of slender, polymorphic, septate hyphae 1.5 to 2.0 μm in diameter with irregular bulbous swellings and peripheral cementing material.

Colonies of *F. falciforme* on SDA are slow growing, reaching 60 to 65 mm in diameter in 2 weeks. They are downy and gray-brown, becoming gray-violet. The reverse of the colony

TABLE 1 Overview of main species causing eumycotic mycetoma

Species	Geography	Color of grains	Phylogeny
Curvularia geniculata	Worldwide	Black	Pleosporales
Curvularia lunata	Worldwide	Black	Pleosporales
Exophiala jeanselmei	Worldwide	Black	Chaetothyriales
Fusarium falciforme	Worldwide	Whitish	Hypocreales
Leptosphaeria senegalensis	West Africa, India	Black	Pleosporales
Madurella grisea	South America, India	Black	Pleosporales
Madurella mycetomatis	East Africa, Middle East	Black	Sordariales
Neotestudina rosatii	Central Africa	Whitish	Sordariales
Phaeoacremonium spp.		Black	Diaporthales
Pseudallescheria boydii	North and South America	Whitish	Microascales
Pyrenochaeta mackinnonii	Central and South America	Black	Pleosporales
Pyrenochaeta romeroi	Arid subtropics	Black	Pleosporales

develops a violet-purple pigment. The hyphae are hyaline, septate, smooth, branched, and 1.5 to 2.5 μm in diameter. They bear erect, undifferentiated, unbranched, repeatedly septate conidiophores. The conidia are borne at the tip of phialidic conidiogenous cells, where they accumulate in mucoid clusters. The conidia are allantoid, slightly curved, and nonseptate to monoseptate and measure 7 to 8.5 by 2.7 to 3.2 μm. The intercalary or, rarely, terminal chlamydospores are smooth, thick walled, and 5 to 8 μm in diameter.

Leptosphaeria senegalensis (Pleosporales)

L. senegalensis and the related species *L. tompkinsii* cause mycetomata in the northern tropical portion of West Africa, especially in Senegal and Mauritania, and in India. The grains of the two species are indistinguishable from each other. They are black, 0.5 to 2 mm in size, and firm to hard. In tissue sections, the grains are round to polylobulated, with large vesicles. At the periphery, the mycelium is embedded in a black, cement-like substance. The central portion of each grain consists of a loose network of hyphae.

In culture, *L. senegalensis* and *L. tompkinsii* grow rapidly and produce gray-brown colonies. On cornmeal agar, both species produce ascostromata that are nonostiolate, scattered, immersed or superficial, globose to subglobose, black, and covered with brown, flexuous hyphae. The asci, produced after prolonged incubation on plant stems, are eight-spored, clavate to cylindrical, and double walled. The major difference between the two species is found in the ascospores, which differ in size, shape, septation, and the nature of the gelatinous sheath that surrounds them (27, 28).

Madurella grisea (Pleosporales)

M. grisea occurs as an etiologic agent of black grain mycetoma in South America, India, Africa, and North and Central America (50, 51). In the United States, five cases caused by *M. grisea* have been described (14, 61). As the fungus is strictly sterile, molecular confirmation is overdue for all these cases.

The grains are black, 0.3 to 0.6 mm in diameter, and soft to firm. In tissue sections, the grains are oval, lobulated or reniform, and sometimes vermiform. They are composed of a dense network of hyphae weakly pigmented in the center and brown to blackish brown in the peripheral region as the result of the presence of a brown, cement-like interstitial material.

In culture, *M. grisea* forms slow-growing, velvety colonies that are cerebriform, radially furrowed or smooth, and dark gray to olive-brown to black. The reverses of the colonies are black. Microscopically, the hyphae are septate, light to dark brown, 1 to 3 μm in diameter, and nonsporulating. Chlamydospores are rare. Large moniliform hyphae 3 to 5 μm in diameter are often present. Some isolates of *M. grisea* have been described as producing abortive or fertile pycnidia (56, 81). Such isolates are morphologically indistinguishable from *Pyrenochaeta mackinnonii* (11, 75), but rRNA internal transcribed spacer (ITS) sequence data (21) show large differences between these species.

Madurella mycetomatis (Sordariales)

Madurella mycetomatis is common in the arid climatic zone of West Africa (Sudan, Mali, and Djibouti) and is occasionally encountered in the Middle East and India. The grains produced by *M. mycetomatis* are reddish brown to black. They may reach 5 mm or more in diameter and are firm to hard. In tissue sections, the sclerotia are compact, variable in size and shape, and frequently multilobulated. They are composed of hyphae 1.2 to 5 μm in diameter that terminate in enlarged hyphal cells at the periphery of the grains, which measure 12 to 15 μm in diameter. The cell wall pigment is minimal, but hyphal cells contain brown particles. The hyphae are embedded in a conspicuous brown matrix that is characteristic of *M. mycetomatis*. Some grains are vesicular and more regular in size and shape. The vesicles are predominantly visible in the peripheral zone in a dense, brown, cement-like matrix.

In culture, *M. mycetomatis* shows wide variation. Colonies are slow growing and white at first, becoming olivaceous, yellow, or brown; flat or dome shaped; and velvety to glabrous, often with a rust brown diffusible pigment. On nutritionally deficient media, sclerotial bodies 750 μm in diameter develop. These are black and consist of undifferentiated polygonal cells. On SDA, the mycelium is sterile. On nutritionally poor media, such as soil extract or hay infusion agar, about 50% of the isolates produce round to pyriform conidia 3 to 4 μm in diameter at the tips of phialides. The phialides are tapering, ranging from 3 to 15 μm in length, often with an inconspicuous collarette (Fig. 5).

M. mycetomatis grows better at 37 than at 30°C, with a maximum of 40°C, whereas *M. grisea* grows better at 30 than at 37°C. *M. mycetomatis* is slowly proteolytic and utilizes glucose, maltose, and galactose but not sucrose. It utilizes potassium nitrate, ammonium sulfate, asparagine, and urea, and it hydrolyzes starch. *M. grisea,* on the other hand, is weakly

FIGURE 6 (bottom right) *N. rosatii.* Cross section of an ascocarp showing the ascomatal wall of interwoven hyphae and containing dark asci and ascospores. Magnification, ×250.

proteolytic and assimilates glucose, maltose, and sucrose but not lactose. Phylogenetic studies suggest that *M. mycetomatis* and *M. grisea* are distantly related. *M. mycetomatis* is probably a member of the order Sordariales, while *M. grisea* clusters with known members of the Pleosporales (21).

Neotestudina rosatii (Sordariales)

The sclerotia of *N. rosatii* are white to brownish white, 0.5 to 1.00 mm in diameter, and soft. In tissue sections, the sclerotia appear to be polyhedral to subregular and consist of hyphae, which are embedded, in the peripheral cementing material. The sclerotia manifest an eosinophilic border. The central portion of each sclerotium consists of more or less disintegrated mycelium and chlamydospores. Mycetomata caused by *N. rosatii* have been described in Australia, Cameroon, Guinea, Senegal, and Somalia (54, 80).

In culture, colonies of *N. rosatii* are slow growing, attaining diameters of 25 to 28 mm in 2 weeks, and have an aerial mycelium that is grayish black to brownish black. On potato-carrot or cornmeal agar incubated at 30°C, most of the ascomata are submerged. The ascostromal walls are smooth and are surrounded by interwoven brown to hyaline hyphae. The eight-spored asci, 12 to 35 by 10 to 25 μm, are scattered in the central part of the ascostroma (Fig. 6) and are globose to subglobose, thick walled, and bitunicate, becoming evanescent as the ascospores mature. The ascospores vary in size (9 to 12.5 by 4.5 to 8.0 μm) and shape, ranging from ellipsoidal to bicampanulate, asymmetrical, or slightly curved; are constricted at the median transverse septum; and have brown smooth walls.

Phaeoacremonium (Diaporthales)

Members of the genus *Phaeoacremonium,* morphologically characterized by slender, gradually tapering, melanized conidiophores with narrow phialide openings producing ellipsoidal to reniform conidia, are occasionally reported as agents of mycetoma. de Albornoz (19) described a case of infection by *P. inflatipes,* Rowland and Farrar (76) and Mostert et al. (63) described cases of infection by *P. krajdenii,* and Hood et al. (40) described a case of infection by *P. parasiticum.*

Pseudallescheria boydii (Anamorph: *Scedosporium apiospermum*) (Microascales)

Grains in tissue are white to yellowish white and soft to firm; they vary from globose to subglobose or lobulated and are 0.2 to 2.0 mm in diameter. They are composed of hyaline hyphae 1.5 to 5.0 μm in diameter that radiate from the center into terminal thick-walled cells 15 to 20 μm in diameter at the peripheries. The central portion of each grain consists of loosely interwoven hyaline mycelium.

Colonies grow rapidly and are floccose and white at first, becoming gray as conidia are produced. With age, the colonies become dark grayish brown. Submerged ascocarps (cleistothecia) (Fig. 9) may be produced when isolates are grown on cornmeal agar and are visible macroscopically as small black dots. They are globose, nonostiolate, 140 to 200 μm in diameter, and often covered with brown, thick-walled, septate hyphae 2 to 3 μm wide. They have a wall 4 to 6 μm thick that is composed of two or three layers of interwoven, flattened, dark brown cells, each 2 to 6 μm wide. The cleistothecia open at maturity by an irregular rupture of the wall. The eight-spored asci are ellipsoidal to nearly spherical and 12 to 18 by 9 to 13 μm. The ascospores are ellipsoidal to oblate, symmetrical or slightly flattened, and 6 to 7 by 3.5 to 4.0 μm; are straw colored; and have two germ pores.

The anamorph, *Scedosporium apiospermum* (Fig. 7), produces conidia that are oval to clavate, truncate, and subhyaline, becoming pale gray to pale brown in mass. Conidia are produced singly. They remain attached at the tips of annellides. Annellations can be detected at the tips of conidiogenous cells as swollen rings. Some isolates also produce a *Graphium* synanamorph (Fig. 8), which is characterized by rope-like bundles of hyphae with annellidic conidiogenesis. The hyphae are fused into long stalks known as synnemata. The conidia produced are hyaline, cylindric to clavate, and truncate at the base. A fungus consisting of elongate, multicellular conidia and described as *Polycytella hominis* (15) was recently proven to be a degenerate anamorph of *P. boydii* (12).

P. boydii is the most common agent of mycetoma in humans as well as lower animals in temperate climates (16), occurring mostly in the limbs (91). Subcutaneous infections frequently lack the formation of grains when the patients' immunity is impaired (70). In addition, arthritis is frequently observed, the species having a predilection for cartilaginous tissues (34, 39, 48, 68). More often it is encountered as an opportunist in respiratory specimens from patients with lung disease (84) and is particularly observed in lungs of patients with cystic fibrosis (20), where it is often concealed by the abundant presence of *Aspergillus fumigatus*. Although its virulence is low, cases of dissemination from lungs to vital organs have been observed (96). Of particular significance is the species' neurotropism, potentially leading to fatal brain abscesses (42, 43). This syndrome is frequently noted after severe debilitation, e.g., after near-drowning, but interestingly also after dissemination from a traumatic, mycetoma-like infection (41).

Pyrenochaeta romeroi (Pleosporales)

Mycetomata caused by *P. romeroi* (Fig. 10) have been reported from Somalia, India, and South America (9, 44, 54). *P. romeroi* produces soft to firm black sclerotia that are oval, lobulated, and sometimes vermiform. They resemble those of *M. grisea* (81).

In culture, colonies of *P. romeroi* are fast growing and floccose to velvety, with a gray surface and whitish margin. The reverse of the colony is black, with no diffusible pigment. On nutritionally deficient media such as oatmeal agar under near-UV light, pycnidia develop after 3 to 4 weeks. The conidiomata are subglobose, 80 to 160 μm in diameter, and dark brick to fawn, later becoming dark brown with short necks. They are ostiolate, and setae around ostioles are septate and roughened and measure 80 to 100 by 3 μm. The conidiophores inside the conidiomata are sparse and have lateral branches. Conidiogenous cells are hyaline and are borne on branches or arise directly from cells lining the conidiomatal cavity, which produce hyaline to yellowish, shortly cylindrical conidia measuring 1 to 2 by 1.0 μm.

The close resemblance of the granules produced by the coelomycete *P. romeroi* and the gray cultures of that species suggests that *Madurella grisea* may be a nonsporulating counterpart of *P. romeroi*. However, Murray and Buckley (64) found serologic differences that allow differentiation between the two species. Romero and Mackenzie (75) studied culture filtrate and cellular antigens prepared from 14 agents of black sclerotial mycetoma by double diffusion and immunoelectrophoresis. They found up to 90% cross-reactivity among *M. grisea* isolates and between *M. grisea* and *Pyrenochaeta mackinnonii* but not between *M. grisea* and *P. romeroi.* Molecular data of rRNA ITS (21) show that all these species are very different from one another.

EPIDEMIOLOGY AND TRANSMISSION

The causal agents of eumycetoma are supposed to be saprobes that live on hard plant materials, such as various types of thorns and spines, associated with soil (5, 8, 29, 49). Segretain and coworkers (80, 82), using specific isolation media and techniques, showed that *L. senegalensis* and *L. tompkinsii* could be recovered from about 50% of the dry thorns of *Acacia* trees that they examined, particularly those that had been stained by mud during the rainy season. *N. rosatii* was reportedly isolated from sandy ground (54), and *M. mycetomatis* was isolated from soil and anthills (78, 79, 89). It should be noted, however, that the identity of these fungi has not been verified with molecular methods; the possibility that environmental strains do not always belong to the same species as the clinical strains cannot be excluded. *M. mycetomatis* is a common agent of mycetoma in the arid climate zones of East Africa but is difficult to isolate directly from the environment (1). Some predilection for human invasion must exist.

Borelli (10) isolated another sterile fungus, reported as *Madurella grisea* from soil in Venezuela; the ecological niche and clinical potential of this rare species have not yet been determined. *P. boydii* is associated with manure and polluted environments (24, 32) and has been known as an agent of human mycetoma in temperate climates since the 1920s (83).

Mycetoma may infect all people living in areas of endemicity but develops more commonly among persons who are in contact with contaminated materials, such as field workers, farmers, and fishermen. Areas of endemicity are particularly located in tropical climate zones. *M. mycetomatis* is limited to semiarid to arid climates, while *Leptosphaeria* species are found in the rain forest. Locally acquired mycetomata in temperate climates invariably concern *P. boydii*. Cases observed in the United States and Europe caused by species other than *P. boydii* are imported by immigrants from tropical countries. For example, de Hoog et al. (22) reported cases in The Netherlands originating from Indonesia and Suriname, while cases of *M. mycetomatis* in France originated from Mali (2).

Climate has a definite influence on the prevalence and distribution of mycetomata. Rivers that flood each year during the wet season in many countries of Africa and Asia influence

the distribution of the causal agents. Rainfall also aids the spread of the etiologic agents on organic matter (26).

CLINICAL SIGNIFICANCE

A mycetoma (plural, mycetomata) (58) is a localized, chronic, noncontiguous, granulomatous infection involving cutaneous and subcutaneous tissues and eventually, in some cases, bones. Mycetomata are generally confined to either the feet or the hands but occasionally affect sites such as the back, shoulders, buttocks, and, rarely, the scalp. The lesions contain granulomata and abscesses that suppurate and drain through fistulae to the skin surface. The pus contains grains (57) that vary from approximately 0.2 to over 5 mm in diameter. The size, color, shape, and internal architecture of the sclerotia vary depending on the species of the etiologic agent. Mycetomata caused by actinomycetes are called actinomycetomata, and those incited by filamentous fungi are referred to as eumycetomata. Eumycetomata, in contrast to actinomycetomata, have a hyphal substructure. The disease is more commonly seen in humans than in lower animals. Only a few cases of mycetoma involving such animals as dogs, horses, and goats have been described in the literature (6, 13, 45, 52).

Fungus balls or fungomata in preexisting lung cavities are sometimes inappropriately called mycetomata (31, 36). In the absence of well-organized grains, they should be referred to, depending on the etiologic agent, as aspergillomata, or simply as fungus balls (55). Similarly, mycelial aggregates formed by dermatophytes in cutaneous or subcutaneous tissues differ from grains of mycetomata by lacking granule ontogeny, a distinct Splendore-Hoeppli reaction (an immune reaction seen histologically as an eosinophilic deposit) surrounding the mycelial aggregates, and the entry of the fungus from the hair follicles into deeper tissue following the rupture of the follicular epithelium. Such infections caused by dermatophytes have been referred to as pseudomycetomata (7).

A mycetoma develops after a traumatic injury by microbe-contaminated thorns, splinters, fish scales or fins, snake bites, insect bites, farm implements, and knives. Most cases occur in otherwise healthy patients. The development of mycetoma after an accidental implantation of the etiologic agent following surgery (69) and in a renal transplant recipient (30) has been reported. The initial lesion is often characterized by a feeling of discomfort and pain at the point of inoculation. Weeks or months later, the subcutaneous tissue at the site of inoculation becomes indurated, abscesses develop, and fistulae may drain to the surface. Mycetomata are characterized by swelling, granulomata, abscesses, and sinuses from which serosanguinous fluid containing fungal grains is discharged. The mycetoma develops slowly beneath thick fibrosclerous tissue. The subsequent phase of proliferation involves the invasion of muscles and intramuscular layers by portions of the sclerotium that break free from their parent structure. The granulomatous lesions can extend as deep as bone, where severe bone destruction, formation of small cavities, and complete remodeling may occur. Early osteolytic damage includes loss of the cortical margin and external erosion of the bone. As the infection progresses, blood, lymphatic vessels, and nerves may be damaged. Frequently, secondary bacterial infections and osteomyelitis producing total bone destruction occur. Pain is often associated with the development of multiple fistulae. Regardless of the etiologic agent involved, the organisms develop in the form of soft or hard, compact mycelial masses (grains) within the infected tissue. The hallmark of a mycetoma is a grain composed of compact mycelium. These structures frequently contain host tissue. Weathered et al. (92) described the cement surrounding grains of *M. mycetomatis* as being an amorphous, electron-dense material with areas containing different-size membrane-bound vesicular inclusions. Some of the host material, especially at the periphery of the grain, provides a protective barrier for the fungus against antifungal agents and humoral immunological responses such as antibodies.

DIRECT EXAMINATION

The grains of eumycetomata are composed of septate mycelial filaments at least 2 to 4 μm in diameter. The mycelium may be distorted and unusual in form and size, and the cell walls of the fungi, especially toward the periphery of the grains, are thickened. Vesicles are frequently present, especially at the periphery of the grain. The mycelium of the grains may be embedded in a cement-like substance, depending on the species involved. Often the sclerotia elicit an immunologic response, known as the Splendore-Hoeppli reaction (antigen-antibody) (17, 58). This reaction is seen histologically in the form of a deposit of amorphous material around the grain. A similar tissue reaction has been described in experimental eumycetoma in mice (4).

Grains are white or yellow-brown with agents mostly producing hyaline mycelium, and black in the case of melanized etiologic agents. Melanin is a high-molecular-weight compound that is anchored to extracellular proteins. A precursor for production of melanin in ascomycetous fungi is 1,8-dihydroxynaphthalene (57, 58). Reports of hyaline fungi such as *Acremonium kiliense* and *Fusarium solani* var. *coeruleum* forming black grains (88) are probably erroneous. Etiologic agents with melanized hyphae or conidia such as *Phaeoacremonium inflatipes* and *Pseudallescheria boydii* produce whitish grains in tissue (18, 19, 49, 59). Melanin production in *Phaeoacremonium* is facultative, while in *P. boydii* dark pigmentation is limited to the conidia. Although the gross and microscopic characteristics of the grains provide insight into the identity of the etiologic agent or a particular group to which it belongs (74), definitive identification of the etiologic agent should be based on isolation of the same fungus from several grains. Physicians should avoid planning a patient's therapy based on grain morphology in clinical materials alone; rather, results of laboratory diagnosis should be awaited.

Nucleic Acid Detection Techniques

Molecular diagnostics has been developed for a number of selected agents. The black yeast *Exophiala jeanselmei* is recognizable by sequence data of the rRNA ITS region (25). Agents of the genus *Phaeoacremonium* can be identified using the same marker (62, 63). Molecular phylogeny and diagnostics of members of the genus *Madurella* based on the ribosomal operon showed that the genus encompasses a hidden diversity beyond the two currently recognized species (21). rRNA restriction fragment length polymorphism was used for species distinction by Ahmed et al. (2, 3), and a specific ITS-PCR was used by Ahmed et al. (3). Van de Sande et al. (90) in an amplified fragment length polymorphism study revealed clones differing in virulence and geographic distribution.

Also the genus *Pseudallescheria* comprises a larger number of species than supposed originally (33, 72). On the basis of multigene sequence data, Gilgado et al. (33) described several new taxa. The ITS region can be used as a marker. PCR-based assays for rapid diagnosis of *Scedosporium apiospermum*

infections from infected tissue are useful (37, 53). Wedde et al. (93) developed specific primers based on ITS rRNA sequences. Given the large infraspecific variability of the species, a less variable region, such as the 26S rRNA operon (77), might also provide successful detection of *S. apiospermum*-like genotypes. Willinger et al. (95) used this marker for detection of *S. apiospermum* and similar organisms from fungus balls in the maxillary sinus. Subspecific typing of *S. apiospermum* at the population level is unproblematic because of the large degree of heterogeneity. Rainer et al. (73) found with M-13 fingerprinting that nearly all strains analyzed belonged to another genotype; several genotypes could be recovered from a single sampling site. The high degree of polymorphism enabled Zouhair et al. (96) to monitor the dissemination of a strain colonizing the lungs of a patient with cystic fibrosis to cutaneous locations by using multilocus enzyme electrophoresis and randomly amplified polymorphic DNA. In a longitudinal study, Defontaine et al. (20) analyzed nine patients with cystic fibrosis, none of which were found to share the same genotype.

Isolation Procedures

To maximize the chances of obtaining pure cultures of the etiologic agents, grains from the eumycotic mycetomata should be washed several times with saline containing antibacterial antibiotics such as penicillin and streptomycin. The grains are then cultured on SDA containing chloramphenicol (50 mg/liter) and SDA containing chloramphenicol and cycloheximide (500 mg/liter) in petri dishes. Plates should be incubated at 25 and 37°C. Because many of the fungi that cause mycetoma grow slowly, culture plates should be incubated for 4 weeks before being discarded as negative. Identification of the isolated fungus is based on gross morphology of fruit bodies and conidia, if present. Certain species *(M. grisea, M. mycetomatis, N. rosatii, Pyrenochaeta mackinnonii,* and *P. romeroi)* do not sporulate readily but can be recognized by molecular techniques, particularly sequencing of the rRNA ITS region (3, 93).

ANTIMICROBIAL THERAPY

The treatment of eumycotic mycetoma is challenging. Antifungal therapy often has to be combined with debridement (surgical removal of infected tissue) when possible (94). Prolonged antifungal therapy usually is necessary to enhance the prognosis of these patients. Amphotericin B is commonly used to treat patients with eumycotic mycetoma; however, this drug is associated with several adverse reactions. Amphotericin B can be administered either intravenously or by inhalation (36). Itraconazole (36, 47) and ketoconazole (94) have been used successfully to treat eumycotic mycetoma patients and in general are associated with less severe adverse reactions than those observed with amphotericin B (36, 47). Fluconazole has been used to treat some patients but has shown poor results (94).

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

Because agents of eumycotic mycetoma are soil or plant saprobes, their etiologic role in mycetoma must be carefully established. A definitive diagnosis is based on the demonstration of grains in tissue, which are expelled through draining sinuses. Grains may become entangled on gauze bandages placed over fistulae.

Pus, exudate, or biopsy material should be examined for the presence of grains that are detectable with the naked eye. Their color, internal architecture, size, and shape give a fair indication of the identity of the possible etiologic agents. Actinomycotic mycetomata are differentiated from eumycotic mycetomata by the examination of crushed, Gram-stained grains. Actinomycotic grains, as well as coccoid and bacillary forms, are composed of gram-positive, interwoven, thin filaments, 0.5 to 1.0 μm in diameter. Grains of the eumycotic agents, on the other hand, are composed of broader, interwoven, septate hyphae, 2 to 5 μm in diameter, with many unusual-shaped, swollen cells up to 15 μm in diameter, especially at the periphery of the grains. In many species, the grains are embedded in cement-like material.

Mycotoxins

WILLIAM J. HALSALL, NANCY C. ISHAM, AND MAHMOUD A. GHANNOUM

127

Mycotoxins are nonvolatile secondary metabolites produced by many different species of ubiquitous fungi having adverse effects on humans and animals. For many years, interest in mycotoxins centered on contamination of agricultural products with mycotoxin-producing fungi and the health effects of consumption of or direct contact with these products. Recently, two events brought interest in mycotoxins to the forefront: (i) the report of black mold as the possible cause of acute idiopathic pulmonary hemosiderosis in newborn infants in Cleveland, Ohio, which suggested that the presence of fungi in buildings (termed sick building syndrome [SBS]) could have deleterious health effects, and (ii) the flooding of New Orleans, La., and the Gulf Coast as a result of Hurricane Katrina. This flooding led to extensive fungal proliferation in homes and businesses and may require the demolition of affected buildings. In this chapter we review various mycotoxins and their relevance to food safety, SBS, veterinary problems, and bioterrorism. We do not describe the health effects of mycotoxins, as this topic has been reviewed extensively elsewhere (15, 30, 33, 38, 44, 61, 62, 70). The reader is also referred to an excellent review on mycotoxins by Bennett and Klich (6).

TAXONOMY

Fungi are eukaryotic organisms with cell walls containing chitin and/or cellulose that belong to the kingdom Fungi. A large number of fungi produce mycotoxins, but the majority of these belong to the anamorphic form-class Hyphomycetes. They may be either hyaline (colorless), such as *Aspergillus, Fusarium,* and *Penicillium* spp., or dematiaceous (darkly pigmented), like *Stachybotrys chartarum*.

MAJOR CATEGORIES OF MYCOTOXINS

Not all toxic compounds produced by fungi are classified as mycotoxins; for example, compounds mainly toxic to bacteria are termed antibiotics, while those toxic to plants are called phytotoxins (6). There are some 300 to 400 compounds, toxic to vertebrates in low concentrations, which are currently recognized as mycotoxins. Table 1 provides a listing of some of the most commonly encountered mycotoxin-producing fungi, many of which produce more than one mycotoxin class.

Aflatoxin

The aflatoxin class of mycotoxins is one of the first to be discovered and studied. Some of the most common aflatoxins (Fig. 1) (6) are aflatoxins B_1, B_2, G_1, and G_2 (based on their blue or green fluorescence under UV light) (86), with aflatoxin B_1 being the most potent natural carcinogen known (74).

Aflatoxins are produced by several species of *Aspergillus,* in particular, *Aspergillus flavus* and *Aspergillus parasiticus*. *A. flavus* is a common contaminant of agricultural products, among which are cereals, rice, figs, nuts, and tobacco (17, 18, 71). Contamination of crops can occur in the fields before harvest, especially in times of drought (18, 36), or during storage, depending upon the moisture content of the substrate and the relative humidity of the storage conditions (17, 82).

Aflatoxin contamination can be the cause of a variety of economic and health problems. For instance, the presence of aflatoxin in grain significantly lowers the grain's value as feed or an export commodity because of the toxin's link to increased mortality in farm animals (72). Further, ingestion of aflatoxin by dairy cows can lead to the presence of aflatoxin M_1 (a hydoxylated form of B_1) in the milk (79).

There are substantial differences in the susceptibilities of different vertebrate species to aflatoxin exposure. One of the first indications of the effects of aflatoxins was observed in 1960, when more than 100,000 turkey poults died from aflatoxin-contaminated feed, an outbreak named "turkey X" disease (1, 8). Other outbreaks have occurred in ducklings and chickens (3), swine (26, 45), and calves (46), due mostly to contaminated Brazilian peanut meal used as feed. The most recent and notable outbreak of acute aflatoxicosis occurred in Kenya, Africa, in 2004 in humans (4, 10, 43). This outbreak illustrates the need for a regulatory body to monitor the amount of mycotoxins present in foods meant for human consumption, a luxury not normally available to developing countries.

Citrinin

Citrinin (Fig. 2) (6) is a simple, low-molecular-weight compound that crystallizes as lemon-colored needles. It had been tested for use as an antibiotic (41, 42, 87) and as a treatment for ulcers (41) before its mycotoxic effects were discovered.

The most common organisms producing citrinin are *Penicillium citrinum, Penicillium expansum, Penicillium viridicatum, Penicillium camembertii* (used to produce cheese), *Aspergillus niveus, Aspergillus oryzae* (used to produce sake and

TABLE 1 Simplified taxonomy of mycotoxin-producing fungi

Mycotoxin class	Genus(era)	Representative species
Aflatoxin	*Aspergillus*, *Penicillium*	*A. fumigatus, A. flavus, A. parasiticus, P. puberulum*
Citrinin	*Penicillium*	*P. citrinin, P. expansum*

Fumonisin	*Fusarium*	*F. verticillioides* (syn. *F. moniliforme*), *F. proliferatum*
Ochratoxin	*Aspergillus*, *Penicillium*	*A. ochraceus, P. verrucosum*
Patulin	*Aspergillus*, *Byssochlamys*, *Penicillium*	*A. clavatus, B. fulva, B. nivea, P. griseofulvum, P. expansum*
Trichothecene	*Stachybotrys*	*S. chartarum*
Zearalenone	*Fusarium*	*F. crookwellense, F. culmorum, F. graminearum, F. semitectum*

soy sauce), *Aspergillus terreus,* and *Monascus* spp. (used to produce red food dyes) (11).

Citrinin, first isolated from *P. citrinum,* has been associated with Japanese yellow rice disease (68). It has also been found in various other grains, peanuts, and fruit, and there is limited evidence of it surviving unchanged in cereal food products (6). Citrinin has demonstrated nephrotoxic effects on all animal species tested (9) and was shown to inhibit dehydrogenase activity in rats' kidneys, liver, and brain (28). However, there have been no reported outbreaks of human citrinin poisoning, and its relevance to human health is unknown.

Ergot Alkaloids

Ergot alkaloids, produced by the ergot fungus *Claviceps purpurea,* are the causative agent of ergotism (also called St. Anthony's fire), which can manifest in either a gangrenous or convulsive condition following ingestion of contaminated grains (especially rye) (5). Two main classes of ergot alkaloids exist: lysergic acid derivatives and clavines. Both are indole alkaloids derived from a tetracyclic ergoline ring system. Lysergic acid, a component common to all ergot alkaloids, often forms amide, amino acid, or peptide derivatives (e.g., ergine, ergonovine, lysergic acid diethylamide [LSD], and ergovaline). The clavines contain the ergoline structure but do not have amino acid or peptide components (e.g., pergolide and lisuride) (5). A representative chemical structure, ergotamine, is shown in Fig. 3 (6).

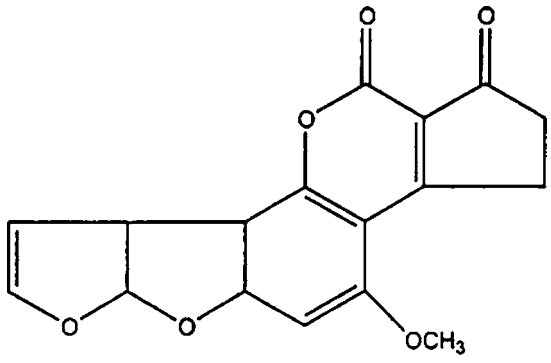

FIGURE 1 Aflatoxin B_1. (Reprinted from reference 6 with permission.)

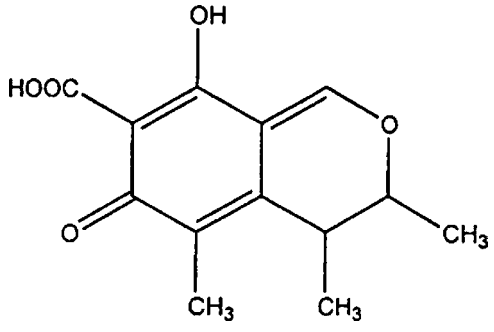

FIGURE 2 Citrinin. (Reprinted from reference 6 with permission.)

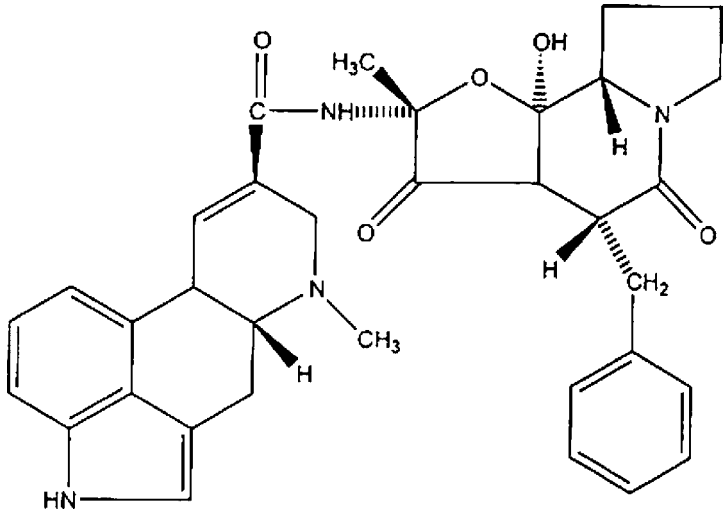

FIGURE 3 Ergotamine. (Reprinted from reference 6 with permission.)

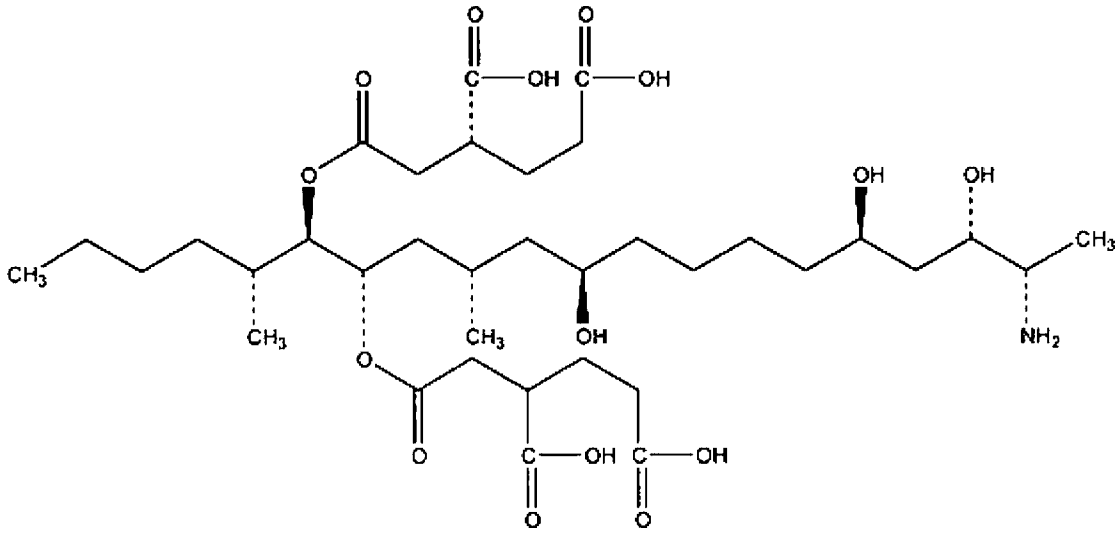

FIGURE 4 Fumonisin B_1. (Reprinted from reference 6 with permission.)

Semisynthetic ergot alkaloids have been developed through decades of research, which began with the series of lysergic acid derivatives that included the infamous hallucinogen LSD (21). Most recently, ergot alkaloids have been investigated for their anticancer potential (22), as well as their effect on serotonin and serotonin receptors (63, 85). However, definition of the mechanisms of action for the myriad of ergot alkaloids is beyond the scope of this chapter.

Aspergillus, Balansia, Claviceps, Epichloë, and *Neotyphodium* spp. have been found to produce ergot alkaloids. *Aspergillus fumigatus* has been shown to produce fumigaclavines A, B, and C and festuclavine (first described for *C. purpurea* and later for *Neotyphodium* spp.) (13, 60).

Modern methods of cleaning grains have all but eliminated the threat to the human food chain. However, ergotism remains an important veterinary concern, as symptoms of gangrene, convulsions, and abortion in cattle, sheep, pigs, and chickens mimic those in humans (47).

Fumonisin

Fumonisins (Fig. 4) (6) are among the most recently discovered mycotoxins. In 1988, Gelderblom et al. (25) determined that fumonisins produced by *Fusarium verticillioides* (then called *F. moniliforme*) were the causative agent of leukoencephalomalacia in horses (50) and hepatocarcinoma in rats (35, 51). As of 2002, there were 28 known fumonisin analogs, separated into four main groups: A, B, C, and P (64).

Fusarium proliferatum, Fusarium nygamai, Alternaria alternata, and *Gibberella fujikuroi*, the teleomorph (sexual form) of *F. verticillioides,* also produce these mycotoxins (16). The reader is referred to Rheeder et al. (64) for a review of the taxonomy of fumonisin-producing fungi.

Besides the syndromes mentioned above, fumonisins have also been shown to cause pulmonary edema and hydrothorax in swine (27). *F. verticillioides,* the major producer of fumonisins, can have an important economic effect on the supply of corn, as it can cause a variety of blights and rots depending on environmental conditions (57).

Ochratoxin

Ochratoxins A and B (OTA and OTB) (Fig. 5) (6) are produced by *Penicillium verrucosum* and many species of *Aspergillus,* especially *Aspergillus ochraceus*. These toxins can be carcinogenic, immunosuppressive, and nephrotoxic (39, 73).

OTA, first discovered to be toxic to animals in 1965 (78), is more common than OTB and can be metabolized after ingestion by cytochrome P450 liver enzymes (89).

Ochratoxins are found most often in contaminated barley but may also be present in oats, rye, wheat, and coffee beans (6, 80). They are of particular concern because of their ability to be carried through the food chain, especially in milk and in the tissues of pork (20, 52). Scandinavian countries (Denmark in particular) have had a high incidence of porcine nephropathy and high levels of OTA contamination (37).

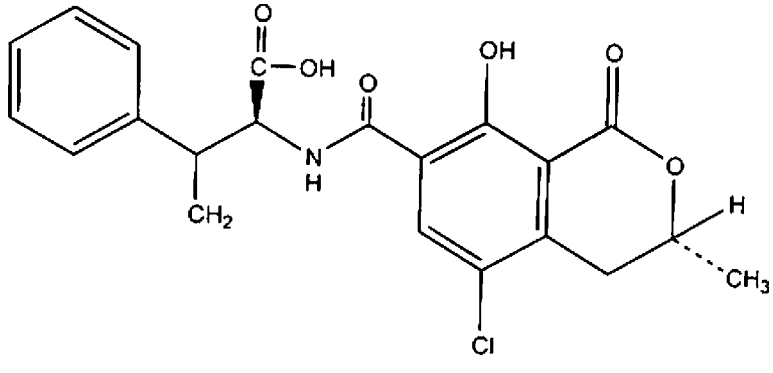

FIGURE 5 OTA. (Reprinted from reference 6 with permission.)

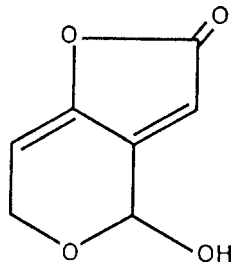

FIGURE 6 Patulin. (Reprinted from reference 6 with permission.)

Patulin

Patulin (Fig. 6) (6) was first isolated in the 1940s from *Penicillium griseofulvum,* and efforts were made to mass-produce this mycotoxin for its antibiotic effects (58). However, patulin was reclassified as a mycotoxin in the 1960s, following the discovery of its toxicity to plants and animals (6).

One of the most common occurrences of patulin is in unfermented juices made from fruit contaminated with *P. expansum* (77). Patulin is toxic at high concentrations in vitro, but natural poisoning in humans has yet to be proven (6).

Trichothecenes

Trichothecene mycotoxins are secondary metabolites of a variety of *Fusarium* spp., but also of *Myrothecium, Phomopsis, Stachybotrys, Trichoderma,* and *Trichothecium,* among others. Some of the most common and well-studied *Fusarium* trichothecenes (Fig. 7) (6) are T-2 toxin, HT-2 toxin, diacetoxyscirpenol, nivalenol, and deoxynivalenol (also called DON or "vomitoxin"). Deoxynivalenol is one of the most common mycotoxins found in grain, including barley, oats, rye, and wheat. When ingested in large quantities by agricultural animals, it can cause nausea, vomiting, and diarrhea; ingestion of smaller quantities results in weight loss and feed refusal (67). DON can also suppress bovine and porcine neutrophil function in vitro (76).

S. chartarum produces several macrocyclic trichothecenes, including verrucarins B and J; roridin E; satratoxins F, G, and H; and isosatratoxins F, G, and H (32, 34). *Stachybotrys*-contaminated straw was first described as causing a highly fatal equine disease (24) and has since become better known as a factor in SBS, discussed below.

Zearalenone

Zearalenone (Fig. 8) (6) is a nonsteroidal estrogen or phytoestrogen produced by various species of *Fusarium*, including *Fusarium roseum* and *Fusarium tricinctum* (19). Zearalenones are common contaminants of cereal crops worldwide and have been implicated in the hyperestrogenism of farm animals as a result of digestion of moldy corn and grains (29, 54, 55). Some of the symptoms of hyperestrogenism are enlargement of the uterus and nipples, vaginal prolapse, and infertility (56).

MAJOR HEALTH RISKS ASSOCIATED WITH MYCOTOXINS

Food Safety

Consumption of moldy food products is the leading cause of mycotoxicoses in agricultural animals and humans alike.

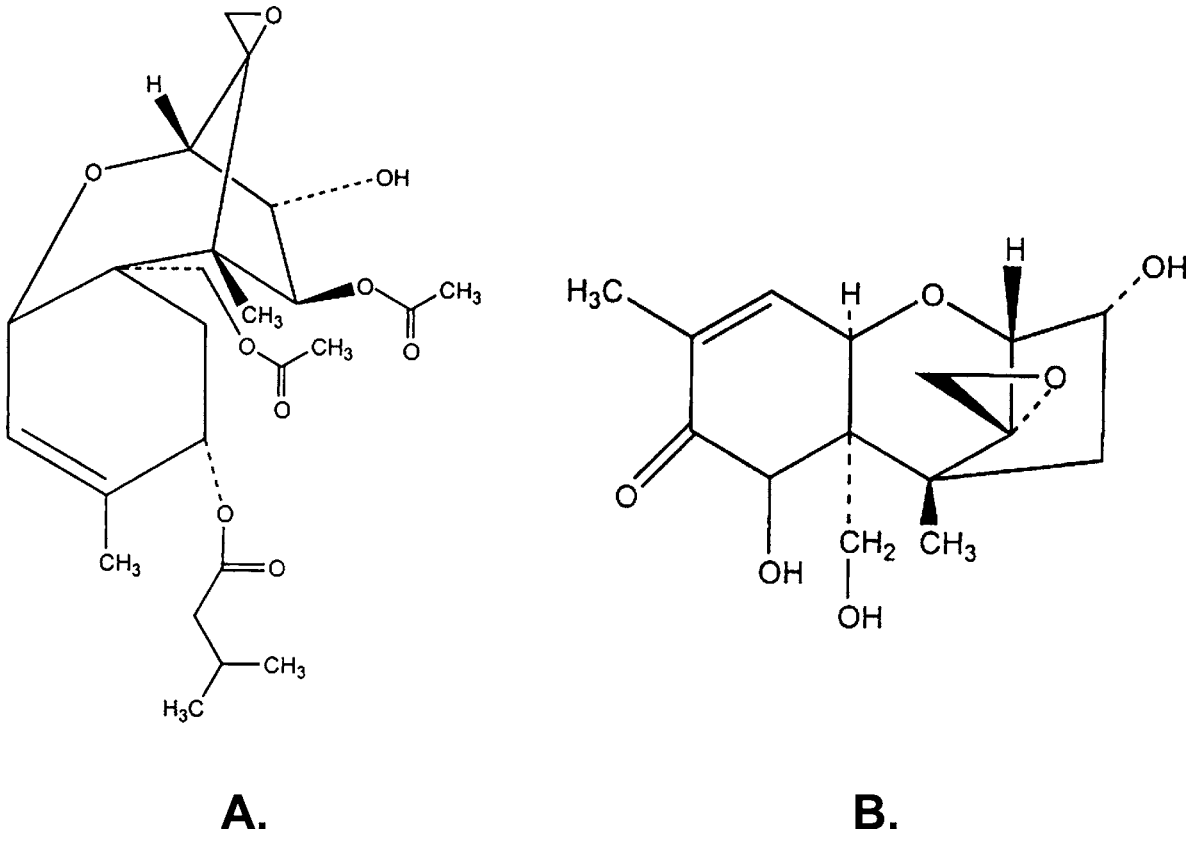

FIGURE 7 (A) T-2 toxin; (B) deoxynivalenol. (Modified and reprinted from reference 6 with permission.)

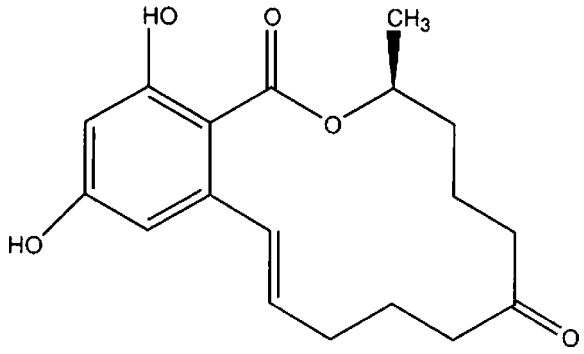

FIGURE 8 Zearalenone. (Reprinted from reference 6 with permission.)

Tables 2 and 3 list the mycotoxins discussed within this chapter, their common food substrates, and the agricultural animals most commonly affected.

It is estimated that one-quarter of the world's crops are contaminated to some extent with mycotoxins (49), which will vary from year to year based on environmental factors. For example, aflatoxin contamination is more abundant when crops are weakened by drought conditions. Contamination can occur at any point, ranging from the crop in the field, through storage and shipping. The economic consequences of mycotoxin contamination are immense, and mycotoxins pose a higher chronic dietary risk than synthetic contaminants, plant toxins, food additives, or pesticide residues (40).

Since it would be impossible to prevent all mycotoxin contamination, methods of monitoring food intended for human and animal consumption must be established. Aflatoxins strongly fluoresce under UV light and can be easily identified in food products, and immunoassays can detect the presence of citrinin. However, the chemical diversity of the mycotoxin group requires that each be separated from its substrate and studied by a unique assay. The reader is referred to the relevant chapters in *Mycotoxins in Agriculture and Food Safety* (83) for a comprehensive review of analytical protocols.

The regulatory guidelines for the limits of mycotoxins in food and feed differ from country to country but have been summarized in a series of compendia published by the Food and Agriculture Organization of the United Nations (23).

Bioterrorism

With the alarming health hazards posed by mycotoxins and the rising level of fear worldwide, concern about the possible use of mycotoxins in bioterrorism has emerged. In 1986, Ciegler proposed the use of mycotoxins as a new class of chemical weapons (12). However, the choice of aflatoxin as a weapon of mass destruction is odd at best, since the effects (liver cancer) of aflatoxicosis are too long-term to be effective during war.

Trichothecenes are much more suited for warfare than aflatoxins because they act immediately upon contact, and several milligrams can be lethal. Of historical note is the "Yellow Rain" incident of 1981 (65). The United States had accused the Soviet Union of using nivalenol, DON, and T-2 as biological weapons against Hmong tribesmen in Kampuchea and Laos. However, it was later concluded that this "yellow rain" was not a weapon but simply the excreta of swarms of wild Asian honeybees (59).

The use of mycotoxins in bioterrorism has been assessed by several investigators in recent years (6, 7, 31, 48, 66, 69, 75, 81, 88). Aflatoxins and trichothecenes have been recently tested for combined toxicity and were found to have additive effects in most cases. The combination of these two mycotoxins resulted in a synergistic effect in a human bronchial epithelial cell line (53). Interestingly, it has been shown that chlorine dioxide may be effective in the detoxification of trichothecenes roridin A and verrucarin A (84) in the case of widespread exposure. In general, it is accepted that while the presence of mycotoxin weapons may cause terror, the actual use of such weapons would not be effective or reliable in a time of war.

SBS

SBS is a loosely defined condition that applies to indoor environments suspected of causing a variety of health complaints for occupants. The buildings usually have many problems, including water damage; improper heating, ventilation, and air conditioning systems; poor construction; and bacterial, fungal, and/or insect infestations. Symptoms may include eye, nose, and throat irritation, fatigue, headache, lack of concentration, frequent respiratory tract infections, shortness of breath, dizziness, and nausea (8).

Mycotoxins are just one of the many factors considered as possible contributors to SBS. Several mycotoxin-producing

fungi have been implicated in SBS, including *Alternaria, Aspergillus, Cladosporium,* and *Penicillium* spp. One of the most widely investigated species is *S. chartarum* (for a comprehensive review, see Kuhn and Ghannoum [38]).

However, it has not been definitively proven that occupants develop illnesses either from these "sick" buildings or from the molds present inside them. Several recent reviews of SBS conclude that (i) there is no evidence that mold presents an imminent threat to life for healthy members of the general population in typical exposures, (ii) indoor airborne microorganisms are only weakly correlated with human disease and a definite causal relationship has not been established, and (iii) the concentration of mold contamination required to create infective doses is improbable and inconsistent with the reported spore concentrations in buildings (2, 14, 38).

A further argument against mycotoxins as the cause of SBS symptoms is the fact that mycotoxins are not volatile, and therefore, widespread exposure is unlikely. Moreover, the conditions conducive for mold growth are not necessarily the same as for mycotoxin production, and fungi differ in the ability to produce mycotoxins. To conclude that the presence of mold found within a "sick building" is indeed associated with symptoms suffered by occupants, the following must be established: (i) existence of the mold presenting a potential health risk in the indoor environment, (ii) mode of transmission—the source colony must be in direct contact or close proximity for contact with spores and related by-products—and (iii) portal of entry—the mold must be absorbed into the body through inhalation, ingestion, or skin absorption. The mere presence of a fungus in an indoor environment is not sufficient evidence to establish a cause-effect relationship and does not necessarily prove that mycotoxin is also present.

CONCLUSION

There are several classes of mycotoxins, produced by a wide range of fungal species, which pose both human and agricultural economic and health problems. There exists a continuing need for objective studies using relevant animal models and proper epidemiological techniques to describe the causative effects of mycotoxins and to develop antidotes, as well as remediation steps for "sick buildings," as more mycotoxins are identified.

Lacazia, Pythium, and *Rhinosporidium*

LEONEL MENDOZA

128

In the past 100 years, the microbial pathogens described in this section have been classified as fungal and/or parafungal protistan pathogens (1, 2, 8, 17). Based on their apparent epidemiological connection with water, they were at one point also placed in a new category of hydrophilic infectious agents (1). But based on taxonomic and other morphological characteristics, these three anomalous species were not well understood (1, 17). This frustrating fact fueled a strong controversy that has only recently been solved with the advent of molecular methodologies (19, 20). Despite the recent finding that both *Pythium insidiosum* and *Rhinosporidium seeberi* are protistan pathogens, they are still studied by medical mycologists continuing a historical tradition. Table 1 summarizes the most prominent features of the pathogens covered in this section.

LACAZIA LOBOI TABORDA, TABORDA, AND McGINNIS 1999

Taxonomy

Jorge de Oliveira Lobo first described lacaziosis in a Brazilian patient from the state of Pernambuco (18). He stated that the causative agent was very similar to the parasitic stages of organisms of the genera *Blastomyces* and *Paracoccidioides*. Earliest attempts to isolate this pathogen in culture met with failure, and soon it was clear that this pathogen resists culture (17). This fact started a great controversy on its epidemiological and taxonomic affinities, reflected in the numerous names by which this pathogen has been known. Taborda et al. in 1999 (35) suggested the binomial *Lacazia loboi* to end more than 70 years of taxonomic ambiguity. Recent phylogenetic studies placed *L. loboi* near *Paracoccidioides brasiliensis* (13, 19), a finding that validated Taborda et al.'s proposal (35). Thus, *L. loboi* is currently classified as an ascomycete fungus in the order Onygenales and the family Ajellomycetaceae.

Description of the Agent

Because *L. loboi* is intractable to culture, what we know about this pathogen is based on the morphological features observed in its parasitic stage. Its in vivo phenotype is characterized by the development of unicellular, thick-walled, yeast-like cells that can be found forming one, two, or more branches in chains of three or more cells characteristically connected by short tubules (Fig. 1). The yeast-like cells of *L. loboi* measure 5 to 12 μm in diameter and can be easily observed with most stains. Interestingly, *L. loboi*'s in vivo phenotype is very similar to that of the parasitic stage of *Paracoccidioides brasiliensis,* which led Lacaz et al. (17) to classify this pathogen in the genus *Paracoccidioides*. Electron microscopic analysis of this pathogen showed thick, chitinous, yeast-like cell walls and amorphous cytoplasmic contents. Approximately 60% of the yeast-like cells observed lacked a defined cytoplasmic region, a finding in agreement with results of viability studies.

Epidemiology and Transmission

Lacaziosis (41) or Jorge Lobo's (lobomycosis) disease is known to occur only in patients inhabiting the tropical areas of the Americas (17). In addition to the many human cases, cases of the disease in species of dolphins around the coasts of South America, Florida, and the Gulf of Mexico have been reported (24, 34). Although the majority of patients with lacaziosis have been from Brazil, cases from Mexico, Central America, Colombia, Suriname, Venezuela, and other nearby countries have also been recorded (17). Two European human patients apparently acquired the infection after contact with an infected bottle-nosed dolphin in an aquarium. In addition, American and Canadian patients were recently reported to have developed the infection after visiting or working in areas where the disease is endemic (6, 9).

It is believed that the infection is acquired through small, traumatic skin lesions after contact with the pathogen in aquatic ecological niches in nature. The report of dolphins with lacaziosis tends to support this tenet. However, the pathogen's real ecological niche is unknown. The disease seems to occur in apparently healthy hosts. It is quite possible that *L. loboi* cells possess hyphae with propagules (perhaps conidia) similar to those of *Paracoccidioides brasiliensis* that may make contact with the hosts through trauma, thus causing lacaziosis. The transmission of the disease from one patient to another is rare, but some cases of autoinoculation and accidental infection by physicians in contact with infected patients (17) or with infected dolphins (34) have been reported. In addition, the disease can be experimentally reproduced in mice (4).

Clinical Significance

The infections caused by *L. loboi* are observed rarely in the tropical areas of the Americas. Recent reports estimate that some 500 human cases, mostly in males with cutaneous

TABLE 1 Taxonomical, epidemiological, clinical, and mycological features of the hydrophilic microbes *L. loboi, P. insidiosum*, and *R. seeberi*

Pathogen	Taxonomy/phylogeny	Epidemiology	Clinical manifestations of infection/in vivo form	In vitro form
L. loboi	Ascomycete fungus located among the dimorphic Onygenales	Restricted to South America; cases of infection occur in dolphins; acquired by trauma; hydrophilic	Parakeloidal skin lesions/ yeast-like cells in chains connected by small tubules	Uncultivated
P. insidiosum	Kingdom Stramenopila (Protista), class Oomycetes (Peronosporomycetes); better known as the aquatic fungi	Found in tropical, subtropical, and temperate areas; acquired in aquatic or terrestrial environments by trauma; hydrophilic	Cutaneous, intestinal, and vascular infection disseminated by metastasis/ coenocytic hyphae exhibiting Splendore-Hoeppli phenomenon	Flat colonies without aerial mycelia; coenocytic hyphae without fruiting bodies; biflagellate zoospores in water cultures
R. seeberi	Kingdom Protista, class Mesomycetozoea; located at the animal-fungal divergence	Found on all continents except Australia; infection is endemic in India and Sri Lanka; acquired by trauma; hydrophilic	Polypoidal mucosal and skin lesions/spherical sporangia, with or without endospores at different stages of development	Uncultivated

lesions, have been diagnosed so far in the areas where the disease is endemic. The disease occurs in apparently normal patients inhabiting such areas. A genetic predisposition theory was abandoned after the finding that the number of cases in a Brazilian tribe with a high occurrence of the disease dramatically decreased when the tribe was moved to a new location. One common problem in the areas where the disease is endemic is that the patients with the disease do not seek medical attention until years later, when the lesions have increased in size and spread to other skin areas. One explanation may be that the affected population is usually poor, with no access to health care, and that the lesions are rarely painful.

Frequently affected areas are arms, ears, back, chest, face, and lower limbs. Some investigators believe that the distribution of the lesions on cooler areas of human skin and on dolphins may indicate that the pathogen does not tolerate a temperature of 37°C well. Initially, a single small (0.5 to 1.0 cm in diameter), smooth, parakeloidal skin lesion develops. Some patients complain of slight pruritus at this stage. The infection is not life threatening and usually evolves very slowly, sometimes over 20 or more years. Usually, when the patients seek medical attention they have already developed more than one lesion. In the chronic phase, lesions are polymorphic. At least five clinical manifestations are recognized, including the typical parakeloidal lesion and four other forms: infiltrative, gummatous, ulcerated, and verrucous. However, Lacaz et al. (17) pointed out that two or more forms, including a macular form, may be found in one patient. The differential diagnosis includes chromoblastomycosis, leprosy, neoplasias, paraccocidioidomycosis, and similar skin conditions.

Collection, Transport, and Storage of Specimens

The guidelines for the collection, processing, storage, and examination of specimens are provided in chapter 116.

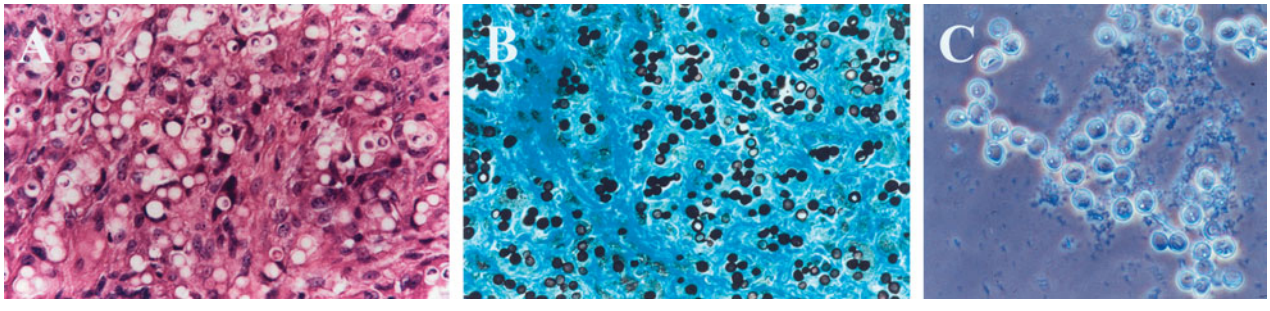

FIGURE 1 *L. loboi*. Histological sections stained with H&E (A) and silver stain (B) show the typical morphological features found in patients with cutaneous lacaziosis. The yeast-like cells of *L. loboi* are poorly stained by H&E and are observed as empty, round structures surrounded by an area of granulomatous reaction. The presence of abundant yeast-like cells in chains is the main feature in silver-stained sections (B). (C) Numerous yeast-like cells of *L. loboi* in chains connected with slender tubules and containing small dancing bodies in their cytoplasm. Magnification for all panels, ×40. Panels A and B are courtesy of P. S. Rosa.

The clinical specimens collected in cases of lacaziosis or rhinosporidiosis are mostly biopsy tissues from the infected sites. Since *L. loboi* resists culture, the clinical specimens from the infected areas are usually fixed upon collection in formaldehyde to be histopathologically evaluated later.

Direct Examination

Microscopy

In contrast to the systemic dissemination of *Paracoccidioides brasiliensis* infections, *L. loboi* infections are typically confined to the cutaneous and subcutaneous tissues. The lesions are characterized by fibrosis, granulomatous reactions with numerous histiocytes, and giant cells containing several yeast-like cells of *L. loboi*. Areas of necrosis and the presence of other inflammatory cells have been reported. When hematoxylin and eosin (H&E) stain is applied, the yeast-like cells arranged in linear chains are not well stained and appear as empty spaces with thick cell walls (Fig. 1A). Special fungal stains such as Gomori methenamine silver (GMS) and periodic acid-Schiff (PAS) are used for the histopathological diagnosis of lacaziosis. Under GMS staining, *L. loboi* yeast-like cells are dark or have the appearance of "empty" cells (Fig. 1B). The yeast-like cells are in chains of two or more cells and form branches, similar to those yeast cells observed in the infected tissue of patients with paracoccidioidomycosis. The cells are typically connected with small tubules, a feature also observed using other fungal stains, including PAS.

For patients with lacaziosis, the biopsy specimens should be cut into pieces of 2 to 5 mm in diameter. One or more pieces are then placed with 1 or 2 drops of 10% KOH on a glass slide with a coverslip. The samples should be heated without boiling and kept for about 15 min at room temperature before microscopic evaluation. In 10% KOH, *L. loboi* yeast-like cells appear in great quantities (Fig. 1C). Cells 2.0 to 12.0 μm in diameter can be found as single yeast-like cells or as chains connected by short tubules of three or more cells. Several moving protoplasmic granules can also be detected within some of the yeast-like cells (Fig. 1C).

Nucleic Acid Detection Techniques

So far, there are no commercially available nucleic acid probes for the detection of this pathogen in clinical samples.

Isolation Procedures, Identification, Typing, and Serologic Tests

Claims that *L. loboi* has been isolated in pure culture have not yet been validated. Most of the recovered organisms have proven to be fungal contaminants or *Paracoccidioides brasiliensis* (17). One major obstacle to developing serological assays for lacaziosis has been the lack of cultures. Thus, most of the serological approaches have been carried out by using the parasitic forms in infected tissues as antigens or by using cultures of closely related pathogens (41). The identification of the etiologic agent is based on the clinical features and the phenotypic characteristics on wet-mount preparations and/or histopathological analyses.

Antimicrobial Susceptibility

Although antifungal therapy has cured some cases of lacaziosis, *L. loboi* is well known for its resistance to antimicrobial drugs, including most antifungals (17). This fact has left clinicians with only one choice: surgery. Due to the pathogen's intractability to culture, susceptibility testing is not possible.

PYTHIUM INSIDIOSUM DECOCK, MENDOZA, PADHYE, AJELLO, AND KAUFMAN 1987

Taxonomy

Although infections caused by *P. insidiosum* were first reported more than 150 years ago in Indonesian equines (8), successful isolation of the pathogen in pure culture was possible only at the beginning of the 20th century. Sixty years later, a similar organism was isolated and the name *Hyphomyces destruens* was introduced. The finding that a strain from New Guinea developed zoospores suggested that this pathogen was an organism in the genus *Pythium*. More recently, deCock et al. (8) introduced the epithet *Pythium insidiosum*. Some dogs were believed to be infected with a new species of *Lagenidium* (10). However, this report is still awaiting verification. Recent molecular studies (28, 31) showed that the strains of *P. insidiosum* cluster phylogenetically according to their geographic distributions. Thus, it is likely that *P. insidiosum* may embrace a phylogenetic complex of closely related species or perhaps a complex of different strains belonging to a single species, *P. insidiosum*, including the *Lagenidium*-like strains described by Grooters (10).

Description of the Agent

Unlike the other microbes described in this section, *P. insidiosum* can be readily isolated on most mycological media (8). This pathogen develops white and submerged colonies with a characteristic radiation pattern and few to no aerial hyphae (Fig. 2A). The hyphae, with perpendicular lateral branches measuring 4 to 10 μm in diameter, possess few cross septa. Zoosporogenesis is possible only in water cultures containing various ions, including Ca^{2+} (8, 22). The structures in which the zoospores develop are termed sporangia.

The zoospores form by progressive cleavage and mature inside 20- to 60-μm-diameter sporangia. Once fully formed, the biflagellate zoospores mechanically break the sporangial wall, swim, and then encyst. Due to their motility, it has been proposed that the zoospores may be the infectious units. The zoospores are reniform, and two unequal flagella arise from inside a lateral groove. Upon encystment, the zoospores lose their flagella and become spherical. Under the right conditions, the encysted zoospores develop a germ tube and form long filaments (7, 22). *P. insidiosum* oogonia (teleomorphic stage) have been rarely observed and are believed to represent the resistant stage.

Epidemiology and Transmission

Infections caused by this hydrophilic pathogen have been recorded in tropical, subtropical, and some temperate areas of the world. In the Americas, pythiosis is common in tropical Central, North, and South America, with most cases reported in Brazil, Colombia, Costa Rica, the United States, and Venezuela (8, 22). In the United States, the infections are more prevalent in animals and humans inhabiting southern states such as Alabama, Georgia, Florida, Louisiana, Mississippi, North Carolina, South Carolina, and Texas. However, cases of the disease have also been reported in northern states, including Illinois, Indiana, Kansas, New Jersey, Missouri, Tennessee, and Virginia, and even in those as far north as Wisconsin and New York. Unusual cases of the disease in California dogs have also been reported. Pythiosis has also been reported in Asia (Japan, India, Indonesia, Pacific islands, South Korea, and Thailand), Australia, New Guinea, and New Zealand. The tropical areas of Africa are

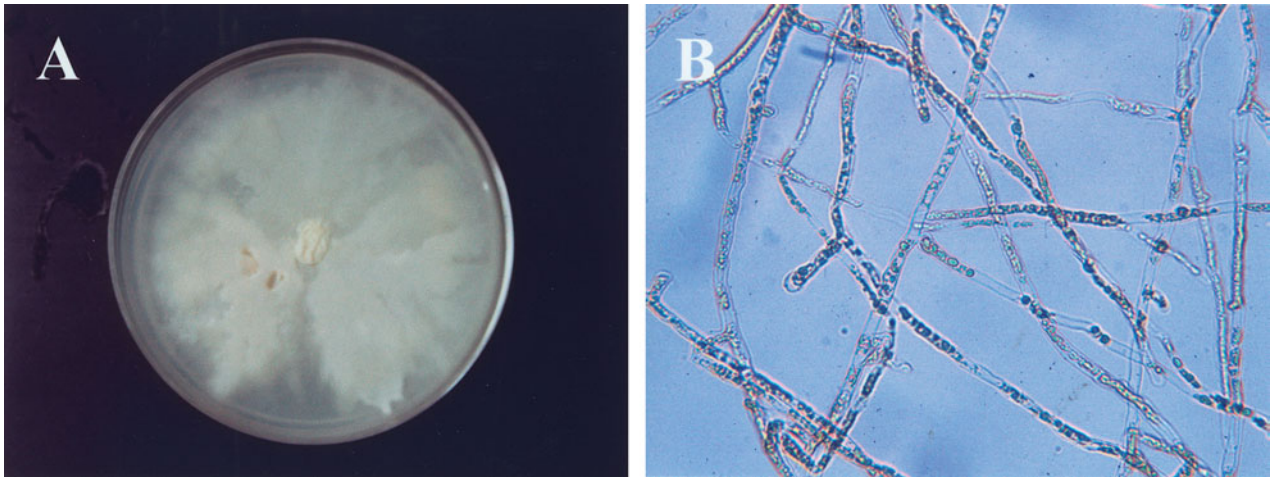

FIGURE 2 *P. insidiosum*. (A) Colony of *P. insidiosum* on Sabouraud dextrose agar. *P. insidiosum* produces cream to white submerged colonies at room temperature and 37°C. (B) Sparsely septate hyphae found on agar plates. No fruiting bodies can be found on dry cultures. Panel B magnification, ×40.

ideal for pythiosis, however; only recently, a case in a dog with a cutaneous form was reported in the northwest African country of Mali, suggesting that the disease is more prevalent on that continent (28).

Until recently, the infections caused by *P. insidiosum* were considered exotic. The disease was believed to be restricted to animals in the tropical regions, with rare to no occurrence in other geographical areas. However, in the last 10 years the number of pythiosis cases has increased on all continents (8, 36). The finding that humans (29, 36, 40, 43), dogs (12, 38), and other animals can be infected indicates that previously pythiosis was erroneously diagnosed as other fungal infections. In general, it is well known that most cases of pythiosis occur in apparently healthy humans and animals. In Thailand, however, the disease in humans is associated with thalassemia or occurs in patients with similar blood disorders (29). Interestingly, no such association has so far been reported in other geographical areas.

The infection is acquired after *P. insidiosum* propagules enter the skin or the intestinal tract through traumatic lesions (22, 38). The infection is believed to be acquired from wet environments; however, cases of pythiosis in the absence of water suggest that *P. insidiosum* can cause infection through contact with resting spores in terrestrial environments. The transmission of *P. insidiosum* from one patient to another (human or animal) has not yet been recorded. Only rabbits seem to be susceptible to experimental inoculation (25).

Clinical Significance

The clinical manifestations of pythiosis vary according to the infection site. Most patients with the disease state that they have had a skin injury prior to the infection. The lesions caused by *P. insidiosum* in humans can be classified as superficial infections (keratitis); a cutaneous and subcutaneous form, including orbital pythiosis; and a vascular form that usually leads to systemic infection and death. Keratitis caused by *P. insidiosum* is similar to that caused by fungi and other etiologic agents (3, 26, 42). It begins with a trauma on the superficial layers of the eye, followed by the development of conjunctivitis, photophobia, corneal ulcers, and hypopyon. The cutaneous and subcutaneous infection is characterized by the formation of granulomatous plaques and/or ulcerated swellings that remain localized. Once the pathogen has reached the subcutaneous tissues, itchy papules may develop. The orbital form of subcutaneous pythiosis is rare and has been observed mainly in children in Australia and the United States (39). Vascular pythiosis starts with a traumatic lesion, usually on the lower extremities, followed by dissemination of the pathogen to the nearby arteries (29, 36). Initially, the infected skin shows signs of dry gangrene, and in some patients, the formation of painful necrotic ulcers has also been reported (36).

The clinical symptoms are claudication of the affected limb, local ischemia, swelling, pain, and the absence of the dorsalis pedis pulse. As the infection progresses, ascending arteritis, with the formation of thrombi and aneurisms of the large arteries, is the main feature. If not treated, *P. insidiosum* infection may spread through the arteries and reach the iliac and renal arteries and abdominal aorta, causing disseminated pythiosis. This form of pythiosis is more common in Thailand among patients with thalassemia, and it is usually fatal (36, 40, 43). Human pythiosis should be differentiated from subcutaneous tuberculosis, cutaneous leishmaniasis, arteriosclerosis, diabetes mellitus, mycotic keratitis, subcutaneous zygomycosis, and other mycoses associated with filamentous fungi.

Collection, Transport, and Storage of Specimens

The clinical specimens required for proper diagnosis of pythiosis vary according to the infected hosts and the clinical form (22, 36). For instance, for patients with keratitis, swabs or scrapings of the affected eyes should be collected. The swabs have to be immediately transported at room temperature in tubes with high humidity (or tubes containing small quantities of sterile distilled water) to the laboratory and should be processed upon arrival. Dryness of clinical specimens from keratitis patients may prevent the visualization and culture of the hyphal elements of *P. insidiosum*. The collected eye scrapings should be placed in small aseptic petri dishes and immediately transported at room temperature to the laboratory for processing. Although some studies indicate that transportation or storage at 4°C of specimens

from patients suspected of having pythiosis does not interfere with the isolation of the pathogen in the laboratory, others report a considerable reduction in the number of positive cultures from samples stored at 4°C (22). Biopsy specimens or samples from necropsies are usually collected in sterile distilled water and transported at room temperature to the laboratory. Specimens collected from patients with cutaneous, subcutaneous, vascular, and disseminated pythiosis can also be placed in tubes containing sterile distilled water plus 100 U of penicillin/ml and 0.25 mg of streptomycin/ml or 0.4 mg of chloramphenicol/ml. If these antibiotics are not available, the use of sterile distilled water is encouraged.

Direct Examination

Microscopy

Clinical specimens of *P. insidiosum* in 10% KOH characteristically show the presence of long, 4.0- to 9.0-μm-diameter, hyaline, sparsely septated hyphal structures (Fig. 3D). Some hyphal elements may have 90°-angle lateral branches, a typical feature of this oomycete. In histopathological preparations stained with H&E, *P. insidiosum* appears as short or long hyaline coenocytic hyphae 6.0 to 10 μm in diameter. The fact that in vivo structures of *P. insidiosum* are detectable under H&E staining has been used to differentiate this oomycete from the hyphal elements developed by members of the order Entomophthorales. In infected tissues, *P. insidiosum* triggers an eosinophilic granuloma with giant cells, mast cells, and other inflammatory cells (Fig. 3A and B). The hyphal elements of *P. insidiosum* are found in the centers of microabscesses with numerous eosinophils that usually degranulate over the organism's hyphae in the Splendore-Hoeppli phenomenon (Fig. 3B). The activation of an eosinophilic inflammatory response with the Splendore-Hoeppli phenomenon is a feature that *P. insidiosum* has in common with the zygomycetes in the order Entomophthorales, from which it has to be differentiated. Although most experts in the diagnosis of pythiosis agree that it is difficult to distinguish between the hyphal structures of *P. insidiosum* and those of the entomophthorales, features such as the poor staining capabilities with H&E, the ribbon type morphology, and the bigger size of the zygomycetes' hyphal filaments sometimes help to distinguish these fungi from *P. insidiosum*. *P. insidiosum*'s hyphal elements are well stained by GMS and appear as short or long, sparsely septate, tubular dark structures (Fig. 3C). Transversely, poorly stained (with GMS or PAS) sectioned hyphae can also be found as ring-shaped bodies.

Note sparsely septate slender hyaline hyphae with branches at 90° angles. Magnification, ×40.

Nucleic Acid Detection Techniques

The first molecular approach for the diagnosis of *P. insidiosum* infection from clinical specimens was carried out with a patient with keratitis (3). The hyphal elements present in the specimen were identified by sequencing part of the 18S small-unit rRNA gene by using the NS1 and NS2 and the internal transcribed spacer universal primers. This approach has been successful with clinical specimens (3, 40). Groosters and Gee (11) introduced a PCR technique for the identification of *P. insidiosum* from cultures and from clinical specimens. A set of primers (PI-1 and PI-2) that amplified 105 bp of the internal transcribed spacer 1 of *P. insidiosum* were tested. These primers have been used by several laboratories (40) and were entirely specific when tested against several filamentous fungi. Schurko et al. (30) recently introduced a dot blot hybridization technique by constructing a 530-bp species-specific DNA probe for the detection of *P. insidiosum*. This DNA probe specifically binds to the intergenetic spacer 1 of this pathogen, and it did not hybridize with the genomic DNA of 23 other *Pythium* species, that of *Lagenidium gigantum,* and the genomic DNA of several pathogenic fungi, including the zygomycetes *Conidiobolus coronatus* and *Basidiobolus ranarum*. This probe may be ideal for the detection of *P. insidiosum* from environmental samples and for the specific diagnosis of pythiosis from clinical specimens containing susceptible species.

Isolation Procedures, Identification, Typing, and Serologic Tests

In contrast with the other hydrophilic pathogens covered in this chapter, *P. insidiosum* can be cultured on various media. The most common media used for the isolation of *P. insidiosum* are 2% Sabouraud dextrose agar or broth with or without antibiotics (see "Collection, Transport, and Storage of Specimens"), blood agar, corn meal agar (Difco), potato dextrose agar, and nutritive agar (Difco). Biopsied or necropsied tissues and kunkers from patients suspected of having pythiosis are usually cut into small fragments of 2.0 to 5.0 mm in diameter, placed into tubes with sterile distilled water, and vigorously washed two to three times before plating. The small fragments are then physically pushed into the agar, and the plates are incubated at 25 and 37°C for two or more days. The relative humidity of the incubator should be enhanced by placing a beaker of water inside the chamber. Specimens that have been transported for more than 24 h can also be inoculated into tubes containing broth and then incubated at 37°C. Usually, cottony colonies surrounding the clinical specimens are detectable after 24 to 48 h of incubation. In solid media, *P. insidiosum* develops only sparsely septate hyphae (Fig. 2B). The appearance of *P. insidiosum* on solid media is described above.

The accurate identification of *P. insidiosum* in the laboratory can be established only if the isolate develops the characteristic oogonia (teleomorphic stage) on culture plates. The formation of oogonia, however, is extremely rare, which further complicates the final identification of this pathogen in the clinical setting. Based on the fact that *P. insidiosum* is the only pathogen that develops zoospores in water, some laboratories have been using this characteristic for identification (7, 40). This approach, however, does not guarantee that the species involved in that particular case is indeed *P. insidiosum*. The identification of this pathogen by using molecular methods with culture and clinical specimens is recommended. A drawback to this approach is that only a few laboratories possess the necessary capabilities. Currently, there are no typing systems available for the identification of *P. insidiosum* in the clinical setting.

Early serological tests showed the presence of anti-*P. insidiosum* immunoglobulins in the sera of infected hosts and, thus, the importance of these immunoglobulins in the diagnosis of pythiosis. The most common assays for pythiosis are agglutination, enzyme-linked immunosorbent assays, immunodiffusion (ID), and Western blotting. In addition, a histochemical assay and an immunofluoresence assay have been used for the specific detection of *P. insidiosum* in the infected tissues. ID proved to be a very specific test, with several precipitin bands, but it was too insensitive and yielded many false negatives, especially for humans and dogs with pythiosis (16). To overcome this drawback, an enzyme-linked immunosorbent assay and a Western blotting method were later introduced (12, 16, 21, 23, 40). These assays are extremely sensitive and specific in detecting anti-*P. insidiosum* immunoglobulin G. Recently, an agglutination test was used for the rapid diagnosis of pythiosis. Although it proved to be a good screening test, it had a high rate of false positives and false negatives. The most important immunohistological tests for the specific identification of the hyphal elements of *P. insidiosum* in infected tissues have been the peroxidase and the immunofluorescence tests (5). Because the hyphal structures of *P. insidiosum* are difficult to differentiate from those of fungi, especially those of the zygomycetes, these assays have been of paramount importance for the accurate identification of this oomycete in the absence of culture. Most of these assays are available through reference laboratories for pythiosis in the United States and in other countries such as Brazil and Thailand.

Antimicrobial Susceptibility

P. insidiosum, like the other oomycetes, does not possess ergosterol in its cytoplasmic membrane. Despite this obvious counterindication, amphotericin B and other antifungal drugs that target ergosterol have been used with mixed results. For instance, two boys with orbital pythiosis were successfully treated with amphotericin B in Australia (39). However, the same antifungal did not have an effect in humans from Thailand with the disease (29, 43). Recently, susceptibility testing of a strain isolated from a boy in Tennessee with orbital pythiosis showed the strain to be sensitive to terbinafine and itraconazole (32). Although this combination was successfully used in this case, the same combination was less effective when tested in other humans and animals. The inconsistent results obtained with most antifungal drugs for the treatment of pythiosis in humans and animals have led to the use of unconventional treatments such as immunotherapy (43).

RHINOSPORIDIUM SEEBERI (WERNICKE 1903; MINCHIN AND FANTHAN 1903) SEEBER 1912, EMEND. ASHWORTH 1923

Taxonomy

The first two cases of rhinosporidiosis were reported in 1900 by Guillermo Rodolfo Seeber in his M.D. thesis in Argentina (1, 2). He stated that in 1896 he had found two patients with nasal polyps containing an organism similar to that reported by Posadas in 1892 (coccidioidomycosis). He also mentioned that an unpublished case of a nasal polyp, previously studied by Malbran in 1892, showed a spherical microbe with morphological features identical to those of the parasite reported by Seeber. A nasal case of rhinosporidiosis observed by O'Kinealy in 1903 in India was later studied in detail by Minchin and Fanthan in 1905 (2). These investigators suggested the binomial *Rhinosporidium kinealyi* to identify this strain. Seeber in 1912 introduced the name *Rhinosporidium seeberi* and called

attention to its priority over *R. kinealyi*. Ashworth in 1923 stated that the genus *Rhinosporidium* proposed by Minchin and Fanthan should be adopted and that, based on the description of Seeber (2) and the name *Coccidioides seeberia* reintroduced by Belou, the binomial *R. seeberi* had priority.

The frustrating fact that this pathogen has not been cultured has led some investigators to extreme hypotheses. The suggestion that *R. seeberi* is in the cyanobacterium genus *Microcystis* is the most recent in a long list of similar views. The placement of *R. seeberi* among the mesomycetozoeans came as a surprise. The class comprises orphan aquatic fish and amphibian parasites with spherical forms strikingly similar to that of *R. seeberi* (19, 20). By using internal transcribed spacers, it was recently found that *R. seeberi* may include several species-specific strains that may well represent new species (33).

Description of the Agent

This anomalous pathogen has resisted culture; thus, its morphological features are known only through in vivo microscopic and ultramicroscopic studies (1, 2). In infected tissues, *R. seeberi* has a complex parasitic cell cycle. It appears as multiple spherical structures known as sporangia (cysts in most mesomycetozoeans) in different stages of development (Fig. 4A and B). Its in vivo cell cycle starts with the release of hundreds of oval or spherical endospores, 7 to 15 μm in diameter, from a pore developed only in mature sporangia. The endospores increase in size and progressively develop from juvenile (10 to 100 μm) to intermediate (100 to 150 μm) and then to mature (150 to more than 450 μm) size. The endospores are released from the mature sporangia, and the in vivo cycle is somehow reinitiated (Fig. 4C). Although the diameter of the sporangium has been used to identify its in vivo stages, the mature sporangium stage differs from other stages by the presence of endospores.

Epidemiology and Transmission

Rhinosporidiosis usually occurs in most tropical and subtropical areas of the world except Australia (1). Although the infection was first recognized in Argentina, India and

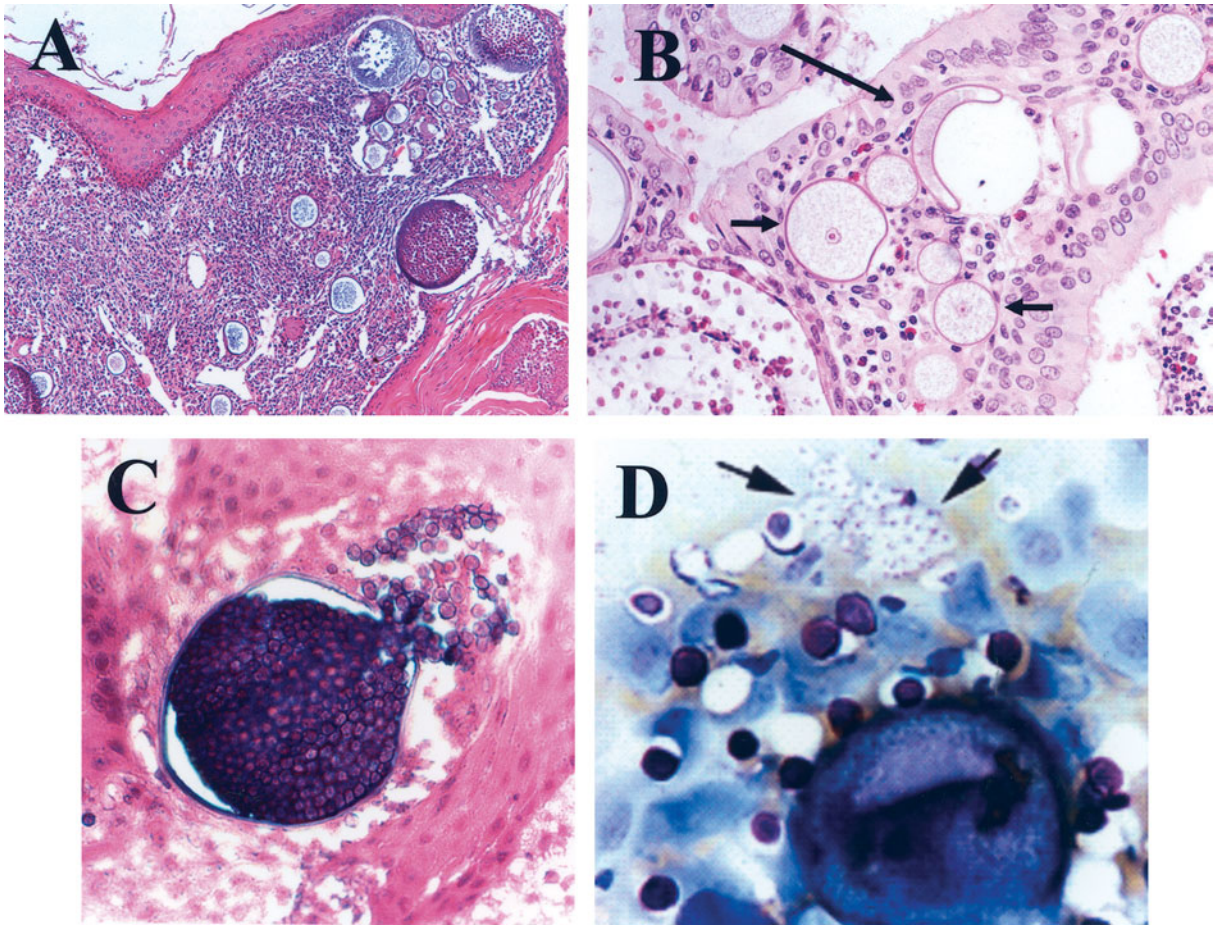

FIGURE 4 *R. seeberi*. H&E-stained mature sporangia with endospores and numerous juvenile sporangia of different sizes are shown in panels A (magnification, ×10) and B (magnification, ×30). A collapsed sporangium in U shape and juvenile sporangia with prominent nuclei and nucleoli are shown in panel B (long and short arrows, respectively). Panel C (magnification, ×30) shows mature sporangia releasing endospores through a cell wall pore. Panel D shows Wright-Giemsa impression smears from a dog with nasal rhinosporidiosis. An immature collapsed sporangium is shown in the lower section of the panel (magnification, ×70). Numerous endospores surrounded by a clear halo are shown in the upper section of panel D (arrows). Panel D is courtesy of William A. Meier.

Sri Lanka show the highest occurrences of the disease (37). Rhinosporidiosis occurs sporadically in other geographical areas such as the Americas, Africa, Europe, and Asian countries including the Middle East. Since some cases of rhinosporidiosis occur in dry areas, especially after sand storms, the hydrophilic nature of this pathogen has been long questioned (1, 2, 37). Based on accounts from patients with the disease, it is believed that rhinosporidiosis is acquired through contact with aquatic environments contaminated with *R. seeberi,* but the precise mechanism of infection from natural sources is unknown.

The finding linking *R. seeberi* to aquatic pathogens of fish and amphibians (14, 19, 20) tends to confirm its hydrophilic nature. Most probably, this pathogen evolved from an aquatic niche, in which it still can be found, and adapted to terrestrial environments by the development of resistant spores. This is a very likely scenario since the formation of zoospores, as in the other members of the dermocystida among which *R. seeberi* is phylogenetically located, has not been established (1, 2, 19, 37). The disease tends to occur as single cases, but two outbreaks of rhinosporidiosis in humans in Serbia (27) and in swans in Florida (15) have also been recorded. The resistant spores present in water and soil may gain entry through small cutaneous or mucocutaneous wounds and establish the infection. Although the disease occurs in apparently normal hosts, some investigators have suggested associations with special occupational and social conditions (1, 37). Little is known about the predisposing factors leading to the disease. The disease has not been induced in experimental animals, and transmission from one host to another has yet to be reported.

Clinical Significance

The most common clinical form is the formation of painless polyps usually located on mucosal areas of the nose, eyes, larynges, genitalia, and rectum. Multicentric skin lesions have also been recorded (37). The disease is not life threatening, but it can cause breathing difficulties when the polyps obstruct the nose or laryngeal passages. Rhinorrhea and bleeding are common on polyps located in the nose. The slow-growing polipoidal masses are usually found as single or multiple, pedunculate, sessile red lesions that bleed easily. Pruritus of the affected areas is also common. The differential diagnosis includes bacterial and fungal infections, neoplasias, and other similar mucosal and skin conditions.

Collection, Transport, and Storage of Specimens

The guidelines for the collection, processing, storage, and examination of specimens are provided in chapter 116. The clinical specimens collected in cases of rhinosporidiosis are usually biopsy tissues from the infected sites. Since *R. seeberi* resists culture, the clinical specimens from the infected areas are usually fixed upon collection in formaldehyde to be histopathologically evaluated later. Nonetheless, fresh samples should also be examined in the laboratory to rule out other etiologic agents and to confirm the histopathological findings. In these cases, the biopsy specimens have to be aseptically collected and transported immediately to the laboratory. For samples collected far from the laboratory, cooling (−80 to 4°C) of collected specimens for shipping or storage purposes may be necessary.

Direct Examination

Microscopy

Wet-mount preparations of clinical specimens from cases of rhinosporidiosis usually show the presence of mature and immature spherical sporangia and numerous endospores. Mature sporangia with endospores have thin cell walls and may measure more than 400 μm in diameter, whereas juvenile and intermediate sporangia are smaller and may have thicker cell walls. In fresh specimens treated only with water, the release of the endospores from mature sporangia has been reported. A purification system to study *R. seeberi* phenotypes was recently proposed (1). The presence of *R. seeberi* sporangia and endospores can also be found on smears stained with Giemsa or Gram stains (Fig. 4D). The spherical unstained elements of *R. seeberi* develop autofluorescence when viewed with a fluorescence microscope.

The parasitic spherical structures of this mesomycetozoean pathogen stain very well with H&E, but they also stain with GMS and PAS, a feature used by many in the past to suggest a link with the members of the fungus kingdom. Biopsy tissue from polypoidal lesions stained with H&E is characterized by the presence of numerous sporangia at different stages of development (Fig. 4A and B). Hyperplasia of the mucous membranes and/or skin with fibrovascular and fibromyxomatous connective tissue containing numerous sporangia is the main feature of the infection. Inflammatory infiltrates of lymphocytes, neutrophils, plasma cells, and, more rarely, giant cells and eosinophils are usually observed in cases of nasal, ocular, and skin infections. The juvenile and intermediary sporangia possess a central nucleus with a prominent nucleolus (Fig. 4B). The collapse of immature sporangia may cause the formation of U-shaped structures. Mature sporangia possessing several thousand endospores are usually found near the mucous epithelium, where they are transported from the internal infected areas by a transepidermal elimination phenomenon (Fig. 4A and C) (37). The mature sporangia's cell wall is usually thin, and the enclosed endospores contain clusters of eosinophilic spherical structures. The endospores have a mucoid capsule that does not stain in H&E preparations. The presence of a pore on the sporangial wall is also observed, depending on the plane of the sectioned tissue (Fig. 4C).

Nucleic Acid Detection Techniques

Currently there are no available DNA-based techniques for the detection of *R. seeberi*.

Isolation Procedures, Identification, Typing, and Serologic Tests

Despite numerous reports claiming that *R. seeberi* has been isolated in pure culture, such claims have not yet been validated. Most of the organisms recovered in cases of rhinosporidiosis have proven to be fungal or bacterial contaminants (1, 37). Because *R. seeberi* has not yet been cultured, the identification of this pathogen is based on its phenotypic characteristics on wet-mount preparations and/or histopathological analyses. The morphological characteristics of *R. seeberi* in infected tissues are almost pathognomonic. Nonetheless, the pathogen's epidemiological features and the clinical signs of disease should be taken into consideration for the final diagnosis of infection. Morphologically, the parasitic stages of *Coccidioides immitis* and *Coccidioides posadasii* mimic the *R. seeberi* sporangia with endospores. However, epidemiological, clinical, and phylogenetic features and the fact that *Coccidioides* spp. can be readily cultured categorically separate these pathogens from *R. seeberi*.

Although early investigators did not find *R. seeberi* antibodies in the sera of infected hosts by using endospores or sporangia as antigens, others suggest that the reason for the failure was the use of insensitive assays such as ID. Recently,

an immunoelectron microscopic approach showed for the first time that anti-*R. seeberi* antibodies against a specific antigen, detected only in mature sporangia, are present in the sera of patients with rhinosporidiosis (19). Despite these efforts, there are no available serological diagnostic assays for rhinosporidiosis in the clinical setting.

Antimicrobial Susceptibility

R. seeberi is resistant to most antifungal drugs (1, 37). Because this pathogen cannot be isolated in culture, susceptibility testing is not possible. Treatment is carried out by surgical removal of the infected tissues.

Antifungal Agents

SEVTAP ARIKAN AND JOHN H. REX

129

Fungi are the causative agents of various superficial and systemic infections in humans. Although superficial infections are of clinical significance in both immunocompetent and immunocompromised hosts, invasive infections tend to threaten particularly the latter. In addition to the common clinically relevant fungal species, a relatively diverse spectrum of fungi are now isolated in clinical mycology laboratories. There is a great demand for novel agents with reduced toxicities and widened spectrums of activity, and the development of antifungal therapy is now enjoying a period of rapid growth.

In this chapter, currently available topical and systemic antifungal agents (Table 1) are reviewed. The mechanism of action, spectrum of in vitro activity, pharmacology, clinical uses, and adverse effects of each are discussed, and comparative activities of the major systemic antifungal agents against well-known groups of fungi are summarized (Table 2). Novel agents that are on the horizon are also briefly reviewed (Table 3).

CURRENTLY AVAILABLE ANTIFUNGAL AGENTS FOR SYSTEMIC USE

Polyenes

The polyene group of antifungal agents includes amphotericin B and nystatin. Amphotericin B and its lipid formulations are used for the treatment of systemic fungal infections and thus will be reviewed in this section. Historically, nystatin has been solely a topical polyene and is discussed in this chapter. A liposomal formulation of nystatin has also been developed, but clinical development appears to have ceased.

Amphotericin B and Its Lipid Formulations

Amphotericin B is an amphoteric compound possessing a hydrophilic polyhydroxyl chain along one side and a lipophilic polyene hydrocarbon chain on the other. Its solubility in water is poor. The commercially available parenteral amphotericin B formulation is amphotericin B deoxycholate (Fungizone; Bristol-Myers Squibb Pharmaceuticals). Due primarily to the nephrotoxic nature of amphotericin B, lipid formulations have been developed and are now in clinical use. These lipid formulations are liposomal amphotericin B (AmBisome; Gilead Sciences), amphotericin B lipid complex (Abelcet; Enzon Pharmaceuticals), and amphotericin B colloidal dispersion (Amphocil or Amphotec; Sequus Pharmaceuticals) (12). Topical formulations of amphotericin B (cream, lotion, and ointment) are also available to be used in the treatment of cutaneous candidiasis.

Mechanism of Action

Similar to the other polyenes, amphotericin B kills the fungal cell via binding primarily to ergosterol, the major sterol found in the fungal cellular membrane. This binding destroys the osmotic integrity of the membrane, followed by leakage of intracellular potassium, magnesium, sugars, and metabolites and finally cellular death (99). Lipid formulations of amphotericin B act via the same mechanism. It has also been suggested that oxidative damage due to amphotericin B may contribute to the drug's activity against *Candida* species (140). However, an antioxidant effect of amphotericin B has been observed more recently, and thus the relevance of pro-oxidant antifungal activity remains unclear (106).

Spectrum of Activity

Amphotericin B is active against a wide variety of pathogenic fungi, including most strains of *Candida*, *Cryptococcus neoformans*, *Aspergillus* spp., *Mucor* spp., *Blastomyces dermatitidis*, *Coccidioides immitis*, *Histoplasma capsulatum,* and *Paracoccidioides brasiliensis*. However, reduced susceptibility and potential resistance to amphotericin B may be associated with some species or strains belonging to these genera, such as *Candida guilliermondii*, *Candida lusitaniae*, *Candida krusei*, and *Aspergillus terreus*. A new sibling species of *Aspergillus fumigatus*, *Aspergillus lentulus*, which is phenotypically similar to *A. fumigatus* but less susceptible to amphotericin B and other antifungal drugs, has been recently identified (17). *Fonsecaea pedrosoi* may also exhibit reduced susceptibility to amphotericin B. The susceptibilities of *Trichosporon and Fusarium* species and *Pseudallescheria boydii* and *Sporothrix schenckii* isolates to amphotericin B vary (141).

Pharmacology

Amphotericin B is not absorbed well orally, and parenteral (intravenous) administration is required. It is distributed in many tissues and organs of the body, including the lungs, spleen, and kidneys. However, penetration into cerebrospinal fluid is poor, and intrathecal administration is required for the treatment of some central nervous system infections (61).

TABLE 1 Systemic and topical antifungal agents in use

Chemical class	Antifungal agent	Formulation(s)[a]
Allylamine	Naftifine	T
	Terbinafine	O, T
Antimetabolite	Flucytosine	O
Azole (imidazole)	Bifonazole	T
	Butoconazole	T
	Clotrimazole	T
	Econazole	T
	Ketoconazole	O, T
	Miconazole	T
	Oxiconazole	T
	Sulconazole	T
	Terconazole	T
	Tioconazole	T
Azole (triazole)	Fluconazole	O, IV
	Itraconazole	O, IV, OS
	Voriconazole	O, IV
Echinocandin	Caspofungin	IV
	Micafungin	IV
Polyene	Amphotericin B	IV, T
	Liposomal amphotericin B	IV
	Amphotericin B lipid complex	IV
	Amphotericin B colloidal dispersion	IV
	Nystatin	T, OS
Other	Amorolfine	T
	Butenafine HCl	T
	Ciclopirox olamine	T
	Griseofulvin	O
	Haloprogin	T
	Tolnaftate	T
	Undecylenate	T

[a] IV, intravenous; O, oral; OS, oral suspension; T, topical.

Clinical Uses

Amphotericin B is indicated primarily in invasive candidiasis, cryptococcosis, blastomycosis, histoplasmosis, coccidioidomycosis, sporotrichosis, and paracoccidioidomycosis and in empirical therapy of febrile neutropenic patients refractory to treatment with antibacterial agents (8, 108). Based on its superior efficacy and safety compared to amphotericin B, voriconazole is now the drug of choice for the primary treatment of invasive aspergillosis (71).

Lipid amphotericin B formulations have enhanced in vivo activity due not only to their improved tolerability but also to a possible change in drug targeting and enhanced delivery to the site of infection. These formulations are indicated primarily as salvage therapy for patients with poor renal function, poor response to amphotericin B deoxycholate, or poor tolerability of amphotericin B deoxycholate (6, 57, 72). Based on the superior safety profiles of these formulations, their clinical use as suitable alternatives to amphotericin B deoxycholate is considered appropriate for the primary treatment of invasive fungal infections (108).

Adverse Effects

The major adverse effect of amphotericin B is nephrotoxicity. Acute side effects (fever, chills, myalgias, hypotension, and bronchospasm) and thrombophlebitis may also be observed during amphotericin B therapy. The major advantages of lipid formulations of amphotericin B compared to the conventional amphotericin B formulation are the significantly reduced side effects, particularly nephrotoxicity (12).

Azoles

The azole group of antifungal agents includes imidazoles and triazoles. These differ with respect to their chemical structures. Azoles are fungistatic in general and exhibit partial growth inhibition of fungal cells (45). Fungicidal activity is observed for some novel triazoles with some fungi. A good example is the fungicidal activity of voriconazole against *Aspergillus* (55).

Mechanism of action. All azole compounds act via the inhibition of cytochrome P450 14α-demethylase (also known as $P45014_{DM}$ and lanosterol demethylase), which functions in the synthesis of ergosterol from lanosterol. The inhibition of ergosterol synthesis results in the termination of fungal cell membrane synthesis (138).

Imidazoles

Imidazoles contain an azole ring with two nitrogens. Although several imidazoles are in clinical use for topical antifungal therapy and will be discussed elsewhere in this chapter, ketoconazole is the only imidazole used for the treatment of systemic fungal infections.

Ketoconazole

Ketoconazole, a lipophilic antifungal agent (Nizoral; Janssen Pharmaceutica), has both oral and topical (cream and solution) formulations to be used in the treatment of systemic mycoses, dermatophytosis, and cutaneous candidiasis (138).

Spectrum of activity. Ketoconazole has favorable in vitro activity against *H. capsulatum*, *C. immitis*, *B. dermatitidis*, *P. brasiliensis,* and *P. boydii*. Although ketoconazole is also active against *Candida* spp. and *C. neoformans,* this activity remains limited compared to those of triazoles in clinical use (fluconazole, itraconazole, and voriconazole). Cross-resistance to ketoconazole in a subset of *Candida* isolates resistant to other azoles is likely (103). The activity of ketoconazole is low against *Scedosporium prolificans* and variable against *Scedosporium apiospermum* (36). Ketoconazole has in vitro activity against *Trichophyton rubrum* (51) and *Malassezia* spp. (67). *Aspergillus* spp., *Fusarium* spp., and zygomycetes are resistant to ketoconazole (35).

Pharmacology. Ketoconazole is a highly lipophilic antifungal agent provided in an oral formulation. Its absorption following oral administration is optimal in a gastric acid environment. Ketoconazole binds to proteins to a great extent (>99%). Due to its lipophilic nature, it has high affinity for and attains considerably high concentrations in fatty tissues and purulent exudates (138).

Clinical uses. Due to its toxic potential, particularly hepatotoxicity, gastric toxicity, and endocrinological adverse effects, and the availability of less toxic, more efficacious alternatives, ketoconazole is now little used (42). It is a second-line drug for the treatment of nonmeningeal true systemic (endemic) mycoses due to *H. capsulatum*, *C. immitis*, *B. dermatitidis,* and *P. brasiliensis* and also infections due to *P. boydii* and *S. schenckii* (92).

TABLE 2 Spectrums and extents of activity of commonly used systemic antifungal agents[a]

Organism	Activity[b] of antifungal agent:					
	AMB	K	F	I	V	C
Aspergillus spp.	+++	0	0	++	+++	++
B. dermatitidis	+++	++	+	+++	+++	++
C. immitis	+++	++	+++	+++	+++	++
C. neoformans	+++	+	+++	++	+++	0
Candida spp.						
C. albicans	+++	++	+++	+++	+++	+++
C. glabrata	++	+	++	++	++	+++
C. guilliermondii	++	+	+++	+++	+++	++
C. krusei	++	+	0	++	++	+++
C. lusitaniae	++	++	+++	+++	+++	+++
C. parapsilosis	+++	++	+++	+++	+++	++
C. tropicalis	+++	++	+++	+++	+++	+++
Fusarium spp.	++	0	0	+	++	0
H. capsulatum	+++	++	++	+++	+++	++
Mucor, *Rhizopus*, and other fungi belonging to the class *Zygomycetes*	+++	0	0	0	0	+
P. brasiliensis	+++	+++	++	+++	+++	++

[a] This table is a general overview for comparison of the activities of some systemic drugs against various fungi. Readers are recommended to refer to the text for more detailed information or data at the species or strain level.

[b] In some cases, the meaning of reduced in vitro susceptibility is far from certain (e.g., the echinocandins). 0, no meaningful activity; +, occasional activity, ++, moderate activity but resistance is noted; +++, reliable activity with occasional resistance. AMB, amphotericin B; K, ketoconazole; F, fluconazole; I, itraconazole; V, voriconazole; C, caspofungin.

Adverse effects. As just noted, ketaconazole may cause serious side effects. Hepatotoxicity, decreases in testosterone and cortisol levels, nausea, vomiting, photosensitivity, pruritis, and rashes may be observed during ketoconazole therapy (142).

Triazoles

Triazoles contain three nitrogens in their azole ring. Fluconazole, itraconazole, and voriconazole are the triazoles currently in use for systemic fungal infections.

Fluconazole

Fluconazole (Diflucan; Pfizer Pharmaceuticals) is extensively used, particularly in the treatment of candidiasis. Its availability in both oral and intravenous formulations; significantly reduced rates of hepatic, gastric, and endocrinological toxic reactions; and the ability to penetrate cerebrospinal fluid are its advantages (35).

Spectrum of activity. Fluconazole is active against most *Candida* spp. and *C. neoformans*. Among the *Candida* spp., *C. krusei* is intrinsically resistant to fluconazole (95). The fluconazole susceptibilities of *Candida glabrata* strains, on the other hand, vary widely. Although some *C. glabrata* isolates may be dose-dependently susceptible to fluconazole, as many as 15% of the *C. glabrata* strains may exhibit true resistance (120). MICs of fluconazole for strains of *Candida tropicalis, Candida norvegensis, Candida dubliniensis,* and *Candida inconspicua* may occasionally be high (18, 122). In addition, fluconazole-resistant strains of any *Candida* spp. may occasionally be observed. Acquired resistance to fluconazole even among *Candida albicans* isolates may occur following long-term fluconazole prophylaxis, particularly in patients with AIDS (130). MICs of fluconazole for isolates of *Blastoschizomyces capitatus* may be high (38). Fluconazole has limited activity against *B. dermatitidis* (31), and resistance may develop when it is used to treat histoplasmosis (158). It has practically no activity against the molds.

Pharmacology. Fluconazole is a water-soluble compound, and its absorption following oral administration is excellent. It is available in oral and intravenous formulations. The absorption of fluconazole is not affected by gastric acidity or the fatty content of the food with which it is ingested. Following administration, it is distributed to almost all organs and tissues. Significantly, fluconazole readily penetrates cerebrospinal fluid as well due to its water solubility (75).

Clinical uses. Fluconazole is used in the treatment of candidiasis, cryptococcosis, and coccidioidomycosis. It is a second-line antifungal agent in the treatment of histoplasmosis, blastomycosis, and sporotrichosis (138). Fluconazole is widely used for both prophylaxis and chronic suppressive therapy in high-risk patients, particularly in transplant recipients (81) and AIDS patients who have recovered from cryptococcal meningitis (94).

Adverse effects. Side effects and toxic reactions due to fluconazole therapy are rare. Allergic reactions, angioedema (1), thrombocytopenia (2), and alopecia (111) may be observed. Reversible adrenal insufficiency has been reported in critically ill patients with multiple organ failures during high-dose fluconazole therapy (5).

Itraconazole

Itraconazole is manufactured by Janssen Pharmaceutica, and its trade name is Sporanox.

Spectrum of activity. Itraconazole is active against a wide variety of clinically relevant fungi: *Candida* spp. (including some, but not all, of the fluconazole-resistant *C. krusei* and

TABLE 3 Novel antifungal agents in development

Generic name(s) (trade name; company)	Notes
Novel Triazoles	
Posaconazole, Sch-56592 (Noxafil; Schering-Plough Pharmaceuticals)	Currently in phase III trials; active in vitro against *Candida* spp., *C. neoformans*, *Aspergillus* spp., *Rhizopus*, *S. apiospermum*, *H. capsulatum*, *C. immitis*, *B. dermatitidis*, dermatophytes, and dematiaceous fungi (47, 53, 104); available data from salvage therapy of invasive zygomycosis are noteworthy (60); approved by European Commission for treatment of serious invasive fungal infections in adults who remain refractory or intolerant to commonly used antifungal agents
Ravuconazole, BMS-207147, ER-30346 (no trade name announced; Bristol-Myers Squibb)	Currently in phase II–III trials; active in vitro against *Candida* spp. (less active against dose-dependently fluconazole-susceptible and fluconazole-resistant isolates than against fluconazole-susceptible ones), *C. neoformans*, *Trichosporon* spp., *A. fumigatus*, *Rhizopus*, *S. apiospermum*, dermatophytes, and dematiaceous fungi (52, 64, 68, 110, 123–125); no detailed human data yet reported
Albaconazole, UR-9825 (no trade name announced; Uriach & Company)	Currently in phase I–II trials; active in vitro against *Candida* spp., *C. neoformans, Malasezzia, Aspergillus, Paecilomyces, S. apiospermum, S. prolificans*, and dermatophytes (29, 30, 50); no human data yet available
Sordarin and azasordarin derivatives	
Sordarins: GM237354 (lead compound), GM193663, GM211676, GM222712; Azasordarins: GW471558 (lead compound), GW506540, GW531920, GW560849 (no trade names announced; Diversa Corporation)	Not yet in clinical studies; active in vitro against *Candida* spp., *C. neoformans*, *Trichosporon* spp., *Pneumocystis carinii*, *P. boydii*, and *Cladosporium carrionii* (46)
Chitin synthase inhibitor	
Nikkomycin Z (no trade name announced)	Not yet in clinical studies; active in vitro against *A. fumigatus*, *H. capsulatum* (some isolates), and *C. immitis* (34, 58)
Candida isoleucyl-tRNA synthetase inhibitor	
Icofungipen, (BAY-10–8888, PLD-118 (no trade name announced; Pliva)	Currently in phase II trials; active in vitro and in vivo against *Candida* spp., including azole-resistant isolates (117); active in treatment of oropharyngeal candidiasis in HIV-positive patients, although dosage regimen tested did not appear to be as effective as fluconazole[a]

[a] Source: N. H. Brockmeyer, M. Ruhnke, K. Oreskovic, and J. Peterson, *Abstr. 44th Intersci. Conf. Antimicrob. Agents Chemother.,* abstr. M-1036, 2004.

C. glabrata isolates), *C. neoformans, Aspergillus* spp., dermatophytes, *P. boydii, Paecilomyces* spp., *C. immitis, H. capsulatum, B. dermatitidis, P. brasiliensis, Penicillium marneffei,* and *S. schenckii* (4, 138, 146). Its activity against *Aspergillus* is the most significant advantage of itraconazole over fluconazole. However, strains of *A. fumigatus* and *Aspergillus nidulans* that are resistant to itraconazole have been reported (37, 144, 150). MICs of itraconazole for isolates of *A. lentulus* are relatively high (17). Itraconazole has no activity against the agents of zygomycosis (148) and *Scopulariopsis* spp. (3) and has limited activity against *Fusarium* (10).

Pharmacology. Itraconazole is available in oral capsule, oral solution (in cyclodextrin), and intravenous (in hydroxy-propyl-beta-cyclodextrin) formulations. Oral absorption of itraconazole is influenced by food and gastric acidity. The intravenous formulation provides consistent and predictable bioavailability and rapidly achieves optimal levels in blood. Itraconazole is lipophilic in nature, resulting in poor penetration into cerebrospinal fluid and high concentrations in purulent exudates and fatty tissues (15).

Clinical uses. Itraconazole has been used in the treatment of candidiasis, including a number of cases unresponsive to other azoles (131), aspergillosis (33, 41), dermatomycosis (24), onychomycosis (9), chromoblastomycosis (23), true systemic (endemic) mycoses (coccidioidomycosis, histoplasmosis, blastomycosis, and paracoccidioidomycosis) (92), and sporotrichosis (112). It is also effective in the treatment of cryptococcosis (41). Itraconazole was found to be more effective than fluconazole and was associated with fewer invasive fungal infections than fluconazole when it was used for long-term prophylaxis after allogeneic hematopoietic stem cell transplantation (HSCT) (161).

Adverse effects. Side effects due to itraconazole therapy are similar to those due to fluconazole therapy. Gastrointestinal side effects are more common with itraconazole than with fluconazole (161). Hepatotoxicity is rarely noted (138). Hypokalemia, edema, and hypertension may be observed, particularly at high doses (137).

Voriconazole

Voriconazole is a triazole structurally related to fluconazole and manufactured by Pfizer Pharmaceuticals. Its trade name is Vfend, and it is available in oral and intravenous formulations.

Spectrum of activity. Voriconazole has a wide spectrum of antifungal activity. The spectrum covers *Candida* spp. (including some fluconazole-resistant isolates), *C. neoformans, Trichosporon* spp., *B. capitatus, Aspergillus* spp. (including itraconazole-resistant *A. fumigatus* and amphotericin B-resistant *A. terreus*), *Fusarium* spp., *S. apiospermum, S. prolificans, B. dermatitidis, H. capsulatum, C. immitis, P. marneffei,* and dermatophytes (10, 79, 93). Due to azole cross-resistance, a significant number of fluconazole-resistant *Candida* isolates are also resistant to voriconazole as well as ketoconazole and itraconazole (135).

The antifungal activity of voriconazole is mostly fungicidal for filamentous fungi, including *Aspergillus, Fusarium,* and

Scedosporium (55). Voriconazole was found to be fungicidal against *C. krusei,* although it had no or minimal fungicidal activity against *C. albicans* and *C. tropicalis* (132).

Voriconazole has no or limited activity against zygomycetes, *S. schenchkii* (82), and a significant number of *Rhodotorula* strains, particularly *Rhodotorula muciloginosa* (59).

Pharmacology. Voriconazole exhibits good oral bioavailability. It distributes widely into tissues, including those of the central nervous system. Most (80%) of the drug is eliminated by the hepatic route (113). It has nonlinear, dose-dependent pharmacokinetics. Maximum concentrations in sera and total-exposure (area-under-the-curve) values demonstrate notable intersubject variability following oral voriconazole administration (79, 126).

Clinical uses. Voriconazole is indicated for the primary treatment of invasive aspergillosis (71), salvage therapy of infections due to *S. apiospermum* and *Fusarium* spp., and the treatment of cases with esophageal candidiasis and non-neutropenic candidemia (80). Successful treatment of *Saccharomyces boulardii* sepsis (28) and cerebral blastomycosis (16) with voriconazole has also been reported. Favorable activity of voriconazole in infections due to dematiaceous fungi has been observed, but the clinical experience is limited (129).

Voriconazole has no meaningful activity against zygomycetes. Cases of invasive zygomycosis during prophylactic, empirical, or therapeutic use of voriconazole have been reported (76, 86, 139).

Adverse effects. Transient visual disturbances (30%) and hepatic enzyme elevations (25) are the most commonly observed adverse effects of voriconazole. Demyelinating peripheral neuropathy (145), rashes, photosensitivity reactions (127), non-concentration-dependent QT interval prolongation, and nonsustained, polymorphic ventricular tachycardia (7) have also been observed. Hallucinations, hypoglycemia, electrolyte disturbance, and pneumonitis related possibly to high voriconazole concentrations have been reported, and measurement of plasma voriconazole concentrations is recommended to optimize voriconazole dosages (27).

Antimetabolites

Flucytosine

Flucytosine (5-flurocytosine; 4-amino-5-fluoro-2-pyrimidone [Ancobon; Ancotil; Valeant Pharmaceuticals]) is a fluorinated pyrimidine and the only available antifungal agent acting as an antimetabolite. It is available in an oral formulation. The intravenous formulation of flucytosine is not broadly available anymore.

Mechanism of Action

Flucytosine exerts its antifungal activity by disrupting pyrimidine metabolism and thus the synthesis of DNA, RNA, and proteins in the fungal cell. Following its entry into the fungal cell with the help of the permease enzyme, flucytosine is converted to 5-fluorouracil (5FU). 5FU is phosphorylated to form 5-fluorouridylic acid. 5-Fluorouridylic acid is further phosphorylated and is incorporated into RNA. This incorporation results in the inhibition of protein synthesis. The conversion of 5FU to 5-fluorodeoxyuridine monophosphate, on the other hand, causes the inhibition of the thymidylate synthase enzyme, which functions in fungal DNA synthesis and nuclear division (56).

Spectrum of Activity

Flucytosine has a narrow spectrum of activity, including *Candida* spp., *C. neoformans,* and the dematiaceous fungi causing chromoblastomycosis (96). It also exhibits favorable in vitro activity against *Rhodotorula* spp. (59). Primary resistance or decreased susceptibility to flucytosine in many fungal species, including *Candida* strains and *C. neoformans,* is not uncommon (21, 32, 155, 159). Moreover, resistance may also develop during flucytosine monotherapy (73).

Pharmacology

Flucytosine achieves high levels in sera and body fluids and readily penetrates into cerebrospinal fluid and other body fluids (153).

Clinical Efficacy

Due to the potential risk of primary or easily emerging flucytosine resistance, flucytosine monotherapy should be avoided (150). Flucytosine is most commonly used in combination with amphotericin B. Flucytosine-fluconazole combination therapy (97) and triple therapy including amphotericin B, fluconazole, and flucytosine (44) also appear to have promising implications for the treatment of cryptococcal and *Candida* meningitis. The most common indication for amphotericin B-flucytosine combination therapy is cryptococcal meningitis, where the drugs have been shown to act synergistically (20, 151). This combination has also been effective in the treatment of *Candida* meningitis (49).

Adverse Effects

Bone marrow depression, hepatotoxicity, and gastrointestinal intolerance are the major adverse effects of flucytosine. Flucytosine is cleared by the kidneys, and concomitant use of nephrotoxic drugs such as amphotericin B must be approached carefully as flucytosine may accumulate to toxic levels in the blood if renal dysfunction develops (153).

Allylamines

The allylamine group of antifungal agents includes terbinafine and naftifine. Terbinafine has oral and topical formulations, but naftifine has only topical preparations and will be discussed elsewhere in this chapter.

Mechanism of Action

Allylamines inhibit ergosterol biosynthesis via the inhibition of the squalene epoxidase enzyme. This effect finally causes fungal cell death primarily due to the increased membrane permeability mediated by the accumulation of high concentrations of squalene, but not due to ergosterol deficiency (56).

Terbinafine

Terbinafine is a widely used lipophilic antifungal agent.

Spectrum of Activity

Terbinafine is active against dermatophytes (65), *Malassezia furfur* (118), various *Candida* spp. (134), *Aspergillus* spp. (136), *S. schenckii* (78), *P. marneffei* (98), *C. neoformans* (134), *Trichosporon* spp., and *Blastoschizomyces* (133). Primary terbinafine resistance and development of resistance to terbinafine after prolonged exposure have been shown to be rare among isolates of *T. rubrum* (102, 107). In combination with azoles, terbinafine may exhibit synergistic effects against some *Candida* strains that are less susceptible to azoles (19, 115).

Pharmacology

Terbinafine is available in oral and topical (cream) formulations (Lamisil; Sandoz Pharmaceuticals). It achieves high concentrations in skin, nail, and fatty tissues (143).

Clinical Uses

Due to its high rate of efficacy, low rate of toxicity, and ability to achieve clinical success after a relatively short course of therapy compared to other agents, terbinafine is often the drug of choice today in the treatment of various dermatomycoses (22). The latter property of terbinafine is particularly significant for the treatment of onychomycosis, which requires longer therapeutic courses with other agents (9). Terbinafine is as effective as or more effective than its alternative, itraconazole (39), and also fluconazole (69) in the treatment of onychomycosis. Recent data indicate that fluconazole-resistant *Candida* infections may respond to fluconazole-terbinafine combination therapy (54). Similarly, the combination of voriconazole and terbinafine has proven to be efficacious in some cases with infections due to *S. prolificans* (74). Terbinafine therapy has also been efficacious in some patients with sporotrichosis, aspergillosis, chromoblastomycosis, and leishmaniasis (48, 116).

Adverse Effects

Terbinafine is well tolerated with a low incidence of adverse reactions, such as those involving the gastrointestinal system and the skin (66) and rarely observed reversible agranulocytosis (105).

Echinocandins

Echinocandins are lipopeptides with a broad spectrum of antifungal activity. Several years after the development of the first echinocandin, cilofungin, which caused serious toxicity in systemic use, systemically applicable new echinocandins have recently been developed. These are anidulafungin (previously known as VER-002, V-echinocandin, and LY303366; Eraxis; Pfizer Pharmaceuticals), caspofungin (previously known as L-743,872 and MK-0991; Cancidas; Merck Research Laboratories), and micafungin (previously known as FK463; Funguard in Japan and Mycamine in the United States; Astellas Pharma Inc.).

Mechanism of Action

Echinocandins inhibit glucan synthesis and thus cause cessation of fungal cell wall synthesis (40, 149).

Spectrum of Activity

Echinocandins are in general active against various *Candida* and *Aspergillus* spp. (13, 91, 121). Their favorable activity against azole- and amphotericin B-resistant as well as azole- and amphotericin B-susceptible *Candida* strains is one of the major advantages of echinocandin use in clinical practice (13, 119). Echinocandins exert fungicidal activity against various *Candida* species. Their activity against *Aspergillus,* on the other hand, is very disruptive to the apical and subapical branching cells of the hyphae and does not appear to be fungicidal for the whole fungus (11, 14, 26). Thus, the anti-*Aspergillus* activity of echinocandins seems beneficial mostly in decreasing the angioinvasive potential of the organism (119).

Among yeast isolates, the activity of echinocandins is more limited against *Candida parapsilosis, C. guilliermondii,* and *Trichosporon* spp. (13, 147). Although there is evidence of favorable in vivo activity of caspofungin against the *Candida* species with relatively higher caspofungin MICs, the data remain limited (K. Bartizal, M. Motyl, P. Hicks, C. A. Sable, M. Dinubile, and N. Kartsonis, *Abstr. 42nd Intersci. Conf. Antimicrob. Agents Chemother.,* abstr. M-1240, 2002). Emergence of resistance to caspofungin and azoles following treatment with caspofungin and fluconazole has been reported in a patient with prosthetic valve endocarditis (101).

Echinocandins have practically no or very limited activity against *C. neoformans*, *Fusarium* spp., and zygomycetes (11, 47, 62, 152).

Pharmacology

In general, echinocandins exhibit favorable, dose-dependent linear pharmacokinetic properties (63). Oral bioavailability is limited, and only intravenous formulations are available or are currently under development.

Clinical Uses

Data on the in vivo efficacy of anidulafungin in human infections remain limited and await further investigations. Available data suggest favorable efficacy for esophageal candidiasis, candidemia, and aspergillosis (89, 90, 119).

Caspofungin is licensed and indicated for the treatment of oropharyngeal and esophageal candidiasis (including those cases due to fluconazole-resistant isolates), candidemia, intra-abdominal abscess, peritonitis, and pleural space infections due to *Candida;* for empirical therapy for febrile neutropenic patients unresponsive to antibacterial therapy; and for salvage therapy for patients with invasive aspergillosis who have been refractory or intolerant to amphotericin B, lipid amphotericin B formulations, and/or itraconazole (109, 154, 156; http://www.cancidas.com).

Micafungin has been found to be efficacious in the treatment of esophageal candidiasis, candidemia, and invasive aspergillosis (43, 62, 85) and in antifungal prophylaxis for HSCT recipients and recipients of livers from living donors. Micafungin appears to be superior to fluconazole for antifungal prophylaxis in HSCT recipients (77, 84). Its use for prophylaxis for *Candida* infections in patients undergoing HSCT and for the treatment of esophageal candidiasis was approved by the U.S. Food and Drug Administration.

Adverse Effects

Echinocandins are in general safe therapeutic agents with minimal toxicity. No serious side effects have so far been reported. Fever, nausea, vomiting, rashes, and infusion-related side effects may be observed during echinocandin therapy (83).

Other Antifungal Agents for Systemic Use

Griseofulvin

Griseofulvin has been available over several decades since its isolation from *Penicillium*.

Mechanism of Action

The antifungal activity of griseofulvin is via the inhibition of fungal mitosis. It disrupts the mitotic spindle through interaction with polymerized microtubules.

Spectrum of Activity

Griseofulvin exhibits activity against dermatophytes (157). However, as reported so far, griseofulvin MICs are higher than those of terbinafine and itraconazole when the drugs are tested against *T. rubrum*. *Trichophyton mentagrophytes* isolates are less susceptible to griseofulvin than *T. rubrum* in vitro (87). The activity of voriconazole against dermatophytes is also superior to that of griseofulvin (160).

Pharmacology

Griseofulvin is practically insoluble in water and is deposited primarily in keratin precursor cells. It has oral formulations in microcrystalline and ultramicrocrystalline forms. Ingestion with a heavy meal and reduction in particle size enhance the absorption of griseofulvin.

Clinical Uses

Griseofulvin is used in the treatment of dermatomycosis. However, due to the current availability of less toxic, more efficacious agents, such as terbinafine and itraconazole (70), it is now a second-line drug in the treatment of dermatomycosis.

Adverse Effects

Adverse effects of griseofulvin are mild in general. Nausea, diarrhea, headache, skin eruptions, photosensitivity, hepatotoxicity, and neurological side effects may be observed (88, 100).

CURRENTLY AVAILABLE ANTIFUNGAL AGENTS FOR TOPICAL USE

Topical antifungal agents are used in the treatment of superficial cutaneous mycoses caused by dermatophytes and *Candida* as well as vulvovaginal and oropharyngeal candidiasis. There are various topical preparations in use that consist of different classes of compounds with antifungal activity (Table 1). These preparations include cream, lotion, nail lacquer, ointment, powder, and solution and spray forms which are applicable for cutaneous lesions and onychomycosis. Oral suspensions may be used for the treatment of patients with localized oropharyngeal candidiasis. Vaginal suppository, troche, and tablet forms are available for the topical treatment of vulvovaginal candidiasis (114, 128, 138).

The preference for topical or systemic therapy depends primarily on the extent and nature of the infection and the immune status of the host. For instance, onychomycosis and tinea capitis usually require systemic therapy, and cutaneous lesions due to dermatophytes or *Candida* may well respond to topical treatment. Oropharyngeal candidiasis may be treated topically. However, systemic agents are preferred for the treatment of esophageal candidiasis.

NOVEL ANTIFUNGAL AGENTS IN DEVELOPMENT

Among the antifungal agents in development are novel triazoles (posaconazole, ravuconazole, and albaconazole), nikkomycin Z, sordarin and azasordarin derivatives, icofungipen, and anidulafungin. Anidulafungin is discussed above under "Echinocandins," and the other novel antifungal agents are summarized in Table 3. These agents remain promising for future antifungal therapy.

Mechanisms of Resistance to Antifungal Agents

THEODORE C. WHITE

130

The use of antifungal drugs has accelerated in the last few decades because new and more effective antifungals have become available and because of a dramatic increase in the number of fungal infections. The currently available antifungal agents and new drugs under development are summarized in chapter 129. The rise in fungal infections in the last 20 years is the result of several factors usually associated with immune dysfunction. The frequency of patients with immune dysfunction has grown dramatically because of the AIDS epidemic, increased bone marrow transplants (BMT) and solid organ transplants, and aggressive cancer chemotherapy. Hospital-acquired fungal infections are also emerging as significant problems. With the increase in fungal infections, there has been a dramatic rise in the use of antifungals for the treatment of both systemic and localized fungal infections. It is not surprising that the expanded use of antifungal drugs has accelerated the development of resistance to these compounds. This chapter represents an updated version of the chapter in the previous edition of this Manual (28). Detailed reviews of the background of antifungal drug resistance have been presented previously (23, 29–30) and should be consulted for background. Primary references published before 2003 can be found in these reviews.

Classes of antifungal drugs include polyenes, azoles, allylamines, 5-flucytosine (5FC), and echinocandins. The mechanisms of action for these antifungal drugs are described in detail in chapter 129. The azoles, such as fluconazole, and the allylamines, such as terbinafine, target ergosterol biosynthesis. The polyenes, such as amphotericin B (AmB), bind to ergosterol in the plasma membrane. 5FC inhibits pyrimidine metabolism and DNA synthesis. The echinocandins target glucan synthetase, inhibiting cell wall synthesis and stability.

CLINICAL COMPONENTS OF ANTIFUNGAL DRUG RESISTANCE

Clinically, infections that are recalcitrant to treatment with these classes of antifungal drugs are considered resistant. A recalcitrant infection can be the result of a variety of factors associated with the host, the drug, and the fungus (summarized in Table 1).

Host Factors

The single factor that is most important in the resolution of a fungal infection is the immune status of the host. The antifungal drugs and the host immune system work together in controlling the infection. Infections in patients with nonfunctional immune systems are more recalcitrant to treatment, as the drug must combat the infection without the additive effect of the immune system. The site of the infection (systemic or localized to skin, oral mucosa, vaginal mucosa, eye, brain, etc.) contributes to clinical resistance since the site may be protected or inaccessible to drug therapy. The severity of the infection can also contribute to clinical resistance, as larger concentrations of fungal cells require higher concentrations of drug and/or longer treatments. The presence of foreign objects, including catheters, dentures, and artificial heart valves, can also contribute to a recalcitrant infection, as the fungus can attach to and invade these objects, creating a source of constant inoculation and protection from drug therapy. Finally, the patient's adherence to prescribed therapy regimens is extremely important for effective treatment. Poor adherence to a drug regimen reduces the effectiveness of the drug and fails to resolve the infection. Poor adherence also contributes substantially to the development of antifungal drug resistance, as intermittent or low-dose therapies commonly allow organisms that are incrementally more resistant to persist and become the dominant strain.

Drug Characteristics

The characteristics of the antifungal drug are also factors in the treatment of a recalcitrant infection. Fungistatic drugs such as the azoles do not kill the cells and are thus more likely to allow cells to develop resistance than a fungicidal drug such as AmB. The absorption, distribution, and metabolism of the drug also contribute to the overall effectiveness at the site of infection. As discussed above, the dosing of the antifungal drug, including the quantity, frequency, schedule, and cumulative dose, can also contribute to resolution of a fungal infection. Finally, other drug therapies administered to the patient can alter the effectiveness of the antifungal drugs.

Fungal Factors

Several factors of the fungus affect the treatment of the infection. First and foremost, the species and strain clearly determine which drugs are effective. Second, the cell type can alter drug efficacy. Fungi exist in a variety of cell types or morphologies, including yeasts (blastospores), hyphae, chlamydospores, conidia, and mycelia, each of which can have a specific susceptibility to antifungal drugs. For example, *Candida albicans*

TABLE 1 Factors that contribute to clinical antifungal drug resistance

Host factors	Drug factors	Fungal factors
Immune status	Fungistatic nature of drug	Cell types
Site of infection	Dosing	Morphology
Severity of infection	Frequency	Cell states
Presence of foreign materials	Quantity	Serotypes
Poor adherence to drug regimen	Cumulative dose	Biofilms
	Pharmacokinetics	Genomic stability of strain
	Absorption	Size of population
	Distribution	Population "bottlenecks"
	Metabolism	Strain MIC
	Drug-drug interactions	

exists in yeast and hyphal forms; and azole drugs can interfere with hyphal production at 0.1 μg/ml, 1/10 the therapeutic concentration of the drug in vivo. However, resistant strains of *C. albicans* form hyphae in the presence of high concentrations of azole drugs. In addition to morphology, several fungi including *C. albicans* exist in different switch phenotypes or cell states and exist in different serotypes determined by cell surface characteristics. These cell states and serotypes vary in susceptibility to antifungal drugs. An important cell state that has received considerable attention in recent years is fungal biofilms, in which cells grow as a plaque or mat on a surface. Fungal biofilms are known to have altered antifungal susceptibilities (2).

The genome stability of the fungus can also affect antifungal susceptibility. The best example is the development of resistance in *Candida* with different ploidy (copies of the genome). The development of resistance is a common occurrence in haploid *Candida glabrata* and infrequent in diploid *C. albicans,* where mutations in both copies may be needed to have an effect. In addition, a larger number of organisms in severe infections increases the chance that a random mutation can occur, resulting in a resistant fungal cell in the infection.

Population bottlenecks may dramatically alter the susceptibility pattern of the cells in an infection. For example, an infected catheter is removed and replaced with a new catheter in a patient with a systemic infection who is receiving antifungal drugs. The remaining fungal cells in the bloodstream could colonize the new catheter, and those cells may be more resistant due to exposure to antifungal drugs. Such a shift in the population structure is known as a population bottleneck and can clearly have effects on the development of resistance.

Level of Susceptibility

The final fungal factor that has an effect on a recalcitrant infection is the level of susceptibility to antifungal drugs of the fungal isolate, usually measured as the MIC, using standardized CLSI (Clinical and Laboratory Standards Institute, previously known as NCCLS) protocols. The specifics of the protocol, clinical breakpoints, and other factors associated with the standardized method are discussed in chapter 131 by Espinel-Ingroff. The standardized CLSI method has been used to demonstrate the existence of true, clinically relevant fungal resistance and the extent of the resistance in various patient populations.

COMPLICATIONS OF SUSCEPTIBILITY TESTING

Clinical Breakpoints

The CLSI protocol determines levels of susceptibility in vitro. These MICs can then be used to predict resistance in vivo by defining clinical breakpoints, the MIC values above which a strain is clinically resistant to drug treatment. It is important to note that these breakpoints are specific for each drug and fungal species. Thus, clinical isolates of *C. albicans* are resistant to fluconazole if the MIC is ≥ 64 μg/ml and resistant to itraconazole if the MIC is ≥1.0 μg/ml (21). Similar breakpoints for the MIC to fluconazole are being tested for *Cryptococcus neoformans* (1), and recently, a clinical breakpoint for voriconazole has been defined (4 μg/ml), although some believe that this number was set too high. While breakpoints for ketoconazole and clotrimazole have not been determined for *C. albicans,* it is likely that those breakpoints are similar to the 1.0-μg/ml breakpoint used for itraconazole, as the MIC values for clinical isolates to all three drugs have the same relative distributions.

The difference between MIC and clinical breakpoints has created some confusion. A clinical breakpoint is defined as the MIC at which a strain behaves as a resistant strain. The clinical breakpoint must be set for every drug. The problem with clinical interpretations is that strains with MICs to itraconazole or other azoles above 1.0 μg/ml are frequently and incorrectly regarded as susceptible, since their MIC is below the 64-μg/ml value that is the clinical breakpoint for the most common azole, fluconazole. It is important to remember that MICs are numbers determined in vitro, and clinical significance can be determined only using clinical breakpoints to correctly interpret these numerical results. In addition, it is vitally important that antifungal pharmacokinetics and pharmacodynamics be taken into account when dealing with clinical resistance.

90-60 Rule

A very important consideration regarding MIC interpretation is the 90-60 rule (20). Essentially, this rule states that infections will respond to therapy about 90% of the time if the infectious agent is judged to be susceptible in vitro, while infections will respond to therapy about 60% of the time if the infectious agent is judged to be resistant in vitro, even with the correct interpretation of clinical breakpoints. This rule appears to be applicable to most, if not all, microbial infections: fungi, bacteria, and parasites. It implies that patients with susceptible strains will respond 90% of the time and patients with a fluconazole-resistant strain of *C. albicans* will respond to fluconazole 60% of the time. The most likely reasons for successful treatment of a resistant strain or failure to treat a susceptible strain are found in Table 1. The 90-60 rule is important when comparing drug therapies. Case reports or studies of salvage therapy do not necessarily imply that one drug is effective against a strain that is resistant to another drug; the successful treatment may be part of the 60% success rate that is true even for drugs to which the strain is resistant in vitro.

The factors that contribute to a recalcitrant or resistant clinical infection have been described above and are summarized in Table 1. The rest of this chapter focuses on the resistance of fungal isolates, as determined by their MICs.

INTRINSIC AND ACQUIRED RESISTANCE

There are two types of resistance: intrinsic resistance, which is an inherited characteristic of a species or strain, and acquired resistance, which occurs when a previously susceptible isolate develops a resistant phenotype, usually as a result of prolonged treatment with antifungals. The ideal antifungal drug would be effective against all fungi, both yeast and molds. However, with each of the current antifungal drugs, there are genera and species that are intrinsically resistant. Fungal genera and species that are intrinsically resistant to antifungal drugs are summarized in chapter 131. In certain genera, there are some species that are susceptible and certain species that are resistant to specific antifungals. These unique species are briefly discussed below.

Intrinsic Azole Resistance

Candida krusei is intrinsically resistant to azoles. In addition, many strains of *C. glabrata* are intrinsically resistant or susceptible dose dependent. Other strains can quickly acquire resistance during therapy. *C. krusei* and *C. glabrata* are increasing in frequency in oral and systemic candidiasis in patient populations that use azole drugs for treatment or prophylaxis. In addition, the frequency of vaginitis caused by these azole-resistant *Candida* species is increasing, although these strains respond to azole therapy for vaginitis.

AmB and 5FC Resistance

Resistance to AmB is a common problem with the yeasts *C. krusei* and *Candida lusitaniae* and the molds *Aspergillus terreus* and *Scedosporium* sp. In some of these species, many but not all of the strains are resistant. These fungal infections are not common, and there is no indication that the frequency of these species has increased in patient populations exposed to large doses of AmB. Intrinsic and acquired resistance to 5FC is relatively common in many fungi. Because this is a common phenomenon, 5FC monotherapy is rarely used to treat fungal infections.

Acquired Azole Resistance

Acquired azole resistance was rare in the 1980s, when azoles were used primarily to treat patients with chronic mucocutaneous candidiasis. However, in the 1990s, azole resistance became a significant problem in *C. albicans* isolates from AIDS patients. Oral candidiasis is the most common opportunistic infection in human immunodeficiency virus (HIV)-infected patients, occurring in over 90% of all patients. Azole drugs were commonly prescribed at relatively low doses for long-term prophylactic therapy that was administered intermittently. Not surprisingly, azole resistance in oral candidiasis became a significant problem. Resistant strains of *C. albicans* were found in 20 to 33% of symptomatic oral candidiasis patients with HIV and in up to 14% of asymptomatic patients with HIV. In recent years, most HIV-infected patients in developed countries have been receiving highly active antiretroviral therapy, which reduces the frequency of most opportunistic infections including oral candidiasis, thus eliminating the need for azole prophylaxis and reducing issues of azole resistance. At this time, the frequency of antifungal resistance in strains from patients receiving highly active antiretroviral therapy is not known. Children with HIV infection are particularly susceptible to oral candidiasis and receive substantial clotrimazole prophylaxis. A survey demonstrated that up to 10% of oral isolates from these children are resistant to clotrimazole and cross-resistant to other azoles and require AmB for treatment. Unlike oral isolates, vaginal isolates of *C. albicans* do not increase their resistance to azoles, even after long-term exposure. In addition to *C. albicans, Candida dubliniensis* is a recently described, closely related species that is very difficult to distinguish from *C. albicans,* but which has the ability to develop increased resistance to azole drugs.

Acquired resistance has best been described in several matched sets of azole-susceptible and azole-resistant isolates from the same strain of *C. albicans,* usually obtained from oral candidiasis in AIDS patients or systemic infections in BMT patients (28). Azole resistance in a patient is most likely the result of a commensal strain that is previously resistant or that develops resistance, although it is possible that a resistant strain can be acquired by nosocomial transmission or intimate contact.

Acquired azole resistance has also developed in isolates of *C. neoformans* from AIDS patients who have been on prophylactic azole therapy to prevent recurrence of cryptococcal meningitis and in isolates of *Aspergillus fumigatus* from patients who have received repeated treatment with itraconazole.

Azoles are commonly used in surgical wards to prevent systemic candidiasis, as nonprescription drugs to treat fungal infections of the skin including athlete's foot, and in agriculture. Epidemiological studies of azole resistance have not been undertaken in these settings.

Acquired Polyene Resistance

Acquired resistance to fungicidal AmB is rare; it occurs mostly in yeasts from cancer patients who have received repeated doses of AmB to treat recalcitrant or recurring systemic fungal infections. The MICs to AmB of yeasts from cancer patients are elevated compared to the MICs of colonizing isolates from controls. Case reports concerning acquired resistance to AmB appear to be increasing. Intrinsic AmB resistance in *C. lusitaniae* may be related to cell switching between two cell states and to deletion/mutation of *ERG6* (31).

Change to a More Resistant Species or Strain

There are clear differences in the antifungal resistance of different species, as discussed above. There are also clear differences between strains within a species due to randomly occurring genetic differences. These small differences in strain susceptibility result in a distribution of MICs for strains within a species. Intrinsically resistant species and strains may be present in individuals by chance as commensal colonizations. If infection or disease develops, the infection will already be resistant to treatment with antifungal therapy.

Resistant species and strains may also be acquired by nosocomial transmission or intimate contact. The frequency at which fungal strains move from person to person has been investigated to some extent with *C. albicans,* where replacement rates are usually under 50%, although the sensitivity of the techniques used to differentiate strains can have a significant impact on determining if strains are identical, similar, or unrelated (26). Transmission of a strain either orally or sexually between patients has been documented, as has transfer of resistant strains (30).

MOLECULAR MECHANISMS OF AZOLE DRUG RESISTANCE

Most molecular analyses of antifungal drug resistance have focused on *C. albicans* and the related yeasts *C. glabrata* and *C. krusei.* Some work has been done with *C. neoformans* and

with *A. fumigatus*. This section concentrates on the mechanisms identified in *C. albicans*, with appropriate discussion of mechanisms identified in other fungi.

Matched Sets

The molecular analysis of antifungal drug resistance in *C. albicans* is complicated by the clonal nature of this diploid yeast. *C. albicans* grows vegetatively with limited sexual reproduction, as documented by the lack of Hardy-Weinberg equilibrium and by balanced lethal experiments. Recent evidence has demonstrated that *C. albicans* has mating loci similar to those of *Saccharomyces cerevisiae*, and "mating" of two diploid cells into a tetraploid cell can be detected under controlled circumstances. Still, mating in *C. albicans* is limited and most strains have diverged by acquiring mutations asexually, resulting in strains with considerable differences in their genomes. Genetic or expression differences identified between unmatched susceptible and resistant isolates could be the causes of resistance or could simply be the result of strain divergence. Thus, it is important to determine the relatedness of a susceptible isolate and resistant isolate before comparing them by molecular analyses.

Strain differences can be detected by several molecular techniques including restriction fragment length polymorphisms, chromosome karyotyping, and random amplification of polymorphic DNA. A recent review summarized the important considerations in each of these analyses (26). Perhaps the most appropriate method for strain typing is restriction fragment length polymorphism analysis with the repetitive marker Ca3, which can be used to detect even minor differences between clinical isolates.

Alterations in Ergosterol Biosynthesis

The target enzyme of the azole antifungals is lanosterol demethylase, the product of the *ERG11* gene (Erg11p). A defective Erg11p does not remove methyl groups at the 14α carbon of ergosterol precursors, resulting in an accumulation of 14α-methyl sterols, including a diol, 14α-methyl-ergosta-8,24(28)-dien-3β,6α-diol. The 14α-methyl sterols alter the fluidity and function of the fungal plasma membrane, and the resulting cells are more susceptible to oxygen-dependent microbicidal systems of the host. The diol also accumulates in these cells. This diol is fungicidal in *S. cerevisiae*, though its effect in *C. albicans* is not clear. Frequently, fungal cells escape the effects of 14α-methyl sterols and the diol with a mutation in the sterol desaturase, the product of the *ERG3* gene.

Alterations in *ERG11*

Several alterations in *ERG11* have been associated with resistance in *C. albicans*, including (i) point mutations in the coding regions, (ii) overexpression of the gene, (iii) gene amplification (which leads to overexpression), and (iv) gene conversion or mitotic recombination.

Point mutations within the coding region of *ERG11* that are present in a resistant isolate and which are not present in the susceptible isolate of the same strain have been identified by several researchers (for a review, see reference 17). That review surveyed point mutations within *ERG11*, cataloguing 29 amino acid substitutions occurring a total of 98 times in 53 sequences. The 29 substitutions were distributed throughout the sequence but clustered in three regions of the gene, suggesting three hot spots of mutation. These mutations are predicted to interfere with several regions of the gene, including the active site, the channel leading to the active site, and the flexible helix that interacts with and covers the channel. Of these 29 substitutions, six have been experimentally linked to resistance. These include Y132H, D278E, S405F, F449L, G464S, and R467K (letters represent amino acids; the wild-type amino acid precedes the numerical position in the protein sequence, and the mutant amino acid follows). Fifteen other substitutions were found in resistant isolates but require further analysis. Eight substitutions were found in both susceptible and resistant isolates, suggesting that these substitutions are not associated with resistance and are most likely the result of allelic differences. The most common amino acid substitutions that have been detected are D116E, K128T, E266D, and G464S. The first three substitutions are commonly found in both susceptible and resistant isolates; only G464S is experimentally associated with resistance. Silent mutations (no amino acid substitution) have also been identified in the *ERG11* gene. These silent mutations are most likely the result of allelic variation and are unlikely to have an effect on azole susceptibility. The R467K and Y132H mutations have been studied for their effect on resistance by expressing the gene in *S. cerevisiae*, where the mutations alter the azole susceptibility of the enzyme.

Overexpression of the *ERG11* gene should also contribute to resistance, as increased amounts of protein require increased amounts of drug. *ERG11* overexpression has been identified in several clinical isolates, although the level of overexpression has usually been less than fivefold. The effect of overexpression alone has not been determined, as these clinical isolates usually have additional alterations such as point mutations within the *ERG11* gene.

Overexpression can be the result of localized gene amplification. In *C. albicans*, gene amplification has not been associated with gene overexpression, although it is not commonly tested. Gene amplification has been identified in an azole-resistant clinical isolate of *C. glabrata*, although this isolate demonstrated other resistance mechanisms as well. The gene amplification was due to a chromosome duplication that was lost when the strain was grown in the absence of drug, although partial resistance was maintained.

Two groups have documented changes in *ERG11* allelic sequences associated with resistance. In both cases, it appears that a mutation occurred in one allele of *ERG11*. Random gene conversion or mitotic recombination then appears to have created strains in which both alleles of the *ERG11* gene contained the mutation. These homozygous strains may then have been selected under drug pressure, as the cells express only a resistant Erg11p. These gene conversions or mitotic recombinations are detected because silent allelic differences in and around the *ERG11* gene are eliminated as resistance develops.

Resistant clinical isolates usually contain mutated but functional *ERG11* genes. In *C. albicans* and *C. glabrata*, deletions of the *ERG11* genes have been studied for their effect on susceptibility and enhanced oxidative killing by the host. Given an increased susceptibility to oxidative killing, it is unlikely that clinical isolates would have a nonfunctional *ERG11* gene.

The *ERG11* gene appears to be important for the intrinsic resistance of *C. krusei*. The Erg11p activities in *C. krusei* cell extracts are 24- to 46-fold less susceptible to fluconazole than extracts from *C. albicans*. Alterations in drug accumulation were not observed in this study but were observed in a separate study. The intrinsic resistance of *C. krusei* is likely to be due to both reduced enzyme susceptibility and reduced drug accumulation (see below). Alterations in the *ERG11* gene have been demonstrated in other fungal species, including *A. fumigatus* and *C. neoformans*.

Additional Alterations in Ergosterol Synthesis

Using the current *C. albicans* genome sequence, most of the genes in the ergosterol pathway have been annotated or can be identified by homology searching with the *S. cerevisiae* homologs. In addition, the *ERG11* gene has been cloned from the resistant species *C. glabrata* and *C. krusei,* as well as *Candida tropicalis*. Several other genes in the ergosterol pathway have been analyzed for their effects on drug susceptibility. However, changes in other *ERG* genes have not been demonstrated in resistant clinical isolates.

The *ERG11* and *ERG3* genes have been deleted in *C. glabrata,* and their viability and drug susceptibilities have been tested. The growth phenotypes for these deletions are similar to those described for *S. cerevisiae*. However, the drug susceptibilities differ between *C. glabrata* and *S. cerevisiae,* suggesting that sterol control and antifungal resistance are not regulated in the same manner in the two species and that regulation in *C. albicans* might be different still. The deletion analysis included an analysis of mRNA in which the *ERG11* gene was overexpressed in the *ERG3* deletion and vice versa, suggesting transcriptional control of ergosterol biosynthesis, perhaps by negative feedback from ergosterol.

Molecular and genetic studies in *S. cerevisiae* indicate that mutations in *ERG3* alone can be sufficient to create an azole-resistant phenotype. Molecular and biochemical analysis of *C. albicans* suggests that *ERG3* mutations are associated with resistance in several clinical isolates, although reintroduction of a functional *ERG3* gene in one strain restored ergosterol synthesis but did not alter susceptibility. The *ERG3* mutations should prevent the production of the diol that may cause growth arrest, as is the case with *S. cerevisiae*.

In *C. neoformans,* the azoles appear to inhibit other gene products in the ergosterol pathway in addition to the inhibition of *ERG11*. The drugs appear to act directly or indirectly to inhibit the C-4 sterol demethylase complex *(ERG25, ERG26,* and *ERG27)*. Inhibition of this complex reduces the production of the growth-arresting diol, without alterations in *ERG3*. Azole-resistant strains of *C. neoformans* may also have defects in *ERG3* and *ERG2*. Itraconazole appears to have an additional inhibitory effect on the product of the *ERG24* gene, at least in *C. neoformans* and *Histoplasma capsulatum,* where itraconazole has an increased effectiveness compared to other azoles. Finally, it appears that the azoles also have activity against the *ERG5* gene product in *S. cerevisiae,* although the effect of this activity on azole susceptibility is unknown for any yeast.

Drug Import and Metabolism

To date, studies on azole import, modification, activation, or degradation have not been reported. Drug import studies require careful analysis of drug accumulation in short time points with minimum drug efflux, which are conditions that have not been applied in the medically important fungi. It has been reported that azoles are not metabolized in *C. albicans,* although this has not been studied in other species or in resistant isolates of *C. albicans.*

Drug Accumulation

Drug accumulation within a fungal cell is the result of a balance between drug import, drug efflux, and drug metabolism. Drug accumulation has been studied primarily in *C. albicans,* where radioactively labeled azoles and the fluorescent dye rhodamine 123 have been used to show drug accumulation within the cells. Drug accumulation has also been observed in *C. glabrata, C. krusei, C. dubliniensis, C. neoformans,* and *A. fumigatus*. This accumulation was saturable, suggesting an import or efflux mechanism other than diffusion. This azole accumulation is dependent on energy, cell viability, pH, and temperature. Drug accumulation is also dependent on the sterol composition of the cell membrane, as modified membranes lacking ergosterol are less fluid and have altered permeability, reducing azole accumulation. Intracellular drug levels are reduced in resistant clinical isolates compared to matched susceptible controls, and several studies have shown that this reduced accumulation is energy dependent.

Two Types of Efflux Pumps

Two classes of efflux pumps, the ATP binding cassette transporters (ABCT) and the Major Facilitators (MF), are involved in the movement of small molecules across the plasma membrane of the cells in both directions. Specific members of each class of pump have been associated with drug resistance in one or more systems. The ABCT pumps are associated with active efflux of small molecules that are toxic to the cells. These small molecules tend to be hydrophobic or lipophilic, as are the azole drugs. The MF pumps are also associated with relatively hydrophobic molecules such as tetracycline.

The complete *S. cerevisiae* genome includes 30 ABCT and 28 MF pumps. While not all of the 58 pumps function as drug pumps and not all are located to the plasma membrane, there are a significant number of pumps that can be involved in drug efflux. The *C. albicans* genome sequence contains a similar number of efflux pumps.

ABCT Pumps

The ABCT pumps consist of two membrane-spanning domains that assemble into a channel in the plasma membrane and two nucleotide binding domains that bind and use ATP as an energy source for the pump. The nucleotide binding domains contain an ABC, which is a conserved motif among proteins that use ATP as an energy source. The ABCT pumps are usually grouped into six gene families based on homology, and members of several of these families have been associated with resistance to a variety of compounds. However, in *C. albicans,* azole drug resistance has only been associated with the *Candida* drug resistance *(CDR)* gene family, which is homologous to the pleiotrophic drug resistance *(PDR)* gene family of *S. cerevisiae*. Ten *CDR* genes have been identified and annotated; only four *(CDR1* to *CDR4)* have been analyzed in detail.

The *CDR1* gene of *C. albicans* was first identified because it complements the *PDR5* gene deletion of *S. cerevisiae*. The *PDR5* mutant was hypersusceptible to cycloheximide, chloramphenicol, azole drugs, and other compounds that are substrates for this pump. Complementation with the *CDR1* gene of *C. albicans* restored normal susceptibility. Overexpression of *CDR1* has been demonstrated in a variety of resistant and susceptible clinical isolates from oral and systemic disease. Both of the alleles of the *CDR1* gene have been experimentally deleted in *C. albicans*. The resulting strain is hypersusceptible to azoles, terbinafine, amorolfine (another ergosterol biosynthesis inhibitor), and several metabolic inhibitors, although there was no change in susceptibility to AmB or 5FC.

CDR2 was also isolated by complementation of the *PDR5* mutant of *S. cerevisiae*. *CDR2* is closely related to *CDR1,* and like *CDR1,* expression of this gene in *S. cerevisiae* increases resistance to azoles, other sterol biosynthetic drugs, and metabolic inhibitors. In *C. albicans,* the gene disruption alone does not alter drug susceptibility, but the double gene disruption, *CDR1* and *CDR2,* was more hypersusceptible than the single *CDR1* gene disruption. Increased mRNA

levels of *CDR2* have been detected in several resistant clinical isolates; most of these also have increased mRNA levels of *CDR1*. The coregulation of *CDR1* and *CDR2* suggests that the genes are both transcriptionally regulated by the same or similar factors and those factors are involved in clinical resistance.

CDR3 and *CDR4* have also been identified in *C. albicans* by homology. Expression of *CDR3* has been documented only in opaque cells of strain WO-1. This strain undergoes phenotypic switching between white cells and opaque cells, which are the mating-competent form of *C. albicans*. Expression of *CDR4* is detected by Northern blot analysis in most cells, but expression does not correlate with azole resistance. The gene disruption is not hypersusceptible to azoles. Six additional *CDR* genes have been identified in the nearly complete *C. albicans* genome sequence, although these genes have not been further characterized.

ABCT pumps have been identified in *C. krusei, C. glabrata, C. tropicalis, C. dubliniensis, C. neoformans, A. fumigatus, Aspergillus nidulans,* and *Aspergillus flavus*. Gene disruptions of pump genes in *C. glabrata* are hypersusceptible to azoles, and upregulation of the pump genes is associated with the development of resistance at a high frequency in *C. glabrata*.

MF Pumps

The MF pumps also consist of two membrane-spanning domains that assemble into a channel, but the MF pumps do not have nucleotide binding domains. Instead these pumps use the proton gradient of the membrane as an energy source. The MF pumps commonly transport molecules by antiport: protons enter the cell, and small molecules are removed from the cell. Two MF pump genes have been characterized in *C. albicans*.

The *MDR1* gene or *Ben-R* gene was cloned as a DNA fragment from *C. albicans* that confers resistance to a variety of drugs in *S. cerevisiae*. The gene disruption in *C. albicans* increased susceptibilities to some of these drugs and had reduced virulence in an animal model of systemic candidiasis. Increased mRNA levels of the *MDR1* gene have been correlated with azole resistance in several clinical isolates of *C. albicans*. The *MDR1* gene shows specificity between azole drugs. When expressed in *S. cerevisiae,* cells are resistant to fluconazole but not to ketoconazole or itraconazole. The *MDR1* gene has been disrupted in azole-resistant clinical isolates overexpressing *MDR1*. The resulting disruptants had an increased susceptibility to azole drugs, the first demonstration that *MDR1* is in fact a cause of azole resistance.

The second MF gene, *FLU1,* was identified as a DNA fragment from *C. albicans* that complemented the *PDR5* gene of *S. cerevisiae* (see above), increasing fluconazole and cycloheximide resistance. Overexpression of the *FLU1* gene has not been documented in any resistant clinical isolates. *MDR1*-related genes have also been shown to be associated with resistance in *C. dubliniensis* and *C. tropicalis*.

Transcriptional Regulation of Resistance Genes

Increased mRNA levels of resistance genes including *ERG11, CDR1, CDR2,* and *MDR1* are usually the result of increased expression, which is usually not the result of gene amplification but of alterations in the promoter activity of the gene.

The *ERG11* gene appears to be coordinately regulated with other genes in the *ERG* pathway by a transcription factor containing a Zn_2Cys_6 binding motif encoded by *UPC2*. *UPC2* is one member of a large family of fungus-specific transcription regulators. It appears that the *UPC2* gene contains a transcription activation domain at the N terminus and a transmembrane segment at the C terminus. Activation may occur by cleavage of the protein, releasing the N terminus from the endoplasmic reticulum membrane and allowing the transcription activation domain to enter the nucleus and activate genes. This is based on the sterol response element binding protein model for cholesterol regulation in mammalian cells (3). Deletion of *UPC2* in *C. albicans* results in cells hypersusceptible to all drugs associated with the ergosterol pathway, as well as drugs associated with cell wall stability (16, 25). The deletion also affects other aspects of sterol metabolism and is important for azole regulation of the ergosterol pathway, suggesting that *UPC2* is a master regulator of sterols.

To date, both *CDR1* and *CDR2* appear to be regulated together, although there are a small number of clinical isolates that overexpress only one or the other gene, suggesting that these isolates may contain promoter mutations. Regions of the *CDR1* and *CDR2* promoters have been identified that are important for regulation, including the Drug Response Element that is important for azole induction of the pumps (9). Two other elements, Steroid Response Elements 1 and 2, are responsible for steroid induction of the pump genes but not other drugs (13). A Negative Response Element which binds to an as-yet-unidentified 55-kDa protein has also been identified (10).

Several transcription factors that regulate expression of *CDR1* and *CDR2* have been identified. The factor that recognizes the Drug Response Elements is known as *TAC1,* another member of the Zn_2Cys_6 transcription factor family (6). *TAC1* was first identified by genetic linkage to the mating locus in *C. albicans* (see below). A second transcription factor known to regulate *CDR1* and *CDR2* was identified by a one-hybrid genetic screen in *S. cerevisiae*. This transcription factor, *NDT80,* is related to the *S. cerevisiae NDT80* gene that is involved in controlling meiosis. The promoter regions of *CDR1* and *CDR2* that are recognized by *NDT80* are not yet known. Two additional factors, *FCR1* and *FCR3,* which may regulate azole resistance, have been identified in *C. albicans* based on their complementation of *S. cerevisiae PDR1* and *PDR3,* transcription factors known to regulate efflux pumps in *S. cerevisiae*. *FCR1* encodes another Zn_2Cys_6 transcription factor, while *FCR3* encodes a member of the bZip transcription factor family. It is not known if *FCR1* and *FCR3* regulate resistance through the efflux pumps or other pathways.

The transcriptional regulation of the MF family of genes has not been studied in detail. The *C. albicans* gene *CAP1* is a homolog of the *S. cerevisiae* gene *yAP1,* which regulates the response of fungal cells to oxidative stress and other stress conditions, in part by inducing MF pump genes related to *C. albicans MDR1*. Recently, regulation of *C. albicans MDR1* has been shown to act through the *CAP1* recognition site found in the *MDR1* promoter (11). This element is responsible for induction of the *MDR1* pump by many compounds related to stress but does not respond to azole drugs. However, the study also identified other regions of the *MDR1* promoter that increase expression in response to other drugs. In azole-resistant clinical isolates, it has been shown that *C. albicans MDR1* overexpression is the result of altered transcription factors. However, the factor(s) has not yet been identified.

Microarrays and Genetic Screens

Transcription profiling using microarrays has recently been used to identify other genes associated with resistance (for examples, see references 12 and 22). Many of the identified genes are upregulated either with *CDR1* and *CDR2* or with *MDR1.* This suggests that some of these additional genes might be coregulated by the transcription factors described

above. In each of these analyses, the genes are correlated with resistance but have yet to demonstrate a role in resistance.

Genetic screens have also been used in both *C. albicans* and *C. glabrata* to identify additional genes associated with resistance. A screen in *C. albicans* identified the *C. albicans CKA2* gene, encoding casein kinase II, suggesting a role for kinase signaling in resistance (4). A screen in *C. glabrata* (5, 15) identified genes encoding efflux pumps and transporters as expected from the molecular mechanisms described above, and Ca^{2+} channel regulators and genes involved in mitochondrial function, as expected from the phenotypes described below.

Summary

The resistance mechanisms described to date are summarized in Fig. 1. In a susceptible cell, azole drugs enter the cell by an unknown mechanism and target lanosterol demethylase, Erg11p, which is part of the ergosterol biosynthesis pathway. The *CDR* pumps and the *MDR1* pump are expressed at low levels in susceptible cells, at certain times in the growth of the cells. In a resistant cell, the interaction between the azoles and Erg11p can be altered by mutation or overexpression of the *ERG11* gene. Alterations in other enzymes in ergosterol biosynthesis can also affect azole susceptibility.

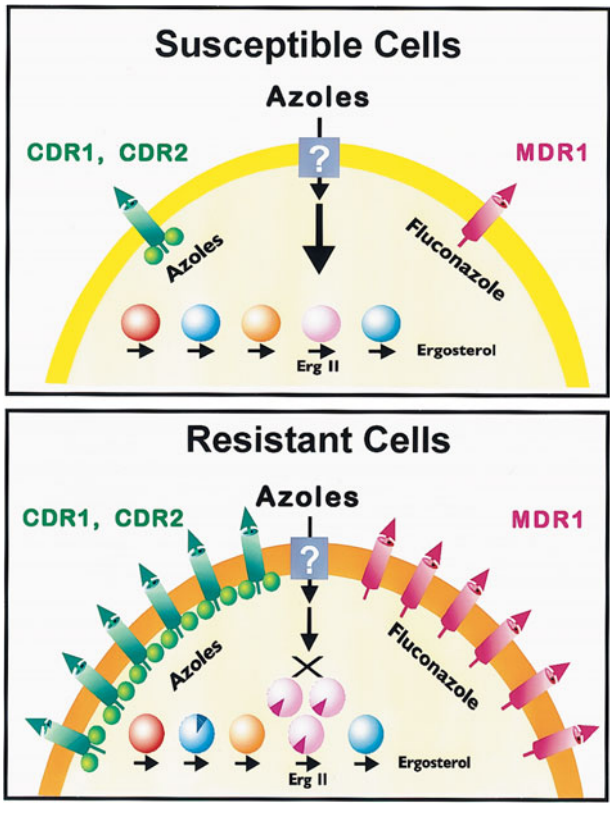

FIGURE 1 Molecular mechanisms of azole resistance. See text for details. Gene products shown in the figure include Erg11p (pink sphere), the *CDR* efflux pumps (green tubes) with ABC domains (green spheres), the *MDR* efflux pump (red tubes), and other ergosterol biosynthetic enzymes (spheres of assorted colors). Point mutations are shown as dark slices in pink and blue spheres. (Figure taken from White [27] with permission.)

Both the *CDR* gene family and the *MDR1* pump can be overexpressed, reducing the amount of drug within the cell. The *CDR* gene family appears to promote efflux for all azoles tested, while the MF pump *MDR1* appears to be specific for fluconazole and voriconazole.

Resistance Is a Composite

Resistance in *C. albicans* clinical isolates is not usually the result of a single alteration. Instead, several alterations appear to contribute to the generation of a resistant cell. Each alteration allows the corresponding isolate to outgrow the other cells in the population, becoming fixed as the major strain. Subsequent alterations allow the strain to gradually develop a highly resistant phenotype, the result of several alterations, each of which increases the resistance of the cell only slightly. This has been well documented in a series of 17 sequential isolates from a single patient (30). All of the isolates were of the same strain, although early in the infection, a substrain appears to have become the major strain. After substrain selection, the *MDR1* gene was overexpressed, correlating with a significant increase in resistance. Later in the infection, isolates acquired an R467K mutation in *ERG11,* so that the Erg11p enzyme became more resistant to azole and the cells had an increased azole resistance. At the same time, the *ERG11* gene was overexpressed, and allelic differences were eliminated, suggesting that a gene conversion or mitotic recombination copied the R467K mutation to both alleles. Even later in the infection, the *CDR1* and *CDR2* genes were overexpressed, again correlating with a significant rise in azole resistance. The timing and the order in which each of these changes occurred is unlikely to have been critical to the development of resistance, but the sum of each of these alterations is a resistant phenotype.

Unidentified Mechanisms

While significant progress has been made in the characterization of molecular mechanisms associated with azole resistance, most of the resistant isolates characterized are oral isolates from AIDS patients with oral candidiasis. When a series of systemic isolates was characterized, some isolates were identified with the same molecular mechanisms of resistance. However, a significant number of azole-resistant systemic isolates showed no alterations in the target enzyme or efflux pumps. It is likely that these strains have alterations in drug import or processing or other, as-yet-unidentified mechanisms.

Resistance in Perspective

Several generalizations concerning resistance can be made based on the work from the last 10 years. First, the predominant molecular mechanism of azole drug resistance in oral isolates is overexpression of efflux pumps, especially *CDR1* and *CDR2*. However, resistance mechanisms in systemic isolates include as-yet-unidentified factors. Unlike resistance in parasite and mammalian systems, drug resistance in the fungi is not normally associated with gene amplification. Fungi in general have elaborate systems for the regulation of gene transcription, and thus, gene amplification is not necessary to alter gene expression. Unlike studies in prokaryotes, studies with fungi have not yet identified any plasmids or other episomes containing resistance markers. Finally, there is no documented situation in which the resistance markers from one isolate were transferred to another isolate, although this situation has not been investigated in detail.

TABLE 2 Cellular phenotypes associated with resistance

Cellular phenotype	Characterization by MIC[a]
Homozygosity at *MTL* locus	Associated with resistant MIC
Trailing	Resistant MIC
Calcineurin effects	No change in standard MIC
Heterogeneous resistance	Susceptible MIC
High-frequency azole resistance	Susceptible → resistant MIC
Inducible resistance	Susceptible → resistant MIC
Transient resistance	Resistant → susceptible MIC
Stable resistance	Consistent resistant MIC
Cross-resistance	Resistant MIC for many drugs
Altered fitness	No change in standard MIC

[a] Standard MIC_{80} at 48 h.

PHENOTYPES ASSOCIATED WITH AZOLE RESISTANCE

MIC susceptibility testing is important in determining a strain's basic response to antifungal drugs. However, in the last several years, several phenotypes associated with resistance have been identified (Table 2) which do not fit simply into the standard susceptible/resistant definitions of MIC testing and which do not appear to be directly the result of the molecular mechanisms described above. Understanding these phenotypes will give additional insight into how a fungal cell responds to antifungal drugs.

Mating Type

As mentioned above, *C. albicans* has two mating types, a and α, defined by the gene set at the *MTL* (mnemonic for mating-type-like) locus. Most strains are diploid a/α. However, strains that are homozygous at the *MTL* locus do exist (a/a and α/α). These homozygous strains are able to undergo phenotypic switching between two cell states, white and opaque. Opaque cells are the mating-competent forms of *C. albicans* that can undergo fusion to form tetraploids. A correlation has been identified between homozygosity at the *MTL* locus and azole resistance. All *MTL* homozygotes are not resistant, and all azole-resistant isolates are not homozygous at the *MTL* locus, but there is an increased frequency of *MTL* homozygotes in azole-resistant strains. This correlation between azole resistance and *MTL* homozygosity has several possible explanations. The transcription factor *TAC1,* which regulates expression of the *CDR1* and *CDR2* efflux pump genes, is genetically linked to the *MTL* locus (6). It is also possible that a mating reaction creates genetic variation, and drug pressure may then select for strains with new genetic compositions. As 50% of the progeny of a mating reaction should be *MTL* homozygotes, then the correlation between azole resistance and *MTL* homozygosity may be the link to mating and genetic variability.

Trailing

Standard susceptibility testing monitors growth at 48 h, and the MIC is defined as the concentration of drug that inhibits growth by 80% (growth is less than 20% of control). Some fungal isolates appear susceptible at 24 h of growth but resistant at 48 h of growth. This difference between the 24- and 48-h growth is known as trailing. Trailing growth at 48 h is usually the result of growth inhibition between 50 and 80%, while growth of true resistant strains is usually similar to the no-drug control. Trailing is a result of residual growth, which is growth of cells above the MIC because the azole drugs are fungistatic, rather than fungicidal. Clinically, infections with these trailing isolates are usually treatable with azole drugs at standard drug concentrations. Consistent with this, trailing isolates behave as susceptible isolates in animal models of candidiasis. It has been observed that trailing can be reduced in acidic media. This may have consequences in the treatment of vaginal isolates in cases where the vaginal pH is more acidic than blood. Under those conditions, trailing would be reduced, which is consistent with the observation that resistance has not been observed in vaginal yeast infections.

Tolerance

Strains that show significant residual growth, or trailing, show drug tolerance, which is associated with fungistatic drugs. Azole drug tolerance is lost in the presence of cyclosporine A, which inhibits fungal calcineurin, an important factor in Ca^{2+} regulation. Cyclosporine A eliminates trailing and drug tolerance, essentially making a fungistatic drug fungicidal. However, cyclosporine does not alter the MIC of the isolate, just its residual growth above the MIC. The use of cyclosporine A with azole drugs decreases the fungal load in animal models, suggesting that the drug combination may have important clinical significance.

Heterogeneous Antifungal Resistance

Heterogeneous resistance is an unusual phenomenon in which a small percentage of the cells in a population are resistant. Only 1 to 5% of isolates in a collection exhibit heterogeneous resistance. When a strain capable of heterogeneous resistance is spread on an agar plate containing drug, colonies form at a low frequency (1 in 10 to 1 in 100,000). The important observation is that these colonies are not 100% resistant; they contain only a small percentage of resistant cells. If the colony is respread on another plate, the same low proportion of resistant cells is observed. The resistant phenotype is not genetically fixed, but the ability of a small percentage to be resistant is fixed in these strains. This phenomenon is called heterogeneous resistance, and it has been observed in bacteria including *Staphylococcus* and *Enterococcus*. Heterogeneous resistance has been observed for azoles in *C. albicans* and *C. neoformans*. The genetic mechanisms of heterogeneous resistance have not been identified in any organism, and this heterogeneous resistance is a significant problem because the strains that show heterogeneous resistance are susceptible by the standard CLSI method for determining MICs.

High-Frequency Azole Resistance

A resistance phenotype that resembles heterogeneous resistance is known as high-frequency azole resistance (HFAR). HFAR isolates are able to form colonies at low frequencies (1 in 10 to 1 in 10,000) on agar containing azole drugs. However, unlike heterogeneous resistant colonies, these HFAR colonies retain their resistance even when grown in the absence of drug. HFAR colonies selected for fluconazole resistance are cross-resistant to all azoles and hypersusceptible to AmB. HFAR has been observed in *C. albicans, C. glabrata,* and even *S. cerevisiae,* although it has not been observed in *C. neoformans*. HFAR in *C. glabrata* has been associated with loss of mitochondrial function. This is consistent with the observation that *C. glabrata* petite mutants (cells lacking mitochondrial DNA) are azole resistant and with the observation that genes with mitochondrial function are identified in a screen for azole resistance (14). It is unlikely that fungal cells without mitochondrial function would survive in an animal model of infection, but these observations provide information on the mechanism behind HFAR.

Inducible Azole Resistance

Most susceptible strains of *C. albicans* cannot be induced in vitro to form resistance, perhaps because *C. albicans* is diploid and point mutations have no effect unless they are dominant or codominant mutations. However, there are a small number of strains in which resistance can be induced. It is possible that these strains have preexisting alterations in genes associated with drug resistance, although the mechanisms allowing the induction of resistance have not been studied. In one set of induced strains, the induction of resistance is associated with an increased expression of the efflux pumps *CDR1* and *CDR2*.

Transient Resistance

Resistance mutations are usually genetically stable and persist in cells in the absence of drug pressure. However, there are reversible mechanisms by which cells can be induced to be resistant in the presence of drug, including gene activation and repression. If resistance is the result of a reversible cell state, then resistance will persist in the presence of drug, and the cells will revert to a susceptible phenotype in the absence of drug. Such inducible resistance has been documented in vitro and in vivo.

Clinical isolates of *C. albicans* from BMT patients have been shown to have transient azole resistance, and some strains are predisposed to induction. When characterized, this transient resistance is associated with increased expression of the *CDR* efflux pumps, while the loss of resistance is associated with reduced expression of the same pumps.

Stable Resistance

Mutations occur randomly in a strain, including alterations that render the strain resistant. Such mutations might include point mutations in the *ERG11*, in the promoters of efflux pumps, or in the transcription factors that regulate those pumps. When these resistance mutations occur during an infection, the mutation would allow those cells to selectively outgrow the other cells in the population under drug pressure. Genetically fixed mutations should render the cell stably resistant to drugs. When these strains are grown in the absence of drugs, the resistant phenotype will persist if the isolates are relatively fit compared to a susceptible version of the strain. In general, stable and fit resistant isolates are obtained from patients who have received long-term antifungal treatment, such as AIDS patients.

Cross-Resistance

Based on the molecular mechanisms outlined above, it is expected that clinical isolates resistant to one azole such as fluconazole should be cross-resistant to other azoles. Point mutations in the target enzyme Erg11p may alter the active site or another part of the enzyme such that one or more azoles are unable to inhibit the enzyme. Overexpression of the *CDR* efflux pumps appears to render cells resistant to most, if not all azoles, while overexpression of the *MDR1* efflux pump does appear to be specific for fluconazole and voriconazole (30). This is consistent with MIC testing for azole-resistant clinical isolates. The *CDR* pumps alter susceptibility to fluconazole, voriconazole, itraconazole, and ketoconazole, as well as nystatin, terbinafine, and amorolfine. They do not have an effect on AmB or 5FC or two other antifungals, nikkomycin or griseofulvin. The *MDR1* efflux pump has an effect on fluconazole and to some extent voriconazole but does not have an effect on the other drugs mentioned above.

Fitness

Alterations in the drug resistance genes described above may affect the overall fitness of a strain, such that it might be less fit in the absence of drug than its susceptible counterparts. Lack of fitness may compromise the virulence of a strain. In one study, fitness was assessed by testing the virulence of matched susceptible and resistant isolates; there was no obvious correlation. Subsequent in vitro studies have been informative (7, 8). When an inducible susceptible isolate was grown in the presence of drug, it developed resistance. The developing resistant population was initially less fit than the susceptible parent when grown in the absence of drug. However, fitness improved under continued drug pressure until the resistant strain was as fit as the parent susceptible strain in the absence of drug. This fitness appears to be independent of the molecular mechanisms of resistance.

Phenotypes and MIC

In this section, several phenotypes associated with resistance have been described. These phenotypes are not usually detected with standard MIC susceptibility testing (Table 2). Even trailing will not be detected unless the investigator measures growth at both 24 and 48 h. There is no progression through these phenotypes during the development of resistance. One does not follow from the other. And strains can exhibit one or more of these phenotypes. The molecular basis has not been determined for most of these phenotypes. Understanding these phenotypes is important, in addition to MIC characterizations, to determine how a strain will behave in a patient.

MOLECULAR MECHANISMS OF NON-AZOLE DRUG RESISTANCE

Resistance to 5FC

Up to 10% of *C. albicans* clinical isolates have intrinsic resistance to 5FC, and 30% of the susceptible isolates develop acquired resistance during drug therapy. Resistance can be associated with mutations in any of the following: cytosine deaminase that converts 5FC to 5-fluorouracil, uracil phosphoribosyltransferase that is important for nucleic acid synthesis, or either of two purine-cytosine permeases. Recently, mutations in one of the purine-cytosine permeases of *C. lusitaniae* were shown to result in cross-resistance to 5FC and fluconazole, suggesting that fluconazole import may be related to 5FC import (18).

C. albicans can be divided into five clades, or groupings, based on molecular markers such as the repetitive marker Ca3 (see above). Recently, *C. albicans* 5FC resistance has been shown to be specific to clade 1 and linked to mutation in the uracil phosphoribosyltransferase gene *FUR1* (19) . In haploid *C. neoformans,* 5FC resistance can result from a single mutation at either of two specific gene loci, *FCY1* and *FCY2*.

Polyene Resistance

AmB-resistant clinical isolates have been identified in *C. tropicalis* and have been constructed in *C. albicans, C. neoformans, A. nidulans,* and *Aspergillus fennelliae* either by mutagenesis or serial passage in the presence of increasing amounts of drug. Most isolates have greatly reduced levels of ergosterol in their plasma membranes, decreasing the binding ability of AmB. Sterol analysis suggests that these isolates are defective in *ERG2* or *ERG3,* although definitive molecular analyses have not been performed. Alterations in the structure of the membrane or the sterol/phospholipid ratio may

also be associated with AmB resistance. Acquired resistance has also been described in cases where environmental isolates of *C. neoformans* were passaged in a mouse model of cryptococcosis. The passaged isolates became more resistant to AmB in the absence of drug, suggesting that resistance levels can be altered by interactions with the host.

Caspofungin Resistance

The echinocandin caspofungin has recently become clinically available, so caspofungin-resistant clinical isolates are limited in number. In vitro, resistance is usually generated by mutation in genes encoding the target enzyme, glucan synthetase, and in proteins that interact with the target. There is some indication in both *C. albicans* and *A. fumigatus* that strains overexpressing *CDR2* may have increased resistance to caspofungin (24), although this change in susceptibility is not detected by MIC analysis.

CLINICAL IMPLICATIONS AND FUTURE DIRECTIONS

Dosing

There have been no clinical studies to determine the optimal dosing of antifungal drugs to prevent resistance. In general, azole drugs should not be used prophylactically in the prevention of oral or vaginal candidiasis. However, the azoles are clearly important in the prevention of systemic infections and in the prevention of recurrent cryptococcal meningitis infections. Based on drug resistance in a variety of organisms, continuous treatment with a large dose of drug for the minimum time period required to cure the infection will have the least risk for the development of resistance.

Detection

The CLSI susceptibility test is satisfactory for determining the MICs of most yeasts and filamentous fungi. Given the multiple molecular mechanisms of resistance presented in Fig. 1 and the real possibility that there exist other mechanisms of resistance which have not been identified, a simple molecular test for resistance would be difficult to develop.

Drug Development

There is always a need for new antifungal agents that are effective against strains and species that show resistance to current therapies. New azole drugs, such as voriconazole, ravuconazole, and posaconazole, need to be carefully monitored for their effect on strains that are resistant to fluconazole.

The multiple efflux pumps in fungal genomes and the broad substrate specificity of each of these pumps suggest that strains or species with high levels of efflux may be resistant to many classes of drug. Strategies to interfere with the pumps or inhibit pump activity are currently the focus of drug development in several industry and biotechnology settings.

Drug combinations are likely to become more important in future antifungal drug strategies. AmB is currently used in combination with 5FC and with azole drugs. Azoles in combination with 5FC or with terbinafine have been discussed and tested. With the development of new antifungal drugs, such as the cell wall inhibitors (echinocandins such as caspofungin by Merck), the possible drug combinations increase dramatically.

The best way to improve the treatment success in a patient is to improve their immune status. Strategies using cytokines have been tested in the treatment of fungal disease, but further work is clearly required before such strategies become clinically applicable.

An increased understanding of antifungal drug resistance should allow for the development of new diagnostic strategies to identify resistant clinical isolates in a patient, new treatment strategies to treat these resistant infections, and new prevention strategies that would forestall the development of antifungal drug resistance in these patient populations. One fact is clear: as strategies emerge to treat resistant fungal infections, the fungal cells will continue to evolve new mechanisms of antifungal drug resistance.

Susceptibility Test Methods: Yeasts and Filamentous Fungi

ANA V. ESPINEL-INGROFF AND MICHAEL A. PFALLER

131

The introduction of modern patient management technologies and therapies has resulted in a rapidly expanding number of chemically induced immunosuppressed patients who are highly susceptible to severe fungal infections. Fungi are also important nosocomial pathogens causing severe morbidity and mortality in hospitalized patients with a combination of a variety of risk factors and immunosuppression (40, 46, 85, 88). Systemic infections caused by non-*albicans Candida* spp., *Aspergillus* spp., and other filamentous fungi (molds) (1, 30, 46) are being reported more frequently. As fungal infections became an important public health problem and resistance to established antifungal agents began to emerge (21, 24, 47, 51, 55, 93), pharmaceutical companies developed new agents with either a broader spectrum or different targets of activity.

Twelve agents have been approved for the treatment of systemic fungal diseases. Conventional amphotericin B (1956; E. R. Squibb & Sons) and its lipid formulations are polyene macrolide antibiotics (50). Resistance to amphotericin B has assumed clinical importance, particularly with certain species, such as *Aspergillus terreus* and other emerging fungal pathogens (55, 93). Amphotericin B is unstable when subjected to heat, light, or acid pH.

Flucytosine (5-FC; Hoffmann-LaRoche Inc.) is a water-soluble, stable, fungistatic antifungal compound used orally in the treatment of systemic infections caused by susceptible pathogenic or opportunistic yeasts and other fungi; development of resistance during treatment is common (23).

Miconazole, ketoconazole, fluconazole, itraconazole, and voriconazole have fungistatic activity against a variety of fungi; voriconazole has fungicidal activity in vitro and in vivo efficacy against *Aspergillus* spp. and other opportunistic molds (27, 36, 49, 67, 81). There are two additional triazoles of note: posaconazole (SCH 56592; Schering-Plough Research Institute, Kenilworth, N.J.), which has recently been approved, and ravuconazole (BMS 207147; Bristol-Myers Squibb, Wallingford, Conn.), which is under clinical evaluation. These two triazoles are non-water soluble and also have a broad spectrum of in vitro and in vivo activity against some yeasts and molds (22, 25, 44, 78, 81). Posaconazole has activity against some zygomycetes (19, 91).

The echinocandins caspofungin (MK-0991; Merck & Co., Inc.), micafungin (SK; Astellas Pharma US Inc., Deerfield, Ill.), anidulafungin (LY 303366, V-echinocandin; Pfizer), and aminocandin (Indevus Pharmaceuticals, Inc.) are inhibitors of 1,3-β-D-glucan synthesis, which leads to the lysis of growing fungal cells. Caspofungin is water-soluble, while aminocandin, anidulafungin, and micafungin lack water solubility. The echinocandins are active in vitro and in vivo against all yeasts except *Cryptococcus neoformans* and *Trichosporon* spp., and against some molds (25, 29, 59, 62, 66, 82, 95). On the other hand, the nikkomycin class inhibits chitin synthase in the fungal cell wall (51).

The mechanisms of resistance to antifungal agents and more detailed information on new and established agents are found elsewhere (chapters 129 and 130).

ANTIFUNGAL SUSCEPTIBILITY TESTING

Rationale

Ideally, in vitro susceptibility tests (i) provide a reliable measure of the relative activities of two or more antifungal agents, (ii) correlate with in vivo activity and predict the likely outcome of therapy, (iii) provide a means with which to monitor the development of resistance among a normally susceptible population of organisms, and (iv) predict the therapeutic potential of newly discovered investigational agents (40). The development of the Clinical and Laboratory Standards Institute (CLSI; formerly the National Committee for Clinical Laboratory Standards [NCCLS]) reference method M27-A2 (13) has improved the reproducibility of in vitro antifungal susceptibility data and facilitated the establishment of interpretive breakpoints for the triazoles fluconazole and itraconazole and more recently for voriconazole (13, 16, 87). Based on historical data and the pharmacokinetics of 5-FC, interpretive breakpoints for 5-FC and *Candida* spp. also have been established (13). Some correlation has been suggested between amphotericin B MIC results obtained by nonstandardized methods and clinical outcome. Unfortunately, most M27-A amphotericin B MICs for yeasts are within a very narrow range (0.25 to 1 μg/ml) (13), precluding a clear discrimination between susceptible and potentially resistant isolates. Also, data are not available for the evaluation of an optimal procedure for the detection of amphotericin B resistance.

With the use of both established and investigational agents has come the recognition of resistance to one or more antifungal agents in selected isolates. As a result, clinical laboratories are now being asked to assume a greater role in the selection and monitoring of antifungal chemotherapy. The methods that have been more frequently applied to

TABLE 1 Methods used for antifungal susceptibility testing

Test method	Means of endpoint determination
Broth macrodilution (yeasts)	Visual comparison of turbidity with turbidity of 80% inhibition standard (1:5 growth control dilution) (M27-A2 document)
Broth microdilution (yeasts)	Visual comparison of growth (≥50% inhibition) with that of growth control (M27-A document)
Colorimetric microdilution (yeasts [YeastOne] and molds)	Visual observation of color change
Spectrophotometric microdilution (yeasts)	Turbidimetric MIC determination by spectrophotometer
Macro- and microdilution (filamentous fungi)	Visual comparison of growth (100% inhibition) with that of growth control (M38-A document)
Agar macrodilution (yeasts and molds, standard dishes)	Visual
Agar diffusion (yeasts and molds)	
Disk (yeasts)	Zone diameter (visual)
Antifungal strip (E test)	Ellipse of inhibition (visual)

antifungal susceptibility testing are listed in Table 1. The CLSI (formerly NCCLS) Subcommittee on Antifungal Susceptibility Testing has developed reference methods for broth macro- and microdilution susceptibility testing of yeasts (CLSI M27-A2 document) and molds (CLSI M38-A document) and more recently a disk diffusion method for yeasts (CLSI M44-A document) (Tables 2 to 8) (13–15).

In vitro antifungal susceptibility testing is influenced by a number of technical variables, including inoculum size and preparation, medium formulation and pH, duration and temperature of incubation, and the criterion used for MIC endpoint determination. In addition, antifungal susceptibility testing is complicated by problems unique to fungi, such as slow growth rates (relative to bacteria) and the ability of

TABLE 2 CLSI (formerly NCCLS M27-A2 document) broth dilution guidelines for antifungal susceptibility testing of yeasts[a]

Parameter	Description
Broth medium	RPMI 1640 broth buffered with MOPS buffer (0.165 M) and 0.2% dextrose to a pH of 7.0 at 25°C
Medium modifications	(i) Yeast nitrogen base broth (pH 7.0) with MOPS provides better growth for *C. neoformans* and (ii) RPMI-1640 with 2% dextrose
Inoculum preparation	From 24-h (*Candida* spp.) or 48-h (*C. neoformans*) cultures on Sabouraud dextrose agar
Stock inoculum suspension	Adjusted by spectrophotometer at 530 nm to match the turbidity of a 0.5 McFarland standard (1×10^6 to 5×10^6 CFU/ml)
Test inoculum	1:2,000 (macrodilution) or 1:1,000 (microdilution) dilutions with medium of the stock inoculum suspension; inoculum size after inoculation, 0.5×10^3 to 2.5×10^3 CFU/ml (both methods)
Drug dilutions	Additive 10× (macrodilution) or 2× (microdilution) twofold drug dilutions with medium (fluconazole, caspofungin, and 5-FC) or 100× with solvent (amphotericin B, other azoles, anidulafungin, and micafungin)
Drug dilution ranges	
5-FC and flucytosine	0.12–64 μg/ml
Other drugs	0.03–16 μg/ml
Methods	
Macrodilution	0.9 ml of diluted test inoculum plus 0.1 ml of 10× drug concentration
Microdilution	100 μl of diluted test inoculum plus 100 μl of 2× drug concentration
Growth control(s)	
Macrodilution	0.9 ml of diluted inoculum plus 0.1 of drug-free medium (or plus 2% of solvent)
Microdilution	100 μl of diluted inoculum plus 100 μl of drug-free medium (or plus 2% of solvent)
MIC by visual examination	
Amphotericin B, macro- and microdilution	Lowest drug concentration that prevents any discernible growth
5-FC, azoles, caspofungin, and other echinocandins	(i) Lowest drug concentration that shows prominent (~50%) growth inhibition (microdilution) and (ii) lowest drug concentration that matches an 80% inhibition standard (macrodilution)
Reading modification[b]	*C. neoformans* MICs determined spectrophotometrically at 492 nm after 48 h of incubation

[a] Data from references 13 and 65.
[b] M27 document includes this reading modification when using the broth microdilution method with yeast nitrogen base broth and a 10^4-CFU/ml inoculum.

TABLE 3 MIC ranges for QC and reference isolates for CLSI broth macrodilution and microdilution methods[a]

QC or reference isolates	Antifungal agent	MIC range (μg/ml)		
		48 h, macrodilution	24 h, microdilution	48 h, microdilution
QC isolates				
Candida parapsilosis ATCC 22019	Amphotericin B	0.25–1.0	0.25–2.0	0.5–4.0

TABLE 4 Zone diameters for QC isolates for CLSI disk diffusion method[a]

Antifungal agent	Disk content (μg)	Zone diameter (mm)			
		C. albicans ATCC 90028	*C. parapsilosis* ATCC 22019	*C. tropicalis* ATCC 750	*C. krusei* ATCC 6258
Fluconazole	25	28–39	33–33	26–37	—[b]
Voriconazole	1	31–42	28–37	—[b]	16–25
Posaconazole	5	24–34	25–36	23–33	23–31

[a] Data from references 7, 15, and 70 and from the CLSI Subcommittee Meeting Minutes, January 2006.
[b] —, zone diameters not established due to lack of interlaboratory reproducibility.

certain fungi (dimorphic) to grow either as a unicellular yeast form that produces blastoconidia or as a hyphal or filamentous fungal form that may produce conidia or sporangiospores, depending on pH, temperature, and medium composition. Finally, the basic properties of the antifungal agents themselves, such as solubility, chemical stability, modes of action, and the tendency to produce partial inhibition of growth over a wide range of concentrations above the MIC, must be taken into account.

Standardized Broth Dilution Methods for Yeasts

As a result of several collaborative studies (8, 39, 43, 72), the M27-A2 document (approved standard, second edition) is available for testing yeast fungi such as *Candida* spp. and *C. neoformans* by both macrodilution and microdilution broth formats (13); breakpoints for fluconazole, itraconazole, voriconazole, and 5-FC versus *Candida* spp. have been established (see Table 6). Other relationships between results obtained with the reference method and patient response have not been established, e.g., among others, for *C. neoformans* and other yeasts and yeast-like organisms or other agents.

Microdilution

The broth microdilution test (Table 2) has become the most widely used technique for antifungal susceptibility testing; this approach is described in the M27-A2 document (13) and also below. Although the antifungal broth macrodilution test was the first method proposed by the CLSI Subcommittee, this test is cumbersome for use in the clinical laboratory. The microdilution test provides consistent MIC results, and interlaboratory agreement of the microdilution MICs can be higher than that of the macrodilution MICs for some drugs (39).

Standard Medium

The test medium recommended by the Subcommittee is the RPMI 1640 (RPMI) with L-glutamine and a pH indicator and without sodium bicarbonate broth (04-525Y from BioWhittaker, Walkersville, Md., and American Biorganics, Inc., Niagara Falls, N.Y.; and R-6504, from Sigma Chemical Co., St. Louis, Mo.). The medium should be buffered to a pH of 7.0 at 25°C with MOPS (morpholinepropanesulfonic acid; final molarity at pH 7.0, 0.165). The RPMI medium is suitable for testing most fungi (13, 14, 35, 39, 43), but it may not be adequate to support the growth of some strains of *C. neoformans* or to determine amphotericin B MICs. RPMI medium containing 2% dextrose (13, 18) and yeast nitrogen base broth (2, 89) may enhance the growth of yeasts, facilitating the determination of MICs. However, 2% dextrose does not have a significant impact on the growth density at 24 h and it could falsely elevate the MICs at 48 h (64) and produce lower MICs at 24 h. The European Committee on Antibiotic Susceptibility Testing (EUCAST) method for testing fermentative yeasts has been proposed in Europe (to be described later), which includes the use of this modified RPMI medium (18).

Drug Stock Solutions

Antifungal standards can be obtained directly from the drug manufacturers or from the U.S. Pharmacopeia (Rockville, Md.). Clinical intravenous or oral preparations should not be used (13, 14). Antifungal stock solutions should be prepared at concentrations at least 10 times the highest concentration to be tested (e.g., 1,280 μg/ml for fluconazole and 5-FC).

TABLE 5 CLSI M44-A document guidelines for antifungal disk diffusion susceptibility testing of *Candida* spp.[a]

Paramenter	Description
Agar medium	Mueller-Hinton agar + 2% dextrose and 0.5 μg of methylene blue dye/ml
Inoculum preparation	From 24-h cultures on Sabouraud dextrose agar as described in Table 2 for broth micro- and macrodilution methods
Test medium	Stock inoculum suspension, adjusted by spectrophotometer at 530 nm to match the turbidity of a 0.5 McFarland standard: 1×10^6 to 5×10^6 CFU/ml
Disk contents	Fluconazole, 25 μg; voriconazole, 1 μg; posaconazole, 5 μg
Incubation conditions	20 to 24 h at 35°C
Reading zone diameter	To the nearest whole millimeter at the point at which there is prominent reduction in growth. Pinpoint microcolonies at the zone edge or large colonies within the zone should be ignored.

[a] Data from reference 15.

TABLE 6 Interpretive MIC breakpoints and corresponding zone diameters for in vitro susceptibility testing of *Candida* species[a]

Antifungal agent	MIC breakpoint, in μg/ml (zone diameter, in mm)			
	Susceptible	Susceptible–dose dependent	Intermediate	Resistant
Fluconazole	≤8 (≤19)	16–32 (15–18)		≥64 (≤14)
Voriconazole	≤1 (≥17)	2 (14–16)		≥4 (≤13)
Itraconazole	≤0.125 (NA)	0.25–0.5 (NA)		≥1 (NA)
Flucytosine (5-FC)	≤4 (NA)		8–16 (NA)	≥32 (NA)

[a] Data from references 13, 15–17, 87. For fluconazole and voriconazole, these guidelines are based on mucosal candidiasis and for fluconazole on limited data for invasive *Candida* infections. For itraconazole, the data are based on mucosal infections only. For fluconazole, susceptibility for S-DD MICs depends on achieving the maximal possible blood level, >400 mg/dose. (*C. krusei* is intrinsically resistant to fluconazole.) For itraconazole, a concentration in plasma of >0.5 μg/ml may be required for optimal response. For flucytosine, the clinical significance of intermediate MICs is still uncertain. NA, not available.

Solutions of standard powders of 5-FC (Hoffmann-LaRoche), fluconazole (Pfizer Pharmaceuticals), caspofungin (Merck Co.), or any other water-soluble agent are prepared in distilled water. For testing non-water-soluble agents, sufficient drug standard should be weighed to prepare a solution of 1,600 μg/ml. These standard substances may be solubilized in dimethyl sulfoxide, polyethylene glycol (posaconazole), or dimethylformamide. The actual amount to be weighed must be adjusted according to the specific biological activity of each standard. Amphotericin B solutions must be protected from light, and drug stock solutions prepared with solvents should be allowed to stand for 30 min before use.

The sterile stock solutions may be stored in small volumes in sterile polypropylene or polyethylene vials carefully sealed at −60°C (preferably) or below for 6 months or more without significant loss of activity, but never at a temperature higher than −20°C. Vials should be removed as needed and used on the same day. Any unused drug should be discarded at the end of the day. The use of quality control (QC) strains (8, 13, 33, 52), such as those listed in Table 3, will help in evaluating drug activity.

Preparation of Inocula

Inocula should be prepared by the spectrophotometric method (13, 72) as outlined in Table 2. The yeasts are grown on plates of Sabouraud agar (Emmons 11589 Sabouraud dextrose agar from BBL; or modified 0747 Sabouraud agar from Difco) at 35°C and subcultured at least twice to ensure purity and viability. The inoculum suspension is prepared by picking five colonies, each at least 1 mm in diameter, from 24-h-old cultures of *Candida* spp. or 48-h-old cultures of *C. neoformans* and suspending the material in 5 ml of sterile 0.85% NaCl. The turbidity of the cell suspension measured at 530 nm is adjusted with sterile saline to match the transmittance produced by a 0.5 McFarland barium sulfate standard. This procedure produces a cell suspension containing 1×10^6 to 5×10^6 CFU/ml, which is then diluted 1:1,000 with RPMI medium to provide the 2× test inoculum (1×10^3 to 5×10^3 CFU/ml). The 2× inoculum is diluted 1:1 when the wells are inoculated to achieve the desired final inoculum size (0.5×10^3 to 2.5×10^3 CFU/ml).

TABLE 7 Optical density ranges and mean inoculum sizes for filamentous fungi[a]

Fungus	OD range	Mean inoculum size (10^6 CFU/ml)
Aspergillus spp.	0.09–0.11	1.6
Bipolaris spp.	0.2–0.4	0.6
Dactylaria constricta	0.15–017	1.1
Cladophialophora bantiana	0.15–0.17	1.1
Fusarium spp.	0.15–0.17	3.0
Paecilomyces lilacinus	0.09–0.13	2.1
Scedosporium apisospermum	0.15–0.17	1.0
Rhizopus arrhizus	0.15–0.17	1.3
Scedosporium prolificans	0.15–0.17	0.8
Sporothrix schenckii	0.09–0.11	2

[a] Data from multicenter studies (14, 34, 35, 37, 38). Optical densities at 530 nm.

Drug Dilutions and Performance of Microdilution Test for Yeasts

For drugs dissolved in solvents other than water (e.g., the polyenes, itraconazole, new triazoles, and anidulafungin), intermediate test drug dilutions are prepared from stock solutions to be 100 times the strength of the final drug concentration, with 100% solvent (e.g., dimethyl sulfoxide) used as a diluent according to the standard additive twofold drug dilution schema (13) (e.g., 1,600 to 3 μg/ml for amphotericin B, anidulafungin, aminocandin, and all azoles except fluconazole). This procedure prevents precipitation of agents with low solubility in aqueous media. Despite this procedure, itraconazole and some other agents do not remain completely solubilized upon dilution into aqueous media. Thus, at high concentrations, a certain amount of turbidity is encountered and may interfere with the interpretation of MIC endpoints. For water-soluble drugs (e.g., fluconazole and caspofungin), drug dilutions are prepared from the stock to be 10 times the final test drug concentrations directly in RPMI medium according to the additive, twofold drug dilution schema (13) (e.g., 640 to 1.2 μg/ml for fluconazole and 5-FC). The 10× and 100× drug concentrations should be diluted 1:5 and 1:50, respectively, with RPMI to achieve the 2× drug concentrations needed for the microdilution test; after the inoculation step the drug concentrations are 16 to 0.03 μg/ml for amphotericin B, echinocandins, and triazoles and 64 to 0.12 μg/ml for fluconazole and 5-FC.

The broth microdilution test is performed by using sterile, disposable, multiwell microdilution plates (96 U-shaped wells) (e.g., Dynatech Laboratories, Inc., Alexandria, Va.). A multichannel pipette (or a large dispensing instrument for 96-well trays) is used to dispense the 2× drug concentrations in 100-μl volumes into the wells of rows 1 to 10 of the microdilution plates. Row 1 contains the highest drug

TABLE 8 CLSI M38-A document guidelines for broth dilution antifungal susceptibility testing of filamentous fungi[a]

Parameter	Description
Medium for conidial growth	Potato dextrose, 35°C (7 days); *Fusarium* spp. may need 30°C incubation for the last 4 days
Inoculum morphology	Conidia or sporangiospores
Recommended OD ranges	For *Aspergillus* and for *R. arrhizus*, 0.09–0.11; for *Fusarium* and *S. apiospermum* 0.15–0.17; stock inoculum suspensions, 0.4×10^6 to 5×10^6 CFU/ml
Inoculum concentration (final)	0.4×10^4 to 5×10^4 CFU/ml or 1:50 dilution of stock suspension (*S. apiospermum*, 2:50)
Test medium	RPMI 1640 for the yeasts (pH, 7.0 ± 0.1)
Format	Microdilution assay; total volume/well, 200 μl
Drug concentration	Amphotericin B and itraconazole, 0.01–8.0 μg/ml
Incubation conditions	For *R. arrhizus,* 24 h; for *C. bantiana, D. constricta, S. prolificans,* and *S. apiospermum,* 72 h; for *Aspergillus* spp., *Bipolaris* spp., *Exserohilum* spp., *Fusarium* spp., *P. lilacinus, T. longibrachiatum, S. schenckii,* and *W. dermatitidis,* 48 h
Endpoint determination, visual	Growth relative to that for positive growth control, absence of growth
Colorimetric (Alamar Blue)	For amphotericin B, first blue well or without color change; for azoles, first blue well or slightly purple well

[a] Data from references 14, 34, 35, 37, and 38.

concentration (either 64 or 16 μg/ml), and row 10 contains the lowest drug concentration (either 0.12 or 0.03 μg/ml). Microdilution trays can be stored at −60°C for 3 to 6 months. Each well is inoculated on the day of the test with 100 μl of the corresponding 2× inoculum, which brings the drug dilutions and inoculum densities to the final test concentrations (final volume in each well, 200 μl). The growth control wells contain 100 μl of sterile drug-free medium (for water-soluble agents) or 100 μl of sterile drug-free medium with 2% solvent (for non-water-soluble agents) and are inoculated with 100 μl of the corresponding 2× inoculum. The QC yeasts are tested in the same manner as the other isolates and are included each time an isolate is tested. Row 11 of the microdilution plate can be used for the sterility control (drug-free medium only).

Incubation and Determination of Microdilution MICs for Yeasts

The microdilution plates are incubated at 35°C for 46 to 50 h *(Candida)* and 70 to 74 h *(C. neoformans)* in ambient air. The determination of MIC endpoints is a critical step in antifungal susceptibility testing, especially with the azoles (for yeasts) and echinocandins (for yeasts and molds). The growth in each well is compared with that in the growth control (drug-free) well with the aid of a reading mirror (e.g., Cooke Engineering Co., Alexandria, Va.). The MIC for amphotericin B is defined as the lowest concentration at which complete absence of growth (optically clear) is observed.

The partial inhibition or trailing that is observed with 5-FC, the azoles, and most of the new and investigational agents precludes the determination of well-defined endpoints and creates a great deal of variability in interpretation. Therefore, the MIC of 5-FC and the azoles is defined as the lowest concentration at which prominent growth inhibition is observed (~50% or less of the growth in the growth control well) (Table 2). Agitation of the microdilution trays (3) (see below) is highly recommended prior to MIC determination; this step facilitates the visual estimate of prominent growth inhibition. In most instances when testing *Candida* spp., azole MICs may be read following incubation for 24 h. The shorter incubation minimizes much of the difficulty with trailing and may improve the clinical correlation slightly (32, 88). Another means to overcome the presence of trailing is the cumbersome measurement of ergosterol production in cells exposed to selected concentrations of fluconazole (6). Trailing growth is also a problem when reading MICs of the echinocandins for some *Candida* spp. It appears that a 50% inhibition endpoint after 24 h of incubation may be the best approach for the echinocandins when testing yeasts (65); however, the optimal testing conditions for this class of agents are still under investigation.

Macrodilution

Broth macrodilution tests are adequate for the testing of all antifungal agents and are suitable for small laboratories in which the volume of these tests is low. Only the steps and testing conditions that are relevant to the macrodilution test are discussed in detail here (Table 2). Each intermediate drug concentration solution is further diluted (1:10) in RPMI medium to obtain 10 times the final strength (e.g., 160 to 0.3 μg/ml). This step reduces the final solvent concentration to 10%. The 10× drug dilutions are dispensed in 0.1-ml volumes into round-bottom, snap-cap, sterile polystyrene tubes (12 by 75 mm; e.g., Falcon 2054; Becton Dickinson Labware, Lincoln Park, N.J.); these tubes can be stored at −60°C for 3 to 6 months. On the day of the test, each tube is inoculated with a 0.9-ml volume of the corresponding diluted yeast inoculum suspension. This step brings the drug dilutions to the final test drug concentrations mentioned above and the corresponding solvent to 1% in each MIC tube. The stock inoculum suspensions are prepared and adjusted as described above for the microdilution test and are then diluted 1:2,000 with RPMI to provide an inoculum of 0.5×10^3 to 2.5×10^3 CFU/ml. The growth control tube(s) is inoculated with a 0.9-ml volume(s) of the inoculum suspension(s) and a 0.1-ml volume(s) of drug-free medium with 1% of the corresponding solvent. The QC yeasts (Table 3) are tested in the same manner as the other isolates and are included each time an isolate is tested. In addition, 1 ml of uninoculated drug-free medium (for water-soluble agents) or drug-free medium with 1% of the corresponding solvent is included as a sterility control.

Incubation and Determination of Macrodilution MICs for Yeasts

The MIC tubes are incubated at 35°C without agitation for 46 to 50 h *(Candida)* and 70 to 74 h *(C. neoformans)* in ambient air; the turbidity or growth in each tube is visually

graded. For amphotericin B, the MIC is read as the lowest concentration that prevents any discernible growth. For azoles and 5-FC, the MIC is defined as the lowest drug concentration that reduces growth by 80% relative to that of the growth control (Table 2) (13). The amount of trailing or partial inhibition can be estimated by diluting the drug-free growth control 1:5 (0.2 ml of growth control plus 0.8 ml of medium) with medium, which provides an 80% inhibition standard tube for comparisons with each MIC tube (13, 39). This approach provides a convenient and direct method of establishing a specific turbidity endpoint for each isolate that more precisely reflects an 80% inhibition.

Quality Control for Yeast Testing

QC of MIC tests is essential to good laboratory practice. *Candida parapsilosis* ATCC 22019 and *Candida krusei* ATCC 6258 have been selected as the QC strains according to the CLSI guidelines for such selection. Table 3 summarizes the expected MIC ranges of 10 antifungal agents for these two QC isolates in both macro- (48-h ranges only) and microdilution (both 24- and 48-h ranges) testing (CLSI M27-S2) (16). Each new batch of medium and lot of macrodilution tubes and microdilution trays should be checked with one of the two QC strains to determine if the MICs are within these ranges (8, 16, 52). In addition, the overall performance of the test system should be monitored by testing either or both QC isolates each day on which a test is performed for each drug. Details regarding corrective measures when the MICs for the QC isolates are not within the expected ranges are found in the M27-A2 document (13).

Expected Results

Most (about 95%) clinical yeast isolates are inhibited by ≤8.0 μg/ml of 5-FC (79, 84); however, isolates of *C. neoformans* for which MICs are ≥16 may be recovered from patients during treatment with 5-FC. *Candida* isolates for which 5-FC MICs are ≥32 μg/ml and ≤4 μg/ml are considered resistant and susceptible, respectively (Table 5) (13). Amphotericin B MICs determined by the microdilution M27-A method for 94% of clinical yeast isolates are ≤1.0 μg/ml and >2 μg/ml for the other 6% (13). An amphotericin B MIC of 2.0 μg/ml (or greater) suggests probable clinical resistance, since this MIC only approximates the concentrations achievable in serum at high doses of amphotericin B (≥1 mg/kg of body weight per day) and exceeds that achievable in cerebrospinal fluid. The difference in amphotericin B MICs for susceptible and potentially resistant isolates is probably very small (see above), so caution should be exercised in the interpretation of results. Although it has been suggested that antibiotic medium 3 provides reliable detection of resistant isolates, lot-to-lot variability has been documented (57). In addition, this medium did not improve the detection of potentially amphotericin B-resistant isolates recovered from patients with candidemia, who had failed amphotericin B therapy (microbiologic failure) (63).

Ketoconazole is fungistatic for most yeast isolates, with MICs of 0.03 to 16 μg/ml by the M27-A2 microdilution method. Fluconazole inhibits the majority (~90%) of *Candida* spp. and *C. neoformans* at concentrations of ≤8 μg/ml; however, MICs for *Candida glabrata* and *C. krusei* generally are 4 to 16 μg/ml and 16 to ≥64 μg/ml, respectively (81). Itraconazole is generally quite active in vitro, with MICs of 0.01 to 1.0 μg/ml or less for most yeast isolates, except for *C. glabrata* (0.06 to 8 μg/ml) and *C. krusei* (0.5 to 2 μg/ml). Overall, ≥99% of isolates of *Candida* spp. and *C. neoformans* are inhibited by ≤1 μg/ml of posaconazole, ravuconazole, and voriconazole, but high voriconazole MICs have been reported for *Sporobolomyces salmonicolor*, *Rhodotorula rubra*, and for some *Candida albicans* and *C. glabrata* isolates (25, 36, 44, 81). MICs of the echinocandins are usually ≤2 μg/ml for most *Candida* isolates, except for *Candida guilliermondii* and some *C. parapsilosis* isolates (22, 25, 29, 62, 82); trailing is observed with these species.

Broth-Based Alternative Approaches for Yeasts

Although the CLSI methods for in vitro susceptibility testing were essential for standardization and to improve interlaboratory reproducibility, they may not be the best methods for testing all organisms or for routine use in clinical laboratories. Modifications of reference methods offer promise as alternative approaches that may better serve clinical laboratory needs; some of these methods are described below.

Colorimetric Methods

A novel alternative to the standard method of visually grading turbidity is the use of colorimetric indicators or fluorescent dyes for the determination of MIC endpoints. Commercial (Sensititre YeastOne and FUNGITEST) and noncommercial (tetrazolium salt methods and substrate uptake indicators) procedures have been adapted for antifungal susceptibility testing (20, 40, 41, 69, 73). The agreement of colorimetric MICs with reference macrodilution and microdilution MICs has been quite good (>90%). However, itraconazole MICs determined by the colorimetric method have been reported to be higher than those determined by the CLSI methods, and agreement has been low with fluconazole for *C. glabrata* and *C. tropicalis* (40). The Sensititre YeastOne method (Trek Diagnostic Systems Inc., Westlake, Ohio), which incorporates Alamar Blue as the oxidation-reduction colorimetric indicator (fungal growth changes the indicator from blue to pink), has obtained FDA clearance for testing fluconazole, itraconazole, and 5-FC; azole and 5-FC MICs should be read after 24 h, and amphotericin B should be read after 48 h (40); the MIC is the first well that does not show a color change from blue (amphotericin B and other drugs) or purple (azoles and 5-FC) to pink. This method minimizes the trailing effect of azoles.

Spectrophotometric Methods

Microdilution methods allow the determination of endpoints with automated plate reading and yield MIC values that are more accurate and objective than those by other tests. Agitation of microtiter plates (3) at 50 rpm for at least 5 min by use of a microdilution tray shaker before spectrophotometric MIC determination is essential to obtain homogeneous cell suspensions in the wells and hence a more precise MIC determination. However, the inability to obtain homogeneous cell suspensions with some yeasts demands manual mixing of the cells in each well by using a micropipette tip. The spectrophotometric method allows the determination of different levels (%) of growth inhibition (GI), e.g., a GI_{50} corresponds to the first well that shows a 50% decrease in optical density (OD) relative to the OD in the drug-free growth control well. Turbidimetric growth inhibition levels of 50% (GI_{50}) with the azoles and 5-FC and of 90% (GI_{90}) with amphotericin B (530- to 550-nm wavelength) have provided the most accurate values (25, 40, 64, 89).

Flow Cytometry

Flow cytometric methods also have been adapted for antifungal susceptibility testing by introducing DNA-binding vital dyes into the culture to detect fungal cell damage after exposure to an antifungal agent (11, 40, 97). MICs determined

by this approach have been comparable to those obtained by the M27-A2 methods (11, 97). Although these methods produce faster results (4 to 6 h), the need for a flow cytometer for MIC determination would preclude their use in small laboratories.

Standardized Disk Diffusion Method for Yeasts

Worldwide, the most commonly used technique for antibacterial susceptibility testing is the disk diffusion test, which yields a quantitative result (zones of inhibition) and a qualitative interpretive category (e.g., susceptible or resistant). Agar disk diffusion testing is a simple, flexible, and cost-effective alternative to broth dilution testing. Disk diffusion testing of antifungal agents has been slow to develop despite the fact that early studies with fluconazole disks showed promise for testing *Candida* spp. The CLSI Subcommittee on Antifungal Susceptibility Testing has developed a disk diffusion method (Table 5) for testing *Candida* spp. with fluconazole and voriconazole (M44-A document) (15). One significant advantage of the M44-A disk diffusion method is that results can be obtained after 20 to 24 h of incubation. A comparison of results of fluconazole disk diffusion testing from 54 laboratories (2,949 isolates of *Candida* spp.) with results from a central reference laboratory showed an overall categorical agreement of 90.4% with only 0.4% very major (false-susceptible) errors (74). It is expected that disk diffusion testing will be expanded to include other azoles and additional classes of antifungal agents (58). Recently, the M44 disk test method has been shown to be a useful approach for determining the susceptibility of *C. neoformans* to fluconazole (83).

Zone interpretive criteria (Table 6) have been approved for fluconazole and more recently for voriconazole (CLSI M44-S1) (15, 17).

Standard Medium

The CLSI M44-A method uses Mueller-Hinton agar supplemented with 2% dextrose and 0.5 μg/ml methylene blue (15). The increased dextrose and the methylene blue supplementation improve yeast growth and provide sharper zones surrounding the fluconazole, posaconazole, and voriconazole disks (15); in addition, this medium is readily available and has shown acceptable batch-to-batch reproducibility. The pH of the medium should be 7.2 to 7.4 at room temperature after gelling, and the surface of the agar should be moist, but moisture droplets on the agar surface or on the petri dish cover should not be present (15). The medium can be prepared and poured with the two supplements, or the supplements can be added to commercially prepared Mueller-Hinton agar plates; the latter enables the use of the routine agar plates from the bacteriology laboratory. A detailed instruction for the preparation of the agar plates is found in the M44-A document (15).

Preparation of Inocula

The M44-A method employs an inoculum suspension adjusted to the turbidity of a 0.5 McFarland by the spectrophotometer, as described above for broth dilution standard methods (Tables 2 and 5) (13, 15).

Performance of Disk Diffusion Method for Yeasts

The agar plates are inoculated within 15 min after adjusting the inoculum suspension as follows (Table 5). Briefly, a sterile cotton swab is dipped into the undiluted inoculum suspension, rotated several times, and pressed firmly against the inside wall of the tube above the fluid level to remove excess fluid. The entire dried agar surface is evenly streaked in three different directions, swabbing the rim of the plate as the final step. The lid of the plate should be left ajar to allow the agar surface to dry for no more than 15 min. Fluconazole (25 μg), posaconazole (5 μg), and voriconazole (1 μg) disks are dispensed onto the inoculated agar surface. Disks must be pressed down to ensure complete contact with the agar and distributed evenly so they are not closer than 24 mm from center to center. After the disks are placed, they cannot be moved because drug diffusion is almost instantaneous. Plates should be incubated within 15 min after disks have been disposed (15).

Incubation and Determination of Disk Diffusion Zone Diameters for Yeasts

After 20 to 24 h of incubation at 35°C, the resulting inhibition zones should be uniformly circular and a confluent lawn of growth should be present. The plates are read above a black, nonreflecting background illuminated with reflected light (15). The zone diameters surrounding the 25-μg fluconazole disks, 5-μg posaconazole disks, and 1-μg voriconazole disks are measured to the nearest whole millimeter at the point at which there is prominent reduction in growth. Pinpoint microcolonies at the zone edge or large colonies within a zone are ignored. If growth is insufficient, the plates should be read at 48 h (Table 5) (15).

Quality Control for Antifungal Susceptibility Disk Testing of Yeasts

QC zone diameter limits have been defined for fluconazole, posaconazole, and voriconazole when testing *Candida* spp. (Table 4) (7, 15, 70; CLSI Subcommittee Minutes, January 2006 meeting).

Agar-Based Alternative Approaches for Yeasts

NeoSensitabs Tablets

A commercial agar diffusion test from Rosco Diagnostica (A/S Rosco, Taastrup, Denmark) is available in Europe for antifungal susceptibility testing of yeasts. Tablets of established and some of the new antifungal agents (e.g., voriconazole, caspofungin, and posaconazole) are available. Preliminary comparisons with both M27-A2 and M44-A methods have provided promising results (A. Espinel-Ingroff, E. Cantón, D. L. Gibbs, and A.Wang, *15th Eur. Congr. Clin. Microbiol. Infect. Dis.*, abstr. P-1736, 2005).

E Test

The E test (AB Biodisk, Solna, Sweden) is based on the diffusion of a stable concentration gradient of an antimicrobial agent from a plastic strip onto an agar medium. E-test strips for amphotericin B, fluconazole, 5-FC, ketoconazole, itraconazole, voriconazole, and caspofungin are commercially available (AB Biodisk). However, for clinical use FDA has approved only fluconazole, itraconazole, and 5-FC strips. Agreement of E-test and reference MICs has been species and medium dependent; low agreement has been reported for *C. glabrata*, *C. tropicalis*, and *C. neoformans* (40). The medium that provides the best performance for E-test MICs is solidified RPMI medium supplemented with 2% dextrose, and reading requires expertise and close adherence to the manufacturer's instructions. The E test may be useful in testing yeasts suspected of being potentially resistant to amphotericin B (68, 71, 96). Amphotericin B MICs of ≥0.38 μg/ml determined by E test for *Candida* spp. have been associated with therapeutic failure in patients treated with amphotericin B for candidemia (12). This method has

been evaluated for testing the susceptibilities of *Candida* spp. to new triazoles and caspofungin (76, 77).

Fungicidal Activity

Standard testing parameters are not available for the evaluation of the fungicidal activity of antifungal agents. The determination of minimum fungicidal concentrations (MFCs) requires the subculturing onto an agar medium of fixed volumes from each MIC tube or well that shows complete inhibition of growth. The criteria for MFC determination vary in different publications, and the MFC has been described as the lowest drug concentration resulting in either no growth or three to five colonies (9, 86). It has been reported that amphotericin B MFCs can be better predictors of microbiological failure than MICs in candidemia (63) and trichosporonosis (94). The clinical relevance and the development of standard guidelines for MFC determination need to be addressed.

EUCAST Method

Subsequent to the development of the CLSI M27-A method for broth microdilution testing of yeasts, a similar method has been developed under the auspices of the Subcommittee on Antifungal Susceptibility Testing (AFST) of the EUCAST (18). This method is similar to the M27-A2 method (Table 2) but employs a higher inoculum (10^5 CFU/ml), RPMI medium supplemented with additional dextrose (2%), and spectrophotometric readings of MIC endpoints following incubation at 35 to 37°C for 24 h. Although good intralaboratory reproducibility of the EUCAST method as well as good agreement between EUCAST and CLSI microdilution methods has been documented, CLSI breakpoints should not be used to interpret EUCAST MICs; the latter MICs are consistently lower than reference values, and falsely susceptible results could be reported (31). However, such global collaboration in standardization of an antimicrobial susceptibility testing method is rare and marks a very positive step in the improvement of antifungal susceptibility testing worldwide.

Standardized Broth Dilution Methods for Molds

Although the number of serious infections caused by the filamentous fungi is lower than the number of yeast infections, antifungal susceptibility testing of these opportunistic pathogens may be important in guiding the selection of antifungal agents for the treatment of invasive disease. On the basis of results from multicenter studies (34, 35, 37, 38), the CLSI Subcommittee has developed both broth micro- and macrodilution methods for testing molds that are more frequently associated with invasive infections (14). These optimal testing conditions are described below (Tables 3, 7, and 8). The other steps are similar to the ones described for broth dilution methods for yeasts (see above).

Microdilution

Standard Medium

The test medium is the same MOPS-buffered standard RPMI recommended for yeast testing (13, 14).

Drug Stock Solutions

Drug stock solutions are prepared as described above for yeast testing (13) and in the CLSI M38-A document (14).

Preparation of Inocula

Since nongerminated conidia are easier to prepare and standardize, this is the method of inoculum preparation described in the M38-A document (14). A comparison of germinated versus nongerminated conidial suspensions has demonstrated that MICs and MFCs of amphotericin B, itraconazole, posaconazole, ravuconazole, and voriconazole for *Aspergillus* spp. are similar or within 2 dilutions with both types of inocula (40).

The inoculum for each isolate is prepared by first growing the mold on potato dextrose agar slants (Remel, Lenexa, Kans.) for 7 days at 35°C. A conidial suspension is prepared by flooding each slant with approximately 1 ml of sterile 0.85% saline. The resulting mixture is withdrawn, and the heavy particles are allowed to settle for 3 to 5 min. The upper homogeneous suspension, containing the mixture of nongerminated conidia or sporangiospores and hyphal fragments, is mixed for 15 s with a vortex. The turbidity of the mixed suspension is measured by using a spectrophotometer at 530 nm and adjusted to a specific final OD range (Table 7) for each species tested (14, 37, 38). Stock inoculum suspensions are diluted 1:50 in medium to obtain 2× the strength needed for the test.

Drug Dilutions and Performance of Microdilution Test for Molds

Drug dilutions are prepared and dispensed in sterile, disposable, multiwell microdilution trays, as described above for yeast testing. On the day of the test, each well is inoculated with 100-μl volumes of the 1:50 conidial or sporangiospore suspensions.

Incubation and Determination of Broth Microdilution MICs for Molds

All microdilution trays are incubated at 35°C, and MICs are determined as described in the M38-A document (14) and as recommended for some uncommon molds (37): (i) at 24 h for *Rhizopus arrhizus;* (ii) at 48 h for *Aspergillus* spp., *Bipolaris* spp., *Fusarium* spp., *Paecilomyces lilacinus, Sporothrix schenckii*, *Trichoderma longibrachiatum*, and *Wangiella dermatitidis;* and (iii) at 72 h for *Pseudallescheria boydii (Scedosporium apiospermum)*, *Cladophialophora bantiana*, *Dactylaria constricta*, and *Scedosporium prolificans*. The MIC endpoint criterion for molds is the lowest drug concentration that shows complete growth inhibition when testing amphotericin B, itraconazole, voriconazole, and posaconazole (14). Experience with both established and investigational agents has demonstrated that MICs for other opportunistic and slower growing filamentous fungi can be determined (sufficient or heavy growth present in the growth control) after 48 to 96 h of incubation. Testing of the dimorphic fungi may require 5 to 7 days of incubation (25, 40).

Macrodilution

Good agreement between results obtained by both micro- and macrodilution methods for molds has been documented (38). Some laboratories would rather perform broth macrodilution testing because of safety concerns and low testing volume. Macrodilution testing conditions are described in the CLSI M38-A document (14). Briefly, inoculum stock suspensions and drug dilutions are prepared as for the microdilution test. The 100-fold drug dilutions should be diluted 1:10 with RPMI to achieve 10 times the strength needed for the macrodilution test. The stock inoculum suspensions are diluted 1:100 with medium to obtain 0.4×10^4 to 5×10^4 CFU/ml. The 10× drug concentrations are dispensed into 12- by 75-mm sterile tubes in 0.1 ml volumes. Each tube is inoculated on the day of the test with 0.9 ml of the corresponding suspension.

Incubation and Determination of Broth Macrodilution MICs for Molds

Tubes are incubated at 35°C without agitation and observed for the presence or absence of visible growth. The MICs are determined as described above for the microdilution method for molds.

Quality Control for Mold Testing

Either one of the QC yeast organisms or the QC *Paecilomyces variotii* ATCC MYA-3630 isolate may be tested in the same manner as the other mold isolates or as described above for yeasts and should be included each time an isolate is evaluated with any antifungal agent. In addition, other molds have been selected as reference isolates (Table 3) (33).

Expected Results

Amphotericin B MICs determined by the M38-A microdilution method are ≤1.0 μg/ml for most mold species. High amphotericin B MICs (>2 μg/ml) have been reported for *P. lilacinus*, most *S. apiospermum* isolates, *S. prolificans,* and some isolates of *Alternaria* spp., *Aspergillus* spp., *Fusarium* spp., *Penicillium marneffei*, *Phialophora* spp., and *S. schenckii* (27, 29, 40). MICs of itraconazole are also usually ≤2.0 μg/ml; the exceptions are its high MICs for *Aspergillus ustus* (some isolates), *Fusarium solani*, *F. oxysporum*, *P. lilacinus*, *S. schenckii*, *S. prolificans*, *T. longibrachiatum,* and some isolates of *R. arrhizus* (27, 29, 40). Similar results are obtained with the other triazoles, but good in vitro activity against the Zygomycetes has been reported with posaconazole (19, 91).

Broth Microdilution Method for Dermatophytes

The M38-A broth microdilution method has also been successfully adapted, with minor modifications, to the testing of dermatophytes (45). These modifications include the use of oatmeal agar for inoculum preparation when testing *Trichophyton rubrum* in order to induce conidium formation and 4 to 5 days of incubation at 35°C for MIC determination (80% growth inhibition endpoints). Two isolates of *Trichophyton* spp. have been selected as reference strains by the Subcommittee for testing this group of fungi (Table 3) (CLSI Subcommittee Minutes, January 2006).

Broth-Based Alternative Approaches for Molds

Evaluation of Morphologic Changes

The trailing growth is not a problem when testing investigational or established azoles against most molds. However, when testing the echinocandins, most *Aspergillus* isolates show trailing growth and conventional MIC determination could categorize these trailing isolates as resistant to caspofungin. A more careful examination of the microdilution wells reveals the presence of compact, round microcolonies. Under microscopic examination, these microcolonies correspond to significant morphologic alterations. The hyphae grow abnormally as short, highly branched filaments with swollen germ tubes. Kurtz et al. (53) defined the concentration of drug producing these morphologic changes as the minimum effective concentration (MEC) to distinguish it from conventional MICs. A multicenter study has demonstrated that caspofungin MECs were reliable endpoints in 14 of 17 laboratories (65) and in another study in the eight laboratories that participated in the study when evaluating anidulafungin against a variety of mold species (A. Espinel-Ingroff, M. Ghannoum, E. Manavathy, L. Ostrosky-Zeichner, M. Pfaller, M. Rinaldi, W. Schell, and T. Walsh, *Abstr. 45th Intersci. Conf. Antimicrob. Agents Chemother.*, abstr. M–1605, 2005). Because conflicting results were reported from three laboratories, caution and further refinement of this testing approach are needed.

MICs/MECs of the echinocandins are usually <1.0 μg/ml for *Aspergillus* spp., but higher for other molds (MICs >8 μg/ml). However, MICs of <1.0 μg/ml have been reported for some isolates of the dimorphic fungi *Phialophora* spp. and *S. apiospermum* (29).

Colorimetric Methods

The YeastOne method has also been evaluated for molds, and it appears to be applicable for such testing (10, 56, 60). The measurement of metabolic activity by reading the color change (OD) produced when tetrazolium salts (yellow) are cleaved to their formazan derivative (purple), using a microtiter plate spectrophotometer, has also been evaluated for molds (48, 61). Again, further evaluations, including interlaboratory studies, are needed with more isolates and species.

Agar-Based Alternative Approaches for Filamentous Fungi

As for yeasts, agar-based methods have been applied to susceptibility testing of molds, including agar dilution, disk diffusion, and E-test methods and semisolid agar (54).

Agar Dilution Methods

Agar dilution methods involve the preparation of 10× double dilutions of the agent, which are incorporated into molten agar. Drug-containing plates are inoculated with suspensions of the organism being tested. Since standard methods are not available, the size of the inoculum varies among the different studies.

Disk Diffusion Method

Disk diffusion methodology has been evaluated for caspofungin (5) and voriconazole (90). The reproducibility of this methodology is under investigation by the CLSI Subcommittee for testing caspofungin, amphotericin B, and the triazoles.

E Test

This convenient method also has been adapted in several studies for testing mold pathogens (26, 28, 42, 60, 75, 80, 90, 92). Since the trailing effect is not a major problem for azole testing against most molds, E-test inhibition ellipses are usually sharp and MICs are easily interpreted. Overall, comparisons of E-test and M38-A methods have demonstrated better agreement when testing the triazoles (>90%) than amphotericin B (>80%). Amphotericin B E-test MICs for *A. flavus*, *S. apiospermum*, and *S. prolificans* are usually higher than reference values, especially after 48 h of incubation (26). The reliability of the E-test method and the clinical relevance of its MICs for molds should be addressed.

Fungicidal Activity

A CLSI study has demonstrated that laboratories may reliably perform MFC testing (37) and time-kill curves. In contrast to what is observed with yeasts, the azoles appear to have a certain degree of fungicidal activity as mentioned above for a variety of common and rare opportunistic mold pathogens. MFCs of 0.2 to 4 μg/ml have been reported with the triazoles for various mold species (25, 27, 36). However, standardization of this procedure is needed to reliably assess the potential value of the MFC endpoint in patient management. These standardization efforts should include the correlation of in vitro results with the clearing of target

organs of the infecting organism in animal models and the further clinical relevance of MFC data.

CLINICAL RELEVANCE

In order to be useful clinically, in vitro susceptibility testing should reliably predict the in vivo response to therapy in human infections. However, factors related to the drug, the host immune response and/or the status of the current underlying disease, proper patient management, the infecting organism, and the interactions of the organism with both the host and the therapeutic agent appear to have more value than the MIC as predictors of clinical outcome (87). Because so many factors can influence the process of antifungal therapy for an infection caused by a presumably susceptible isolate, a low MIC does not necessarily predict clinical success. However, in vitro resistance may be able to identify, among a population of susceptible strains, those isolates that are less likely to respond to a specific antifungal regimen. In order to appreciate the clinical value of the in vitro antifungal testing result, one must understand that the predictor value of in vitro susceptibility in bacterial infections has been accurately summarized as the "90-60 rule" (88). Infections due to susceptible isolates respond to therapy ~90% of the time, whereas infections due to resistant isolates respond ~60% of the time. There is now a considerable body of data indicating that standardized antifungal susceptibility testing (CLSI M27-A2) for *Candida* spp. and some triazoles provides results that have a predictive utility consistent with the "90-60 rule."

Interpretive MIC breakpoints (Table 6) have been established for fluconazole, itraconazole, and voriconazole following correlation with clinical data (oropharyngeal candidiasis [fluconazole and itraconazole], candidemia in nonneutropenic patients [fluconazole and voriconazole], and other infections [voriconazole] [13, 17, 87]). Isolates inhibited by ≥64 μg of fluconazole per ml and ≥1 μg of itraconazole per ml are considered resistant to these agents, whereas isolates inhibited by ≤8 μg of fluconazole per ml and ≤0.12 μg of itraconazole per ml are considered susceptible. In addition, fluconazole MICs of 16 to 32 μg/ml and itraconazole MICs of 0.25 to 0.5 μg/ml have been designated susceptible–dose dependent (S-DD). For fluconazole, this novel designation encompasses isolates in which susceptibility is dependent on achievable peak levels in serum of 40 to 60 μg/ml at fluconazole dosages of 800 mg/day, versus the expected peak levels of ≤30 μg/ml at lower dosages. The pharmacodynamic parameter that predicts efficacy for fluconazole is ~25 (area under the concentration-time curve [AUC]/MIC). For itraconazole, an MIC within the S-DD range indicates the need for plasma concentrations of >0.5 μg/ml for an optimal response. However, host factors, rather than azole resistance, can be responsible for clinical failure. Recently, a susceptible breakpoint of ≤1 μg/ml, S-DD of 2 μg/ml, and a resistant breakpoint of ≥4 μg/ml were established for voriconazole and *Candida* spp. (16) (Table 6). Isolates for which the voriconazole MIC is ≥4 μg/ml (resistant endpoint) are mostly *C. glabrata* (93%) and represent a concentration of voriconazole that cannot be maintained with the currently recommended doses (200 to 300 mg administered orally or an intravenous dose of 4 mg/kg every 12 h); as a consequence, patients infected with these isolates are less likely to respond clinically to voriconazole therapy (<60% response). Therefore, the 60% clinical response rate at the voriconazole-resistant breakpoint is consistent with the 90-60 rule. In support of the susceptible breakpoint of ≤1 μg/ml, plasma concentrations of ≥1 μg/ml are determined throughout the dosing interval with the recommended doses; the 1-μg/ml MIC encompasses 99% of all clinical isolates of *Candida*. Pharmacokinetics and pharmacodynamic parameters indicate that a 24-h free drug AUC/MIC ratio of 20 is predictive of efficacy and recommended doses would produce free drug AUCs of ~20 μg·h/ml (4). Therefore, it can be predicted that current recommended dosing regimens could be used successfully to treat patients infected with isolates for which voriconazole MICs are ≤1 μg/ml as determined by the reference method.

Lack of response to fluconazole therapy has been documented in a few cases of fluconazole resistance in invasive candidal infections (24). In cryptococcal infections, fluconazole MICs of >16 μg/ml have correlated with clinical failure to fluconazole maintenance therapy (2).

Very few correlations of in vitro results with in vivo response have been reported for mold infections (30). Clinical failure with amphotericin B has been associated with MICs of >0.8 μg/ml for *Aspergillus fumigatus*, *Fusarium* spp., and *S. prolificans* infections (30); both primary resistance and acquired resistance have been demonstrated. Clinical failures of itraconazole and amphotericin B in the treatment of aspergillosis have been correlated with MICs of >8 μg/ml and >2 μg/ml, respectively (21, 55).

SUMMARY AND CONCLUSIONS

A great deal of progress has been achieved in the field of antifungal susceptibility testing since 1982. Standardized broth macrodilution and microdilution methods are available for testing molds and yeasts, as is the 24-h disk diffusion methodology to test fluconazole and voriconazole against *Candida* spp. More suitable and promising modifications of these methods for use in clinical microbiology laboratories are also available. It must be emphasized that a critical next step in establishing the clinical usefulness of standardized procedures will be to determine the relationship between test results and patient responses to therapy in other clinical settings and for other organism-drug combinations. Additional studies are needed for the establishment of standard methodology for testing the echinocandins versus both yeasts and molds.

Taxonomy and Classification of Human Parasites

FRANCIS E. G. COX

132

The term "parasite" is traditionally applied to several disparate groups of eukaryotic organisms, mainly protozoa and helminths (embracing nematode, cestode, trematode, and acanthocephalan worms) but also some arthropods, annelids, and molluscs. Medical parasitology is concerned with the 200 or so species of helminth worms and about 80 species of protozoa that infect humans. Many of these are rare and accidental parasites, but about 100 species are commonly found in humans; a small number of these are responsible for a disproportionate number of important diseases, particularly in the tropics, and these inevitably receive the most attention. This chapter is concerned with the classification of the parasites that are commonly encountered in humans, together with a number that are rarer but are occasionally encountered.

Taxonomy is the science of establishing and defining systematic groups of organisms in a hierarchical manner that reflects the evolutionary past and present relationships between the groups. The basic unit is the species, a grouping in which, among higher organisms, all members are morphologically similar and able to interbreed successfully. The taxonomic groups of higher organisms are largely based on morphological criteria reinforced, wherever possible, by palaeontological evidence of past relationships. The classification of the multicellular helminth worms, which have well-defined morphological characters, clear affinities with free-living species, and characteristic life cycles involving sexual reproduction, is based on sound taxonomic principles, but the single-celled protozoa have always constituted an enigmatic group and have been difficult to classify. This subject will be discussed further below.

In his 1758 classification of living things, Carl Linnaeus recognized two kingdoms, Animalia and Plantae. By the middle of the 19th century, scientists had added a third category to include organisms that we now regard as protozoa, and the concept of three kingdoms, Animalia, Plantae, and Protista (= protozoa) emerged. This was later expanded to four kingdoms, Animalia, Plantae, Protoctista (= Protista = Protozoa), and Mychota (prokaryote organisms) (9). When the fungi were separated from the plant kingdom, a fifth kingdom, Fungi, was created, and this formed the basis of what became known as the widely accepted five-kingdom classification, Prokaryota, Animalia, Plantae, Fungi, and Protista (19, 26).

Over the past 30 years, these five kingdoms have been subjects of controversy and have undergone a number of modifications, often on a somewhat arbitrary basis. Gradually, however, a new consensus has emerged based mainly on advances in our understanding of the biochemistry and molecular biology of lower organisms. Comparisons of small subunit ribosomal RNA (SSU rRNA) and protein sequences (2, 16, 25) have made it possible to arrange organisms within groups based on evolutionary distances but not necessarily in a hierarchical way. The identification of certain organelles found in eukaryotic cells with their prokaryote origins, however, has now made it possible to organize all living organisms within a realistic and evolutionarily sound overall scheme (3), which is adopted here. The most important aspect of this classification is that the major elements in it are compatible with more traditional classifications. Essentially there are now six kingdoms, Bacteria, Protozoa, Animalia, Fungi, Plantae, and Chromista. This classification establishes the Protozoa as the basal eukaryotic kingdom and has necessitated the redistribution of some taxa, including some parasites of humans. The six-kingdom classification reestablishes the validity of the kingdom Protozoa and brings the protozoa and helminths under the same rules whereby all species are named according to the guidelines set out in the International Code of Zoological Nomenclature (http://www.iczn.org). From a practical point of view, this confers stability in the naming of species and ensures priority for the name originally given while permitting corrections or amendments when necessary. In this chapter, therefore, some of the generic and specific names are different from those in the previous edition of this Manual, but all such changes have had to be justified on grounds of new discoveries and interpretations. The International Code is, however, not a panacea for all taxonomic problems, and the correct specific name of the species of *Giardia* that infects humans, *G. lamblia* as used here or *G. duodenalis* or *G. intestinalis* as used elsewhere, is still unresolved.

CLASSIFICATION OF THE PROTOZOA

There are estimated to be over 200,000 named species of single-celled eukaryotic organisms (10), of which only about 10,000, some 5%, are parasitic; thus, any system of classification must primarily satisfy zoologists and protozoologists

working with free-living protozoa. Traditionally, the phylum Protozoa embraced four great groups of single-celled organisms, recognized on the basis of their mode of locomotion: Rhizopoda or Sarcodina (amoebae, moving by pseudopodia), Mastigophora (flagellates, moving by flagella), Ciliophora or Ciliata (ciliates, moving by cilia), and Sporozoa (sporozoans, spore-forming protozoans without any obvious means of locomotion). Rapid developments in our understanding of the protozoa during the 1960s and 1970s spawned new and ever more complex classifications, but by the beginning of the 1990s a number of protozoologists (12, 24) had decided to revert to what was essentially the traditional four "groups": the flagellated protozoa, the amoeboid protozoa, the ciliated protozoa, and the sporozoans (including the microsporidians and myxosporidians). This approach had the merit of simplicity and clear links with the traditional classification but was merely a classification of convenience and did not stand up to rigorous analysis at either the evolutionary or molecular level. Further attempts to resolve this problem resulted in an "interim user friendly" classification (10) that served its purpose well until more rational and natural classifications emerged.

Over the past decade or so, developments in molecular biology have given us a clearer understanding of phylogenetic relationships involving particular groups of single-celled eukaryotic organisms, but unfortunately, this has once again resulted in a plethora of classifications. It now seems unlikely that protozoologists, particularly those working with free-living organisms, will ever come up with a scheme of classification acceptable to everyone (22). These apparent vacillations have irritated parasitologists, most of whom are concerned with fewer than 0.05% of all species and simply require a stable framework within which to classify parasites, particularly those of medical and veterinary importance.

The classification outlined below is based on that developed over many years by Cavalier-Smith (3–7). It embraces traditional and novel elements, meets the requirements of parasitologists, and bridges the gap between those working with free-living protozoa and those working with parasitic protozoa. The main advantage of this classification is that it is compatible with traditional and molecular classifications and with the "interim classification" (10) that has found much favor. It is not appropriate here to go into any details of the rationale behind this classification, which is discussed in more detail elsewhere (13), but there are several important features with respect to traditional classifications and the interim classification that must be mentioned. The myxosporidians, formerly classified among the sporozoans (but which do not affect humans), are now clearly recognized as metazoans and placed in the kingdom Animalia. Similarly, the microsporidians, some of which do infect humans, particularly immunocompromised individuals, are now thought to be more closely related to fungi than to protozoa and should now be classified with the Fungi (7, 18). The taxonomic position of *Blastocystis* has always been enigmatic, and this genus has been shuffled between the Fungi and Protozoa but now seems to have to come to rest in the kingdom Chromista (3, 6). The kingdom Chromista was created in 1989 to accommodate a number of plant-like organisms, mainly algae, that were originally chimeras between eukaryotic biflagellate hosts and symbiotic red algae but which had lost their chloroplasts over evolutionary time yet still retain elements of their red algal ancestry (3). Phylogenetic trees based on 18S rRNA and other molecular evidence now place *Blastocystis* firmly within this group, which lies close to the sporozoans and ciliates (6). With the removal of these groups, the Protozoa becomes a kingdom with 13 phyla, of which 7 contain parasites that infect humans. The phylum Amoebozoa, containing the amoebae, is equivalent to the old Rhizopoda (Sarcodina), and the flagellates belonging to the former Mastigophora are now distributed among four phyla, Metamonada, Parabasalia, Percolozoa, and Euglenozoa. Two phyla remain unchanged, the Ciliophora, containing the ciliates, and the Sporozoa. The status of the phylum Sporozoa requires some more explanation. Sporozoa is the traditional name applied to a large group of sexually reproducing, spore-forming protozoans with recognizably similar morphology at the electron microscope level and comparable life cycles. In the 1970s, a new parasite genus, *Perkinsus,* containing parasites of marine molluscs and quite different from any of the other sporozoans, was allocated to this group. The phylum Sporozoa was downgraded to a class, and the name of the phylum was changed to Apicomplexa in order to incorporate two classes, Sporozoea and Perkinsea (11). Not all parasitologists liked this change, but the word Apicomplexa has gradually crept into the literature. It is now clear, however, that *Perkinsus* spp. do not belong with the sporozoans and should be classified close to, or with, the dinoflagellates (15, 23); therefore, the taxon Apicomplexa is redundant and should not be used. References to Apicomplexa or apicomplexans should now revert to Sporozoa or sporozoans, the original names. One final point concerns the microsporidians. Microsporidians have traditionally been considered to belong with the protozoa sensu stricto, and parasitologists have been reluctant to part with this group, whereas mycologists have been equally reluctant to accept it. It therefore seems sensible, at least for the time being, to retain the microsporidians alongside the Protozoa while acknowledging that they are, in fact, fungi.

OUTLINE CLASSIFICATION OF EUKARYOTIC PARASITES

Table 1 shows an outline classification of parasites; its sole purpose is to provide a taxonomically sound and convenient set of pigeonholes to which the various parasitic organisms can be assigned. The classification of all living organisms, and the Protozoa in particular, is discussed in more detail elsewhere (3–6), as are the classifications of the parasitic protozoa (13) and the parasitic helminth worms (17) of humans. Elsewhere there are full annotated lists of the parasitic protozoa, helminths, and arthropods of humans (1) and parasitic helminths (8); comprehensive coverage of all human parasites (14); and additional information about helminth worms (20, 21). The levels of the taxa used for the protozoa and helminths are different, and this is deliberate. Protozoa are classified as far as orders because this is the lowest taxonomic level normally used by parasitologists. Helminth worms are usually classified as far as superfamilies and families, taxa rarely used by protozoologists. For simplicity and clarity, orders are omitted in the lists of nematodes. As well as the formal taxa, common names, such as flagellates, have been added. The most important parasites, either because of their capacity to cause disease or because they are very common and therefore likely to be featured in textbooks, are given in bold.

I thank Tom Cavalier-Smith, Department of Zoology, University of Oxford, for helpful discussions while I was writing the previous version of this chapter.

TABLE 1 Outline classification of parasites that infect humans[a]

KINGDOM PROTOZOA
- Subkingdom 1 Archezoa
  - Phylum Metamonada
    - Class Trepomonadea (intestinal flagellates)
      - Order Diplomonadida ***Giardia lamblia***[b]
      - Order Enteromonadida *Enteromonas hominis*
    - Class Retortamonadea
      - Order Retortamonadida *Chilomastix mesnili, Retortamonas intestinalis*
  - Phylum Parabasala (flagellates)
    - Class Trichomonadea (intestinal and related flagellates)
      - Order Trichomonadida ***Dientamoeba fragilis, Trichomonas vaginalis,*** *T. tenax, Pentatrichomonas hominis*
- Subkingdom 2 Neozoa
  - Infrakingdom 1 Discicristata
    - Phylum Percolozoa (flagellates)
      - Class Heterolobosea (flagellated amoebae)
        - Order Schizopyrenida ***Naegleria fowleri***
    - Phylum Euglenozoa (flagellates)
      - Class Kinetoplastidea (kinetoplastid flagellates)
        - Order Trypanosomatida ***Leishmania donovani, L. infantum, L. major, L. tropica, L. braziliensis, L. mexicana,*** *L. aethiopica, L. amazonensis,* L. colombiensis,* L. garnhami,* L. guyanensis, L. lainsoni,* L. naiffi,* L. panamensis, L. peruviana, L. pifanoi,* L. shawi,** ***Trypanosoma cruzi, T. brucei gambiense,***[c] ***T. brucei rhodesiense,***[c] *T. rangeli*
  - Infrakingdom 2 Sarcomastigota
    - Phylum Amoebozoa (amoebae)
      - Subphylum Lobosa
        - Class Amoebaea (amoebae)
          - Order Acanthopodida ***Acanthamoeba castellanii,*** *A. culbertsoni,* A. hatchetti,* A. polyphaga,** ***Balamuthia mandrillaris***
      - Subphylum Conosa
        - Class Entamoebidea (intestinal amoebae)
          - Order Euamoebida ***Entamoeba histolytica, E. coli, E. dispar, E hartmanni,*** *E. gingivalis, E. moshkovskii,* E. chattoni,* E. polecki,* Endolimax nana, Iodamoeba bütschlii*
  - Infrakingdom 3 Alveolata
    - Phylum Sporozoa (sporozoans)
      - Class Coccidea
        - Order Eimeriida ***Cryptosporidium parvum,*** *C. hominis, Cryptosporidium* spp.,* ***Toxoplasma gondii, Cyclospora cayetanensis,*** *Isospora belli,* Sarcocystis hominis, S. lindemanni,* S. suihominis*
        - Order Piroplasmida ***Babesia microti,*** *B. divergens,* B. gibsoni,* Babesia* spp.[d]

- Order Cyclophyllidea
  - Family Anoplocephalidae *Bertiella mucronata,* B. studeri,* Inermicapsifer cubensis, I. madagascariensis, Mathevotaenia symmetrica**
  - Family Davaineidae *Buginetta alouettae,* Raillietina celebensis,* R. demerariensis**
  - Family Dipylidiidae *Dipylidium caninum*
  - Family Hymenolepididae ***Hymenolepis* (= *Rodentolepis*) *nana,***[g] *Hymenolepis diminuta*
  - Family Mesocestoidae *Mesocestoides* spp.*
  - Family Taeniidae ***Taenia saginata, T. solium,*** *Taenia* spp.,* ***Echinococcus granulosus,*** *E. multilocularis, Echinococcus* spp.,* *Multiceps* spp.*

Subkingdom 4 Mesozoa (no parasites of humans)

[a] Parasites in bold type are the most important species. Symbols: *, rare or very rare parasites of humans; +, accidental infections with larval forms and in which the parasite fails to develop to its adult stage.

[b] There is no agreement about the name of this organism, which is also known as *Giardia duodenalis* or *G. intestinalis*.

[c] *Trypanosoma brucei gambiense* and *T. brucei rhodesiense* are subspecies but are often referred to as species *T. gambiense* and *T. rhodesiense*, respectively.

[d] Increasing numbers of *Babesia microti*-like isolates have been identified, mainly in the northeastern and midwestern United States but also elsewhere; they have not yet been given specific status and are currently known by their codes, e.g., WA-1, CA-1, MO-1, and EU-1.

[e] The classification of the microsporidians is in a state of flux pending agreement as to how they should be classified with the fungi, so these organisms are not assigned to any class or order in this classification.

[f] Zoologists have assigned the various species of *Capillaria*, including those found in humans, to other genera *(Calodium*, *Eucoelus*, *Pearsonema*, *Paracapillaria,* and *Crossicapillaria)*, but as these genera have largely been ignored by medical parasitologists, and in order to avoid confusion, they are not listed here.

[g] Zoologists have assigned this worm, commonly known as *Hymenolepis nana,* to the genus *Rodentolepis* (17), but this change has not been widely accepted by parasitologists working with human parasites.

Specimen Collection, Transport, and Processing: Parasitology

PETER DEPLAZES, LYNNE S. GARCIA, AND ROBYN Y. SHIMIZU

133

Routine diagnostic parasitology generally includes laboratory procedures that are designed to detect organisms within clinical specimens by using morphologic criteria rather than culture, biochemical tools, and/or physical growth characteristics (Table 1). Parasite identification is frequently based on light microscopic analysis of concentrated and/or stained preparations. Small organisms often require high magnification such as oil immersion (×1,000) (ranging from 1.5 μm [microsporidia] upwards). Electron microscopy for species characterization of organisms has been replaced in recent years mainly by molecular methods (PCR and sequence analyses of selected genes). Furthermore, new commercial test kits designed especially for detection of antigens (e.g., coproantigens of *Giardia*, *Cryptosporidium,* and *Entamoeba histolytica* [Table 2] or circulating *Plasmodium* antigens [Table 3]) have expanded the methodical repertoire. In addition to those methods for direct parasite detection (morphology, antigens, and DNA), methods for indirect detection of parasite infections demonstrating specific antibodies directed to a variety of native or recombinant parasite antigens have been developed and partially commercialized (Table 4). Diagnostic techniques are available to detect a large range of protozoan and helminth species. They are generally characterized by a variety of methods depending on clinical specimens and the biology of the parasites. An important precondition for reliable diagnostic results is the proper collection, processing, and examination of clinical specimens. Based on the biology of the parasites and the procedural features of the tests, multiple specimens must often be submitted and examined before the suspected organism(s) is found and its identity is confirmed.

SPECIMEN COLLECTION AND TRANSPORT

Various collection methods are available for specimens suspected of containing parasites or parasitic elements (Tables 5, 6, 7, and 8) (3, 9, 10, 18, 21, 25, 31). When collection methods are selected, the decision should be based on a thorough understanding of the value and limitations of each. The final laboratory results are based on parasite recovery and identification and will depend on the initial handling of the specimen. Unless the appropriate specimens are properly collected and processed, these infections may not be detected. Therefore, specimen rejection criteria have become much more important for all diagnostic microbiology procedures. Diagnostic laboratory results based on improperly collected specimens may require inappropriate expenditures of time and supplies and may also mislead the physician. As a part of any continuous quality improvement program for the laboratory, the generation of test results must begin with stringent criteria for specimen acceptance or rejection.

All fresh specimens should be handled carefully, since each specimen represents a potential source of infectious material. Safety precautions should include proper labeling of fixatives; specific areas designated for specimen handling (biological safety cabinets may be necessary under certain circumstances, such as parasite cultures); proper containers for centrifugation; acceptable discard policies; appropriate policies of no eating, drinking, or smoking within the working areas; and, if applicable, correct techniques for organism culture and/or animal inoculation. Universal Precautions as outlined by the Occupational Safety and Health Act must be followed when applicable, particularly when blood and other body fluids are being handled (7).

Collection of Stool (Fresh)

Collection of stool for parasite detection should always be performed before barium is used for radiological examination. Stool specimens containing the opaque, chalky sulfate suspension of barium are unacceptable for examination, and intestinal protozoa may be undetectable for 5 to 10 days after barium is given to the patient. Certain substances and medications also interfere with the detection of intestinal protozoa; these include mineral oil, bismuth, antibiotics (metronidazole, tetracyclines), antimalarial agents, and nonabsorbable antidiarrheal preparations. After administration of any of these compounds, parasites may not be recovered for a week to several weeks. Therefore, specimen collection should be delayed for 5 to 10 days or at least 2 weeks after barium or antibiotics, respectively, are administered (9, 10, 20, 24). Some laboratories add the following comment to their negative reports: "Certain antibiotics such as metronidazole or tetracycline may interfere with the recovery of intestinal parasites, particularly the protozoa."

Fecal specimens should be collected in clean, wide-mouth containers; often a waxed cardboard or plastic container with a tight-fitting lid is selected for this purpose. The specimens should not be contaminated with water or urine because water may contain free-living organisms that can be mistaken for human parasites and urine may destroy motile organisms. Stool specimen containers should be placed in

TABLE 1 Body sites and possible parasites recovered[a]

Site	Parasites
Blood	
Erythrocytes	*Plasmodium* spp., *Babesia* spp.
Leukocytes	*Leishmania* spp., *Toxoplasma gondii*
Whole blood/plasma	*Trypanosoma* spp., microfilariae
Bone marrow	*Leishmania* spp., *Trypanosoma cruzi, Plasmodium* spp.
Central nervous system	*Taenia solium* (cysticerci), *Echinococcus* spp., *Naegleria fowleri*, *Acanthamoeba* spp., *Balamuthia mandrillaris, Toxoplasma gondii,* microsporidia, *Trypanosoma* spp.
Cutaneous ulcers	*Leishmania* spp., *Acanthamoeba* spp.
Intestinal tract	*Entamoeba histolytica, Entamoeba dispar, Entamoeba coli, Entamoeba hartmanni, Endolimax nana, Iodamoeba bütschlii, Blastocystis hominis*, *Giardia, Chilomastix mesnili, Dientamoeba fragilis, Pentatrichomonas hominis, Balantidium coli, Cryptosporidium* spp., *Cyclospora cayetanensis, Isospora belli, Enterocytozoon bieneusi, Encephalitozoon* spp., *Ascaris lumbricoides, Enterobius vermicularis,* hookworm, *Strongyloides stercoralis, Trichuris trichiura, Hymenolepis nana, Hymenolepis diminuta, Taenia saginata, Taenia solium, Diphyllobothrium latum, Clonorchis sinensis (Opisthorchis), Paragonimus* spp., *Schistosoma* spp., *Fasciolopsis buski, Fasciola hepatica, Metagonimus yokogawai, Heterophyes heterophyes*
Liver, spleen	*Echinococcus* spp., *Entamoeba histolytica, Leishmania* spp., microsporidia, *Capillaria hepatica*
Lungs	*Cryptosporidium* spp.,[b] *Echinococcus* spp., *Paragonimus* spp., *Toxoplasma gondii,* helminth larvae
Muscle	*Trichinella* spp., *Taenia solium* (cysticerci), *Onchocerca volvulus* (nodules), *Trypanosoma cruzi,* microsporidia
Skin	*Leishmania* spp., *Onchocerca volvulus,* microfilariae
Urogenital system	*Trichomonas vaginalis, Schistosoma* spp., microsporidia, microfilariae
Eyes	*Acanthamoeba* spp., *Toxoplasma gondii, Loa loa,* microsporidia, *Thelazia* spp.

[a] Parasites include trophozoites, cysts, oocysts, spores, adults, larvae, eggs, and amastigote and trypomastigote stages. This table does not include every possible parasite that could be found in a particular body site. However, the most likely organisms have been listed.

[b] Disseminated in severely immunosuppressed individuals.

plastic bags when transported to the laboratory for testing. Specimens should be identified with the following information: patient's name and identification number, physician's name, and the date and time the specimen was collected. The specimen must also be accompanied by a request form indicating which laboratory procedures should be performed. The presumptive diagnosis or relevant travel history information is helpful and should accompany the test request. In some situations, it may be necessary to contact the physician for additional patient history.

In the past, it has been recommended that a normal examination for stool parasites before therapy include three specimens. Three specimens, collected as outlined above, have also been recommended for posttherapy examinations. However, a patient who has received treatment for a protozoan infection should be checked 3 to 4 weeks after therapy, and those treated for *Taenia* infections should be checked 5 to 6 weeks after therapy. In many cases, the posttherapy specimens will not be collected, often as a cost containment measure; if the patient becomes symptomatic again, additional specimens can be submitted (18, 21).

Although some recommend collection of only one or two specimens, there are differences of opinion regarding this approach. It has also been suggested that three specimens be pooled and examined as a single specimen; again, this approach is somewhat controversial. However, physicians should be aware that the probability of detecting clinically relevant parasites in a single stool specimen may be as low as 50 to 60% but is >95% if three samples are examined (21).

If a series of three specimens is collected, they should be submitted on separate days; if possible, the specimens should be submitted every other day; otherwise, the series of three specimens should be submitted within no more than 10 days. If a series of six specimens is requested, the specimens should also be collected on separate days or within no more than 14 days. Many organisms, particularly the intestinal protozoa, do not appear in the stool in consistent numbers on a daily basis, and the series of three specimens is considered the

TABLE 2 Commercially available kits for immunodetection of parasitic organisms or antigens in stool samples

Organism and kit name[a]	Manufacturer and/or distributor	Type of test[b]	Comments[c]
Cryptosporidium spp.			The tests detect *C. hominis,* different *C. parvum* genotypes, and other species depending on intensity of the infection

minimum for an adequate examination. Multiple specimens from the same patient should not be submitted on the same day. One possible exception would be a patient who has severe, watery diarrhea, in whom any organisms present might be missed because of a tremendous dilution factor related to fluid loss. These specimens should be accepted only after consultation with the physician. It is also not recommended for the three specimens to be submitted one each day for three consecutive days; however, use of this collection time frame would not be cause enough to reject the specimens.

To evaluate patients who are at risk for giardiasis, the negative predictive value of some of the immunoassays on a single stool specimen is not sufficiently high to exclude the possibility of a *Giardia lamblia* infection. In cases where the clinical suspicion for *G. lamblia* infection is moderate or high and the first assay yields a negative result, testing of a second specimen may be recommended (17).

Fresh specimens are mandatory for the recovery of motile trophozoites (amebae, flagellates, or ciliates). The protozoan trophozoite stage is normally found in cases of diarrhea; the intestinal tract contents are moving through the system too rapidly for cyst formation to occur. Once the stool specimen is passed from the body, trophozoites do not encyst but may disintegrate if not examined or preserved within a short time after passage. However, most helminth eggs and larvae, coccidian oocysts, and microsporidian spores will survive for extended periods. Liquid specimens should be examined within 30 min of passage, not 30 min from the time they reach the laboratory. If this general time recommendation of 30 min is not possible, the specimen should be placed in one of the available fixatives (9). The current College of American Pathologists checklist requires that "the microscopic examination of fresh (unpreserved) liquid stools should include a wet mount of fresh specimen by direct technique." Soft (semiformed) specimens may have a mixture of

[c] Abbreviations: EIA, enzyme immunoassay; IFT, immunofluorescence test; IB, immunoblot; Rapid, rapid immunochromatographic (some are dipstick, cartridge, or other rapid test formats).

protozoan trophozoites and cysts and should be examined within 1 h of passage; again, if this time frame is not possible, preservatives should be used. Immediate examination of formed specimens is not as critical; in fact, if the specimen is examined any time within 24 h after passage, the protozoan cysts should still be intact.

Collection of Stool (Preserved)

If there are delays from the time of specimen passage until examination in the laboratory, the use of stool preservatives should be considered. To preserve protozoan morphology and to prevent the continued development of some helminth eggs and larvae, the stool specimens can be placed in preservative either immediately after passage (by the patient using a collection kit) or once the specimen is received by the laboratory. There are several fixatives available; these include formalin, sodium acetate-acetic acid-formalin (SAF), Schaudinn's fluid, and polyvinyl alcohol (PVA) (Table 8). Regardless of the fixative selected, adequate mixing of the specimen and preservative is mandatory. Specimens preserved in stool fixatives should be stored at room temperature.

When selecting an appropriate fixative, keep in mind that a permanent stained smear is mandatory for a complete examination for parasites (9, 10, 20, 24, 27). You may also want to use some of the newer immunoassay procedures or molecular diagnostic methods (PCR); make sure that the fixative you are using is compatible with the kit or the method you have selected. It is also important to remember that disposal regulations for compounds containing mercury are becoming stricter; each laboratory will have to check applicable regulations to help determine fixative options.

Formalin

Formalin is an all-purpose fixative that is appropriate for helminth eggs and larvae and for protozoan cysts. Two concentrations are commonly used: 5%, which is recommended for preservation of protozoan cysts, and 10%, which is recommended for helminth eggs and larvae. Although 5% is often recommended for all-purpose use, most commercial manufacturers provide 10%, which is more likely to kill all helminth eggs. To help maintain organism morphology, the formalin can be buffered with sodium phosphate buffers, i.e., neutral formalin. Selection of specific formalin formulations

TABLE 5 Specimen preparation and procedures, recommended stain(s), relevant parasites, and additional information

Body site	Procedures[a] and specimens	Recommended methods and relevant parasites[a]	Additional information
Blood	Microscopy[b]: thin and thick blood films. Fresh blood (preferred) or EDTA-blood (fill EDTA tube completely with blood, then mix).	Giemsa stain (all blood parasites); hematoxylin-based stain (sheathed microfilariae). For malaria, thick and thin blood films are definitely recommended and should be prepared within 30 to 60 min of blood collection via venipuncture (other tests may be used as well).	Most drawings and descriptions of blood parasites are based on Giemsa-stained blood films. Although Wright's stain (or Wright-Giemsa combination stain) will work, stippling in malaria may not be visible and the organisms' colors will not match the descriptions. However, with other stains (those listed above, in addition to some of the "quick" blood stains), the organisms should be detectable on the blood films.
	Concentration methods: EDTA blood	Buffy coat, fresh blood films for detection of moving microfilariae or trypanosomes. QBC, a screening method for blood parasites (hematocrit tube contains acridine orange) has been used for malaria, *Babesia,* trypanosomes, and microfilariae. It is usually impossible to identify malaria organisms to the species level; requires high levels of training.	The use of blood collected with anticoagulant (rather than fresh) has direct relevance to the morphology of malaria organisms seen in peripheral blood films. If the blood smears are prepared after more than 1 h, stippling may not be visible, even if the correct pH buffers are used. Also, if blood is kept at room temperature (with the stopper removed), the male microgametocyte may exflagellate and fertilize the female macrogametocyte, and development continues within the tube of blood (as it would in the mosquito host). The ookinete may actually resemble a *Plasmodium falciparum* gametocyte.
	Antigen detection: EDTA-blood for malaria, serum or plasma for circulating antigens (hemolysed blood can interact in some tests)	Commercial test kits for malaria and some microfilariae (see Table 3)	
	PCR: EDTA blood, ethanol fixed or unfixed thin and thick blood films, coagulated blood, possible with hemolyzed or frozen blood samples	Sensitivity not higher than thick films for *Plasmodium* spp., much more sensitive for *Leishmania* (peripheral blood is used from immunodeficient patients only). Sequencing of PCR product is often used for species or genotype identification.	So far, no commercial tests are available; high laboratory standards are needed (may work with frozen, coagulated, or hemolyzed blood samples).
	Specific antibody detection: serum or plasma, anticoagulated or coagulated blood (hemolyzed blood can cause problems in some tests)	Most commonly used are EIA (many test kits commercially available), EITB (commercially available for some parasites), and IFT.	Many labs are using in-house tests; only a few fully defined antigens are available; sensitivities and specificities of the tests should be documented by the lab.
Bone marrow	Biopsies or aspirates Microscopy: thin and thick films with aspirate collected in EDTA	Giemsa stain (all blood parasites)	*Leishmania* amastigotes are recovered in cells of the reticuloendothelial system; if films are not prepared directly after sample collection, infected cells may disintegrate. Sensitivity of microscopy is low; use only in combination with other methods.
	Cultures: sterile material in EDTA or culture medium	Culture for *Leishmania* (or *Trypanosoma cruzi*)	
	PCR: aspirate in EDTA	PCR for blood parasites including *Leishmania* and *Toxoplasma* and rare other parasites	
Central nervous system	Microscopy: spinal fluid and CSF (wet examination, stained smears), brain biopsy material (touch or squash preparations, stained)	Stains: Giemsa (trypanosomes, *Toxoplasma*); Giemsa, trichrome, or calcofluor (amebae [*Naegleria*-PAM, *Acanthamoeba*- or *Balamuthia*- GAE]); Giemsa, acid-fast, PAS, modified trichrome, silver methenamine (microsporidia) (tissue Gram stains also recommended for microsporidia in	If CSF is received (with no suspect organism suggested), Giemsa would be the best choice; however, modified trichrome or calcofluor is also recommended as a second stain (amebic cysts, microsporidia). If brain biopsy material is received (particularly from an immunocompromised patient), cultivation is recommended for microsporidia isolation and PCR for

(Continued on next page)

TABLE 5 *(Continued)*

Body site	Procedures[a] and specimens	Recommended methods and relevant parasites[a]	Additional information
		routine histological preparations); H&E, routine histology (larval cestodes, *Taenia solium* cysticerci, *Echinococcus* spp.)	identification to the species or genotype level. A small amount of the sample should always be stored frozen for PCR analyses in case the results of the other methods are inconclusive.
	Culture: Sterile aspirate or biopsy material (in physiologic NaCl)	Free-living amebae (exception: *Balamuthia* will not grow in the routine agar/bacterial overlay method), microsporidia, and *Toxoplasma*	
	PCR: Aspirate or biopsy material native, frozen, or fixed in ethanol	Protozoa and helminths, species and genotype characterization	
Cutaneous ulcers	Microscopy: aspirate, biopsy (smears, touch or squash preparations, histological sections)	Giemsa *(Leishmania)*; H&E, routine histology *(Acanthamoeba* spp., *Entamoeba histolytica)*.	Most likely causative parasites would be *Leishmania,* which would stain with Giemsa. PAS could be used to differentiate *Histoplasma capsulatum* from *Leishmania* in tissue.
	Cultures (less common)	*Leishmania*, free-living amebae (often bacterial contaminations)	In the immunocompromised patient, skin ulcers have been documented with amebae as causative agents.
	PCR: aspirate, biopsy material (native, frozen, or fixed in ethanol)	*Leishmania* (species identification), free-living amebae	
Eye	Microscopy: smears, touch or squash preparations; biopsy specimens, scrapings, contact lens, sediment of lens solution	Calcofluor, cyst only (amebae *[Acanthamoeba]*); Giemsa trophozoites, cysts (amebae); modified trichrome (preferred) or silver methenamine stain, PAS, acid-fast, (microsporidial spores), H&E, routine histology (cysticerci, *Loa loa, Toxoplasma*)	Some free-living amebae (most commonly *Acanthamoeba*) have been implicated as a cause of keratitis. Although calcofluor will stain the cyst walls, it will not stain the trophozoites. Therefore, in suspected cases of amebic keratitis, both stains should be used. H&E (routine histology) can be used to detect and confirm cysticercosis. The adult worm of *Loa loa*, when removed from the eye, can be stained with a hematoxylin-based stain (Delafield's) or can be stained and examined by routine histology.
	Culture: native material (see above) in PBS supplemented with antibiotics, if possible, to avoid bacterial growth	Cultures: free-living amebae, *Toxoplasma,* microsporidia	
	PCR: native material in physiological NaCl or PBS, ethanol, or frozen	Free-living amebae, *Toxoplasma,* microsporidia species and genotype identification	Microsporidia confirmation to the species or genotype levels by PCR and sequence analyses; however, the spores could be found by routine light microscopy with modified trichrome, calcofluor, and/or tissue Gram stains.
Intestinal tract	(a) Stool and other intestinal material		
	Microscopy: stool, sigmoidoscopy material, duodenal contents (all fresh or preserved; see Table 4), direct wet smear, concentration methods	Concentration methods: ethyl acetate sedimentation of SAF-fixed stool samples (most protozoa); flotation or combined sedimentation flotation methods (helminth ova); agar- or Baermann-concentration (larvae of *Strongyloides* spp., native stool required)	Stool fixation with formalin or fixatives containing formalin preserves trophozoite morphology, allows prolonged storage (room temperature) and long transportation, and prevents hatching of *Schistosoma* eggs, but makes *Strongyloides* larval concentration impossible and impedes further PCR analyses.
		Direct wet smear (examination of unpreserved fresh material [motile protozoan trophozoites, helminth eggs, protozoan cysts])	Taeniid eggs can be identified morphologically, but require PCR so they can be identified to the species level.
		Stains: trichrome or iron hematoxylin (intestinal protozoa); modified trichrome (microsporidia); modified	Microsporidia: identification to the species or genotype level requires PCR; however, modified trichrome and/or calcofluor stains can be used to confirm the presence of spores.

(Continued on next page)

TABLE 5 Specimen preparation and procedures, recommended stain(s), relevant parasites, and additional information *(Continued)*

Body site	Procedures[a] and specimens	Recommended methods and relevant parasites[a]	Additional information
		acid-fast (*Cryptosporidium, Cyclospora,* and *Isospora)*	
	Anal impression smear	Adhesive cellulose tape, no stain *(Enterobius vermicularis)*	Four to six consecutive negative tapes required to rule out infection with pinworm *(Enterobius vermicularis)*.
	Adult worms or tapeworm segments (proglottids)	Carmine stains (rarely used for adult worms or cestode segments). Proglottids can usually be identified to the genus level *(Taenia, Diphyllobothrium,* and *Hymenolepis)* without using tissue stains.	Worm segments can be stained with special stains. However, after dehydration through alcohols and xylenes (or xylene substitutes), the sexual organs and the branched uterine structure will be visible, allowing identification of the proglottid to the species level.
	Antigen detection: fresh native or frozen material, suitability of fixation is test dependent	Commercial immunoassays (Table 2), e.g., EIA, FA, cartridge formats (*Entamoeba histolytica,* the *Entamoeba histolytica/E. dispar* group, *Giardia, Cryptosporidium* spp.); in-house tests for *T. solium* and *T. saginata*	Coproantigens can be detected in the prepatent period and independently from egg excretion.
	PCR: native fresh or frozen or ethanol-fixed material	No commercial tests available. Primers for genus or species identification of most helminths and protozoa are published.	Due to potential inhibition after DNA extraction from stool samples, concentration or isolation methods may be required prior to DNA extraction. However, new DNA isolation kits facilitate isolation of high-quality DNA from stool. Sequence analyses may be required for species or genotype identification.
	(b) Biopsies Microscopy: fixed for histology or touch or squash preparations for staining PCR: see above	H&E, routine histology (*Entamoeba histolytica, Cryptosporidium, Cyclospora, Isospora belli, Giardia*, microsporidia); less common findings would include *Schistosoma* spp., hookworm, or *Trichuris*	Special stains may be helpful for the identification of microsporidia (tissue Gram stains, silver stains, PAS, and Giemsa) or of cryptosporidia (modified acid-fast stains).
Liver and spleen	Biopsies or aspirates		
	Microscopy: unfixed material in physiological NaCl; fixed for histology	Examination of wet smears for *Entamoeba histolytica* (trophozoites), protoscolices of *Echinococcus* spp. or eggs of *Capillaria hepatica*. Giemsa (*Leishmania,* other protozoa and microsporidia); H&E (routine histology).	There are definite risks associated with punctures (aspirates and/or biopsy) of spleen or liver lesions *(Echinococcus)*. Keep always a small amount of material frozen for PCR.
	Culture: sterile preparation of native material	For *Leishmania* (not common)	
	Animal inoculation: sterile preparation of native material	Intraperitoneal inoculation of *E. multilocularis* cyst material for viability test after long-term chemotherapy	
	PCR: native, frozen, or ethanol fixed	Species or genotype identification (e.g., *Echinococcus* spp.)	
Respiratory tract	Sputum, induced sputum, nasal and sinus discharge, bronchoalveolar lavage fluid, transbronchial aspirate, tracheobronchial aspirate, brush biopsy specimen, open-lung biopsy specimen	Helminth larvae *(Ascaris, Strongyloides),* eggs (*Paragonimus, Capillaria),* or hooklets *(Echinococcus)* can be recovered in unstained respiratory specimens. Stains: Giemsa for many protozoa including *Toxoplasma* tachyzoites, modified acid-fast stains *(Cryptosporidium)*; modified trichrome (microsporidia)	There are immunoassay reagents (FA) available for the diagnosis of pulmonary cryptosporidiosis. Routine histologic procedures allow the identification of any of the helminths or helminth eggs present in the lung. Disseminated toxoplasmosis or microsporidiosis is well documented, with organisms being found in many different respiratory specimens.

(Continued on next page)

TABLE 5 *(Continued)*

Body site	Procedures[a] and specimens	Recommended methods and relevant parasites[a]	Additional information
	Microscopy: unfixed material, treated for smear preparation	Routine histology (H&E; silver methenamine stain, PAS, acid-fast, tissue Gram stains for helminths, protozoa, and microsporidia)	
	PCR: unfixed native, frozen, or fixed in ethanol		
Muscle	Biopsy material Microscopy: unfixed, touch and squash preparations, or fixed for histology and EM	Larvae of *Trichinella* spp. can be identified unstained (species identification with single larvae by PCR). H&E, routine histology (*Trichinella* spp, cysticerci); silver methenamine stain, PAS, acid-fast, tissue Gram stains, EM (rare microsporidia).	If *Trypanosoma cruzi* are present in the striated muscle, the organisms could be identified in routine histology preparations. Modified trichrome and/or calcofluor stains can be used to confirm the presence of microsporidial spores.
	PCR: unfixed or native, frozen, ethanol fixed	Microsporidia identification to the species level requires subsequent sequencing.	
Skin	Aspirates, skin snips, scrapings, biopsy specimens	See cutaneous ulcer (above).	Any of the potential parasites present can be identified by routine histology procedures.
	Microscopy: wet examination, stained smear (or fixed for histology or EM)	Wet preparations (microfilariae), Giemsa stained smears or H&E, routine histology (*Onchocerca volvulus, Dipetalonema streptocerca*, *Dirofilaria repens*, other larvae causing cutaneous larva migrans [zoonotic *Strongyloides* spp., hookworms], *Leishmania*, *Acanthamoeba* spp., *Entamoeba histolytica*, microsporidia, and arthropods [*Sarcoptes* and other mites])	
	PCR: unfixed native or frozen or fixed in ethanol.	Primers for most parasite species are available.	
Amniotic fluid	PCR (and/or culture): native material Animal inoculation (Toxoplasmosis)	PCR-based detection of highly repetitive gene sequences is the method of choice.	Only applicable to confirm suspected prenatal *Toxoplasma* infections
Urogenital system	Vaginal discharge, saline swab, transport swab (no charcoal), air-dried smear for IFT, urethral discharge, prostatic secretions, urine (single unpreserved, 24-h unpreserved, or early-morning specimens)	Giemsa, immunoassay reagents (IFT) *(Trichomonas vaginalis);* Delafield's hematoxylin (microfilariae); modified trichrome (microsporidia); H&E, routine histology PAS, acid-fast, tissue Gram stains, (microsporidia). Direct examination of urine sediment for *Schistosoma haematobium* eggs or microfilariae.	Although *T. vaginalis* is probably the most common parasite identified, there are others to consider, the most recently implicated organisms being in the microsporidia group. Microfilariae could also be recovered and stained. Fixation of urine with formalin prevents hatching of *Schistosoma* eggs.
	Microscopy: wet smears, smears of urine sediment, stained smears Cultivation: vaginal or urethral discharge or swab preparations	Identification and propagation of *T. vaginalis* (commercialized plastic envelope culture systems available); moving trophozoites can be detected under inverted microscope.	Material must be put into culture medium immediately after collection; do not cool or freeze.
	PCR: material unfixed native, frozen, or fixed in ethanol		

[a] EIA, enzyme immunoassay; EM, electron microscopy; EITB, enzyme-linked immunoelectro transfer blot (Western blot); GAE, granulomatous amebic encephalitis; GI, gastrointestinal; H&E, hematoxylin and eosin; IFT, immunofluorescence test; PAM, primary amebic encephalitis; PAS, periodic acid-Schiff stain; QBC, quantitative buffy coat; CSF, cerebrospinal fluid.

[b] Many parasites or parasite stages may be detected in standard histological sections of tissue material. However, species identification is difficult and additional examinations may be required. Usually, these techniques are not considered first-line methods. Additional methods like EM (electron microscopy) are carried out only by specialized laboratories and are not available for standard diagnostic purposes. EM examination for species identification has largely been replaced by PCR assays.

TABLE 6 Fecal specimens for parasites: options for collection and processing[a]

Options	Pros	Cons
Although physicians can order stools for parasitology when deemed appropriate, many laboratories include in their protocols the rejection of stools from inpatients who have been in-house for >3 days.	Patients may become symptomatic with diarrhea after they have been inpatients for a few days; symptoms are usually not attributed to parasitic infections but generally other causes.	There is always the chance that the problem is related to a nosocomial parasitic infection (rare), but *Cryptosporidium, Giardia,* and microsporidia may be possible considerations.
Examination of a single stool (O&P examination). Of organisms present, 40–50% will be found with only a single stool exam; two O&P exams are acceptable, but with three specimens the procedure is more sensitive; any patient remaining symptomatic would require additional testing.	If parasites are diagnosed in the first sample or if the patient becomes asymptomatic after collection of the first stool, subsequent specimens may not be necessary. However, with some intestinal parasitic infections, patients may alternate with constipation and diarrhea.	Diagnosis from examination of a single stool specimen depends on the parasite load in the specimen. In a series of three stool specimens, frequently not all three specimens are positive and/or may be positive for different organisms (may be a cost-effective approach).
Examination of a second stool specimen only after the first one is negative and the patient is still symptomatic.	With additional examinations, yield of protozoa increases (*E. histolytica,* 22.7%; *Giardia,* 11.3%; and *D. fragilis,* 31.1%).	Assumes that the second (or third) stool specimen is collected within the recommended 10-day time frame for a series of stools; protozoa are shed periodically. May be inconvenient for patient.
Examination of a single stool, O&P examination, and an immunoassay (EIA, FA, cartridge format) *(Giardia)*	If the examinations are negative and the patient's symptoms subside, then no further testing is probably required.	Patients may exhibit symptoms (off and on), so it may be difficult to rule out parasitic infections with only a single stool and immunoassay. If the patient remains symptomatic, then even if the *Giardia* immunoassay is negative, other protozoa may be missed *(Cryptosporidium, E. histolytica/ E. dispar, D. fragilis).*
Pooling of three specimens for examination; one concentration and one permanent stain are performed. The laboratory will pool the specimens.	Three specimens are collected over 7–10 days, which may save time and expense.	Procedure not recommended. Decreases strongly the sensitivity of the procedure; organisms present in low numbers may be missed due to the dilution factor.
Permanent stained smears performed, one from each of the three specimens, subsequently pooling of the three specimens for a single concentration on the pooled specimen.	Three specimens are collected over 7–10 days; this would maximize recovery of protozoa in areas where these organisms are most common.	Might miss light helminth infection (eggs, larvae) due to the pooling procedure.
Collection of three stool specimens; samples of stool from all three are placed into a single vial (patient is given a single vial only).	Pooling of the specimens would require only a single vial.	Absolutely not recommended. Lack of sensitivity; proper mixing of specimen and fixative complicates patient collection and depends on patient compliance.
Immunoassays performed only on selected patients[b] (children <5 yr old, children from day care centers, patients with immunodeficiencies, and patients from diarrheal outbreaks) for intestinal protozoa (see Table 7).	Would be more cost-effective than performing immunoassay procedures on all specimens.	The competence and the information needed to group patients are often not available in the laboratory.

[a] See key references 26 and 30.

[b] It's difficult to recognize an early outbreak situation where screening of all specimens for either *Giardia, Cryptosporidium* spp., or both may be relevant. If it appears that an outbreak is in the early stages, then performing the immunoassays on request can be changed to screening all stools.

TABLE 7 Approaches to stool parasitology: test ordering[a]

Patient and/or situation	Test ordered[b]	Follow-up test ordered
Immunocompromised patients with diarrhea Potential waterborne outbreak from (municipal) water supply	*Cryptosporidium* or *Giardia*/*Cryptosporidium* immunoassay[b] (see Table 2)	If immunoassays are negative and symptoms continue, special tests for microsporidia (modified trichrome stain) and coccidia (modified acid-fast stain) and O&P exam should be performed.
Patient with diarrhea (nursery school, day care center, camper, backpacker) Patient with diarrhea and potential waterborne outbreak (resort setting)	*Giardia* or *Giardia*/*Cryptosporidium*[c] immunoassay	If immunoassays are negative and symptoms continue, special tests for microsporidia and coccidia (see above) and O&P exam should be performed.
Patient with diarrhea and relevant travel history Patient with diarrhea who is a past or present resident of a developing country Patient in areas of the United States where parasites other than *Giardia* are found (e.g., in large metropolitan areas)	O&P exam, the *Entamoeba histolytica*/*E. dispar* group immunoassay, confirmation for *E. histolytica*, *Cryptosporidium* or *Giardia*/*Cryptosporidium* immunoassay[c]	If exams are negative and symptoms continue, special tests for coccidia and microsporidia should be performed.
Patient with unexplained eosinophilia	O&P exam with emphasis on helminths (unfixed stool, for sedimentation/flotation techniques); it is very important to make sure that an infection with *Strongyloides stercoralis* has been ruled out–particularly if the patient is immunosuppressed or may become immunosuppressed from therapy, etc. (unfixed stool, Baermann-concentration or agar plate culture).	If the O&P exams are negative, agar plate cultures for *S. stercoralis* are recommended, particularly if the history is suggestive for this infection. The serological detection of specific antibody is an additional diagnostic option.
Patient with diarrhea (suspected food-borne outbreak)	Test for *Cyclospora cayetanensis* (modified acid-fast stain)	If test is negative and symptoms continue, special procedures for microsporidia and other coccidia and O&P exam should be performed.

[a] Modified from reference 10.
[b] Depending on the particular immunoassay kit used, various single or multiple organisms may be included. Selection of a particular kit depends on many variables: clinical relevance, cost, ease of performance, training, personnel availability, number of test orders, training of physician clients, sensitivity, specificity, equipment, time to result, etc. Very few laboratories will handle this type of testing in exactly the same way. Many options are clinically relevant and acceptable for patient care.
[c] More than one stool specimen may need to be tested using an immunoassay in order to rule out an infection with *Giardia;* fecal immunoassays may also be negative in cases with a low parasite load.

is at the user's discretion. Aqueous formalin will permit the examination of the specimen as a wet mount only, a technique much less accurate than a stained smear for the identification of intestinal protozoa.

Protozoan cysts (not trophozoites), coccidian oocysts, helminth eggs, and larvae are well preserved for long periods in 10% aqueous formalin. Hot (60°C) formalin can be used for specimens containing helminth eggs, since in cold formalin some thick-shelled eggs may continue to develop, become infective, and remain viable for long periods. Several grams of fecal material should be thoroughly mixed in 5 or 10% formalin (ratio, 1:10).

Formaldehyde vapor concentrations must be monitored and maintained at concentrations below the following: 8-h time-weighted average, i.e., 0.75 ppm, and 15-min short-term exposure limit, i.e., 2.0 ppm (9). The amount of formaldehyde used in microbiology is quite small; laboratory monitoring values are generally well below the required maximum concentrations. Initial monitoring must be repeated any time there is a change in production, equipment, process, personnel, or control measures which may result in new or additional exposure to formaldehyde. Stool fixatives that contain formaldehyde indicate that fact on the label. A number of single-vial fixative collection systems are now available; although they may not contain formaldehyde, the actual formulas are proprietary.

SAF

Both the concentration and the permanent stained smear can be performed with specimens preserved in SAF, which does not contain mercuric chloride, which is found in Schaudinn's fluid and PVA. It is a liquid fixative, much like the 10% formalin described above. The sediment is used to prepare the permanent smear, and it is frequently recommended that the stool material be placed on an albumin-coated slide to improve adherence to the glass (29, 33).

TABLE 8 Fecal preservatives: pros and cons

Stool preservative	Pros	Cons
Formalin	Good overall fixative for stool concentration. Easy to prepare, long shelf life. Concentrated sediment can be used with different stains[a] but not with all immunoassays (see Table 2).	Does not preserve trophozoites well. Does not adequately preserve organism morphology for a good permanent stained smear; not optimal for all immunoassays; not appropriate for molecular diagnosis (PCR).
SAF	Can be used for concentration and permanent stained smears. Contains no mercury compounds. Easy to prepare, long shelf life. Concentrated sediment can be used with most of the new immunoassay methods and special stains.	Poor adhesive properties; albumin-coated slides recommended. Protozoan morphology better if iron hematoxylin stain is used for permanent stained smears (trichrome is not quite as good). May be a bit more difficult to use; however, this is really not a limiting factor; formalin (see above).
Schaudinn's fixative	Fixative for smears prepared from fresh fecal specimens or samples from the intestinal mucosa surfaces. Provides excellent preservation of protozoan trophozoites and cysts.	Not generally recommended for concentration procedures. Contains mercuric chloride; creates disposal problems. Poor adhesive qualities with liquid or mucoid specimens.
PVA	Can prepare permanent stained smears and perform concentration techniques (less common). Provides excellent preservation of protozoan trophozoites and cysts. Specimens can be shipped to the laboratory for subsequent examination; organism morphology excellent after processing. Suitable for DNA-PCR analysis.	*Trichuris trichiura* eggs and *Giardia* cysts are not concentrated as easily as from formalin-based fixatives. *Strongyloides stercoralis* larval morphology will be poor (better from formalin-based preservation). *Isospora belli* oocysts may not be visible from PVA-preserved material (better from formalin-based preservation). Contains mercury compounds (Schaudinn's fluid). May turn white and gelatinous when it begins to dehydrate or when refrigerated. Difficult to prepare in the laboratory. Specimens containing PVA cannot be used with the immunoassay methods.
Modified PVA	Can prepare permanent stained smears and perform concentration techniques (less common). Many workers prefer the zinc substitutes over those prepared with copper sulfate. Does not contain mercury compounds.	Overall protozoan morphology of trophozoites and cysts is poor when preserved in the copper-sulfate-based fixative, particularly when compared with organisms preserved in mercuric chloride-based fixatives. Zinc-based fixatives appear to be some of the better alternatives. Staining characteristics of protozoa not consistent; some are good, some are poor. Organism identification may be difficult, particularly with small protozoan cysts *(Endolimax nana)*.
Single-vial systems	Can prepare permanent stained smears and perform concentration techniques. Can perform immunoassays—"universal fixative" under development. Do not contain mercury compounds. Unless organism numbers are very low, acceptable organism recovery and identification are possible; additional training may be required to recognize the organisms because the overall morphology will not be comparable to that seen using mercury-based fixatives.	Overall protozoan morphology of trophozoites and cysts is not as good as when compared with organisms preserved with mercuric chloride-based fixatives; similar to modified PVA options. Staining characteristics of protozoa not consistent; some are good, some are poor. Identification of *Endolimax nana* cysts may be difficult. Not all immunoassays can be performed from stool specimens preserved in these fixatives.

[a] Modified acid-fast and modified trichrome stains.

SAF is considered to be a "softer" fixative than mercuric chloride. The organism morphology will not be quite as sharp after staining as will that of organisms originally fixed in solutions containing mercuric chloride. The pairing of SAF-fixed material with iron hematoxylin staining provides better organism morphology than does staining of SAF-fixed material with trichrome (personal observation). Although SAF has a long shelf life and is easy to prepare, the smear preparation technique may be a bit more difficult for less experienced personnel who are not familiar with fecal specimen techniques. Laboratories that have considered using only a single preservative have selected this option. Helminth eggs and larvae, protozoan trophozoites and cysts, coccidian oocysts, and microsporidian spores are preserved using this method.

Schaudinn's Fluid

Schaudinn's fluid (contains mercuric chloride) is used with fresh stool specimens or samples from the intestinal mucosal

surface. Many laboratories that receive specimens from in-house patients (no problem with delivery times) often select this approach. Permanent stained smears are then prepared from fixed material. A concentration technique using Schaudinn's fluid-preserved material is also available but is not widely used (3, 9, 20, 24).

PVA

PVA is a plastic resin that is normally incorporated into Schaudinn's fixative. The PVA powder serves as an adhesive for the stool material; i.e., when the stool-PVA mixture is spread onto the glass slide, it adheres because of the PVA component. Fixation is still accomplished by the Schaudinn's fluid itself. Perhaps the greatest advantage in the use of PVA is that a permanent stained smear can be prepared. Like SAF, PVA fixative solution is recommended as a means of preserving cysts and trophozoites for later examination and permits specimens to be shipped (by regular mail service) from any location in the world to a laboratory for subsequent examination. PVA is particularly useful for liquid specimens and should be used in the ratio of 3 parts PVA to 1 part fecal specimen (5).

Modified PVA

Although preservatives that do not contain mercury compounds have been developed, substitute compounds have not provided the quality of preservation necessary for good protozoan morphology on the permanent stained smear. Copper sulfate has been tried but does not provide results equal to those seen with mercuric chloride (19). Zinc sulfate has proven to be an acceptable mercury substitute and is used with trichrome stain. Although zinc substitutes have become widely available, each manufacturer has a proprietary formula for the fixative (14, 16).

Single-Vial Collection Systems

Several manufacturers now have available single-vial stool collection systems, similar to SAF or modified PVA methods. From the single vial, both the concentration and permanent stained smear can be prepared. It is also possible to perform immunoassays from some of these vials. Ask the manufacturer about all diagnostic capabilities (concentrate, permanent stained smear, immunoassay procedures, molecular analyses) and for specific information indicating that there are no formula components that would interfere with any of the methods. Like the zinc substitutes, these formulas are proprietary (16). The ability to perform immunoassays using fixed specimens will vary depending on the fixative and specific immunoassay being used.

New-Formulation Single-Vial Collection Systems

New formulations continue to be developed, some of which appear to adhere to the slide without the use of albumin or PVA. These formulations can be used to perform concentrations and some of the immunoassays and to prepare permanent stained smears.

Collection of Blood

Depending on the life cycle, there are a number of parasites that may be recovered in a blood specimen, either whole blood, buffy coat preparations, or various types of concentrations (10, 20, 24). These parasites include *Plasmodium, Babesia, Trypanosoma, Leishmania, Toxoplasma,* and microfilariae. Although some organisms may be motile in fresh, whole blood, species identification will normally be accomplished from the examination of permanent stained blood thin and/or thick films. Blood films can be prepared from fresh, whole blood collected with no anticoagulants, anticoagulated blood, or sediment from the various concentration procedures.

Unless it is certain that well-prepared slides will be available, it is necessary to request a tube of fresh blood (EDTA anticoagulant is preferred) and prepare the smears. The tube should be filled with blood to provide the proper blood/anticoagulant ratio. For detection of stippling, the smears should be prepared within 1 h after the specimen is drawn. After that time, stippling may not be visible on stained films; however, the overall organism morphology will still be excellent. Most laboratories routinely use commercially available blood collection tubes; preparation of EDTA collection tubes in-house is neither necessary nor cost-effective.

The time the specimen was drawn should be clearly indicated on the tube of blood and also on the result report. The physician will then be able to correlate the results with any fever pattern or other symptoms that the patient may have. There should also be some comments on the test result report that is sent back to the physician, stating that one negative specimen does not rule out the possibility of a parasitic infection (9, 28).

Collection of Specimens from Other Body Sites

Although clinical specimens for examination can be obtained from many other body sites, these specimens and appropriate diagnostic methods are not as commonly performed as those used for the routine stool specimen or for blood specimens. The majority of specimens from other body sites (Table 1) would be submitted as fresh specimens for further testing.

DIRECT DETECTION BY ROUTINE METHODS

Intestinal Tract Specimens

The most common specimen submitted to the diagnostic laboratory is the stool specimen, and the most commonly performed procedure in parasitology is the ova and parasite examination (O&P), which is composed of three separate protocols: the direct wet mount, the concentration, and the permanent stained smear. The direct wet mount requires fresh stool, is designed to allow the detection of motile protozoan trophozoites, and is examined microscopically at low and high dry magnifications (×100, entire 22- by 22-mm coverslip [larvae, larger helminth eggs]; ×400, one-third to one-half of a 22- by 22-mm coverslip [protozoan cysts and/or trophozoites, smaller helminth eggs]). However, due to potential problems with the lag time between specimen passage and receipt in the laboratory, the direct wet examination has been eliminated from the routine O&P in favor of receipt of specimens collected in stool preservatives; if specimens are received in the laboratory in stool collection preservatives, the direct wet preparation is not performed.

The second part of the O&P is the concentration, which is designed to facilitate the recovery of protozoan cysts, coccidian oocysts, microsporidial spores, and helminth eggs and larvae. Both flotation (zinc sulfate, zinc chloride, and others) and sedimentation methods are available, the most common procedure being the formalin-ethyl acetate sedimentation method (formerly called the formalin-ether method). The concentrated specimen is examined as a wet preparation, with or without iodine, using low and high dry magnifications (×100 and ×400) as indicated for the direct wet smear

examination. It is important to remember that large, heavy helminth eggs (unfertilized *Ascaris* eggs) or eggs that are operculated (trematode and some cestode eggs) will not float optimally when flotation fluids with densities of <1.35 are used; both the surface film and sediment must be examined by this method.

The third part of the O&P is the permanent stained smear, which is designed to facilitate the identification of intestinal protozoa. Several staining methods are available, the two most common being the Wheatley modification of the Gomori tissue trichrome and the iron hematoxylin stains. This part of the O&P examination is critical for the confirmation of suspicious objects seen in the wet examination and identification of protozoa that might not have been seen in the wet preparation. The permanent stained smears are examined using oil immersion objectives (×600 for screening, ×1,000 for final review of ⩾300 oil immersion fields).

Other specimens from the intestinal tract such as duodenal aspirates or drainage, mucus from the Entero-Test Capsule technique (HDC Corp., San Jose, Calif.), and sigmoidoscopy material can also be examined as wet preparations and as permanent stained smears after processing with either trichrome or iron hematoxylin staining. Although not all laboratories will examine these types of specimens, they are included to give some idea of the possibilities for diagnostic testing.

Amniotic Fluid

Methods for the diagnosis of congenital *Toxoplasma* infection are summarized in chapter 138, "Toxoplasma." Amniotic fluid collected under sterile conditions allows both mouse or tissue culture inoculation and molecular diagnosis by PCR. PCR is the recommended test of choice for the detection of *Toxoplasma* in amniotic fluid.

Urogenital Tract Specimens

The identification of *Trichomonas vaginalis* is usually based on the examination of wet preparations of vaginal and urethral discharges and prostatic secretions or urine sediment. Multiple specimens may have to be examined before the organisms are detected. These specimens are diluted with a drop of saline and examined under low power (×100) and reduced illumination for the presence of motile organisms; as the jerky motility begins to diminish, it may be possible to observe the undulating membrane, particularly under high dry power (×400). Culture systems (InPouch TV; BioMed Diagnostics, San Jose, Calif. [http://www.biomed1.com/TV.htm] and Empyrean Diagnostics, Inc., Mountain View, Calif.) that allow direct inoculation, transport, culture, and microscopic examination are available commercially (2, 9). Stained smears such as Papanicolaou or Giemsa can be used but are usually not necessary for the identification of this organism and can be difficult to interpret. If a dry smear is received by the laboratory, it can be fixed with absolute methanol and stained with Giemsa stain; this approach is not optimal, but the smear can be examined and may confirm a positive infection. The number of false-positive and false-negative results reported on the basis of stained smears strongly suggests the value of confirmation by observation of motile organisms from the direct mount, from appropriate culture media, or from direct detection by more sensitive immunological or molecular methods (Table 3) (6).

Examination of urinary sediment may be indicated in certain filarial infections. Administration of the drug diethylcarbamazine (Hetrazan) has been reported to enhance the recovery of microfilariae from the urine. The triple-concentration technique is recommended for the recovery of microfilariae (9). The membrane filtration technique can also be used with urine for the recovery of microfilariae (9). *Schistosoma haematobium* eggs can be concentrated by centrifugation of urine specimens; a membrane filter technique for the egg recovery has also been useful (9). Fresh samples or fixed samples in formalin should be used to prevent hatching of eggs.

Sputum

Although not one of the more common specimens, expectorated sputum may be submitted for examination for parasites. Organisms in sputum that may be detected and may cause pneumonia, pneumonitis, or Loeffler's syndrome include the migrating larval stages of *Ascaris lumbricoides, Strongyloides stercoralis,* and hookworm; the eggs of *Paragonimus* spp.; *Echinococcus granulosus* hooklets; and *Entamoeba histolytica, Entamoeba gingivalis, Trichomonas tenax, Cryptosporidium* spp., and possibly the microsporidia. In a *Paragonimus* infection, the sputum may be viscous and tinged with brownish flecks, which are clusters of eggs ("iron filings"), and may be streaked with blood. Sputum is usually examined as a wet mount (saline or iodine), using low and high dry power (×100 and ×400). The specimen is not concentrated before preparation of the wet mount. If the sputum is thick, an equal amount of 3% sodium hydroxide (NaOH) (or undiluted chlorine bleach) can be added; the specimen is thoroughly mixed and then centrifuged at 500 × *g* for 5 min. NaOH should not be used if one is looking for *Entamoeba* spp. or *T. tenax.* After centrifugation, the supernatant fluid is discarded and the sediment can be examined as a wet mount with saline or iodine. If examination has to be delayed for any reason, the sputum should be fixed in 5 or 10% formalin to preserve helminth eggs or larvae or in PVA fixative to be stained later for protozoa.

Aspirates

The examination of aspirated material for the diagnosis of parasitic infections may be extremely valuable, particularly when routine testing methods have failed to demonstrate the organisms. These specimens should be transported to the laboratory immediately after collection. Aspirates include liquid specimens collected from a variety of sites where organisms might be found. The aspirates most commonly processed in the parasitology laboratory include fine-needle and duodenal aspirates. Fluid specimens collected by bronchoscopy include bronchoalveolar lavage fluid and bronchial washings (23).

Fine-needle aspirates may be submitted for slide preparation, culture, and/or molecular analyses. Aspirates of cysts and abscesses for amebae may require concentration by centrifugation, digestion, microscopic examination for motile organisms in direct preparations, and cultures and microscopic evaluation of stained preparations. Antigen detection and PCR are other possibilities, depending on individual laboratory testing options.

Bone marrow aspirates for *Leishmania* amastigotes, *Trypanosoma cruzi* amastigotes, or *Plasmodium* spp. require Giemsa staining. Examination of these specimens may confirm an infection that has been missed by examination of routine blood films. In certain situations, culture, immunoassays for antigen detection, or PCR will also provide more-sensitive results (22).

Biopsy Specimens

Biopsy specimens are recommended for the detection of tissue parasites (Table 5). The following procedures may be used for this purpose in addition to standard histologic

preparations: impression smears and teased and squash preparations of biopsy tissue from skin, muscle, cornea, intestine, liver, lung, and brain. Tissue to be examined by permanent sections or electron microscopy should be fixed as specified by the laboratories that will process the tissue. In certain cases, a biopsy may be the only means of confirming a suspected parasitic infection. Specimens that are going to be examined as fresh material rather than as tissue sections should be kept moist in saline and submitted to the laboratory immediately.

Detection of parasites in tissue depends in part on specimen collection and on having sufficient material to perform the recommended diagnostic procedures. Biopsy specimens are usually quite small and may not be representative of the diseased tissue. Multiple tissue samples will often improve diagnostic results. To optimize the yield from any tissue specimen, all areas should be examined by as many procedures as possible. Tissues are obtained from invasive procedures, many of which are very expensive and lengthy; consequently, these specimens deserve the most comprehensive procedures possible.

Tissue submitted in a sterile container in sterile saline or on a sterile sponge dampened with saline may be used for cultures or molecular analyses of protozoa after mounts for direct examination or impression smears for staining have been prepared. If cultures for parasites are to be made, sterile slides should be used for smear and mount preparation.

Blood

Depending on the life cycle, a number of parasites may be recovered in a blood specimen, either whole blood, buffy coat preparations, or various types of concentrations (9, 28). Although some organisms may be motile in fresh whole blood, species identification will normally be accomplished from the examination of permanent stained blood films, both thick and thin films. Blood films can be prepared from fresh whole blood collected with no anticoagulants, anticoagulated blood, or sediment from the various concentration procedures. The recommended stain of choice is Giemsa stain; however, the parasites can also be seen on blood films stained with Wright's stain. Delafield's hematoxylin stain is often used to stain the microfilarial sheath; in some cases, Giemsa stain does not provide sufficient stain quality to allow differentiation of the microfilariae.

Thin Blood Films

In any examination of thin blood films for parasitic organisms, the initial screen should be carried out with the low-power objective (10×) of a microscope. Microfilariae may be missed if the entire thin film is not examined. Microfilariae are rarely present in large numbers, and frequently only a few organisms are present in each thin film preparation. Microfilariae are commonly found at the edges of the thin film or at the feathered end of the film because they are carried to these sites during spreading of the blood. The feathered end of the film, where the erythrocytes (RBCs) are drawn out into one single, distinctive layer of cells, should be examined for the presence of malaria parasites and trypanosomes. In these areas, the morphology and size of the infected RBCs are most clearly seen.

Depending on the training and experience of the microscopist, examination of the thin film usually takes 15 to 20 min (≥300 oil immersion fields) for the thin film at a magnification of ×1,000. Although some people use a 50× or 60× oil immersion objective to screen stained blood films, there is some concern that small parasites such as plasmodia, *Babesia* spp., or *Leishmania* spp. may be missed at this lower total magnification (×500 or ×600) compared with the ×1,000 total magnification obtained using the more traditional 100× oil immersion objective. Because people tend to scan blood films at different rates, it is important to examine a minimum number of fields. If something suspicious has been seen in the thick film, the number of fields examined on the thin film is often considerably greater than 300. The request for blood film examination should always be considered a STAT procedure, with all reports (negative as well as positive) being relayed by telephone to the physician as soon as possible. If positive, notification of appropriate governmental agencies (local, state, and federal) should be done within a reasonable time frame in accordance with guidelines and laws. Most county or state public health laboratories require reporting of *Plasmodium*- and *Babesia*-positive cases; the local public health facility should be consulted for a list of reportable parasitic diseases relevant for your location.

Both malaria and *Babesia* infections have been missed with automated differential instruments, and therapy was delayed. Although these instruments are not designed to detect intracellular blood parasites, the inability of the automated systems to discriminate between uninfected RBCs and those infected with parasites may pose serious diagnostic problems (15).

Thick Blood Films

In the preparation of a thick blood film, the highest concentration of blood cells will be in the center of the film. The examination should be performed at low magnification to detect microfilariae more readily. Examination of a thick film usually requires 5 to 10 min (approximately 100 oil immersion fields). The search for malarial organisms and trypanosomes is best done under oil immersion (total magnification, ×1,000). Intact RBCs are frequently seen at the very periphery of the thick film; such cells, if infected, may prove useful in malaria diagnosis since they may demonstrate the characteristic morphology necessary to identify the organisms to the species level.

Blood Stains

For accurate identification of blood parasites, a laboratory should develop proficiency in the use of at least one good staining method. It is better to select one method that will provide reproducible results than to use several on a hit-or-miss basis. Blood films should be stained as soon as possible, since prolonged storage may result in stain retention. Failure to stain positive malarial smears within a month may result in failure to demonstrate typical staining characteristics for individual species.

The most common stains are of two types. Wright's stain has the fixative in combination with the staining solution, so that both fixation and staining occur at the same time; therefore, the thick film must be laked before staining. In Giemsa stain, the fixative and stain are separate; therefore, the thin film must be fixed with absolute methanol before staining.

Buffy Coat Films

Trypanosomes, occasionally *Histoplasma capsulatum* (a fungus with intracellular elements resembling those of *Leishmania* amastigote stages) and, in immunocompromised patients, potentially *Leishmania* spp. (*L. infantum, L. chagasi,* and *L. donovani)* are detected in the peripheral blood. The parasite or fungus will be found in the large mononuclear cells in the buffy coat (a layer of leukocytes resulting from

centrifugation of whole anticoagulated blood). The nuclear material will stain dark red-purple, and the cytoplasm will be light blue (*Leishmania* spp.). *H. capsulatum* will appear as a large dot of nuclear material (dark red-purple) surrounded by a clear halo area. Trypanosomes in the peripheral blood will also concentrate with the buffy coat cells.

Screening Methods

Microhematocrit centrifugation with use of the QBC malaria tube, a glass capillary tube and closely fitting plastic insert (CBC malaria blood tubes; Becton Dickinson, Tropical Disease Diagnostics, Sparks, Md.), has been used for the detection of blood parasites. At the end of centrifugation of 50 to 60 μl of capillary or venous blood (5 min in a QBC centrifuge, 14,387 × *g*), parasites or RBCs containing parasites are concentrated into a small, 1- to 2-mm region near the top of the RBC column and are held close to the wall of the tube by the plastic float, making them readily visible by microscopy. Tubes precoated with acridine orange provide a stain which induces fluorescence in the parasites. This method automatically prepares a concentrated smear, which represents the distance between the float and the walls of the tube. Once the tube is placed into the plastic holder (Para-viewer) and immersion oil is applied to the top of the hematocrit tube (no coverslip is necessary), the tube is examined with a 40× to 60× oil immersion objective (which must have a working distance of 0.3 mm or greater) (9).

Antigen and DNA Detection for Blood Parasites

Several antigen detection tests are available. Many among them are designed for rapid and individual diagnoses (Table 3; see also below). Most of the kits are not available in the United States but have proven to be very useful in other countries. Rapid tests are available to diagnose specifically *P. falciparum* or, on a genus level, *Plasmodium* sp. infections (Table 3). These tests are simple to perform and can be applied during the more time-consuming microscopic identification of the thin and thick blood smears. However, one has to be aware that false-positive and false-negative reactions do occur (4, 8, 32). The general recommendation is to use these tests only in addition to the microscopical examination of thick and thin blood smears. Various PCR-based methods haven been described in the scientific literature. Although the methods are more sensitive than standard microscopical examinations of blood films, they are not routinely used for malaria diagnosis (see below).

Knott Concentration

The Knott concentration procedure is used primarily to detect the presence of microfilariae in the blood, especially when a light infection is suspected. The disadvantage of the procedure is that the microfilariae are killed by the formalin and are therefore not seen as motile organisms.

Membrane Filtration Technique

The membrane filtration technique using Nuclepore filters (25-mm Nuclepore filter [5-μm porosity]) has proved highly efficient in demonstrating filarial infections when microfilaremias are of low density. It has also been successfully used in field surveys (9).

Culture Methods

Very few clinical laboratories offer specific culture techniques for parasites. The methods for in vitro culture are often complex, while quality control is difficult and not really feasible for the routine diagnostic laboratory. In certain institutions, some techniques may be available, particularly where consultative services are provided and for research purposes.

Few parasites can be routinely cultured, and the only procedures that are in general use are for *Entamoeba histolytica, Naegleria fowleri, Acanthamoeba* spp., *Trichomonas vaginalis, Toxoplasma gondii, Trypanosoma cruzi, Encephalitozoon* spp., and the leishmanias. These procedures are usually available only after consultation with the laboratory and on special request. Commercialized tests are available only for *T. vaginalis* (InPouch TV; BioMed Diagnostics [http://www.biomed1.com/TV.htm]).

Animal Inoculation and Xenodiagnosis

Most routine clinical laboratories do not have the animal care facilities necessary to provide animal inoculation capabilities for the diagnosis of parasitic infections. Host specificity for many animal parasite species is well known and will limit the types of animals available for these procedures. In certain suspect infections animal inoculation may be requested and can be very helpful in making the diagnosis, although animal inoculation certainly does not take the place of other, more routine procedures. Mouse inoculation with amniotic fluid has been used in the past for diagnosis of congenital toxoplasmosis; this method, however, has mostly been replaced by PCR. Intraperitoneal inoculation of *Echinococcus multilocularis* metacestode material from surgical resection or from biopsies in mice or gerbils is still the most reliable procedure available for viability testing after long-term chemotherapy.

Xenodiagnosis is a technique that uses the arthropod host as an indicator of infection. Uninfected reduviid bugs are allowed to feed on the blood of a patient who is suspected of having Chagas' disease (*T. cruzi* infection). After 30 to 60 days, feces from the bugs are examined over a 3-month time frame for the presence of developmental stages of the parasite, which are found in the hindgut of the vector. This type of procedure is used primarily in South America for fieldwork, and the appropriate bugs are raised in various laboratories specifically for this purpose.

Antigen Detection

The detection of parasite-specific antigen is indicative of current infection. Immunoassays are generally simple to perform. Some formats allow the processing of large numbers of tests at one time, thereby reducing overall costs; others are specially designed for rapid individual diagnoses (cartridge formats) (Tables 2 and 3). A major disadvantage of antigen detection is that in most cases the method can detect only a single pathogen at one time. Therefore, additional parasitological examinations must be performed to detect other parasitic pathogens. The current commercially available immunoassays for the detection of intestinal protozoa have excellent sensitivity and specificity compared to routine microscopy (1, 11, 12, 13). Specific ordering approaches using both immunoassays and routine O&P examinations are listed in Table 7. Rapid tests for the diagnosis of malaria should be used only in parallel to the examination of thick and thin blood smears.

Parasite DNA Detection

Nucleic acid-based diagnostic tests (particularly PCR with its inherent potential for highly efficient and specific amplification of DNA) have been developed for almost all species of parasites. However, only a few are routinely used in diagnostic settings. The main reason for this minor role of diagnostic

PCR in parasitology is the fact that many parasite stages can be adequately diagnosed using established, more traditional techniques (microscopy, detection of antigens and antibodies, in vitro cultivation) that are generally less expensive than PCR and technically less demanding. Therefore, diagnosis by PCR is of great value in cases where these techniques are insufficient, i.e., in cases where (i) the immune response is not informative (e.g., acute infections, short-term follow-up after therapy, congenital infections); (ii) high sensitivity is needed because of low parasite levels (e.g., cutaneous leishmaniasis); or (iii) morphologically indistinguishable organisms need to be identified (e.g., *E. histolytica*/*E. dispar,* eggs of taeniid tapeworms).

Diagnostic PCR may become more widespread when simple, fully standardized (commercialized) test kits are available and costs are reduced through the implementation of pre- and post-PCR automated techniques. Furthermore, the possibilities to not only detect and identify but also quantify organisms and determine their genotypes by analyzing the diagnostic PCR product extend the diagnostic power of PCR. Indeed, PCR coupled with genetic characterization is already widely being used in parasitology to address questions such as parasite host range and host specificity, ways of transmission, and molecular epidemiology. Such genotyping applications should increase in the future with increasing knowledge of the relationship between genetic variation in parasites and features such as virulence or drug resistance. An important limitation of PCR-based diagnosis is the fact that sensitivity dramatically decreases with material stored for more than 1 day in formalin due to the fragmentation (fragment length of a few hundred base pairs) of the DNA. However, by selecting primers that produce PCR products as short as possible, which is recommended for real-time PCR, sensitivity might be reasonably high. Such tests, however, are not yet widely available in parasitology. Therefore, it seems to be the best choice to avoid formalin fixation if PCR analyses have to be considered.

Reagents, Stains, and Media: Parasitology

SUSAN E. SHARP

134

The evaluation of clinical specimens for ova and parasites in the clinical laboratory can involve the use of direct macroscopic examination of the specimen and microscopic examination of fresh and preserved specimens, as well as culture for some parasitic organisms. These examinations necessitate the use of a variety of stains, reagents, and media, the most common of which are discussed in this chapter.

As many parasitic organisms cannot be cultured, microscopic examination is the mainstay of diagnostic parasitology. Examination after proficient staining of fresh and unconcentrated specimens, as well as preserved and/or concentrated specimens with permanent stained preparations, most often provides for a rapid and accurate diagnosis. A variety of reagents and stains are available for these purposes, and each laboratory must decide which ones to use to best serve its patient population. In addition, as most specimens are submitted in fixatives and preservatives because of the inability to perform immediate direct observation, the reader should note the specific interference of polyvinyl alcohol (PVA) and mercury reagents with immunoassays that are commonly used for parasitic diagnosis.

Caution should be taken when using reagents in the parasitology laboratory. Many routinely used compounds can be dangerous if not handled appropriately. For example, formalin and formaldehyde solutions can cause severe skin irritation and if swallowed can cause violent vomiting and diarrhea; mercury compounds are local irritants and systemic poisons that can be absorbed through the skin; phenol is a skin irritant and can affect the central nervous system if one is exposed to large amounts; and xylene can cause serious skin irritation, with extended exposure causing gastrointestinal, neurologic, and tissue damage (5).

REAGENTS

All of the following reagents listed are preservatives and/or fixatives.

Formalin Preparations

■ Formalin

Formalin has always been used in parasitology as an all-purpose preservative and for use in concentration procedures. Formalin alone cannot be used for concentration techniques and permanent stained smears. It is easy to prepare and has a long shelf life. It is most routinely used as a preservative for stool and duodenal aspirate specimens. Formalin works well to preserve the morphologies of helminth ova and larvae and those of protozoan cysts, oocysts, and spores, although it does not preserve protozoan trophozoites well. Although both 5 and 10% solutions of formalin are currently used (5% for the best preservation of protozoan stages and 10% for ova and larvae), the 10% formulation is most widely used in clinical parasitology today. Formalin (10%) is prepared as indicated below:

Formaldehyde (37 to 40% HCHO solution)	100 ml
Saline (0.85% NaCl) OR distilled water	900 ml

Buffered formalin

Formalin buffered with sodium and potassium phosphates can be used to help maintain the morphology of parasites for long-term storage. To make buffered formalin, mix the following dry ingredients together and store in a tightly closed container. Add 0.8 g of this mixture to 1 liter of 10% (or 5%) formalin.

Sodium phosphate, dibasic (Na_2HPO_4)	6.1 g
Potassium phosphate, monobasic (KH_2PO)	0.15 g

■ Merthiolate-iodine-formalin (MIF)

Protozoa and helminth ova and larvae can be distinguished on direct wet mount after stool and duodenal aspirate specimens are fixed in MIF. MIF allows not only for fixation but also for staining of the organisms, although organism morphology is not as good as when other permanent staining compounds are used. This method requires that two stock solutions be combined into a fresh working solution immediately prior to use. In addition, after mixing of specimens with MIF, the mixture must be left undisturbed for 24 h prior to preparation of smears from the bottom two layers of the three layers that will form. Parasitological examination of specimens placed in MIF can be performed for several weeks after preservation, making it very useful for field surveys. MIF is also readily available commercially.

PVA-Containing Preservatives/Fixatives

PVA acts as an adhesive for stool material, allowing the stool to adhere to glass slides. Several modifications are commercially available. The accompanying compound with the PVA, specifically, mercuric chloride, zinc sulfate, or cupric-sulfate, acts as the preservative and allows fixation of protozoan cysts and trophozoites for use with trichrome or iron hematoxylin stains for permanents smears. All PVA-containing preservatives interfere with immunoassays.

■ Mc-PVA

The Mc-PVA fixative uses mercuric chloride as the preservative. Protozoan morphology is best preserved with PVA incorporating mercury compounds. However, due to the toxic nature of mercury compounds and the difficulty in preparation, most laboratories no longer prepare Mc-PVA.

■ ZN-PVA

The ZN-PVA fixative uses zinc sulfate in place of mercury as a preservative and fixative for protozoans. Specimens treated with ZN-PVA may also be stained with trichrome or iron hematoxylin stains for permanent smears.

■ Cu-PVA

The Cu-PVA fixative uses cupric sulfate in place of mercury as a preservative and fixative for protozoans. Specimens treated with Cu-PVA may also be stained with trichrome or iron hematoxylin stains for permanent smears.

Studies have shown that zinc sulfate provides a satisfactory, but not equal, substitute for mercury in the permanent staining procedures and that copper sulfate does not preserve morphology equal to that seen with mercuric chloride (6, 7).

■ Schaudinn's fixative/solution

Schaudinn's solution is a fixative made of mercuric chloride, distilled water, and 95% ethyl alcohol that gives excellent morphological preservation of protozoan organisms. It is used primarily in the preparation of permanent stained smears for parasitological examination from fresh, nonpreserved specimens. Specimens fixed in Schaudinn's solution can be used with either trichrome or iron hematoxylin stains. As with Mc-PVA, due to the toxic nature of mercuric compounds and the difficulty in preparation of this fixative, Schaudinn's solution is not routinely made in the clinical microbiology laboratory. In addition, Schaudinn's fixative is becoming increasingly more difficult to purchase commercially.

■ Sodium acetate-acetic acid-formalin (SAF)

SAF is very similar to formalin in that it is a liquid fixative and contains no mercury. However, unlike formalin, SAF can be used for both concentration techniques and permanent stained smears. The sediment from the concentration procedure is used for both the wet preparation and the permanent stain. Albumin-coated slides allow for better adhesion of the concentrated material to the slide and are recommended for use with SAF. SAF is an acceptable substitute for PVA or Schaudinn's solution for permanent smears stained with either trichrome or iron hematoxylin. SAF is available commercially and has a long shelf life, but it can also readily be made in the laboratory by mixing the reagents indicated below:

Sodium acetate	1.5 g
Glacial acetic acid	2.0 ml
Formaldehyde (37 to 40% HCHO solution)	4.0 ml
Distilled water	92.0 ml

■ Nonmercury, nonformalin fixatives—single-vial systems

There are several nonmercury, nonformalin proprietary fixatives commercially available that can be used for concentration of stool specimens, preparations of permanently stained smears, and fecal immunoassays (check with manufacturers for specific uses). Special stains are also available for use with some of these fixatives.

Table 1 lists several types of preservatives along with their content, specific permanent stained smears that can be performed, and immunoassays for which they can be used, as well as additional comments concerning the fixative.

STAINS

■ Iodine (Lugol's or D'Antoni's)

A solution of iodine can be used when preparing direct or concentrated wet mounts for parasitological examination. These nonspecific dyes allow the differentiation of parasitic cysts from leukocytes, the former of which retain the iodine and appear light brown. Iodine stains can be purchased commercially for use in routine parasitology. These solutions should be stored in dark containers in a dark environment. D'Antoni's iodine preparation has the advantage of use without further dilution, whereas Lugol's iodine must first be diluted into a working solution (1:5 dilution in distilled water) prior to use. Working solutions of both iodine preparations fade with time and should be discarded and replaced when their dark tea color lightens.

Basic procedure

Place 1 drop of iodine on a slide and add to this a small amount of fecal specimen and mix until homogeneous. The iodine stains fecal material immediately, and the timing of this step is not important. Place a coverslip on top of the suspension and view under ×100 magnification. Examine any suspicious material under ×400 magnification.

Acid-Fast Stains (Modified)

■ Modified Kinyoun stain (cold method)

■ Modified Ziehl-Neelsen stain (hot method)

Cryptosporidium parvum, Isospora belli, and *Cyclospora cayetanensis* are parasites that can cause diarrheal disease in humans. All three of these organisms require special staining for detection, and modifications of the classic acid-fast staining techniques used for the detection of mycobacteria are used. The modifications include the use of decolorizing agents less harsh than those used for staining of mycobacteria (see chapter 21). In the modified acid-fast staining procedures, a 1% solution of sulfuric acid (1 ml of sulfuric acid in 99 ml of water) is used as opposed to the 3% solution that is used in the acid-fast bacillus (AFB) Kinyoun staining procedure, and a 5% sulfuric acid solution (5 ml of concentrated sulfuric acid in 95 ml of distilled water) is used as opposed to the 3% HCl solution in 95% ethanol that is used

TABLE 1 Preservatives used in diagnostic parasitology (intestinal tract specimens)

Preservative	Concn	Permanent stained smear	Immunoassays (*Giardia lamblia*, *Cryptosporidium parvum*)	Comments[g]
5 or 10% formalin	Yes	No	Yes	EIA, FA
5 or 10% buffered formalin	Yes	No	Yes	EIA, FA
MIF	Yes	Polychrome IV stain[e]	ND[f]	No published data for immunoassay systems
SAF	Yes	Iron hematoxylin	Yes	EIA, FA
Mc-PVA[a]	Yes	Trichrome or iron hematoxylin	No	PVA interferes with immunoassays
Cu-PVA[b]	Yes	Trichrome or iron hematoxylin	No	PVA interferes with immunoassays
Zn-PVA[c]	Yes	Trichrome or iron hematoxylin	Some, but not all	PVA interferes with immunoassays
Single-vial systems[d]	Yes	Trichrome or iron hematoxylin	Some, but not all	Check with the manufacturer
Schaudinn's (without PVA)[a]	No	Trichrome or iron hematoxylin	No	Mercury interferes with immunoassays

[a] PVA and Schaudinn's fixatives use a mercuric chloride base and are still considered to be the "gold standard" against which all other fixatives are evaluated (organism morphology after permanent staining). Additional fixatives prepared with nonmercuric chloride-based compounds are continuing to be developed and tested.
[b] This modification uses a copper sulfate base rather than mercuric chloride.
[c] This modification uses a zinc base rather than mercuric chloride and apparently works well with both trichrome and iron-hematoxylin stains.
[d] These modifications use a combination of ingredients (including zinc) but are prepared from proprietary formulas. The aim is to provide a fixative that can be used for the fecal concentration, permanent stained smear, and available immunoassays for *G. lamblia*, *C. parvum*, and *Entamoeba histolytica* (or the *E. histolytica*/*E. dispar* group).
[e] This stain can be used in place of trichrome for staining fecal smears preserved with MIF, PVA, or SAF methods. It is available commercially.
[f] ND, no data.
[g] EIA, enzyme immunoassay; FA, fluorescent antibody.

in the AFB Ziehl-Neelsen staining procedure. Application of heat in the modified Ziehl-Neelsen staining procedure facilitates the entry of the carbol fuchsin dye into the organisms to stain them pink or red, whereas phenol replaces heat in the modified Kinyoun staining procedure. Staining reagents for mycobacteria are readily available commercially, and the only preparation that is required for these stains is for the modification of the decolorizing agents. See "Modified safranin stain" in "Other Stains" at the end of this section.

Basic procedure (modified Kinyoun stain)
Specimen (1 or 2 drops) is applied to a slide, allowed to air dry, and fixed with absolute methanol for 1 min. Carbol fuchsin is applied to the slide for 5 min, and then the slide is rinsed with 50% ethanol, followed by a water rinse. Sulfuric acid (1%) decolorizer is added for 2 min, and the slide is rinsed again with water. Methylene blue is added for 1 min, and then the slide is rinsed again with water. The slide is then air dried and examined at ×100 to ×1,000 magnification.

Blood Film Stains

■ Giemsa and Wright's stains

Examination of blood films for parasites includes the use of two common stains, the Giemsa and the Wright's stains, both derivatives of the original Romanowsky stain. These stains are very similar, differing primarily in that no fixative is included in the Giemsa stain and the blood film must be fixed with absolute methanol prior to staining. Although both stains work well with thinly prepared blood films, thick films stained with Wright's stain are reported to be inferior to those stained with Giemsa solution (5, 18). Although stock solutions of these stains can be prepared in the laboratory, the procedure is very cumbersome and involves grinding of powdered stain with methanol and/or glycerin with a mortar and pestle, days to weeks of storage with shaking, and removal of supernatant or filtering prior to use. Alternatively, Giemsa, Wright's, and Wright-Giemsa stains are readily available from commercial suppliers in liquid form and may need only dilution in a buffer solution. Blood films may be stained manually, but many laboratories rely on automated hematological instruments for staining of thin (not thick) blood films with acceptable results. These stains allow the detection of blood parasites including the agent of malaria, microfilariae, and *Leishmania*, *Babesia*, and *Trypanosoma* species.

Basic procedure
Cover the surface of a thin blood film with stain for 1 to 3 min. Add an equal volume of buffered water to the slide and mix by gently blowing on the surface of the slide. Wait 4 to 8 min and flood the slide with buffered water. Allow the slide to dry and examine it under ×1,000 magnification. Thick films must be laked in distilled water for approximately 2 min prior to performance of the staining procedure described above (4). Satisfactorily stained smears show the following characteristics for the Giemsa and Wright's stains: erythrocytes, pale red and light tan, reddish, or buff, respectively; nuclei of leukocytes, purple with pale purple cytoplasm and bright blue with contrasting light cytoplasm, respectively; eosinophilic granules, bright purple-red and bright red, respectively; and neutrophilic granules, deep pink-purple and pink or light purple, respectively.

■ Calcofluor white stain

Calcofluor white, one of a number of optical brighteners, binds to cellulose and chitin and fluoresces best when exposed to long-wavelength UV light. These properties allow for its use in detecting fungi, *Pneumocystis jirovecii*, free-living amebae like *Naegleria*, *Acanthamoeba*, and *Balamuthia*

species, as well as the larvae of *Dirofilaria* species (its cuticle contains chitin). Calcofluor white is available through several commercial suppliers and is also easily made in the laboratory following the manufacturer's recommendations.

Basic procedure
Place the specimen on a slide and allow it to air dry. Fix the slide in methanol for 1 to 2 min, rinse with distilled water, and allow it to air dry. Add 1 or 2 drops of 10% KOH, place 1 or 2 drops of calcofluor white solution on the specimen for 3 min, and view the slide with a fluorescent microscope and barrier filter (refer to summary table) at ×100 to ×400 magnification.

Hematoxylin Stains

■ Delafield's hematoxylin stain

Delafield's hematoxylin stain is used for thin and concentrated blood films for the detection of microfilaria and may show greater detail of the nuclei and sheaths than that shown with Giemsa and Wright's stains. Although the stain is not procedurally difficult to prepare, it does involve aging processes of 1 week followed by 1 month before it can be used. Delafield's hematoxylin stain is not readily available commercially and is used only in specialized circumstances. Preparation of the stain involves dissolving 180 g of aluminum ammonium sulfate in 1 liter of distilled water, heating until dissolved, and cooling (ammonium alum). Hematoxylin crystals (4 g) are dissolved in 25 ml of 95% ethyl alcohol, and the solution is then added to 400 ml of the ammonium alum. The solution is then covered with a cotton plug and exposed to sunlight and air for 1 week, after which it is filtered. To this solution, 100 ml each of glycerin and 95% ethyl alcohol is added. This solution is placed in sunlight for at least 1 month (5).

Basic procedure
Allow the specimen on a slide to air dry. Lake blood films with distilled water for 15 min and fix in absolute methanol for 5 min, followed by air drying. Stain for 10 to 15 min and rinse in water. Air dry, add a coverslip with mounting fluid, and examine the slide under ×1,000 magnification.

■ Iron hematoxylin stain

Iron hematoxylin stains are used for the detection, identification, and enumeration of intestinal protozoan parasites. There are many derivations of the iron hematoxylin stain, all of which can be used with fresh fecal specimens, fixed specimens containing PVA, specimens preserved in Schaudinn's solution, or specimens preserved in SAF to make permanent stained smears. Solutions of hematoxylin-ethanol and ferrous ammonium sulfate-hydrochloric acid are combined in equal parts to make working iron hematoxylin stain, and both solutions are available commercially.

Basic procedure
Place prepared slides in 70% ethanol for 5 min. Place the slide in 70% ethanol with iodine for 5 min if mercury-based fixatives are being used and then again in 70% ethanol for 5 min more (these last two steps are not necessary for non-mercury-based fixatives). Wash the slide in running tap water for 10 min, followed by placement in iron hematoxylin working solution for 5 min. After this staining step, wash again in running tap water for 10 min and then place the slide in the following reagents for 5 min each: 70% ethanol, 95% ethanol, 100% ethanol (two times), xylene (or a substitute) (two times). Add Permount, and add a coverslip. Examine under ×1,000 magnification.

■ Trichrome stain (Wheatley trichrome stain)

The Wheatley trichrome stain, a modification of the Gomori tissue stain, is used for the detection, identification, and enumeration of intestinal protozoan parasites (22). This stain uses chromotrope 2R and light green SF stains to visually distinguish internal elements of protozoan parasitic cysts and trophozoites. Trichrome staining is usually performed on fixed fecal specimens containing PVA or Schaudinn's solution-preserved specimens. MIF- or SAF-preserved specimens may also be stained with the trichrome stain, as well as specimens preserved with single-vial systems. In addition, some proprietary stains are also available that may work better with these and other fixatives to make permanent stained preparations. Trichrome stain can be easily prepared in the laboratory or purchased from a commercial supplier.

Basic procedure
Place a prepared slide in 70% ethanol for 5 min. For mercury-based fixatives only, place the slide in 70% ethanol with iodine for 1 min (fresh specimens) or up to 10 min (for PVA-fixed air-dried specimens). Then place again in 70% ethanol for 5 min (two times). Place in trichrome stain for 10 min, followed by a 1- to 3-s rinse in 90% ethanol with acetic acid. Dip the slide several times in 100% ethanol, and then place it in 100% ethanol for 3 min (two times), followed by xylene for 5 to 10 min (two times). Add Permount, and add a coverslip. Dry overnight or for 1 h at 37°C. Examine under ×1,000 magnification. If 95%/5% alcohol is substituted for 100% ethanol and xylene substitutes are used, it is important to increase the dehydration times for both the alcohol and xylene substitute by at least 5 to 10 min.

Modified Trichrome Stains for Microsporidia

■ Weber green

■ Ryan blue

Modifications of the trichrome stain have been successfully developed for the detection of microsporidia and are commercially available. Smears prepared from fresh or preserved fecal material can be used in this staining procedure. These stains are based on the standard trichrome technique, but a much more concentrated trichrome reagent is used and a longer staining time is incorporated. These changes are necessary because the microsporidia are not easily stained due to the difficulty in penetrating their outer spores. The Weber stain (21) stains the organisms pink with a green background, while the Ryan stain (13) also stains the organisms pink but gives a blue background. Staining at a temperature of 50°C for 10 min (7) or at 37°C for 30 min (3) may provide more intensely staining organisms and a cleaner background.

Basic procedure
Place a prepared smear in absolute methanol for 5 min and air dry prior to placement in trichrome stain for 90 min. Rinse in acid-alcohol (995.5 ml of 90% ethyl alcohol plus 4.5 ml of glacial acetic acid) for 10 s, dip several times in 95% alcohol, and place in 95% alcohol for 5 min. Prior to mounting, the slide is placed in 100% alcohol for 10 min. Examine at ×1,000 magnification. A study evaluating modifications to this procedure can be found in the reference by Kokoskin and colleagues (10).

TABLE 2 Media used for cultivation of parasites

Media	Organism(s)	Comments
Acanthamoeba monoxenic culture	*Acanthamoeba* and *Naegleria* species	• Acanthamoeba medium plus nonnutrient agar overlaid with *Escherichia coli* or *Enterobacter aerogenes* • Used for cerebrospinal fluid, tissue, or soil samples
Balamuth's aqueous egg yolk infusion medium	Intestinal amebae	• Cannot grow *Balamuthia* • *Balamuthia* grows only in cell culture lines
Boeck and Drbohlav's Locke-eff-serum (LSE) medium	Intestinal amebae	• Inspissated egg base slant with serum and rice powder
Buffered charcoal-yeast extract (BCYE) agar	*Acanthamoeba* species	• Some manufacturers' media support growth better than others • Some of these media support growth of trophozoites and/or cysts
Cysteine-peptone-liver-maltose (CPLM) medium	*Trichomonas vaginalis*	• Methylene blue dye is added to aid in the visualization of the organisms
Defined medium for pathogenic *Naegleria* species	*Naegleria fowleri*	• Defined medium
DGM-21A medium	*Acanthamoeba* species	• Defined medium
Diamond's Trypticase-yeast extract-maltose (TYM) complete medium, Diamond's complete medium modified by Klass	*Trichomonas vaginalis*	• TYM contains no antibiotics; a nonselective medium • Klass modification contains penicillin G, streptomycin sulfate, and amphotericin B to inhibit bacterial overgrowth
Evan's modified Tobie's medium	*Leishmania* species and *Trypanosoma cruzi*	• Uses beef extract, defibrinated horse blood, and phenol red as a pH indicator
InPouch TV (Biomed Diagnostics, Inc.)	*Trichomonas vaginalis*	• Commercially available
Lash's casein hydrolysate-serum medium	*Trichomonas vaginalis*	• Contains beef blood serum, which is absent from other media for *T. vaginalis*
LYI-S-2 medium	*Entamoeba histolytica*	• Similar to TYI-S-33
M-11 medium	*Acanthamoeba culbertsoni*	• Defined medium containing 11 amino acids
Modified Columbia agar	*Trichomonas vaginalis*	• Solid agar medium, *T. vaginalis* colonies change pH and appearance of the agar plates
Nelson's medium	*Naegleria fowleri*	• Contains fetal calf serum, which is necessary for the growth of *N. fowleri*
NIH medium	*Leishmania* and *Trypanosoma* species	• Similar to Evan's modified Tobie's medium
Novy-MacNeal-Nicolle (NNN) medium	*Leishmania* and *Trypanosoma* species	• NaCl base agar medium
Novy-MacNeal-Nicolle (NNN) medium with Offutt's modifications	*Leishmania* species	• Contains blood in base medium, differentiating it from NNN medium
4 N (NNNN) media	*Leishmania* and *Trypanosoma* species	• Uses a sugar base • Uses NIH medium overlay
Nonnutrient agar with live or dead bacteria	*Acanthamoeba* species	• Some manufacturers' media support growth better than others
Proteose peptone yeast extract glucose (PPYG) medium	*Acanthamoeba* species	• Basic medium to support growth of *Acanthamoeba* species
Peptone yeast extract glucose (PYG) medium	*Acanthamoeba* species	• Similar to PPYG
SCGYEM medium	*Naegleria fowleri*	• Undefined medium
Schneider's *Drosophila* medium with 30% fetal calf serum	*Leishmania* and *Trypanosoma* species	• Liquid media, less costly than blood-based agars
Trichomonas culture system	*Trichomonas vaginalis*	• Commercially available
Trypticase soy agar with 5% sheep, rabbit, or horse blood	*Acanthamoeba* species	• Some manufacturers' media support growth better than others
TYI-S-33 medium	*Entamoeba histolytica*	• Contains no antibiotics; a nonselective medium
TYSGM-9 medium	*Entamoeba histolytica*	• Contains penicillin G and streptomycin sulfate to inhibit bacterial overgrowth
USAMRU	*Leishmania* species	• Particularly useful in isolation of *Leishmania brasiliensis* complex
Yeager's LIT (liver infusion trypose) mediumgut specimens	*Trypanosoma cruzi*	• Hemin and antibiotics are added to isolate *T. cruzi* from triatoma gut specimens
YI-S medium	*Entamoeba histolytica*	• Similar to TYI-S-33 medium

■ Acid-fast trichrome stain

This staining technique allows for the detection of acid-fast organisms *(C. parvum, I. belli,* and *C. cayetanensis)* and microsporidia from the same smear (9). Smears prepared from fresh or preserved fecal material can be used in this staining procedure. This procedure stains the microsporidial organisms pink and the acid-fast organisms pink to violet on a blue background.

Basic procedure

Place a prepared, air-dried slide in absolute methanol for 5 to 10 min and then again allow it to air dry. Place in carbol fuchsin solution for 10 min before rinsing in tap water. Decolorize with 0.5% acid-alcohol and rinse in tap water. Place in trichrome stain for 30 min at 37°C. Rinse in acid-alcohol for 10 s and then dip the slides several times in 95% alcohol for 10 s. Place the slide in 95% alcohol for 30 s and then allow it to air dry. Examine at ×1,000 magnification.

Other Stains

■ Modified Field's stain

This stain facilitates the identification of *Acanthamoeba* species. The modified Field's stain was evaluated and shown to give very good contrast compared with other stains, such as Wright's, Giemsa, Ziehl-Neelsen, and trichrome stains. For information on preparation and use of the modified Field's stain, the reader is referred to the article by Pirehma and colleagues (12).

■ Modified safranin stain

This staining technique allows for the detection of *Cyclospora* oocysts in formalin-fixed specimens and fecal concentrates. The stain most commonly used in the past for these organisms was the modified acid-fast stain; however, tremendous variations in staining properties can be seen with this stain. The modified safranin stain reportedly uniformly stains oocysts of *Cyclospora*. It has also been shown to be fast, reliable, and easy to perform (20).

Basic procedure

Place a prepared, thin smear of stool on a 60°C slide warmer until dried. Cover smear with a 1% safranin solution and heat in a microwave oven at full power (650 W) for 30 to 60 s. Rinse the smear with tap water for 30 s, counterstain with 1% aqueous methylene blue for 1 min, rinse with tap water, and air dry. Examine at ×1,000 magnification.

MEDIA

Cultures can be performed for only a few parasitic organisms, including *Acanthamoeba* species, *Naegleria fowleri,* intestinal amebae (like *Entamoeba histolytica*), *Trichomonas vaginalis, Leishmania* species, and *Trypanosoma* species (6). However, most clinical diagnostic microbiology laboratories do not provide parasite cultures. Cultures of these organisms are done only at large reference laboratories or research facilities. The exception is *Trichomonas vaginalis,* for which commercial products have been adapted for the routine laboratory. Many of the media listed in Table 2 are not commercially available but are listed for reference. Additional information regarding these media is available in the literature (1, 2, 8, 11, 14, 15, 16, 17, 19).

Algorithms for Detection and Identification of Parasites

LYNNE S. GARCIA, ROBYN Y. SHIMIZU, AND GRAEME P. PALTRIDGE

135

This chapter discusses various approaches and diagnostic methods currently in use for the diagnosis of parasitic infections. Assuming that clinical specimens have been properly collected and processed according to specific specimen rejection and acceptance criteria, the examination of prepared wet mounts, concentrated specimens, permanent stained smears, blood films, and various culture materials can provide critical information leading to organism identification and confirmation of the suspected cause of clinical disease (4, 5, 12, 13, 15). With the exception of relatively few immunoassay diagnostic kits, the majority of this diagnostic work depends on the knowledge and microscopy skills of the microbiologist. The field of diagnostic parasitology has taken on greater importance during the past few years for a number of reasons. Expanded world travel has increased the potential levels of exposure to a number of infectious agents. It is important to be aware of those organisms commonly found within certain areas of the world and the makeup of the patient population being ser-viced at your institution, particularly if immunocompromised patients are frequently seen as a part of your routine patient population. It is also important for the physician and microbiologist to recognize and understand the efficacy of any diagnostic method for parasite recovery and identification. Specific information on specimen collection and processing can be found in chapter 133.

STOOL SPECIMENS

For review, see the list of options for the collection of fecal specimens in chapter 133, Tables 3 and 6. Algorithms for the processing of stool specimens are presented in Fig. 1 to 3. The procedures that normally comprise the ova and parasite (O&P) examination are provided below and include the direct wet mount in saline, the concentration, and the permanent stained smear (1, 2, 4, 6, 9–11, 13, 16).

Direct Wet Mount in Saline

The purpose of a direct wet mount is to confirm the possibility of infection with certain protozoa and helminths, to assess the worm burden of the patient, and to look for organism motility (Table 1) (4, 6, 11). Any fresh stool specimens that have not been refrigerated and that have been delivered to the laboratory within specified time frames are acceptable for testing; however, it is extremely important to examine liquid or soft stools rather than formed stools. Liquid and soft stools are much more likely to contain motile protozoan trophozoites rather than cysts, which will not demonstrate motility. Low-power examination (magnification, ×100) of the entire coverslip preparation (22 mm by 22 mm) and high dry power examination (magnification, ×400) of at least one-third of the coverslip area are recommended before the preparation is considered negative. Often, results from the direct smear examination should be considered presumptive; however, some organisms (*Giardia lamblia* cysts, *Entamoeba coli* cysts, *Iodamoeba bütschlii* cysts, helminth eggs and larvae, *Isospora belli* oocysts) can be definitively identified. Reports of results obtained by this method should be considered preliminary, with the final report being provided after the results of the concentration wet mount and permanent stained smear are available.

If iodine is added to the preparation for increased contrast, the organisms will be killed and motility will be lost. Specimens that arrive in the laboratory in stool preservatives do not require a direct smear examination; proceed to the concentration and permanent stained smear.

Concentration Wet Mount

The purpose of the concentration method is to separate parasites from fecal debris and to concentrate any parasites present through either sedimentation or flotation (4, 6, 11). The concentration is specifically designed to allow recovery of protozoan cysts, coccidian oocysts, microsporidian spores, and helminth eggs and larvae (Table 2). Any stool specimen that is fresh or preserved is acceptable for testing. Wet mounts prepared from concentrated stool are examined in the same manner as that used for the direct wet mount method. The addition of too much iodine may obscure helminth eggs (the eggs may resemble debris). Often, results from the concentration examination should be considered presumptive; however, some organisms (*G. lamblia* cysts, *E. coli* cysts, *I. bütschlii* cysts, helminth eggs and larvae, *I. belli* oocysts) can be definitively identified. Reports of results obtained by this method should be considered preliminary, with the final report being provided after the results of the permanent stained smear are available.

The formalin-ethyl acetate sedimentation concentration procedure is the most commonly used procedure, and the recommended centrifugation speed and time are 500 × *g* and 10 min, respectively. In this procedure, the use of ether has been replaced with ethyl acetate. However, it is important to

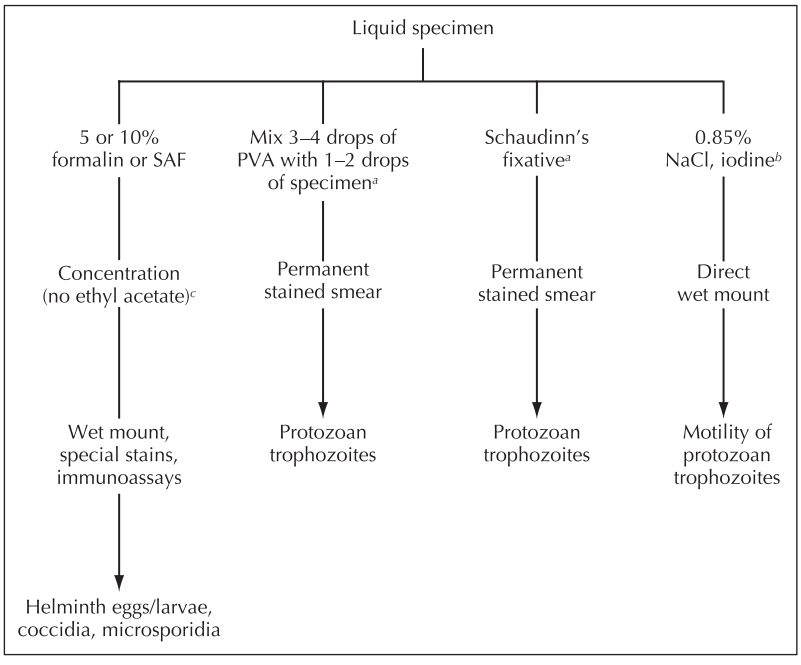

FIGURE 1 Processing liquid stool for O&P examination. [a]Either PVA or Schaudinn's fixative can be used for the preparation of the permanent stained smear. [b]Organism motility will be seen using saline; iodine will kill the organisms, so motility will no longer be visible. [c]The use of ethyl acetate may remove the entire specimen and pull it into the layer of debris that will be discarded (liquid specimen normally contains mucus); centrifuge at 500 × *g* for 10 min (normal centrifugation time), but do not use ethyl acetate in the procedure. In general, laboratories have switched to nonmercury substitutes; the original Schaudinn's fixative contains mercuric chloride. However, in some instances the term "Schaudinn's fixative" is still used to describe the original fixative in a different formulation that is prepared with a copper or zinc base or other proprietary compounds. When selecting fixatives, it is important to know their contents in order to comply with disposal regulations.

remember that ethyl acetate should not be used for liquid specimens or those containing a great deal of mucus. The ethyl acetate may pull the liquid/mucus specimen contents into the debris layer, which will be discarded. The standard zinc sulfate flotation procedure will not detect operculated or heavy eggs; when using this method, both the surface film and sediment should be examined before a negative result is reported.

Permanent Stained Smears

Trichrome, Iron-Hematoxylin, or Iron-Hematoxylin/Carbol Fuchsin

The permanent stained smear provides contrasting colors for both the background debris and the parasites present (Tables 3–5) (4, 6, 11). Permanent stained stool smears are designed to allow examination and recognition of detailed organism morphology under oil immersion magnification (magnification, ×1,000). This method is primarily designed to allow the recovery and identification of the more common intestinal protozoan trophozoites and cysts, excluding the coccidia and microsporidia. Oil immersion examination of a minimum of 300 oil immersion fields is recommended; additional fields may be required if suspect organisms have been seen in the wet mounts. Although review of 300 fields seems like a time-consuming procedure, it takes less time than one would assume. This is particularly true for a trained microscopist in microbiology. Based on their expertise, patient population, and percentage of positive specimens, different laboratories may approach the examination of permanent stained smears by using different guidelines. Some laboratories may use a 60× oil immersion objective for screening purposes (magnification, ×600); however, it is important to examine a sufficient number of fields at a total magnification of ×1,000 before reporting the specimen as negative (no parasites seen).

Modified Acid-Fast Staining

The modified acid-fast staining method is used to provide contrasting colors for both the background debris and the parasites present and to allow examination and recognition of the acid-fast characteristic of the organisms under high dry magnification (magnification, ×400) (4, 16). Organisms that can be identified with this stain are the coccidia *Cryptosporidium* spp., *Cyclospora cayetanensis,* and *I. belli;* it is important to remember that *C. cayetanensis* stains much more acid-fast variable than *Cryptosporidium* spp. Although some microsporidian spores are acid-fast positive, their small size will make recognition very difficult; modified trichrome stains are recommended for the detection of microsporidian spores. Oil immersion examination of a minimum of 300 oil immersion fields is recommended.

Both hot and cold modified acid-fast staining methods are excellent for staining coccidian oocysts. Limitations of

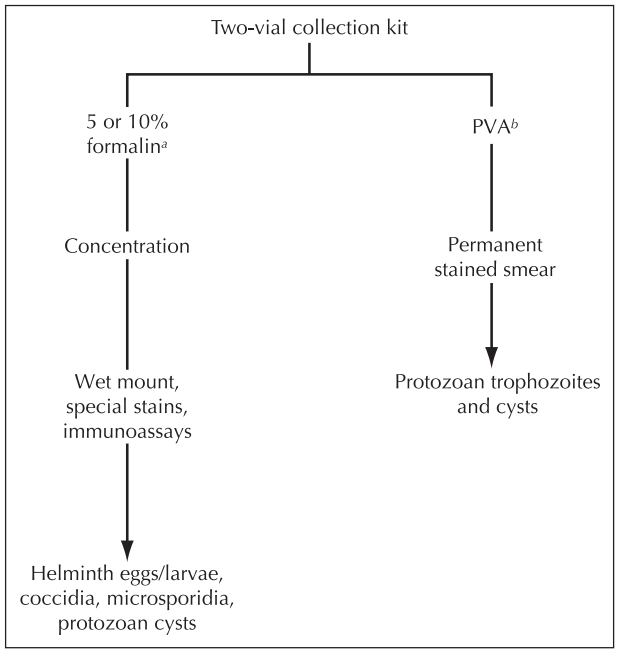

FIGURE 2 Processing preserved stool for O&P examination (two-vial collection kit). [a]The formalin can be buffered or nonbuffered, depending on the laboratory protocol in use. [b]PVA fixative prepared with mercuric chloride provides the best organism preservation. Alternatives are available, including zinc-based PVA, copper sulfate-based PVA, and SAF.

the procedure are generally related to specimen handling, including proper collection and centrifugation speed and time.

Modified Trichrome

Modified trichrome stains were primarily designed to allow recovery and identification of microsporidial spores from centrifuged stool specimens; internal morphology (horizontal and diagonal stripes of the polar tubule) may be seen in some spores under oil immersion (magnification, ×1,000). Any stool specimen that is submitted fresh or preserved in formalin or sodium acetate-acetic acid-formalin (SAF) is acceptable. Oil immersion examination of a minimum of 300 oil immersion fields is recommended. The identification of microsporidial spores may be possible; however, their small size makes recognition difficult, particularly in infections with few organisms in the clinical specimen. Identification to the species level will require electron microscopy or molecular methods such as PCR.

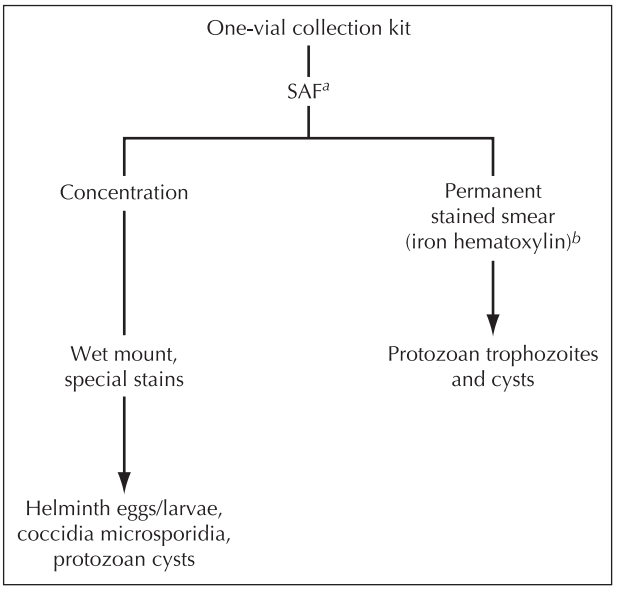

FIGURE 3 Processing preserved stool for O&P examination (one-vial collection kit). [a]There are single-vial collection systems for which the formulas are proprietary; however, many contain zinc sulfate as one of the key ingredients. With the exception of SAF, compatibility of these fixatives with immunoassay reagents has been difficult to achieve. [b]If the iron hematoxylin method containing the carbol fuchsin step is used, the coccidian oocysts will stain pink (*Cryptosporidium* spp., *Cyclospora cayetanensis*, *Isospora belli*). Also, when using SAF, some recommend the use of an adhesive such as egg albumin to "glue" the fecal material onto the slide prior to staining. It is highly recommended that special stains be performed for the detection and identification of the coccidia (modified acid-fast stains) and the microsporidia (modified trichrome stains) from concentrated sediment to enhance organism recovery. Coccidian oocysts of *Isospora belli* can easily be detected in the concentration sediment wet mount; however, unless a very heavy infection is present, *Cryptosporidium* spp. oocysts may not be seen without special modified acid-fast stains. The small size of the microsporidian spores prevents identification without the use of special modified trichrome stains and microscopic examination using the 100× oil immersion objective.

Immunologic Methods

Immunoassay reagents are available commercially for several of the protozoan parasites, including *G. lamblia*, *Cryptosporidium* spp., the *Entamoeba histolytica-Entamoeba dispar* group, and *Entamoeba histolytica* (Table 6). These methods (enzyme immunoassay [EIA], fluorescent-antibody assay, and immunochromatographic assay) are

TABLE 1 Diagnostic characteristics of organisms in wet mounts

Specimen	Protozoa	Helminths
Stool, other specimens from gastrointestinal tract, urogenital system specimens	Size, shape, stage (trophozoite, precyst, cyst, oocyst), motility (fresh specimens only), refractility, cytoplasm inclusions (chromatoidal bars, glycogen vacuoles, axonemes, axostyles, median bodies, sporozoites)	Egg, larvae, or adult; size; internal structure: Egg: embryonated, opercular shoulders, abopercular thickenings or projections, hooklets, polar filaments, spines Larvae: head and tail morphology, digestive tract Adult: nematode, cestode, or trematode

TABLE 2 Identification of helminth eggs[a]

1. Eggs small (~25–40 μm)	
A. Operculate, generally oval (egg <35 μm); *Clonorchis*, operculated shoulders, bile stained, may be an abopercular knob, miracidium present, but difficult to see	*Clonorchis (Opisthorchis)* spp. (Chinese liver fluke) or intestinal flukes *(Heterophyes heterophyes* or *Metagonimus yokogawai)*
B. Thick, radially striated shell (six-hooked oncosphere, individual eggs resemble those of *Taenia* spp.; eggs passed in egg packets containing 6–10 eggs; each egg is 25–40 μm)	*Dipylidium caninum* (dog, cat tapeworm); note: egg packets could measure >150 μm
C. Thick, radially striated shell (six-hooked oncosphere may not be visible in every egg from formalinized fecal specimens) (eggs cannot be identified to species level without special stains) (each egg is 30–47 μm)	*Taenia* spp. (*T. saginata,* beef tapeworm; *T. solium,* pork tapeworm)
D. Thin egg shell, clear space between developing shell and embryo, spherical or subspherical, containing a six-hooked oncosphere; polar filaments (filamentous strands) present between thin egg shell and embryo (each egg is 31–43 μm)	*Hymenolepis nana* (dwarf tapeworm)
2. Eggs medium (~40–100 μm)	
A. Egg barrel-shaped, with clear polar plugs (each egg is 50–54 by 20–23 μm)	*Trichuris trichiura* (whipworm)
B. Egg flattened on one side, may contain larva (each egg is 70–85 by 60–80 μm)	*Enterobius vermicularis* (pinworm)
C. Egg with thick, tuberculated (bumpy) capsule (in decorticate eggs, capsule may be missing) (each egg is 45–75 by 35–50 μm)	*Ascaris lumbricoides* (large roundworm), fertilized eggs
D. Egg bluntly rounded at ends, thin shell (contains developing embryo at 8–16-ball stage of development) (each egg is 56–75 by 36–40 μm)	Hookworm
E. Operculate, operculum break in shell sometimes hard to see, smooth transition from shell to operculum; small "bump" may be seen at abopercular end (each egg is 58–75 by 40–50 μm)	*Diphyllobothrium latum* (broad fish tapeworm)
F. Thin egg shell, clear space between developing shell and embryo, spherical or subspherical, containing a six-hooked oncosphere; no polar filaments (filamentous strands) present between thin egg shell and embryo (each egg is 70–85 by 60–80 μm)	*Hymenolepis diminuta* (rat tapeworm)
3. Eggs large (~100–180 μm)	
A. Egg with opercular shoulders into which the operculum fits (looks like a teapot lid and the flange into which the lid fits), abopercular end somewhat thickened (not always visible) (each egg is 80–120 by 48–60 μm); egg has been described as "urn-shaped"	*Paragonimus* spp. (lung fluke)
B. Egg tapered at one or both ends; long thin shell containing developing embryo (each egg is 73–95 by 40–50 μm)	*Trichostrongylus* spp.
C. Egg with thick, tuberculated (bumpy) capsule (in decorticate eggs, capsule may be missing) (each egg is 85–95 by 43–47 μm)	*Ascaris lumbricoides* (large roundworm), unfertilized eggs
D. Egg spined, ciliated miracidium larva may be seen, lateral spine very short (each egg is 70–100 by 55–65 μm)	*Schistosoma japonicum* (blood fluke, stool), *Schistosoma mekongi* (rounder and smaller than *S. japonicum*); measure 50–65 by 30–55 μm
E. Egg spined, ciliated miracidium larva may be seen, spine terminal (each egg is 112–170 by 40–70 μm)	*Schistosoma haematobium* (blood fluke, urine)
F. Egg spined, ciliated miracidium larva may be seen, spine terminal (each egg is 140–240 by 50–85 μm)	*Schistosoma intercalatum* (blood fluke, stool)
G. Egg spined, ciliated miracidium larva may be seen, large lateral spine (each egg is 114–180 by 45–70 μm)	*Schistosoma mansoni* (blood fluke, stool)
H. Egg >85 μm, operculum break in shell sometimes hard to see; smooth transition from shell to operculum; egg passed in undeveloped stage (each egg is 130–140 by 80–85 μm)	*Fasciolopsis buski* (giant intestinal fluke) or *Fasciola hepatica* (sheep liver fluke) or *Echinostoma* spp.

[a] This table does not include every possible helminth that could be found as a human parasite; however, the most likely helminth infections are included.

designed to detect the antigens of selected organisms; a negative result does not rule out the possibility that these organisms are present in low numbers or that other intestinal parasites are etiologic agents causing disease, including *Dientamoeba fragilis*, the microsporidia, and helminth parasites (4, 7, 8, 18). Immunoassay reagents are currently under development and trial for *D. fragilis* and the microsporidia.

TABLE 3 Diagnostic characteristics of organisms in permanent stained smears

Specimen	Protozoa	Helminths
Stool, other specimens from gastrointestinal tract, urogenital system specimens	Size, shape, stage (trophozoite, precyst, cyst, oocyst, spore)	Egg, larvae, and/or adults may not be identified because of excess stain retention or distortion
	Nuclear arrangement, cytoplasm inclusions (chromatoidal bars, vacuoles, axonemes, axostyles, median bodies, sporozoites, polar tubules)	

ADDITIONAL TECHNIQUES FOR STOOL EXAMINATION

Although the routine O&P examination consisting of the direct wet mount, the concentration, and the permanent stained smear is an excellent procedure recommended for the detection of most intestinal parasites, several other diagnostic techniques are available for the recovery and identification of specific parasitic organisms (4, 6). Most laboratories do not routinely offer all of these techniques, but many can be performed relatively simply and inexpensively. Occasionally, it is necessary to examine stool specimens for the presence of scolices and proglottids of cestodes and adult nematodes and trematodes to confirm the diagnosis and/or for species identification (Table 7). A method for the recovery of these stages is also described in this chapter.

Culture of Larval-Stage Nematodes

Nematode infections giving rise to larval stages that hatch in soil or in tissues may be diagnosed by using fecal culture methods to concentrate the larvae (1, 4, 6, 16). *Strongyloides stercoralis* larvae are the most common larvae found in stool specimens. Depending on the fecal transit time through the intestine and the patient's condition, rhabditiform and filariform larvae may be present. Caution must be exercised when handling larval cultures because infective filariform larvae may be present. If there is a delay in the preservation of the stool specimen, then embryonated ova as well as larvae of hookworm may be present. Culture of feces for larvae is useful for (i) revealing their presence when they are too scanty to be detected by concentration methods; (ii) distinguishing whether the infection is due to *S. stercoralis* or hookworm on the basis of rhabditiform larval morphology by allowing hookworm egg hatching to occur, releasing first-stage larvae; and (iii) allowing the development of larvae into the filariform stage for further differentiation.

Fecal culture methods are especially helpful for the detection of light infections with hookworm, *S. stercoralis,* and *Trichostrongylus* spp. and for the specific identification of parasites. Also, such techniques are useful for obtaining a large number of infective-stage larvae for research purposes. One enhanced recovery method, the agar plate culture for

TABLE 4 Key to identification of intestinal amebae (permanent stained smear)

1. Trophozoites present	2
Cysts present	7
2. Trophozoites >12 μm	3
Trophozoites <12 μm	4
3. Karyosome central, compact; peripheral nuclear chromatin evenly arranged; "clean" cytoplasm	*Entamoeba histolytica*[a]
Karyosome eccentric, spread out; peripheral nuclear chromatin unevenly arranged; "dirty" cytoplasm	*Entamoeba coli*
4. Peripheral nuclear chromatin	5
Other than above	6
5. Karyosome central, compact; peripheral nuclear chromatin evenly arranged; "clean" cytoplasm	*Entamoeba hartmanni*
Karyosome large, blot-like; extensive nuclear variation	*Endolimax nana*
6. No peripheral chromatin, karyosome large, junky cytoplasm	*Iodamoeba bütschlii*
No peripheral chromatin, karyosome variable, clean cytoplasm	*Endolimax nana*

Multiple nuclei	9
9. Four *Entamoeba*-like nuclei, chromatoidal bars have smooth, rounded ends	*Entamoeba histolytica*[a]
Five or more *Entamoeba*-like nuclei, chromatoidal bars have sharp, pointed ends	*Entamoeba coli*
10. Single nucleus (may be "basket" nucleus), large glycogen vacuole	*Iodamoeba bütschlii*[c]
Multiple nuclei	11
11. Four *Entamoeba*-like nuclei, chromatoidal bars have smooth, rounded ends (nuclei may also number only two)	*Entamoeba hartmanni*
Four karyosomes, no peripheral chromatin, round to oval shape	*Endolimax nana*

[a] *Entamoeba histolytica* refers to the *Entamoeba histolytica/Entamoeba dispar* group. *E. histolytica* (pathogenic) can be determined by finding red blood cells in the cytoplasm of the trophozoites. Otherwise, on the basis of morphological grounds *E. histolytica* (pathogen) and *E. dispar* (nonpathogen) cannot be differentiated.

[b] It is very difficult to differentiate *Entamoeba polecki* trophozoites from those of the *E. histolytica/E. dispar* group or *E. coli.*

[c] Although some *I. bütschlii* cysts are larger than 10 μm, the majority of cysts measure 9 to 10 μm and the presence of the typical glycogen vacuole ensures correct identification.

One nucleus, bird's beak fibril	*Retortamonas intestinalis*

Strongyloides, and several culture techniques are described in this chapter. Since these procedures are less common, brief descriptions are included.

Agar Plate Culture for *S. stercoralis*

Agar plate cultures are recommended for the recovery of *S. stercoralis* larvae and tend to be more sensitive than some of the other diagnostic methods (4, 6). Approximately 2 g of stool (diameter, about 1 in.) is placed in the center of the agar plate; the plate is sealed to prevent accidental infections and is held for 2 days at room temperature. As the larvae crawl over the agar, they carry bacteria with them, thus creating visible tracks over the agar. The plates are examined under the microscope for confirmation of the presence of larvae, the surface of the agar is then washed with 10% formalin, and final confirmation of larval identification is made via wet examination of the sediment from the formalin washings.

Baermann Technique

Another method of examining a stool specimen suspected of having small numbers of *Strongyloides* larvae is the use of a modified Baermann apparatus. The Baermann technique uses a funnel apparatus and relies on the principle that active larvae will migrate from a fresh fecal specimen that has been placed on a wire mesh with several layers of gauze, which are in contact with tap water (4). Larvae migrate through the gauze into the water and settle to the bottom of the funnel, where they can be collected and examined. The main difference between this method and the Harada-Mori and petri dish methods is the greater amount of fresh stool used, possibly providing a better chance of larval recovery in a light infection. Besides being used for patient fecal specimens, this technique can be used to examine soil specimens for the presence of larvae. However, the agar plate method is considered to be a more sensitive method for the recovery of *S. stercoralis* larvae.

Harada-Mori Filter Paper Strip Culture

To detect light infections with hookworm, *S. stercoralis*, and *Trichostrongylus* spp., as well as to facilitate specific identification, the Harada-Mori filter paper strip culture technique is very useful (1, 4, 6). The technique requires filter paper (strip cut to fit into a 15-ml test tube) to which fresh fecal material (similar in size to a raisin or a small grape) is added to the middle of the filter paper and a test tube into which the filter paper is inserted. Moisture is provided by adding water to the tube (within a half-inch of the stool, but not covering the stool), which continuously soaks the filter paper by capillary action. Incubation under suitable conditions favors hatching of ova and/or development of larvae. Fecal specimens to be cultured should not be refrigerated, since some parasites are susceptible to cold and may fail to develop after refrigeration. Also, caution must be exercised in handling the filter paper strip itself, since infective *Strongyloides* larvae may migrate upward as well as downward on the paper strip.

Filter Paper/Slant Culture Technique (Petri Dish)

An alternative technique for culturing *Strongyloides* larvae is a filter paper/slant culture on a microscope slide placed in a glass or plastic petri dish (4). As with the techniques described above, sufficient moisture is provided by continuous soaking of filter paper in water. Fresh stool material is

TABLE 7 Additional helminth recovery and identification techniques (other than O&P examination)

Organism	Specimen	Procedure
Nematodes		
S. *stercoralis*	Fresh stool, not refrigerated (all organisms	Harada-Mori filter paper strip
Hookworm	can be recovered by any of the procedures	Filter paper/slant culture
Trichostrongylus spp.	indicated in the column to the right)	Charcoal culture
		Baermann test
		Agar plate culture (primarily for *S. stercoralis*)
Hookworm	Fresh stool, refrigeration acceptable	Direct smear (Beaver)
Ascaris lumbricoides		Dilution egg count (Stoll)
Trichuris trichiura		Either method acceptable for estimation of worm burden
Enterobius vermicularis	Scotch tape preparations, paddles, anal swab, other collection devices	Direct microscopic examination
Trematodes		
Schistosoma spp.	Fresh stool, not refrigerated	Egg hatching test
	Fresh urine (24-h and single collection)	Egg viability test
Cestodes		
Tapeworms	Proglottids (gravid in alcohol)	India ink injection
	Stool in 5–10% formalin	Scolex search

placed on filter paper, which is cut to fit the dimensions of a standard (1- by 3-in.) microscope slide. The filter paper is then placed on a slanted glass slide in a glass or plastic petri dish containing water. This technique allows direct examination of the culture system with a dissecting microscope to look for nematode larvae and free-living stages of *S. stercoralis* in the fecal mass or the surrounding water without having to sample the preparation.

Egg Studies and Scolex Search

Estimation of Worm Burdens

The only human parasites for which it is reasonably possible to correlate egg production with adult worm burdens are *Ascaris lumbricoides*, *Trichuris trichiura*, and the hookworms *(Necator americanus* and *Ancylostoma duodenale)*. The specific instances in which information on approximate worm burdens is useful are when one is determining the intensity of infection, deciding on possible chemotherapy, and evaluating the efficacies of the drugs administered. With current therapy, the need for the monitoring of therapy through egg counts is no longer as relevant. Remember that egg counts are estimates; you will obtain count variations regardless of how carefully you follow the procedure. If two or more fecal specimens are being compared, it is best to have the same individual perform the technique with both samples and to do multiple counts. A number of methods have been described (1, 4, 6, 9, 11, 13).

Hatching of Schistosome Eggs

When schistosome eggs are recovered from either urine or stool, they should be carefully examined to determine viability. The presence of living miracidia within the eggs indicates an active infection that may require therapy. The viability of the miracidia can be determined in two ways: (i) the cilia of the flame cells (primitive excretory cells) may be seen on a wet smear by using high dry power and are usually actively moving, and (ii) the miracidia may be released from the eggs by the use of a hatching procedure (4). The eggs usually hatch within several hours when placed in 10 volumes of dechlorinated or spring water (hatching may begin soon after contact with the water). The eggs that are recovered in the urine (24-h specimen collected with no preservatives) are easily obtained from the sediment and can be examined under the microscope to determine viability. A sidearm flask has been recommended, but an Erlenmeyer flask is an acceptable substitute.

Both urine and stool specimens must be collected without preservatives and should not be refrigerated prior to processing. Hatching will not occur until the saline is removed and nonchlorinated water is added. If a stool concentration is performed, use saline throughout the procedure to prevent premature hatching. Make sure that the light is not too close to the side arm or top layer of water in the Erlenmeyer flask. Excess heat will kill the miracidia. The lamp light mimics the sun shining on a water source, and the hatched larvae tend to swim toward the light. The absence of live miracidia does not rule out the presence of schistosome eggs. Nonviable eggs or eggs that failed to hatch are not detected by this method. Microscopic examination of direct or concentrated specimens should be used to demonstrate the presence or absence of eggs. Egg viability can be determined by placing some stool or urine sediment (the same material used for the hatching flask) on a microscope slide. Low-power magnification (×100) can be used to locate the eggs. Individual eggs can be examined with high dry magnification (×400); moving cilia on the flame cells (primitive excretory system) confirm egg viability.

Search for Tapeworm Scolex

Since therapy for the elimination of tapeworms is usually very effective, a search for the tapeworm scolex is rarely requested and is no longer as clinically relevant as previously. However, stool specimens may have to be examined for the presence of scolices and gravid proglottids of cestodes for proper species identification. This procedure requires mixing a small amount of feces with water and straining the mixture through a series of wire screens (graduated from coarse to fine mesh) to look for scolices and proglottids. Remember to use standard precautions and to wear gloves when performing this procedure. The appearance of scolices after therapy is an indication of successful treatment. If the scolex has not been passed, it may still be attached to the mucosa; the parasite is capable of producing more segments from the neck region of the scolex, and the infection continues.

EXAMINATION OF OTHER SPECIMENS FROM THE INTESTINAL TRACT

Examination for Pinworm

A roundworm parasite that has a worldwide distribution and that is commonly found in children is *Enterobius vermicularis*, known as pinworm or seatworm. The adult female worm migrates out of the anus, usually at night, and deposits her eggs on the perianal area. The adult female (8 to 13 mm long) may occasionally be found on the surface of a stool specimen or on the perianal skin. Since the eggs are usually deposited around the anus, they are not commonly found in feces and must be detected by other diagnostic techniques. Diagnosis of pinworm infection is usually based on the recovery of typical eggs, which are described as thick-shelled, football-shaped eggs with one slightly flattened side. Each egg often contains a fully developed embryo and is infective within a few hours after being deposited. Commercial collection devices are available and can be used for specimen collection, similar to the approach with cellulose tape indicated below (4). Some clinicians may treat patients on the basis of clinical symptoms without confirmation of the suspected diagnosis of pinworm infection.

Cellulose Tape Preparations

The most widely used procedure for the diagnosis of pinworm infection is the cellulose tape (adhesive cellophane tape) method (2, 4, 9, 10). Specimens should be obtained in the morning, before the patient bathes or goes to the bathroom. The tape is applied to the anal folds and is then placed sticky side down on a microscope slide for examination. At least four to six consecutive negative slides should be observed before the patient is considered free of infection.

Anal Swabs

The anal swab technique (4) is also available for the detection of pinworm infections; however, most laboratories use the cellulose tape method because it eliminates the necessity of preparing and storing swabs. At least four consecutive negative preparations should be observed before the patient is considered negative; some recommend six consecutive negative preparations.

A paraffin-coated swab should be gently rubbed over the perianal surface and into the folds. Place the swab into the anal opening about 1/4 in. and then replace the swab in the tube. The tube containing the swab is half filled with xylene substitute and is allowed to stand for a few minutes. After centrifugation, the sediment is examined microscopically for the presence of eggs.

Sigmoidoscopy Material

Material obtained from sigmoidoscopy can be helpful in the diagnosis of amebiasis that has not been detected by routine fecal examinations, and the procedure is recommended for this purpose. However, usually a series of at least three routine stool examinations for parasites should be performed for each patient before a sigmoidoscopy examination is done (4).

Material from the mucosal surface should be aspirated or scraped and must not be obtained with cotton-tipped swabs. At least six representative areas of the mucosa should be sampled and examined (six samples, six slides). Usually, the amount of material is limited and should be processed immediately to ensure the best examination possible (Table 8). Three methods of examination can be performed. All three are acceptable; however, depending on the availability of trained personnel, the availability of proper fixation fluids, or the amount of specimen obtained, one or two procedures are recommended. If the amount of material limits the examination to one procedure, the use of polyvinyl alcohol (PVA) fixative is highly recommended for the subsequent preparation of permanent stains.

Although the fecal immunoassays are rarely used for this purpose and are not the tests of choice, if the material is going to be examined by using any of the fluorescent-antibody assay, EIA, or immunochromatographic immunoassay detection kits (*Cryptosporidium* spp. or *G. lamblia*), then 5 or 10% formalin or SAF fixative is recommended. However, immunoassays for the detection of the *Entamoeba histolytica*/*E. dispar* group or confirmation of the pathogen *Entamoeba histolytica* require fresh or frozen stool for testing; preserved stool is not acceptable.

Physicians performing sigmoidoscopy procedures may not realize the importance of selecting the proper fixative for material to be examined for parasites by the concentration and permanent stained smear methods. It is recommended that a parasitology specimen tray (containing Schaudinn's fixative, PVA, and 5 or 10% formalin) be provided or that a trained technologist be available at the time of sigmoidoscopy to prepare the slides.

Direct Saline Mount

If there is no lag time after collection and a microscope is available in the immediate vicinity, some of the material should be examined as a direct saline mount for the presence of motile trophozoites (4). A drop of material is mixed with a drop of 0.85% sodium chloride and is examined under low light intensity for the characteristic movement of amebae. It may take time for the organisms to become acclimated to this type of preparation; hence, motility may not be obvious for several minutes. There will be epithelial cells, macrophages, and possibly polymorphonuclear leukocytes and erythrocytes, which will require a careful examination to reveal amebae.

Since specific identification of protozoan organisms can be difficult when only the direct saline mount is used, this technique should be used only when there is sufficient material left to prepare permanent stained smears.

Permanent Stained Smear

Most of the material obtained at sigmoidoscopy can be smeared (gently) onto a slide and immediately immersed in Schaudinn's fixative (4). These slides can then be stained with trichrome or iron hematoxylin stain and examined for specific cell morphology, either protozoan or otherwise. The procedure and staining times are identical to those for routine fecal smears.

If the material is bloody, contains a lot of mucus, or is a "wet" specimen, a few (no more than 2 or 3) drops of PVA can be mixed with 1 or 2 drops of material directly on the slide, which is allowed to air dry (a 37°C incubator can be used) for at least 2 h before staining. If time permits, the PVA smears should be allowed to dry overnight; they can be routinely stained with trichrome stain and examined as a permanent mount.

Material from sigmoidoscopy can be placed in small amounts of SAF. After fixation for 30 min, the specimen can be centrifuged at 500 × *g* for 10 min and smears from the small amount of sediment can be prepared for permanent staining with iron hematoxylin (trichrome stain would be the second choice). One of the organisms most suspected when sigmoidoscopy is performed is *E. histolytica*, the

TABLE 8 Recovery of parasites from other intestinal tract specimens

Source	Organism	Procedure
Sigmoidoscopy specimens		
Unpreserved	Ameba trophozoites (motility)	Direct wet mount, immunoassay tests[a]
Air-dried smears	Coccidia	Modified acid-fast stain
	Microsporidia	Modified trichrome, optical brighteners, immunoassay tests[b]
Preserved 5–10% formalin or SAF	Helminth eggs and larvae (rare), ameba and flagellate cysts,[c] and trophozoites (SAF only)	Concentration wet mount, immunoassay tests
	Coccidia	Modified acid-fast smear, immunoassay tests
	Microsporidia	Modified trichrome, optical brighteners, immunoassay tests[b]
PVA	Helminth eggs and larvae (rare), ameba and flagellate cysts[c]	Wet mount
	Ameba and flagellate cysts[c] and trophozoites	Permanent stained smear
Schaudinn's fixative	Ameba and flagellate cysts[c] and trophozoites	Permanent stained smear
Duodenal specimens[d]		
Unpreserved	Helminth eggs and larvae, flagellate trophozoites (motility)	Direct wet mount
Entero-Test capsule		
Preserved 5–10% formalin or SAF	Helminth eggs and larvae, flagellate trophozoites	Concentration wet mount, immunoassay tests
		Permanent stained smear
Entero-Test capsule	Coccidia	Modified acid-fast smear, immunoassay tests
	Microsporidia	Modified trichrome, optical brighteners, immunoassay tests[b]
PVA	Flagellate trophozoites	Permanent stained smear
Anal impression smear	Pinworm adult and eggs	No stain, cellulose tape preparation and other collection devices
Adult worm or segments	Helminth adult worms or proglottids	Carmine stain (rarely used), India ink
Tissue biopsy	Helminth eggs, larvae, and adults; protozoan cysts; trophozoites; oocysts; sporozoites; and spores	Touch preparations, squash preparations, permanent stains, histology

[a] Immunoassay tests for the *Entamoeba histolytica/E. dispar* group or *Entamoeba histolytica* require fresh or frozen stool; preserved stool specimens are not acceptable for testing. Immunoassays for *Cryptosporidium* spp. and *Giardia lamblia* are approved for use with stool; immunoassay use for other intestinal tract specimens may or may not be appropriate, depending on specimen source, consistency, and volume.

[b] Some genus-specific immunoassay reagents for the microsporidia are being used on an experimental basis but are not yet available commercially.

[c] Although cysts may be present in stool, sigmoidoscopy specimens are often obtained from patients with severe diarrhea or dysentery. In such cases, the cyst forms are usually absent; trophozoites would be the most likely stage seen, particularly in the case of *Entamoeba histolytica*.

[d] Duodenal specimens are often submitted as aspirates; in such cases the volume may be sufficient to perform concentrations. However, if small amounts of duodenal mucus and/or biopsy material are obtained, squash preparations preserved with Schaudinn's fixative are preferred. This approach may require the use of slides precoated with albumin to facilitate adhesion. Mucus obtained from the Entero-Test capsule string may be treated as a fresh specimen; the string can also be immediately placed in preservative after retrieval, and the mucus can be processed as a permanent stained smear.

morphology of which is normally seen from the permanent stained smear. However, if fresh stool or aspirated material is obtained, then both the permanent stained smear and an antigen detection reagent kit for the detection of the *Entamoeba histolytica/E. dispar* group or confirmation of the pathogen *Entamoeba histolytica* can be used. If enough material is present for only a single procedure, then the permanent stained smear is recommended, particularly if the iron hematoxylin stain (incorporating the carbol fuchsin step) is used (4). This method would enhance the detection of the coccidia, which are modified acid-fast positive. However, this approach is less commonly used for the detection of *Cryptosporidium* spp. or *G. lamblia*, which can be confirmed using special stains and/or fecal immunoassays performed on routine stool specimens rather than sigmoidoscopy material.

Duodenal Contents

Duodenal Drainage

In infections with *G. lamblia* or *S. stercoralis*, routine stool examinations may not reveal the organisms. Duodenal drainage material can be submitted for examination (Table 8).

A fresh, unpreserved specimen should be submitted to the laboratory; the amount may vary from 0.5 ml to several milliliters of fluid. The specimen may be centrifuged (at 500 × *g* for 10 min) and should be examined immediately as a wet mount for motile organisms (iodine may be added later to facilitate identification of any organisms present). If the specimen cannot be completely examined within 2 h after it is taken, any remaining material should be preserved in 5 to 10% formalin.

If the duodenal fluid contains mucus, this is where the organisms tend to be found. Therefore, centrifugation of the specimen is important, and the sedimented mucus should be examined. *Giardia* trophozoites may be caught in mucus strands, and the movement of the flagella on the trophozoites may be the only subtle motility seen for these flagellates. *Strongyloides* larvae will usually be very motile. Immunoassay methods for *Cryptosporidium* spp. and *G. lamblia* can also be used with fresh or formalinized material.

If the amount of duodenal material submitted is very small, rather than using any of the specimen for a wet smear examination, permanent stains can be prepared. This approach provides a more permanent record, and the potential problems with unstained organisms, very minimal motility, and a lower-power examination can be avoided by using oil immersion examination of the stained specimen at ×1,000 magnification.

Duodenal Capsule Technique (Entero-Test)

A method of sampling duodenal contents that eliminates the need for intestinal intubation has been devised and consists of the use of a length of nylon yarn coiled inside a gelatin capsule (4, 6). The yarn protrudes through one end of the capsule, and this end of the line is taped to the side of the patient's face. The capsule is then swallowed, the gelatin dissolves in the stomach, and the weighted string is carried by peristalsis into the duodenum. The weight is released and passes out in the stool when the line is retrieved after a period of 4 h. Bile-stained mucus clinging to the yarn is then scraped off with gloved fingers and is collected in a small petri dish. Usually 4 or 5 drops of material are obtained.

The specimen should be examined immediately as a wet mount for motile organisms. If the specimen cannot be completely examined within an hour after the yarn has been removed, the material should be preserved in 5 to 10% formalin or PVA-mucus smears should be prepared. Organism motility will be similar to that described above for duodenal drainage.

The pH of the terminal end of the yarn should be checked to ensure adequate passage into the duodenum (a very low pH means that it never left the stomach). Also, since the bile duct drains into the intestine at this point, the terminal end of the yarn should be a yellow-green color.

UROGENITAL SPECIMENS

Several parasites may be recovered and identified from urogenital specimens. Although the most common pathogens are probably *Trichomonas vaginalis* and *Schistosoma haematobium*, other organisms such as the microsporidia are becoming much more important (Table 9). Also, the Knott concentration for the recovery of microfilariae can be performed from blood, as can the membrane filtration approach from urine.

Direct Wet Mount

The identification of *T. vaginalis* is usually based on the examination of a wet preparation of vaginal and urethral discharges and prostatic secretions or urine sediment and may require the testing of multiple specimens to confirm the diagnosis. These specimens are diluted with a drop of saline and are examined under low power under reduced illumination for the presence of actively motile organisms. As the jerky motility begins to diminish, it may be possible to observe the undulating membrane, particularly under high dry power (magnification, ×400).

While the membrane filtration technique can be used for the recovery of microfilariae, examination of urinary sediment may be indicated in certain filarial infections. The occurrence of microfilariae in urine has been reported with increasing frequency in *Onchocerca volvulus* infections in Africa.

TABLE 9 Detection of urogenital parasites

Organism	Procedure
Trichomonas vaginalis	Wet mount (motility) Culture Giemsa stain Direct fluorescent antibody DNA probe Latex agglutination EIA Rapid immunochromatographic assay (dipstick)
Schistosoma haematobium	Wet mount (urine sediment) Membrane filtration Tissue section
Microfilariae	Knott concentration Membrane filtration (Nuclepore filter) Giemsa stain Delafield's hematoxylin stain
Microsporidia	Modified trichrome stain[a] Optical brighteners (calcofluor)[a] Immunoassay tests[a,b] Routine histology Electron microscopy

[a] Staining procedures and fluorescent antibody tests for organism detection performed on centrifuged sediment (500 × *g* for 10 min).

[b] Immunoassays are available in the research setting; commercial reagents are not yet available.

Urine is collected in a bottle, this volume is recorded, and thimerosal (1 ml/100 ml of urine) is added. The specimen is placed in a funnel fitted with tubing and a clamp; this preparation is allowed to settle overnight. On the following day, 10 to 20 ml of urine is withdrawn and centrifuged. The supernatant is discarded, and the sediment is resuspended in 0.85% NaCl. This preparation is again centrifuged, and 0.5 to 1.0 ml of the sediment is examined under the microscope for the presence of nonmotile microfilariae. The membrane filtration technique can also be used with urine for the recovery of *Schistosoma haematobium* eggs (4). This approach uses a 25-mm-diameter Nuclepore filter (5-μm porosity) (4, 6).

The use of stained smears is usually not necessary for the identification of *T. vaginalis*. Many times the number of false-positive and false-negative results reported on the basis of stained smears strongly suggests the value of confirmation by observation of motile organisms from the direct mount, from appropriate culture media (4, 6, 13), or from direct detection with immunoassay reagents (4).

Stained smears may be prepared from material obtained from the membrane filtration techniques used for the recovery of microfilariae; Delafield's hematoxylin or Giemsa stain may be used. It is important to remember that Giemsa stain may not adequately stain the sheath, and correct identification of the organisms may require staining with a hematoxylin-based stain.

Some microsporidial infections can also be diagnosed from the examination of urine sediment that has been stained by one of the modified trichrome methods or using optical

brightening agents such as calcofluor (4). Multiple methods are recommended for confirmation of the diagnosis.

Culture

Specimens from women for culture (for *T. vaginalis*) may consist of vaginal exudate collected from the posterior fornix on cotton-tipped applicator sticks or genital secretions collected on polyester sponges. Specimens from men can include semen, urethral samples collected with a polyester sponge, or urine. Urine samples collected from the patient should be the specimen first voided in the morning. It is critical that clinical specimens be inoculated into culture medium as soon as possible after collection (4, 10, 13). Although collection swabs can be used, there are often problems with specimens drying prior to culture; immediate processing is mandatory for maximum organism recovery. Another approach would be to use the plastic envelope methods (*Trichomonas* Culture System [Empyrean Diagnostics, Mountain View, Calif.]; InPouch TV [BIOMED Diagnostics, San Jose, Calif.]), which are simplified techniques for transport and culture (4). The following control strain should be available when using these cultures for clinical specimens: *T. vaginalis* ATCC 30001. Many media for the isolation of *T. vaginalis* are available, and some of these can be purchased commercially and have relatively long shelf lives, particularly the plastic envelope methods.

If no trophozoites are seen after 4 days of incubation, then discard the tubes and report the culture as negative. Results for patient specimens should not be reported as positive unless control cultures are positive. Since culture may take as long as 3 to 4 days and the clinical specimens may contain nonviable organisms, it is recommended that microscopic examination of wet smears be performed as well.

Antigen Detection *(Trichomonas vaginalis)*

The culture method is considered to be the most sensitive for the diagnosis of trichomoniasis; however, due to the time and effort involved, some laboratories have decided to use some of the new immunoassay detection kits (4). The OSOM Trichomonas Rapid Test (Genzyme Diagnostics, Cambridge, Mass.) is an immunochromatographic method for antigen detection using the dipstick format. Results are available within 10 min, and according to the manufacturer, there is a 95% agreement with the reference standard (culture and wet mount).

SPECIMENS FROM OTHER BODY SITES

When routine testing methods have failed to demonstrate the organisms, the examination of aspirated material for the diagnosis of parasitic infections may be extremely valuable (Table 10). Specimens should be transported to the laboratory immediately after collection. Aspirates include liquid specimens collected from a variety of sites as well as fine-needle aspirates and duodenal aspirates. Fine-needle aspirates are often collected by cytopathology staff who process the specimens, or they may be collected and sent to the laboratory directly for slide preparation and/or culture. Fluid specimens collected by bronchoscopy include bronchoalveolar lavage and bronchial washing fluids.

Procedural details for processing sigmoidoscopic aspirates and scrapings for the recovery of *E. histolytica* and techniques for preparation of duodenal aspirate material have been presented earlier in this chapter.

Biopsy specimens are recommended for use in the diagnosis of parasitic infections in tissues (Table 10). In addition to standard histologic preparations, the following can be used: impression smears and teased and squash preparations of biopsy tissue from skin, muscle, cornea, intestine, liver, lung, and brain. Tissue to be examined as permanent sections or by electron microscopy should be fixed as specified by the laboratories that will process the tissue, and in certain cases, testing of a biopsy specimen may be the only means of confirming a suspected parasitic problem. Specimens that are going to be examined as fresh material rather than as tissue sections should be kept moist in saline and submitted to the laboratory immediately.

Detection of parasites in tissue depends on specimen collection and the retrieval of sufficient material for examination. Biopsy specimens are usually quite small and may not be representative of the diseased tissue. Multiple tissue samples will often improve diagnostic results. To optimize the yield from any tissue specimen, examine all areas and use as many procedures as possible. Tissues are obtained from invasive procedures, many of which are very expensive and lengthy; consequently, these specimens deserve the most comprehensive procedures possible.

Tissue submitted in a sterile container on a sterile sponge dampened with saline may be used for cultures of protozoa after mounts for direct examination or impression smears for staining have been prepared. If cultures for parasites are to be made, use sterile slides for smear and mount preparation or inoculate cultures prior to smear preparation.

Bone Marrow

Bone marrow aspirates to be evaluated for *Leishmania* amastigotes, *Trypanosoma cruzi* amastigotes (African trypanosomiasis organisms not relevant), *Plasmodium* spp., or *Toxoplasma gondii* (less common site) require Giemsa staining. However, when a hematoxylin/Giemsa combination stain is used, the organisms will be visible as well. If specimens are going to be processed for culture, it is important to maintain sterility of the specimen prior to inoculation of media for parasitology cultures. After inoculation of appropriate media, the remaining specimen can be processed for smear preparation and staining.

Brain

Generally, when cerebrospinal fluid or brain aspirates or biopsy specimens are received, the most likely parasites would include the free-living amebae, *Acanthamoeba* spp., *Balamuthia mandrillaris*, or *Naegleria fowleri.* The use of nonnutrient agar (with bacterial overlays) cultures is recommended for *Acanthamoeba* spp. and *N. fowleri;* quality control cultures with known positive organisms are recommended as a basis for acceptable interpretation of patient culture results. If free-living ameba cultures are ordered for central nervous system specimens, the agar plates should be incubated at 37°C (room air) (4, 6). Unfortunately, cultures for *B. mandrillaris* are difficult to perform; consultation with CDC is recommended if this infection is suspected. The remaining specimen can then be processed for smear preparation and staining. Although *T. gondii* would also be seen in stained smears, one could also use immunospecific reagents or PCR. Spinal fluid should not be diluted before examination. Impression smears from tissues should be prepared and stained with Giemsa stain. The material is pressed between two slides, with the smear resulting when the slides are pulled apart (one across the other). The smears are allowed to air dry and are then processed like a thin blood film (fixed in absolute methanol and stained with Giemsa stain).

Patients with primary amebic meningoencephalitis are rare, but the examination of spinal fluid may reveal the amebae, usually *Naegleria fowleri*. Unspun sedimented spinal fluid

TABLE 10 Specimen, possible parasite recovered, and appropriate tests (other than intestinal tract)[a]

Body site	Specimen	Possible parasites	Tests
Bone marrow	Aspirate	*Leishmania* spp., *Trypanosoma cruzi*, *Plasmodium* spp., *Toxoplasma gondii*	Giemsa, culture
Brain	Tissue biopsy specimen, cerebrospinal fluid	*Naegleria* spp., *Acanthamoeba* spp.	Giemsa, trichrome, culture
		Balamuthia mandrillaris, *Sappinia diploidea* *Entamoeba histolytica*	Giemsa, trichrome
		Toxoplasma gondii	Giemsa, immunospecific reagent, culture, PCR
		Microsporidia *(Encephalitozoon* spp., *Trachipleistophora antropophtera)*	Modified trichrome, acid-fast stain, Giemsa, optical brightening agent (calcofluor), histology[b] (methenamine silver, PAS[c], tissue Gram stains), electron microscopy
		Taenia solium (cysticerci), *Echinococcus* spp.	Routine histology
Eye	Cornea, conjunctiva, contact lens, lens solutions[d]	Microsporidia (*Encephalitozoon* spp., *Trachipleistophora* spp., *Nosema* spp.)	Acid-fast stain, Giemsa, modified trichrome, methenamine silver, optical brightening agent calcofluor), histology (methenamine silver, PAS, tissue Gram stains), electron microscopy
		Acanthamoeba spp.	Giemsa, trichrome, culture, calcofluor (cysts only)
		Toxoplasma gondii	Giemsa, immunospecific reagent, culture
	Larval or adult worms	*Loa loa, Dipetalonema, Thalezia, Dirofilaria immitis, Gnathostoma* spp., *Toxocara canis, Taenia solium* (cysticerci), *Echinococcus* spp.	Direct examination, routine histology
	Fly larvae, adult lice	Myiasis, lice infestation	Direct examination
Kidney, bladder	Biopsy specimen	Microsporidia *(Encephalitozoon* spp., *Enterocytozoon bieneusi)*	Modified trichrome, acid-fast stain, Giemsa, optical brightening agent (calcofluor), histology (methenamine silver, PAS, tissue Gram stains), electron microscopy
		Schistosoma haematobium	Direct examination
	Adult worm, eggs	*Dioctyphyma renale*	Direct examination
Liver, spleen	Aspirates, biopsy specimen	*Echinococcus* spp.	Wet mount, routine histology
		Clonorchis spp., *Opisthorchis* spp.	Routine histology
		Capillaria hepatica, Toxocara canis, T. cati, *Toxoplasma gondii, Leishmania donovani*	Giemsa, culture
		Cryptosporidium spp.	Modified acid-fast stain, immunospecific reagents
		Microsporidia *(Encephalitozoon* spp., *Enterocytozoon bieneusi)*	Modified trichrome, acid-fast stain, Giemsa, optical brightening agent (calcofluor), histology (methenamine silver, PAS, tissue Gram stains), electron microscopy
		Entamoeba histolytica[e]	Wet mount, trichrome
Lymph node, lymphatics	Aspirates, biopsy specimen	*Toxoplasma gondii, Trypanosoma cruzi, Trypanosoma brucei rhodesiense, T. brucei gambiense*	Direct examination, routine histology, Giemsa, culture
		Microsporidia	Modified trichrome, acid-fast stain, Giemsa, optical brightening agent (calcofluor), histology (methenamine silver, PAS, tissue Gram stains), electron microscopy

(Continued on next page)

TABLE 10 Specimen, possible parasite recovered, and appropriate tests (other than intestinal tract)[a] *(Continued)*

Body site	Specimen	Possible parasites	Tests
		Wuchereria bancrofti, Brugia malayi, Brugia spp.	Thick blood films, concentration, membrane filtration
Lung	Sputum (expectorated or induced), bronchoalveolar lavage, transbronchial aspirates, brush biopsy, specimen open lung biopsy specimen	*Ascaris lumbricoides, Strongyloides stercoralis,* hookworm, *Paragonimus* spp., *Echinococcus granulosus*	Wet mount, routine histology
		Microsporidia *(Encephalitozoon* spp., *Enterocytozoon bieneusi)*	Modified trichrome, acid-fast stain, Giemsa, optical brightening agent (calcofluor), histology (methenamine silver, PAS, tissue Gram stains), electron microscopy
		Toxoplasma gondii	Giemsa, immunospecific reagent, culture
		Cryptosporidium spp.	Modified acid-fast stain, immunospecific reagent
	Saliva	*Entamoeba gingivalis, Trichomonas tenax*	Trichrome
Muscle	Biopsy specimen	*Trichinella* spp.	Wet examination, squash preparation, routine histology
		Microsporidia *(Pleistophora* spp., *Nosema* spp., *Trachipleistophora hominis)*	Modified trichrome, acid-fast stain, Giemsa, optical brightening agent (calcofluor), histology (methenamine silver, PAS, tissue Gram stains), electron microscopy
		Sarcocystis spp., *Baylisascaris procyonis*, *Ancylostoma* spp., *Taenia solium* (cysticerci), *Multiceps* (coenurus), *Echinococcus* spp., Spirometra (spargana), *Onchocerca volvulus* (nodules), *Gnathostoma* spp., *Trypanosoma cruzi*	Routine histology
Nasopharynx, sinus cavities	Scraping, biopsy specimen, aspirates	Microsporidia *(Encephalitozoon* spp., *Enterocytozoon bieneusi, Trachipleistophora hominis)*	Modified trichrome, acid-fast stain, Giemsa, optical brightening agent (calcofluor), histology (methenamine silver, PAS, tissue Gram stains), electron microscopy
		Acanthamoeba spp.	Giemsa, trichrome, culture, calcofluor (cysts only)
		Naegleria spp.	Giemsa, trichrome, culture
		Leishmania spp.	Giemsa, culture
Rectal tissue	Scraping, aspirate, biopsy specimen	*Schistosoma mansoni*, *S. japonicum*	Direct examination
Skin	Skin snips	*Onchocerca volvulus, Mansonella streptocerca*	Giemsa, routine histology
	Scraping, aspirates, biopsy specimen	*Leishmania* spp.	Giemsa, culture, routine histology
		Acanthamoeba spp.	Giemsa, trichrome, culture, calcofluor (cysts only)
		Entamoeba histolytica, *Schistosoma* spp.	Routine histology

[a] This table does not include every possible parasite that could be found in a particular body site. Parasite stages include trophozoites, cysts, oocysts, spores, adults, larvae, eggs, hooklets, amastigotes, and trypomastigotes. Although PCR methods have been used in the research setting for most of the organisms listed in the table, reagents are generally not commercially available.

[b] Routine histology can be used for the detection and identification of many parasites. In some cases, it may be the only means of diagnosis.

[c] PAS, periodic acid-Schiff stain.

[d] Although eye specimens are much preferred, free-living amebae have been cultured from patient contact lenses and lens solutions; we would not reject these specimens. An exception would be *unopened* commercial lens care solutions; these solutions would be rejected.

[e] The examination of abscess aspirates for the presence of *Entamoeba histolytica* trophozoites is an uncommon procedure and not always reliable in diagnosing extraintestinal amebiasis; serologic tests are preferred.

should be placed on a slide, under a coverslip, and observed for motile amebae; smears can also be stained with Trichrome, Wright's, or Giemsa stain. Spinal fluid, exudate, or tissue fragments can be examined by light microscopy or phase-contrast microscopy. Care must be taken not to confuse leukocytes with actual organisms and vice versa. The spinal fluid may appear cloudy or purulent (with or without erythrocytes), with a cell count of from a few hundred to more than 20,000 leukocytes (primarily neutrophils) per ml. Failure to find bacteria in this type of spinal fluid should alert one to the possibility of primary amebic meningoencephalitis; however, false-positive bacterial Gram stains have been reported because of excess debris. Isolation of these organisms from tissues can be done by using special media. When spinal fluid is placed in a counting chamber, organisms that settle to the bottom of the chamber tend to round up and look very much like leukocytes. For this reason, it is better to examine the spinal fluid on a slide directly under a coverslip, not in a counting chamber.

Possible infection with microsporidia (the most likely organism would be *Encephalitozoon* spp.; less common, *Trachipleistophora antropophtera*) should also be considered. Specific methods include modified trichrome, acid-fast, and Giemsa stains; a nonspecific optical brightening agent (calcofluor); routine histology (methenamine silver, periodic acid-Schiff stain [PAS], tissue Gram stains); and electron microscopy. Electron microscopy or immunospecific reagents are required to identify the microsporidia to the genus and species levels.

Helminth parasite stages such as *Taenia solium* cysticerci and hydatid cysts of *Echinococcus* spp. are generally identified through examination of routine histologic slides; however, confirmation of hydatid disease could also be made from the hooklets seen in the hydatid cyst fluid contents.

Eye

Eye specimens include those from the cornea, conjunctiva, contact lens, or contact lens solutions. Although eye specimens are preferred, *Acanthamoeba* spp. have been cultured from patient contact lenses and lens solution. These specimens are acceptable; however, due to risk management issues, the laboratory should not accept unopened commercial lens care solutions. After appropriate media have been inoculated, smears from acceptable specimens should be prepared and stained using Giemsa or trichrome stains. Although *T. gondii* can be seen in stained smears, one can also use an immunospecific reagent or PCR for confirmation. Most individuals who are infected with *T. gondii* do not develop ocular disease; however, two populations are at risk, the immunocompromised patient with HIV and neonates who have been exposed transplacentally to the mother's acute infection.

In addition to the free-living amebae, microsporidia are highly suspect from this body site, and specific methods include modified trichrome, acid-fast, and Giemsa stains; a nonspecific optical brightening agent (calcofluor); routine histology (methenamine silver, PAS, tissue Gram stains); and electron microscopy. Electron microscopy or immunospecific reagents are required to identify the microsporidia to the genus and species levels, which could include *Encephalitozoon* spp., *Trachipleistophora* spp., and *Nosema* spp.

Ocular disease caused by nematodes includes onchocerciasis, loiasis, dirofilariasis, gnathostomiasis, and toxocariasis. Diagnosis of onchocerciasis can be accomplished by confirming the presence of microfilariae in a corneal biopsy specimen or from the microscopic examination of multiple skin snips. The diagnosis of loiasis can be confirmed from the detection of circulating microfilariae of *Loa loa* in the blood or direct examination of the eye for the presence of the adult worm. Ocular disease can occur with the migration of *Dirofilaria immitis* larvae through periorbital or palpebral tissue; however, laboratory diagnosis of this infection is rare. Diagnosis of infections with *Gnathostoma* spp. and *Toxocara canis* is difficult but should be considered for patients with marked eosinophilia and elevated immunoglobulin E.

Eye disease can also be caused by cestodes, including *T. solium* (cysticercosis) and *Echinococcus* spp. (hydatid disease). These infections would generally be identified through direct ophthalmoscopic demonstration of the larval *T. solium*, computed tomography scans for hydatid cysts, or examination of routine histologic slides.

Ocular myiasis and infestations with lice are also possible; laboratory personnel may be asked to identify various fly larvae *(Dermatobia*, *Gasterophilus*, *Oestra*, *Cordylobia*, *Chrysomia*, *Wohlfahrtia*, *Cochliomyia*, and *Hypoderma)* and/or lice *(Pediculus humanus corporis* or *P. humanus capitis,* or *Phthirus pubis)*.

Kidney and Bladder

The kidney serves as the primary site for the adult worm *Dioctyphyma renale.* These worms generally live in the pelvis of the right kidney or in body cavities. Although these infections have been isolated from dogs in many areas of the world, they tend to be uncommon in humans. Infections can be confirmed at autopsy, by observation of the migration of worms from the urethra or discharge of worms from the skin over an abscessed kidney, or by recovery of eggs in the urine. Possible infection with microsporidia (the most likely organism would be *Encephalitozoon* spp.; less common, *Enterocytozoon bieneusi*) should also be considered. Specific methods would include modified trichrome, acid-fast, and Giemsa stains; a nonspecific optical brightening agent (calcofluor); routine histology (methenamine silver, PAS, tissue Gram stains); and electron microscopy. Electron microscopy or immunospecific reagents would be required to identify the microsporidia to the genus and species levels.

Mucosa from the bladder wall may reveal eggs of *Schistosoma haematobium* when they are not being recovered in the urine. The eggs in the bladder wall should be checked for viability by either a hatching technique or microscopic observation of the functioning flame cells within the miracidium larva (4).

Liver and Spleen

Although the liver and spleen can serve as secondary sites for a number of organisms, specific organisms that need to be considered for these organs as primary sites include the following: *Leishmania donovani*, *Toxoplasma gondii*, and *Echinococcus* sp. (spleen and liver) and *Toxocara canis, T. cati, Capillaria hepatica, Clonorchis* spp., *Opisthorchis* spp., *Cryptosporidium* spp., *Entamoeba histolytica*, *Encephalitozoon* spp., and *Encephalitozoon intestinalis* (liver). Typical methods for diagnosis include wet mounts, routine histology, Giemsa stain, culture, modified acid-fast stains, immunospecific reagents, and trichrome stains (routine and modified).

Examination of aspirates from lung or liver abscesses may reveal trophozoites of *E. histolytica;* however, demonstration of the organisms may be difficult (4). Liver aspirate material should be taken from the margin of the abscess rather than the necrotic center. The organisms are often trapped in the viscous pus or debris and do not exhibit typical motility. A minimum of two separate portions of exudate should be removed (more than two are recommended). The first portion of the aspirate, usually yellowish white, rarely contains

organisms. The last portion of the aspirated abscess material is reddish and is more likely to contain amebae. The best material to be examined is that obtained from the actual wall of the abscess. The Amoebiasis Research Unit, Durban, South Africa, has recommended the use of proteolytic enzymes to free the organisms from the aspirate material.

After the addition of the enzyme streptodornase to the thick pus (10 U/ml of pus), the mixture is incubated and shaken. After centrifugation (500 × *g* for 5 min), the sediment may be examined microscopically as wet mounts or may be used to inoculate culture media. Some of the aspirate can be mixed directly with PVA on a slide and examined as a permanent stained smear (4).

Aspiration of cyst material for the diagnosis of hydatid disease is a dangerous procedure and is usually performed only when open surgical techniques are used for cyst removal. Aspirated fluid usually contains hydatid sand (intact and degenerating scolices, hooklets, and calcareous corpuscles). Some older cysts contain material that resembles curded cottage cheese, and the hooklets may be very difficult to see. Some of this material can be diluted with saline or 10% KOH; usually, scolices or daughter cysts will have disintegrated. However, the diagnosis can be made from seeing the hooklets by using high dry power (magnification, ×400). The absence of scolices or hooklets does not rule out the possibility of hydatid disease, since some cysts are sterile and contain no scolices and/or daughter cysts. Histologic examination of the cyst wall should be able to confirm the diagnosis.

Lung

Expectorated Sputum, Induced Sputum

Although it is not one of the more common specimens, expectorated sputum may be submitted for examination for parasites (Table 10). Organisms in sputum that may be detected and that may cause pneumonia, pneumonitis, or Loeffler's syndrome include the migrating larval stages of *Ascaris lumbricoides*, *S. stercoralis*, and hookworm; the eggs of *Paragonimus* spp.; *Echinococcus granulosus* hooklets; the protozoa *E. histolytica* and *Cryptosporidium* spp.; and possibly the microsporidia (4). In a *Paragonimus* infection, the sputum may be viscous and tinged with brownish flecks ("iron filings"), which are clusters of eggs, and may be streaked with blood. Although *Entamoeba gingivalis* and *Trichomonas tenax* may be found in sputum, they are generally indicators of poor oral hygiene and/or periodontal disease, not pulmonary disease.

A sputum specimen should be collected properly so that the laboratory receives a "deep sputum" from the lower respiratory tract for examination rather than a specimen that is primarily saliva from the mouth. If the sputum is not induced, then the patient should receive specific instructions regarding collection.

Care should be taken not to confuse *E. gingivalis*, which may be found in the mouth and saliva, with *E. histolytica*, as this could result in an incorrect suspicion of pulmonary abscess. *E. gingivalis* usually contains ingested polymorphonuclear leukocytes, while *E. histolytica* may contain ingested erythrocytes but not polymorphonuclear leukocytes. *T. tenax* is also found in saliva from the mouth and thus would be an incidental finding and normally not an indication of pulmonary problems.

Direct Wet Mount

Sputum is usually examined as a wet mount (saline or iodine), using low and high dry power (magnifications, ×100 and ×400, respectively). The specimen is not concentrated before preparation of the wet mount. If the sputum is thick, an equal amount of 3% sodium hydroxide (or undiluted chlorine bleach) can be added; the specimen is thoroughly mixed and then centrifuged. However, NaOH will destroy any protozoan trophozoites that might be present. After centrifugation, the supernatant fluid is discarded, and the sediment can be examined as a wet mount with saline or iodine. If examination must be delayed for any reason, the sputum should be fixed in 5 or 10% formalin to preserve helminth eggs or larvae or in PVA fixative to be stained later for protozoa.

Permanent Stained Smears

If *Cryptosporidium* spp. is suspected (rare), then acid-fast or immunoassay techniques normally used for stool specimens can be used (4). Trichrome or iron hematoxylin stains of material may aid in differentiating *E. histolytica* from *E. gingivalis*, and Giemsa stain may better define larvae and juvenile worms.

Bronchoscopy Aspirates

Fluid specimens collected by bronchoscopy may be from lavages or washings, with bronchoalveolar lavages preferred. Specimens are usually concentrated by centrifugation prior to microscopic examination of stained preparations. Organisms that may be detected in such specimens are *Paragonimus* spp., *S. stercoralis*, *T. gondii*, *Cryptosporidium* spp., and the microsporidia.

If *T. gondii* is suspected, Giemsa stain, immunospecific reagents, and/or culture (tissue culture) can be used to confirm the diagnosis. A number of cell lines have been used (human foreskin fibroblast is one example), and most routine cell lines work well for the growth and isolation of this organism.

Lymph Node and Lymphatics

Material from lymph nodes and lymphatics confirm parasitic infections (toxoplasmosis, Chagas' disease, trypanosomiasis, microsporidiosis, filariasis) and should be processed as follows. Fluid material can be examined under low power (magnification, ×100) and high dry power (magnification, ×400) as a wet mount (diluted with saline) for the presence of motile organisms.

Material obtained from lymph nodes should be processed for tissue sectioning and as impression smears that should be processed as thin blood films and stained with Giemsa stain. Appropriate culture media can also be inoculated, again making sure that the specimen has been collected under sterile conditions.

If microsporidia are suspected, modified trichrome stains can be used; calcofluor white and immunoassay methods (currently under development) are also excellent options (4). If *T. gondii* is suspected, Giemsa stain, immunospecific reagents, and/or culture (tissue culture) can be used to confirm the diagnosis.

Specific filarial infections are generally caused by *Wuchereria bancrofti*, *Brugia malayi*, and *Brugia* spp. In most cases, the microfilariae can be recovered and identified through examination of thick blood films, specific concentration sediment, and/or membrane filtration methods (4).

Muscle

Muscle is considered the primary site for the following organisms: *Sarcocystis* spp., microsporidia (*Pleistophora* spp., *Nosema* spp.), *Gnathostoma* spp., *Trichinella* spp. larvae, and cestode larval forms (coenurus/*Taenia* spp., cysticercosis/*T. solium*, sparganum). As a secondary site, *T. cruzi* amastigotes can also

be found in muscle; *Baylisascaris procyonis* and *Ancylostoma* spp. are also possibilities, as are hydatid cysts (*Echinococcus* spp.). In most cases, biopsy specimens processed using routine histologic methods provide the most appropriate specimen for examination and confirmation of the causative agent.

The presumptive diagnosis of trichinosis is often based on patient history: ingestion of raw or rare pork, walrus meat, or bear meat; diarrhea followed by edema and muscle pain; and the presence of eosinophilia. Generally, the suspected food is not available for examination. The diagnosis may be confirmed by finding larval *Trichinella spiralis* in a muscle biopsy specimen. The encapsulated larvae can be seen in fresh muscle if small pieces are pressed between two slides and examined under the microscope (4). Larvae are usually most abundant in the diaphragm, masseter muscle, or tongue and may be recovered from these muscles at necropsy. Routine histologic sections can also be prepared.

Human infection with any of the larval cestodes may present diagnostic problems, and frequently, the larvae are referred for identification after surgical removal. In addition to *E. granulosus* (hydatid disease) and the larval stage of *Taenia solium* (cysticercosis), other larval cestodes occasionally cause human disease. The larval stage of tapeworms of the genus *Multiceps*, a parasite of dogs and wild canids, is called a coenurus and may cause human coenurosis. The coenurus resembles a cysticercus but is larger and has multiple scolices developing from the germinal membrane surrounding the fluid-filled bladder. These larvae occur in extraintestinal locations, including the eye, central nervous system, and muscle.

Human sparganosis is caused by the larval stages of tapeworms of the genus *Spirometra*, which are parasites of various canine and feline hosts; these tapeworms are closely related to the genus *Diphyllobothrium*. Sparganum larvae are elongated, ribbon-like larvae without a bladder and with a slightly expanded anterior end lacking suckers. These larvae are usually found in superficial tissues or nodules, although they may cause ocular sparganosis, a more serious disease.

Finding prominent calcareous corpuscles in the tapeworm tissue frequently supports the diagnosis of larval cestodes; specific identification usually depends on referral to specialists.

Nasopharynx and Sinus Cavities

Organisms that might be found in these body sites include the microsporidia, *Acanthamoeba* spp., and *Naegleria*. Specimens submitted for examination could include scrapings, aspirates, and/or biopsy specimens. The special stains include modified trichrome, acid-fast, and tissue Gram stains. Giemsa, calcofluor, and regular trichrome stains would also be appropriate. If *Naegleria* or *Acanthamoeba* spp. are suspected, culture is highly recommended. In certain cases of mucocutaneous leishmaniasis, *Leishmania* spp. can also be found from these body sites; Giemsa stain is recommended for confirmation for both aspirates and biopsy specimens; cultures are also an option (4).

Rectal Tissue

Often when a patient has an old, chronic infection or a light infection with *Schistosoma mansoni* or *Schistosoma japonicum*, the eggs may not be found in the stool and an examination of the rectal mucosa may reveal the presence of eggs. The fresh tissue should be compressed between two microscope slides and examined under the low power of the microscope (low-intensity light) (4). Critical examination of these eggs should be made to determine whether living miracidia are still found within the egg. Treatment may depend on the viability of the eggs; for this reason, the condition of the eggs should be reported to the physician.

Skin

The use of skin snips is the method of choice for the diagnosis of human filarial infections with *O. volvulus* and *M. streptocerca* (1, 4). Microfilariae of both species occur chiefly in the skin, although *O. volvulus* microfilariae may rarely be found in blood and occasionally in urine. Skin snip specimens should be thick enough to include the outer part of the dermal papillae. With a surgical blade, a small slice may be cut from a skin fold held between the thumb and forefinger, or a slice may be taken from a small "cone" of skin pulled up with a needle. Significant bleeding should not occur, and there should be just a slight oozing of fluid. Corneal-scleral punches (either Holth or Walser type) have been found to be successful in taking skin snips of uniform size and depth and an average weight of 0.8 mg (range, 0.4 to 1.2 mg); this procedure is easy to perform and is painless. It has been demonstrated that in African onchocerciasis, it is preferable to take skin snips from the buttock region (above the iliac crest); in Central American onchocerciasis, the preferred skin snip sites are from the shoulders (over the scapula).

Skin snips are placed immediately in a drop of normal saline or distilled water and are covered so that they will not dry; teasing of the specimen with dissecting needles is not necessary but may facilitate release of the microfilariae. Microfilariae tend to emerge more rapidly in saline; however, in either solution, the microfilariae usually emerge within 30 min to 1 h and can be examined with low-intensity light and the 10× objective of the microscope. To see definitive morphological details of the microfilariae, allow the snip preparation to dry, fix it in absolute methyl alcohol, and stain it with Giemsa stain.

Skin biopsy specimens used for the diagnosis of cutaneous amebiasis (*Entamoeba histolytica, Acanthamoeba* spp.) and cutaneous leishmaniasis should be processed for tissue sectioning and subsequently stained by the hematoxylin-eosin technique.

Although cutaneous disease is an unusual presentation for schistosomiasis, it does occur with skin lesions as the only manifestation. Based on routine histologic examination of skin biopsies, eggs can be found in the cellular infiltrate from within the lesion. When evaluating patients with unusual skin lesions, a complete history may reveal travel to an area where schistosomiasis is endemic.

Material containing intracellular *Leishmania* organisms can be aspirated from below the ulcer bed through the uninvolved skin, not from the surface of the ulcer. The surface of the ulcer must be thoroughly cleaned before specimens are taken; any contamination of the material with bacteria or fungi may prevent recovery of the organism from culture. Aspirated material is placed on a slide and stained with Giemsa stain.

Some prefer to take a punch biopsy through the active margin of the lesion (after cleaning the lesion); good results have also been seen when using dermal scrapings from the bottoms of the ulcers. When microscopic examinations of dermal scrapings of both the ulcer bottom and active margins are combined, the sensitivity of diagnosis may increase to 94% (17). Aspirate culture has been shown to be the most sensitive method for the diagnosis of patients with chronic ulcers. However, any successful culture depends on the prevention of contamination with bacteria and/or fungi; sampling of the ulcer must be done correctly in order to prevent false-negative culture results.

BLOOD

Depending on the life cycle, a number of parasites may be recovered in a blood specimen, either whole-blood or buffy

coat preparations or following concentration by various types of procedures. These parasites include *Plasmodium*, *Babesia*, and *Trypanosoma* species, *Leishmania donovani*, and microfilariae. Although some organisms may be motile in fresh, whole blood, species identification will usually be accomplished by the examination of permanent stained thick and thin blood films. Blood films can be prepared from fresh, whole blood collected with no anticoagulants; anticoagulated blood (EDTA is recommended; heparin is acceptable, but organism morphology is not as good; other anticoagulants are not recommended); or sediment from the various concentration procedures. The recommended stain of choice is Giemsa stain; however, the parasites can also be seen on blood films stained with Wright's stain. Delafield's hematoxylin stain is often used to stain the microfilarial sheath; in some cases, Giemsa stain does not provide sufficient stain quality to allow differentiation of the microfilariae (Table 11). When handling blood, as well as other clinical specimens, universal precautions should be observed (3, 4, 13, 14, 15).

Preparation of Thick and Thin Blood Films

Microfilariae and trypanosomes can be detected in fresh blood by their characteristic shape and motility; however, specific identification of the organisms requires a permanent stain. Two types of blood films are recommended. Thick films allow a larger amount of blood to be examined, which increases the possibility of detecting light infections (4, 10, 14). However, only experienced workers can usually make species identification with a thick film, particularly in the case of malaria, and the morphological characteristics of blood parasites are best seen in thin films.

The accurate examination of thick and thin blood films and identification of parasites depend on the use of absolutely clean, grease-free slides for preparation of all blood films. Old (unscratched) slides should be cleaned first in detergent and then with 70% ethyl alcohol; new slides should also be cleaned with alcohol and allowed to dry before use.

Blood films should be prepared when the patient is admitted or seen in the emergency room or clinic; typical fever patterns are frequently absent, and the patient may not be suspected of having malaria. If malaria remains a possible diagnosis, after the first set of negative smears samples should be taken at intervals of 6 to 8 h for at least three successive days. Another option is to collect blood immediately on admission; if the initial blood films are negative, collect daily specimens for two additional days (ideally between paroxysms if present). Using either collection option, quality patient care depends on the fact that both the physician and laboratory staff know that one negative set of blood films does not eliminate *Plasmodium* spp. as possible etiologic agents.

TABLE 11 Techniques for the recovery of blood parasites (EDTA or heparin)[a]

Organism	Procedure	Stain
Malaria	Thick and thin films	Giemsa, Wright's, Field's, rapid stains
	QBC[b]	Stain not relevant (centrifugation, acridine orange, microscopy)
	ParaSight F[c]	Stain not relevant (HRP-2 immunochromatographic assay)
	Binax Now Malaria[d]	Stain not relevant (HRP-2 and aldolase immunochromatographic assay)
	PATH IC Falciparum malaria IC[e]	Stain not relevant (HRP-2 immunochromatographic assay)
	Malaria Ag-CELISA[f]	Stain not relevant (HRP-2 immunochromatographic assay)
	Rapimal Dipstick[f]	Stain not relevant (HRP-2 immunochromatographic assay)
	Rapimal Cassette[f]	Stain not relevant (HRP-2 immunochromatographic assay)
	OptiMAL[g]	Stain not relevant (pLDH immunochromatographic assay)
Babesia spp.	Thick and thin films	Giemsa, Wright's, Field's, rapid stains
Microfilariae	Thick and thin films, Knott concentration, membrane filtration, gradient centrifugation	Giemsa, Wright's or Delafield's hematoxylin
	QBC	Stain not relevant
	NOW ICT Filariasis	Rapid, tends to be dipstick format
	Filariasis Ag-CELISA	EIA
	TropBio[h]	Rapid, tends to be dipstick format
Trypanosomes	Thick and thin films, buffy coat smears, triple centrifugation, culture	Giemsa, Wright's, Field's, rapid stains
	QBC	Stain not relevant
Leishmaniae	Thick and thin films, buffy coat smears, culture	Giemsa, Wright's, Field's, rapid stains

Subsequent to a finger stick, the blood should flow freely; blood that has to be "milked" from the finger will be diluted with tissue fluids, which decrease the number of parasites per field. An alternative approach to the fingerstick is collection of fresh blood containing anticoagulant (preferably EDTA) for the preparation of blood films. Ideally, the smears should be prepared within 1 h after the specimen is drawn. After that time, stippling may not be visible on stained films; however, the overall organism morphology may still be acceptable.

The time that the specimen was drawn should be clearly indicated on the tube of blood and also on the result report. The physician will then be able to correlate the results with any symptoms that the patient may have. There should also be some indication on the slip that is sent back to the physician that one negative specimen does not rule out the possibility of a parasitic infection.

Thick Blood Films

To prepare the thick film, place 2 or 3 small drops of capillary blood directly from the fingerstick (no anticoagulant) on an alcohol-cleaned slide. With the corner of another slide and using a circular motion, mix the drops and spread them over an area 2 cm in diameter. Continue stirring for 30 s to prevent the formation of fibrin strands that may obscure the parasites after staining. If blood containing an anticoagulant is used, 1 or 2 drops may be spread over an area about 2 cm in diameter; it is not necessary to continue stirring for 30 s, since there will be no formation of fibrin strands. If too much blood is used or any grease remains on the slide, the blood may flake off during staining. Allow the film to air dry (at room temperature) in a dust-free area. Never apply heat to a thick film, since heat will fix the blood, causing the erythrocytes to remain intact during staining; the result is stain retention and an inability to identify the parasites. However, the thick films can be placed in a 37°C incubator for 10 to 15 min to dry; this seems to work quite well. Remember, do not make the films too thick; one should be able to see newsprint through the wet film prior to drying. After the thick films are thoroughly dry, they can be laked to remove the hemoglobin. To lake the films, place them in buffer solution before staining for 10 min or directly into a dilute, buffered aqueous Giemsa stain. If thick films are to be stained at a later time, they should be laked before storage (4).

Thin Blood Films

The thin blood film is routinely used for specific parasite identification, although the number of organisms per field is much reduced compared with the number in the thick film. The thin film is prepared exactly as one used for a differential count, and a well-prepared film is thick at one end and thin at the other (one layer of evenly distributed erythrocytes with no cell overlap). The thin, feathered end should be at least 2 cm long, and the film should occupy the central area of the slide, with free margins on both sides. Holes in the film indicate the presence of grease on the slide. After the film has air dried (do not apply heat), it may be stained. The necessity for fixation before staining will depend on the stain selected.

Staining Blood Films

For accurate identification of blood parasites, a laboratory should develop proficiency in the use of at least one good staining method (2, 4, 9). Since prolonged storage may result in stain retention, blood films should be stained on the same day or within a few days of collection. If thick blood films are not prepared or received, it is possible to stain one of the thin blood films as a thick film and examine the thick portion of the thin film. During staining the red blood cells will be laked, thus leaving the white blood cells, platelets, and any parasites present.

Wright's stain has the fixative in combination with the staining solution, so that both fixation and staining occur at the same time; therefore, the thick film must be laked before staining. In aqueous Giemsa stain, the fixative and stain are separate; thus, the thin film must be fixed with absolute methanol before staining.

When slides are removed from either type of staining solution, they should be dried in a vertical position. After being air dried, they may be examined under oil immersion by placing the oil directly on the uncovered blood film. If slides are to be stored for a considerable length of time (for teaching or legal purposes), they should be protected with a coverglass by being mounted in a medium such as Permount. Blood films that have been stained with any of the Romanowsky stains and that have been mounted with Permount or other resinous mounting media are susceptible to fading of the basophilic elements and generalized loss of stain intensity. One can add an antioxidant such as 1% (by volume) 2,6-di-*t*-butyl-*p*-cresol (butylated hydroxytoluene; Sigma-Aldrich) to the mounting medium. Without the addition of this antioxidant, mounted stained blood films eventually become pink; stained films protected with this compound generally remain unchanged in color for many years.

Giemsa Stain

Each new lot number of Giemsa stain should be tested for optimal staining times before being used on patient specimens. If the blood cells appear to be adequately stained, the timing and stain dilution should be appropriate to demonstrate the presence of malaria and other parasites. The use of prepared liquid stain or stain prepared from the powder depends on personal preference; there is apparently little difference between the two preparations.

The commercial liquid stain or the stock solution prepared from powder should be diluted by approximately the same amount to prepare the working stain solution (4, 14). Stock Giemsa liquid stain is diluted 1:10 with buffer for both thick and thin blood films, with dilutions ranging from 1:10 up to 1:50. Staining times usually match the dilution factor (e.g., 1:20 for 20 min or 1:50 for 50 min). Some people prefer to use the longer method with more dilute stain for both thick and thin films. The phosphate buffer used to dilute the stock stain should be neutral or slightly alkaline (pH 7.0 to 7.2). A phosphate buffer solution may be used to obtain the right pH. In some laboratories, the pH of tap water may be satisfactory and may be used for the entire staining procedure and the final rinse. Some workers recommend the use of pH 6.8 to emphasize Schüffner's dots.

Giemsa stain colors the blood components as follows: erythrocytes, pale red; nuclei of leukocytes, purple with pale purple cytoplasm; eosinophilic granules, bright purple-red; and neutrophilic granules, deep pink-purple. In malaria parasites, the cytoplasm stains blue and the nuclear material stains red to purple-red. Schüffner's dots and other inclusions in the erythrocytes stain red. The nuclear and cytoplasmic staining characteristics of the other blood parasites such as *Babesia* spp., trypanosomes, and leishmaniae are like those of the malaria parasites. While the sheath of microfilariae may not always stain with Giemsa, the nuclei within the microfilaria itself stain blue to purple.

Wright's Stain

Wright's stain is available in liquid form and also as a powder, which must be dissolved in anhydrous, acetone-free methyl alcohol before use. Since Wright's stain contains

alcohol, the thin blood films do not require fixation before staining. Thick films stained with Wright's stain are usually inferior to those stained with Giemsa solution. Great care should also be taken to avoid excess stain precipitate on the slide during the final rinse. Before staining, thick films must be laked in distilled water (to rupture and remove erythrocytes) and air dried. The staining procedure is the same as that for thin films, but the staining time is usually somewhat longer and must be determined for each batch of stain. Wright's stain colors blood components as follows: erythrocytes, light tan, reddish, or buff; nuclei of leukocytes, bright blue with contrasting light cytoplasm; eosinophilic granules, bright red; and neutrophilic granules, pink or light purple.

In malaria parasites, the cytoplasm stains pale blue and the nuclear material stains red. Schüffner's dots and other inclusions in the erythrocytes usually do not stain or stain very pale with Wright's stain. Nuclear and cytoplasmic staining characteristics of the other blood parasites such as *Babesia* spp., trypanosomes, and leishmaniae stain like those seen in the malaria parasites. While the sheath of microfilariae may not always stain with Wright's stain, the nuclei within the microfilaria itself stain pale to dark blue.

Proper Examination of Thin and Thick Blood Films

In cases where malaria has not been indicated as the suspect organism, the initial screen of the thin blood film should be carried out with the low-power objective of a microscope because microfilariae may be missed if the entire thin film is not examined. Microfilariae are rarely present in large numbers, and frequently, only a few organisms occur in each thin film preparation. Microfilariae are commonly found at the edges of the thin film or at the feathered end of the film because they are carried to these sites during the process of spreading the blood. This approach to thin film examination is particularly important in cases where a suspect organism has not been indicated. The feathered end of the film where the erythrocytes are drawn out into one single, distinctive layer of cells should be examined for the presence of malaria parasites and trypanosomes. In these areas, the morphology and size of the infected erythrocytes are most clearly seen.

In the case of a suspect malaria diagnosis, the request for blood film examination should always be considered a STAT procedure, with all reports (negative as well as positive) being reported by telephone to the physician as soon as possible (4, 14). Examination of the thin film should include viewing of 200 to 300 oil immersion fields at a magnification of ×1,000. Although some people use a 50× or 60× oil immersion objective to screen stained blood films, there is some concern that small parasites such as *Plasmodium* spp., *Babesia* spp., or *Leishmania donovani* may be missed at this smaller total magnification (×500 or ×600), although they are usually detected at the ×1,000 total magnification obtained with the more traditional 100× oil immersion objective. Because people tend to scan blood films at different rates, it is important to examine a minimum number of fields, regardless of the time that it takes to perform this procedure. If something suspicious has been seen in the thick film, often the number of fields examined on the thin film may be considerably more than 200 to 300.

Diagnostic problems with the use of automated differential instruments have been reported (4). Both malaria and *Babesia* infections can be missed with these instruments, and therapy is therefore delayed. Because these instruments are not designed to detect intracellular blood parasites, any reliance on the automated systems for discrimination between uninfected erythrocytes and those infected with parasites may pose serious diagnostic problems, particularly in light infections.

In the preparation of a thick blood film, the greatest concentration of blood cells is in the center of the film. A search for parasitic organisms should be carried out initially at low magnification to detect microfilariae more readily. Examination of a thick film usually requires 5 to 10 min (approximately 100 oil immersion fields). The search for malarial organisms and trypanosomes is best done under oil immersion (total magnification, ×1,000). Close examination of the very periphery of the thick film may reveal intact erythrocytes; such cells, if infected, may prove useful in malaria diagnosis since the characteristic morphology necessary to identify the organisms to the species level is more easily seen.

Immunochromatographic Tests for Malaria

Immunochromatography relies on the migration of liquid across the surface of a nitrocellulose membrane. Using monoclonal antibodies prepared against a malaria antigen target that has been incorporated onto the strip of nitrocellulose, these tests are based on the capture of parasite antigen from peripheral blood. Currently, malaria antigens used for these rapid diagnostic tests are the histidine-rich protein-2 (HRP-2), parasite lactate dehydrogenase (pLDH), and *Plasmodium* aldolase (Table 11). These dipsticks offer the possibility of more rapid, nonmicroscopic methods for malaria diagnosis. The tests are easy to perform and interpret; however, there are a number of questions that remain concerning the relevant uses for this type of testing, especially considering the fact that they are not yet approved by the Food and Drug Administration (FDA).

Sensitivity remains a problem, particularly for nonimmune populations. Parasite densities of >100 parasites/μl (0.002% parasitemia) should be detected, and this is a reasonable target to expect from dipsticks for *P. falciparum* diagnosis. However, this level of sensitivity is at the lower end of the capability of most devices using capture methods for HRP-2 or pLDH. It is probably as good as the sensitivity that clinical laboratory staff in nonspecialized laboratories with limited exposure to malaria cases could expect to provide using microscopy diagnosis. One of the potential benefits would be for inexperienced evening staff personnel for whom the dipstick identification of a life-threatening parasitemia with *P. falciparum* could prevent a missed infection. However, a negative test could not be accepted and would require confirmation by microscopic examination of both thick and thin blood films for the detection of parasitemia below the present threshold of detection by these rapid tests. Although these tests are not yet approved for use in the United States, FDA approval may be possible in the future. The U.S. military has conducted FDA-approved trials because of possible use of the devices in the field.

Concentration Procedures

Buffy Coat Films

L. donovani, trypanosomes, and *Histoplasma capsulatum* (a fungus with intracellular elements resembling those of *L. donovani*) may occasionally be detected in the peripheral blood. The parasite or fungus is found in the large mononuclear cells that are found in the buffy coat (a layer of leukocytes resulting from centrifugation of whole citrated blood). The nuclear material stains dark red-purple, and the cytoplasm is light blue (*L. donovani*). *H. capsulatum* appears as a dot of nuclear material (dark red-purple) surrounded by a clear halo area. Trypanosomes in the peripheral blood also concentrate with the buffy coat cells.

Use alcohol-cleaned slides for preparation of the blood films. A microhematocrit tube can also be used; the tube is carefully scored and snapped at the buffy coat interface, and the leukocytes are prepared as a thin film. The tube can also be examined prior to removal of the buffy coat under low and high dry powers of the microscope. If trypanosomes are present, the motility may be observed in the buffy coat. Microfilaria motility would also be visible.

QBC Microhematocrit Centrifugation Method

Microhematocrit centrifugation with use of the QBC malaria tube (glass capillary tube and closely fitting plastic insert; QBC malaria blood tubes; Becton Dickinson, Tropical Disease Diagnostics, Sparks, Md.) has been used for the detection of blood parasites (4). At the end of centrifugation of 50 to 60 μl of capillary or venous blood (5 min in a QBC centrifuge, 14,387 $\times$ *g*), parasites or erythrocytes containing parasites are concentrated into a small, 1- to 2-mm region near the top of the erythrocyte column and are held close to the wall of the tube by the plastic float, thereby making them readily visible by microscopy. Tubes precoated with acridine orange provide a stain that induces fluorescence in the parasites. This method automatically prepares a concentrated smear that represents the distance between the float and the walls of the tube. Once the tube is placed into the plastic holder (Paraviewer) and immersion oil is applied onto the top of the hematocrit tube (no coverslip is necessary), the tube is examined with a 40$\times$ to 60$\times$ oil immersion objective (it must have a working distance of 0.3 mm or greater).

Although a malaria infection could be detected by this method (which is much more sensitive than the thick or the thin blood smear), appropriate thick and thin blood films need to be examined to accurately identify the species of the organism causing the infection.

Knott Concentration

The Knott concentration procedure is used primarily to detect the presence of microfilariae in the blood, especially when a light infection is suspected (4, 10). The disadvantage of the procedure is that the microfilariae are killed by the formalin and are therefore not seen as motile organisms.

Membrane Filtration Technique

The membrane filtration technique is highly efficient in demonstrating filarial infections when microfilaremias are of low density. This method is unsatisfactory for the isolation of *Mansonella perstans* microfilariae because of their small size. A 3-μm-pore-size filter can be used for recovery of this organism. Other filters with similar pore sizes are not as satisfactory as the Nuclepore filter (4).

Delafield's Hematoxylin

Some of the material that is obtained from the concentration procedures can be allowed to dry as thick and thin films and then stained with Delafield's hematoxylin, which will demonstrate greater nuclear detail as well as the microfilarial sheath, if present. In addition, fresh thick films of blood containing microfilariae can be stained by this hematoxylin technique (4).

Triple-Centrifugation Method for Trypanosomes

The triple-centrifugation procedure may be valuable in demonstrating the presence of trypanosomes in the peripheral blood when the parasitemia is light (4). After repeated centrifugation of the supernatant, the sediment is examined as a wet preparation or is stained as a thin blood film.

Plasmodium and *Babesia*

WILLIAM O. ROGERS

136

TAXONOMY

The agents of malaria and babesiosis are members of the phylum Apicomplexa, which includes protozoa characterized by the presence of an apical complex consisting of polar rings, conoid micronemes, rhoptries, subpellicular microtubules, and a small plastid related to a red algal chloroplast, the apicoplast. The phylum Apicomplexa is classified within the superphylum Alveolata, which includes apicomplexans, ciliates, and dinoflagellates. Although the exact evolutionary pathway is controversial, there is good evidence that the Alveolata acquired chloroplasts by secondary endosymbiosis of a red alga (21). While some dinoflagellates retain functional chloroplasts and are photosynthetic, in apicomplexans the apicoplast does not photosynthesize but is involved in lipid, heme, and isoprenoid synthesis (22, 81). All members of the phylum Apicomplexa are parasitic. The agents of malaria and babesiosis are classified within the orders Haemospororida and Piroplasmorida, respectively.

PLASMODIUM

Introduction

The genus *Plasmodium* includes at least 172 named species of intraerythrocytic parasites infecting a wide range of mammals, birds, reptiles, and amphibians (45). Four species, *P. falciparum, P. vivax, P. ovale,* and *P. malariae,* commonly infect humans. Rarely, *Plasmodium* species normally infecting nonhuman primates may infect humans. Recently, a large focus of naturally occurring infection of humans with *P. knowlesi,* a species normally infecting long-tailed macaques *(Macaca fascicularis),* was described in Malaysian Borneo (69).

Life Cycle

The *Plasmodium* life cycle (Fig. 1) begins with the injection of sporozoites by the bite of an infected mosquito. Sporozoites move rapidly to the liver, where they invade hepatocytes and undergo exoerythrocytic development for 7 to 10 days, leading to the formation of liver schizonts. Rupture of each liver schizont releases thousands of free merozoites into the peripheral blood, where they invade erythrocytes. In the erythrocyte the early trophozoites (rings) develop into mature trophozoites with an enlarged cytoplasm and an accumulation of hemozoin pigment. Nuclear and cytoplasmic division leads to production of the mature schizont, which ruptures, releasing merozoites and completing the erythrocytic cycle. A fraction of the merozoites undergo sexual differentiation into gametocytes, which undergo fertilization and zygote formation following ingestion with a mosquito blood meal. Fertilized gametes develop into ookinetes, which penetrate the intestinal lining and develop into oocysts on the extraluminal wall of the intestine. Oocysts rupture, releasing sporozoites, which migrate to the salivary glands to complete the life cycle.

There are important species-specific variations in the life cycle. The late trophozoites and schizonts of *P. falciparum* insert an antigenically variable, high-molecular-weight protein in the erythrocyte membrane, which causes the infected erythrocyte to adhere to the vascular endothelium (7). Thus, these stages of the life cycle do not circulate in the peripheral blood. *P. vivax* and *P. ovale* may be associated with relapse from the liver months to years after clearance of the initial blood stage parasitemia. Sporozoites of these species may enter hepatocytes and complete exoerythrocytic stage development normally, or they may arrest development in the liver as hypnozoites, which subsequently develop into mature liver schizonts, leading to relapse of parasitemia months to a few years later.

Epidemiology

Malaria imposes an enormous burden of illness and substantial mortality on the tropical world and in many subtropical regions. There are an estimated 515 (330 to 660) million clinical episodes of malaria due to *Plasmodium falciparum,* the most common cause of malaria (71), and 1.5 to 2.7 million deaths due to malaria each year (89). Transmission depends on the presence and abundance of an effective anopheline mosquito vector and a reservoir of infected humans. Transmission cannot occur at temperatures outside the range from 16 to 33°C or above 2,000 m of altitude, because development in the mosquito cannot take place. The intensity of transmission in any location depends on temperature, rainfall, the abundance and behavior of the local anopheline vector, and the existence of a reservoir of infected humans. The level of endemicity of malaria is classified based on the percentage of children ages 2 to 9 with splenomegaly or patent parasitemia as follows: hypoendemic, 0 to 10%; mesoendemic, 10 to 50%; hyperendemic, 50 to 75%; holoendemic, >75%. In areas where malaria is holoendemic, such as much of sub-Saharan Africa, the most

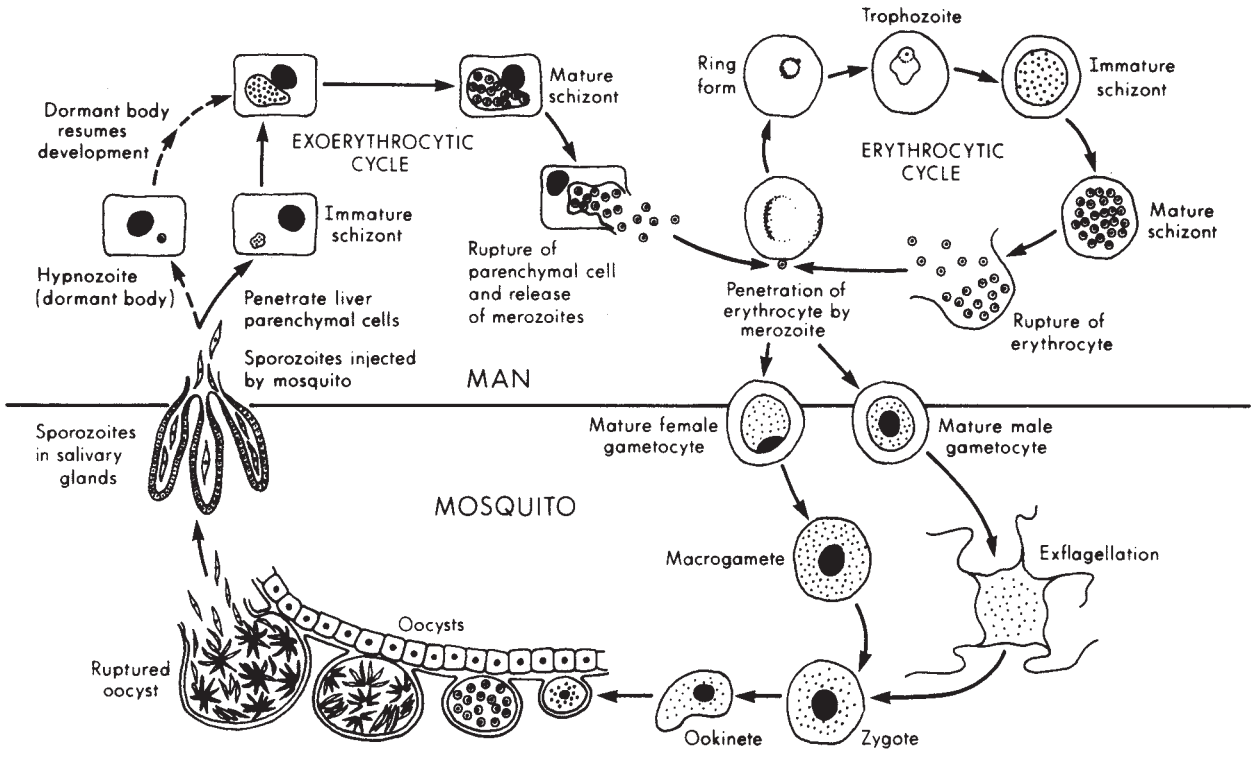

FIGURE 1 Life cycle of the malaria parasite. (Reproduced with permission from Blackwell Publishing [41a].)

severe morbidity and mortality occur in early childhood and the majority of deaths are due to severe anemia. Individuals surviving through early childhood develop partial clinical immunity and are less likely to die from malaria. In areas of lesser endemicity, particularly where transmission is seasonal or unstable, development of clinical immunity is less effective, symptomatic and severe malaria occurs at all ages, and cerebral malaria is a common manifestation of severe infection.

Although malaria was eradicated from North America by the mid-20th century, competent vector species of anopheline mosquito are widely present, and small, focal outbreaks of malaria can occur when a gametocytemic immigrant or traveler serves as a reservoir of infection (9–11, 43, 49, 75).

Clinical Disease

The classic clinical manifestation of malaria is the febrile paroxysm, which begins with a chill and rigors, leading to an abrupt fever lasting 1 to 2 h, and finally resolves with profuse sweating and a return to normal temperature. The typical periodicity of these paroxysms, approximately 48 h in disease caused by *P. falciparum, P. vivax,* and *P. ovale,* and 72 h in that caused by *P. malariae,* is not always seen, particularly in nonimmune individuals. The fever is frequently accompanied or preceded by headache, myalgias, and malaise. Splenomegaly and anemia are common. Gastrointestinal complaints, nausea, vomiting, and diarrhea, which may be bloody, are also not uncommon and should not distract the clinician from the diagnosis of malaria. Infection with *P. falciparum* may be complicated by various forms of severe malaria. Table 1 shows the World Health Organization criteria for severe malaria (88). Severe malaria due to *P. falciparum* may develop rapidly in a patient who initially presents with mild symptoms and a low parasitemia. It is therefore critical to make the diagnosis of *P. falciparum* quickly.

P. vivax and *P. ovale* preferentially invade reticulocytes and therefore only very rarely cause parasitemias greater than 2%. They may relapse from the liver following successful therapy of blood stage infection and must therefore be treated with primaquine to eradicate hypnozoites in the liver. *P. malariae* preferentially infects older erythrocytes and may cause chronic, asymptomatic parasitemia lasting for many years. Proteinuria is a common finding in *P. malariae* infection and may progress to the nephrotic syndrome in children.

Diagnosis

Specimen Collection and Patient History

Because *P. falciparum* infection can progress rapidly to severe malaria, the diagnosis of malaria is an urgent matter and all requests for malaria diagnosis should be handled on a STAT basis. Although it is important that thick smears dry completely before staining, drying can be accomplished at 37°C in 15 to 30 min; laboratory protocols should not specify long periods for drying at room temperature (e.g., 4 h to overnight), as this may unduly delay diagnosis. Ideally, blood for preparation of peripheral smears may be collected by finger prick. If other tests are to be performed, blood may be collected by venipuncture, using EDTA as the anticoagulant. Use of heparin as an anticoagulant may lead to some morphological distortion. Smears should be prepared and stained within an hour of drawing the specimen. Otherwise, confusing alterations in morphology may occur. For example, *P. falciparum* may continue to develop within the stored blood to the mature trophozoite stage, which is normally not

TABLE 1 Classification of severe malaria

Category	Criteria
Cerebral malaria	Unrousable coma or Blantyre Coma Score of 3 or less
	Coma persists for more than 30 min after any seizures have passed
	Normal CSF findings
	No other pathological process accounts for coma
Generalized convulsions	Generalized convulsions lasting more than 30 min
	Generalized convulsions more than twice in 24 h in spite of cooling
Severe anemia	Hemoglobin, <5 mg/dl
Respiratory distress	Presence of any of the following: alar flaring, intercostal retractions, use of accessory muscles of respiration, Kussmaul's respiration
Hypoglycemia	Blood glucose < 40 mg/dl
Circulatory collapse	Systolic blood pressure < 80 mmHg (adults) or < 50 mmHg (children)
Renal failure	Urine output < 12 ml/kg/24 h, or serum creatinine > 3.0 mg/dl
Malarial hemoglobinuria	Hemoglobinuria by urine dipstick in patient with malaria
Other	Hyperparasitemia (>100,000 parasites/μl)
	Jaundice (serum bilirubin, ≥3.0 mg/dl)
	Hyperpyrexia (rectal temperature, ≥40°C)
	Impaired consciousness (rousable)

seen in peripheral smears, leading to misidentification of the species. Diagnostic malaria smears should always be prepared, stained, and read on a STAT basis. However, if a laboratory is to prepare large numbers of slides from a single patient for later teaching purposes, it is acceptable to prepare the smears immediately but to delay staining for up to a few days. Unstained slides cannot be stored indefinitely, however, as the morphology degrades over time. It is therefore not possible to maintain a supply of unstained, malaria-positive slides to use for quality control of the Giemsa stain; adequate staining of the normal blood elements in the smear is a sufficient quality control marker. Blood containing malaria parasites is infectious, and universal precautions should be strictly followed.

Requests for malaria smears should include several important pieces of historical information. If the following historical information is not submitted with the request for malaria smears, the laboratory must be proactive in obtaining the history. (i) The patient's travel history and date of return to or arrival in the United States can suggest the likelihood of infection and the possible species involved. The interval between exposure to an infective bite and development of symptoms is typically 9 to 14 days for *P. falciparum, P. vivax,* and *P. ovale* and up to 40 days for *P. malariae.* Because there may be no primary attack in *P. vivax* or *P. ovale,* if all sporozoites that invaded hepatocytes transformed into hypnozoites, the first symptoms may occur months to as many as 3 years after exposure. There have been extremely rare reports of *P. falciparum* malaria first being detected up to 24 months after exposure (42), but in general, malaria appearing more than 1 month after return from an area of endemicity is relatively unlikely to be due to *P. falciparum,* unless the patient has received antimalarial agents which might have suppressed parasitemia. (ii) A history of prophylaxis or treatment for malaria may result in low parasitemia. Since currently available prophylactic regimens are difficult to comply with, and since drug resistance is common in *P. falciparum,* a history of prophylaxis should never be used to exclude malaria from the differential diagnosis. (iii) A history of transfusions or shared needles may suggest direct person-to-person transmission, although cases of transfusion-related malaria are extremely rare in the United States (53). (iv) A history of malaria in the patient suggests the possibility of relapse or recrudescence. (v) Knowledge of the periodicity of the fever pattern and the time in relation to a paroxysm when the specimen was obtained is helpful because in a regularly periodic *P. falciparum* infection the circulating parasitemia can be very low and difficult to detect between paroxysms. Regardless of the presence or absence of a fever pattern, blood should be taken immediately for an initial malaria smear when the patient presents.

Blood Film Examination

Detection and identification of the organisms are performed by examination of Giemsa-stained thick and thin blood films. Examination of thick films is the "gold standard" for detection of organisms because of the relatively large volume of blood (10 μl) that can be examined directly. Hyposmotic lysis of the erythrocytes during staining with Giemsa stain deposits the free parasites onto a background of red cell ghosts, white cell nuclei, and platelets. Approximately 20-fold more blood is examined in each high-power (1,000×) field examined than in a thin film. Although substantial training and practice are required to develop proficiency at distinguishing the free parasites from platelets, leukocyte granules, and other debris present in thick films, thick-film examination is substantially more sensitive than thin-film examination. Early in infection, or following relapse or partial treatment, patients may be symptomatic with parasitemias low enough that they require thick smear examination for detection. While it is often possible to identify parasites to the species level in thick films, thin films are the gold standard for species identification. Although fewer parasites are present in thin films, methanol fixation prior to staining preserves erythrocyte morphology, allowing evaluation of infected erythrocyte size and the position of organisms within the erythrocytes. In difficult cases, therefore, examination of thin films may be necessary to make a specific identification. Morphology is best preserved in thin areas of the smear near the feathered edge; scanning of the thicker areas of the slide may facilitate detection of rare gametocytes or schizonts but must not replace careful examination of the thick film. Smears should be examined at length under oil immersion; a negative report should not be rendered until 200 oil immersion fields of a thick film have been examined. A single set of negative smears does not

exclude malaria. Additional specimens should be examined at 12-h intervals for the subsequent 36 h.

The morphology of the four species of *Plasmodium* that commonly infect humans in thin films is reviewed in the literature (25) and is demonstrated in Fig. 2 to 6 and summarized in Table 2. The appearance of *P. falciparum* in thick films is demonstrated in Fig. 7. When abundant organisms encompassing several life cycle stages are present for examination, species identification is not difficult. A high parasitemia consisting only of ring forms suggests *P. falciparum*, even if, as is commonly the case, no gametocytes are found. In samples containing only rare early trophozoites, a species identification may not be possible. Ring morphology is quite variable; early trophozoites of *P. falciparum* may mimic early "band" forms of *P. malariae* or early ameboid trophozoites of *P. vivax*. It is important not to exclude *P. falciparum* solely on the basis

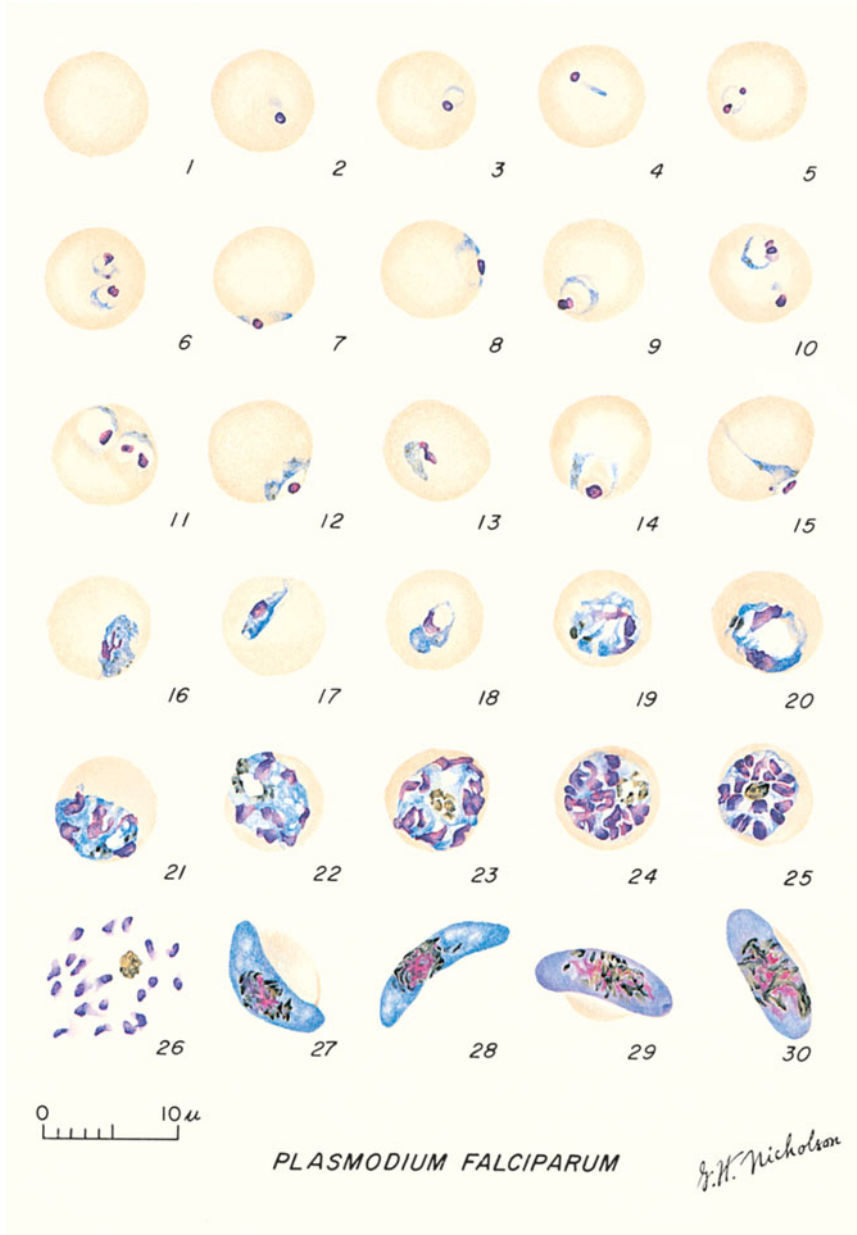

FIGURE 2 *P. falciparum:* morphology of successive developmental stages in Giemsa-stained thin blood smears. The cytoplasm of the rings is normally paler than shown in this figure: color intensity has been increased for purposes of illustration. Rings and gametocytes are found in peripheral blood smears; other stages occur in infected erythrocytes but are sequestered in the capillaries and venules of internal organs and are rarely found in the periphery. Drawings: 1, normal erythrocyte; 2 to 11, young trophozoites (rings); 12 to 15, growing trophozoites; 16 to 18, mature trophozoites; 19 to 22, immature schizonts; 23 to 26, nearly mature and mature schizonts; 27 and 28, mature macrogametocytes: 29 and 30, mature microgametocytes. (Reproduced from reference 13a.)

of ring morphology. Finally, the possibility of mixed infections should be borne in mind; examination of the smear should not be ended prematurely simply because one species of *Plasmodium* has been identified. *P. knowlesi* infections in humans are not morphologically distinguishable from *P. malariae* infections; this difficulty is not serious, however, as *P. knowlesi* is sensitive to chloroquine and does not cause severe malaria in humans.

Although many North American clinicians treat all malaria patients with regimens designed to cover drug-resistant *P. falciparum*, species-specific identification of *Plasmodium* spp. is clinically important for several reasons. *P. falciparum* should be identified because it is both more clinically aggressive and more likely to be multiply drug resistant than the other species. *P. vivax* and *P. ovale* should be identified because radical cure of these infections requires supplemental treatment with primaquine to eliminate dormant hypnozoites in the liver. Primaquine may cause hemolytic anemia in some patients with G6PD deficiency; correct species identification prevents its unnecessary use in *P. falciparum* or *P. malariae* infection.

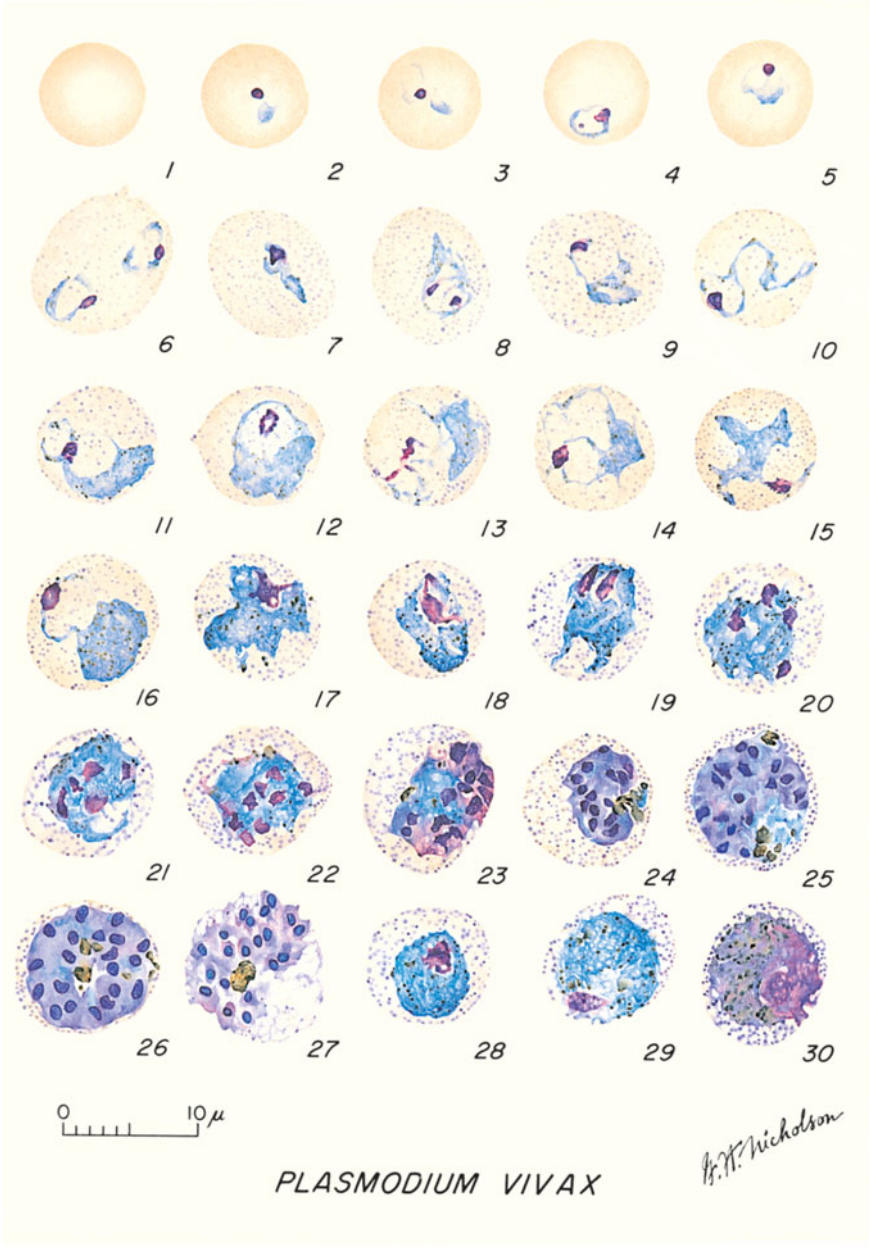

FIGURE 3 *P. vivax:* morphology of successive developmental stages in Giemsa-stained thin blood smears. The cytoplasm of the developing trophozoites and immature schizonts is normally paler than shown in this figure: color intensity has been increased for purposes of illustration. Drawings: 1, normal erythrocyte; 2 to 5, young trophozoites (rings); 6 to 16, growing trophozoites; 17 and 18, mature trophozoites; 19 to 21, young immature schizonts; 22 and 23, older immature schizonts; 24 to 27, nearly mature and mature schizonts; 28 and 29, nearly mature and mature macrogametocytes; 30, mature microgametocyte. (Reproduced from reference 13a.)

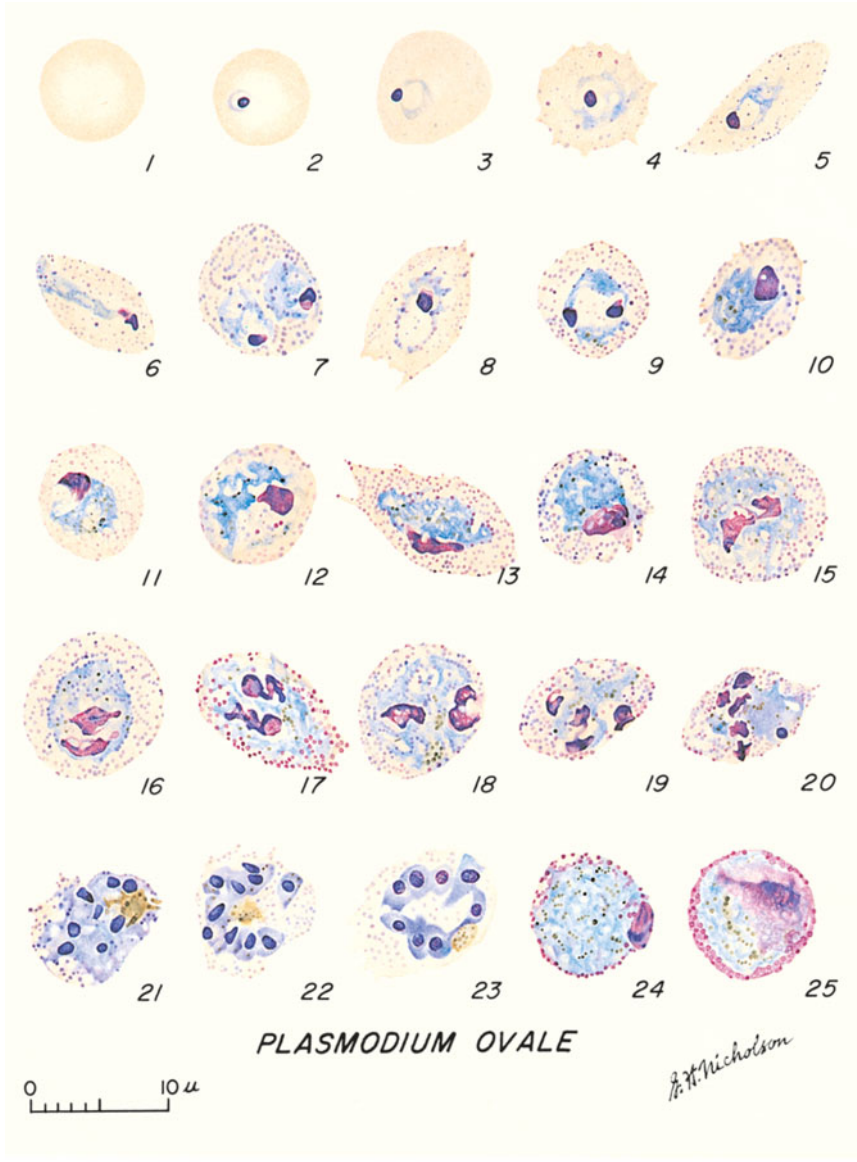

FIGURE 4 *P. ovale:* morphology of successive developmental stages in Giemsa-stained thin blood smears. The Schüffner's dots (James' stippling) are normally larger than shown here. Drawings: 1, normal erythrocyte; 2 to 5, young trophozoites (rings); 6 to 12, growing trophozoites; 13 to 15, mature trophozoites; 16 to 22, immature schizonts; 23, mature schizont; 24, mature macrogametocyte; 25, mature microgametocyte. (Reproduced from reference 13a.)

Alternative Diagnostic Methods

A number of new approaches to detection of malaria parasites have been described, including staining with acridine orange (AO) (63), PCR (4, 20), and antigen detection (14, 68). These and other alternative approaches have been recently reviewed (51) and are summarized in Table 3.

Thin or thick blood films can be stained with AO in place of Giemsa stain. AO is a fluorescent dye that binds to DNA; since mature erythrocytes do not contain DNA, the brightly staining parasite nuclei stand out clearly against a background of uninfected erythrocytes. Nonetheless, particularly in thick films stained with AO, it may be difficult to detect parasite nuclei in the presence of leukocyte nuclei and erythrocytes containing Howell-Jolly bodies. In addition, since it may be difficult to evaluate erythrocyte morphology, species identification can be difficult. The method can be performed with a fluorescence microscope or a standard microscope with an excitation filter (470 to 490 nm) mounted in the transmitted light path and a separate filter (590 nm) mounted in the ocular. A number of comparisons of AO staining to standard malaria microscopy have been recently reviewed (40); sensitivity and specificity were adequate in most studies. The most frequently cited advantage of AO staining was the speed with which slides could be prepared and read. An alternative version of the AO technique, designated Quantitative Buffy Coat, is available, in which whole blood is stained with AO and spun in a microcentrifuge tube; the resulting buffy coat is examined directly within the microcentrifuge tube by using a

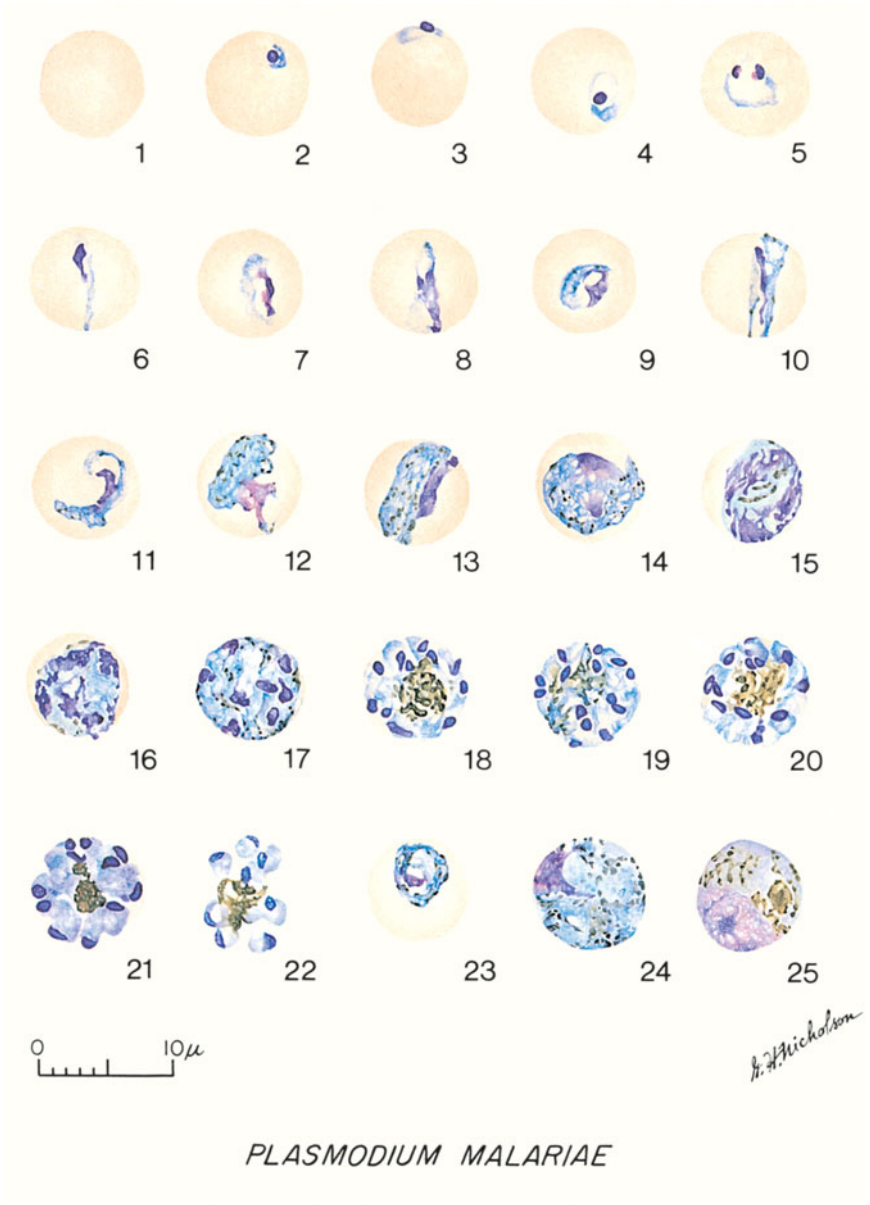

FIGURE 5 *P. malariae:* morphology of successive developmental stages in Giemsa-stained thin blood smears. Drawings: 1, normal erythrocyte; 2 to 5, young trophozoites (rings); 6 to 11, growing trophozoites; 12 and 13, nearly mature and mature trophozoites; 14 to 20, immature schizonts; 21 and 22, mature schizonts; 23, developing gametocyte; 24, mature macrogametocyte; 25, mature microgametocyte. fluorescence microscope fitted with a specialized long-focal-length objective.

The immunochromatographic rapid dipstick antigen detection assays are potentially very useful, both in areas where malaria is endemic and trained laboratory personnel are scarce and in the developed world, where laboratory personnel may be inexperienced in malaria diagnosis. Rapid immunochromatographic methods for malaria diagnosis have been developed based on several *Plasmodium* antigens. Histidine-rich protein 2 (HRP-2) is a *P. falciparum* protein with roles in heme polymerization and actin binding and is localized in the infected erythrocyte cytoplasm. Dipsticks for diagnosis of *P. falciparum* based on antigen detection of HRP-2 have been widely tested and found to have sensitivity and specificity close to that of expert microscopy (6, 44, 77, 78, 86) and probably superior to that of routine microscopy. These HRP-2-based tests are not appropriate for monitoring therapy, as they may remain positive for up to 28 days after successful therapy (36, 68). HRP-2 is unique to *P. falciparum;* immunochromatographic tests based on HRP-2 cannot detect infection due to the other *Plasmodium* spp. Aldolase is an enzyme within the glycolytic pathway and is found in

TABLE 2 Comparative morphology of *Plasmodium* spp. in Giemsa-stained thin smears

Characteristic	*P. falciparum*	*P. vivax*	*P. ovale*	*P. malariae*
Size and shape of infected erythrocytes	Normal size and shape	Enlarged up to twofold; may be oval	Normal to enlarged, frequently oval, may be fimbriated	Small to normal size, normal shape
Stippling (best seen with Giemsa stain pH 7.0–7.2)	Occasional Maurer's dots, less numerous than Schüffner's	Schüffner's dots usually present, except in rings	James' stippling, darker than Schüffner's present in all stages, including rings	Ziemann's dots, rarely seen; requires deliberate overstaining
Stages seen in peripheral blood	Rings and gametocytes	All	All	All
Multiply infected erythrocytes	Common	Occasional	Occasional	Rare
Early trophozoites	Delicate ring, frequently with two small chromatin dots. Often at edge of erythrocyte (appliqué form)	Ring up to 1/3 diameter of erythrocyte; larger chromatin dot than *P. falciparum*	Similar to *P. vivax*	Smaller than *P. vivax;* otherwise similar
Mature trophozoites	Not seen in peripheral blood	Ameboid shape, fine golden-brown pigment	Similar to *P. vivax* except less ameboid, pigment darker brown	Compact cytoplasm, oval, round, or band-shaped, dark brown pigment
Schizonts	Not seen in peripheral blood	12–24 merozoites	8–12 merozoites	6–12 merozoites often radially arranged around central pigment ("daisy-head" schizont)
Gametocytes	Crescent or "banana" shaped	Round to slightly oval	Round to slightly oval	Round to slightly oval
Most characteristic findings	Absence of mature trophozoites and schizonts; normal size of infected erythrocytes; multiple infections; appliqué forms; "banana"-shaped gametocytes	Enlarged infected erythrocytes; Schüffner's dots frequently present; ameboid trophozoite; 12–24 merozoites in each schizont	Normal to enlarged, oval or fimbriated infected erythrocytes; James' stippling may be seen in rings; schizonts with 8–12 merozoites	Normal size of infected erythrocytes; no stippling; "band" trophozoite; "daisy head" schizont with 6–12 merozoites

all species of *Plasmodium*. Monoclonal antibodies raised against *Plasmodium* aldolase recognize aldolase from all *Plasmodium* species which infect humans. Recently, dipsticks combining antibodies against HRP-2 and aldolase which allow detection of *P. falciparum* and non-*P. falciparum* infections have been devised (19, 78). An alternative dipstick test uses monoclonal antibodies to capture parasite lactate dehydrogenase (LDH) (61). *P. falciparum* species-specific and *Plasmodium* genus-specific anti-LDH antibodies distinguish between *P. falciparum* and non-*P. falciparum* infections. Preliminary studies suggest that the LDH-based assay may have useful sensitivity and specificity (24, 37, 56). Both HRP-2- and LDH-based assays lose sensitivity when parasitemias are low, i.e., <50 to 100/mm^3, and no dipstick assay is yet licensed for clinical diagnostic use in the United States. While such assays will not soon replace microscopy, they may shortly become an important adjunct in malaria diagnosis. It should be pointed out that automated hematology instrumentation does not reliably detect malaria parasites. Finally, it is important that negative results obtained by the alternative diagnostics methods be confirmed by repeated thick-film examination. As of 2005, thick-film examination remains the gold standard for malaria diagnosis.

Serology

Indirect fluorescent-antibody tests using antigens prepared from the four species of *Plasmodium* that infect humans have been described (74). However, serologic testing is not a reliable method for identifying the infecting species, because of cross-reactions among the four species, and is not useful in clinical diagnosis of malaria because antibodies may be absent in an acute attack and because their presence may reflect past rather than current infection. It has a role in the investigation of transfusion malaria, where it may be used to determine which of a number of potential donors may have been the source of a transfusion-associated case of malaria, and in epidemiological studies, to determine the prevalence of exposure to malaria in a population. Assistance in serological evaluation of suspected transfusion malaria can be obtained from the Malaria Epidemiology Branch, Division of Parasitic Diseases, Centers for Disease Control and Prevention, Atlanta, Ga. (phone: 770-488-7788).

Interpretation and Reporting of Results

A positive finding of malaria parasites is a critical result, which must be reported immediately to the clinician. The report should include the species identification, if possible. When identification to this level is not possible, an explicit

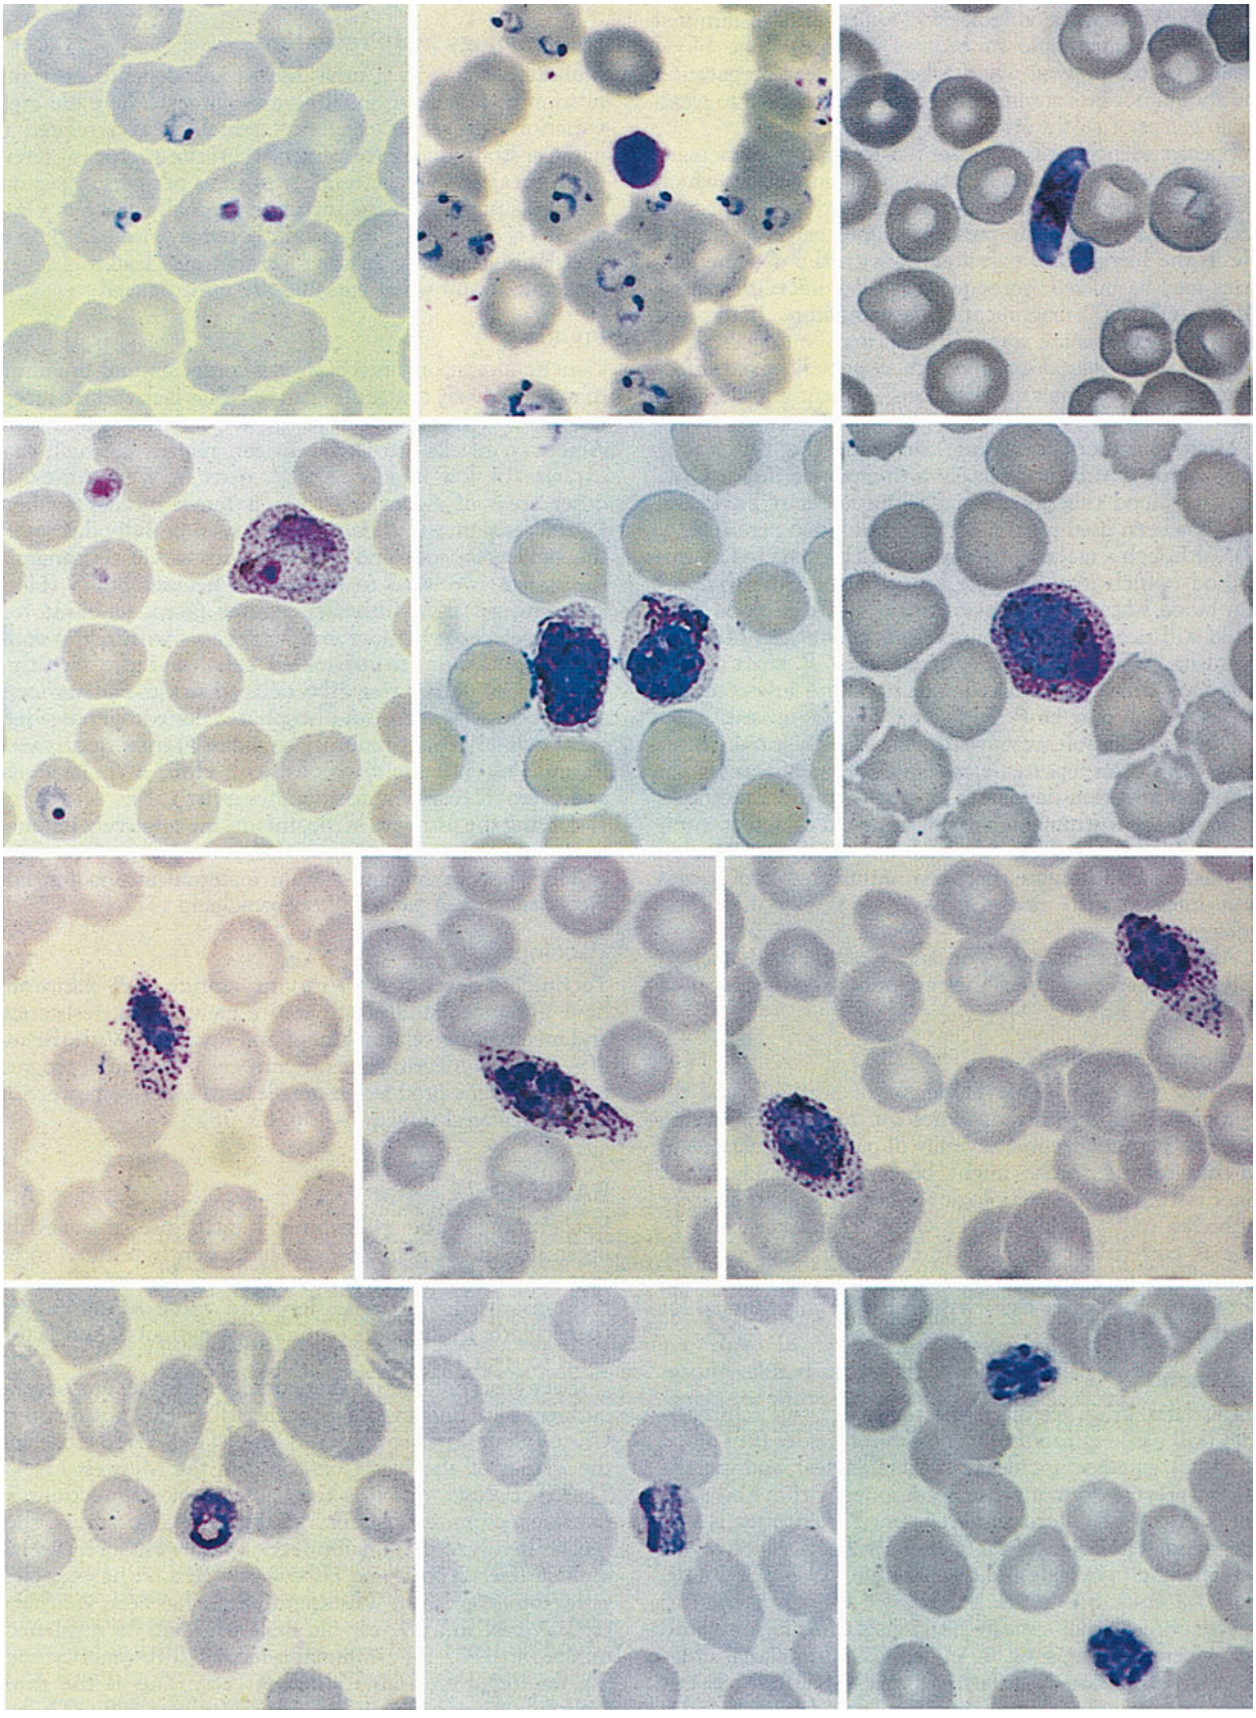

FIGURE 6 Photomicrographs of *Plasmodium* species in thin blood films (Giemsa stain; magnification, ×1,000). First row: *P. falciparum.* (Left) Two ring trophozoites. Note also two platelets overlying erythrocytes. (Center) Abundant rings in erythrocytes of a patient with *P. falciparum* hyperparasitemia. (Right) Banana-shaped gametocyte. Second row: *P. vivax.* (Left) Developing trophozoite in enlarged erythrocyte with Schüffner's dots; ring trophozoite in lower left corner. (Center) Mature and immature schizonts, left to right. (Right) Macrogametocyte. Third row: *P. ovale.* (Left) Developing trophozoite in enlarged, elongated erythrocyte with Schüffner's dots. (Center) Mature schizont. (Right) Schizont in upper right, macrogametocyte in lower left. Fourth row: (Left) Trophozoite in normal-size erythrocyte. (Center) Band trophozoite. (Right) Mature schizonts; note peripheral placement of nuclei around central hemozoin pigment granule. (Photomicrographs from Lawrence Ash; used with permission.)

statement that *P. falciparum* cannot be excluded is advisable. Because patients with high parasitemias (>3 to 5%) require intensive therapy, quantification of parasitemia is useful. This is typically performed after species identification and may be variously expressed as percent parasitemia (parasites/100 erythrocytes), number of parasites per 200 leukocytes, or number of parasites/mm^3. At high parasitemias, the direct counting of parasites and erythrocytes in a thin film will provide an accurate parasitemia. In low parasitemias and, of course, in thick smears, it is necessary to count the number of parasites/200 leukocytes and to calculate the percent parasitemia or the parasite density based on the patient's complete blood count. A negative report may be accompanied by a reminder that a single negative set of smears does not exclude the diagnosis of malaria. Serial malaria smears may be performed to monitor therapy. Parasitemia normally resolves within 2 to 3 days following initiation of treatment with a drug to which the patient's strain is susceptible. Continued parasitemia at day 7 or failure of the parasitemia to decrease by 75% within the first 48 h following treatment is an indication of drug resistance. However, gametocytes may continue to circulate for up to 2 weeks after successful cure, and their presence is not an indication that treatment has failed.

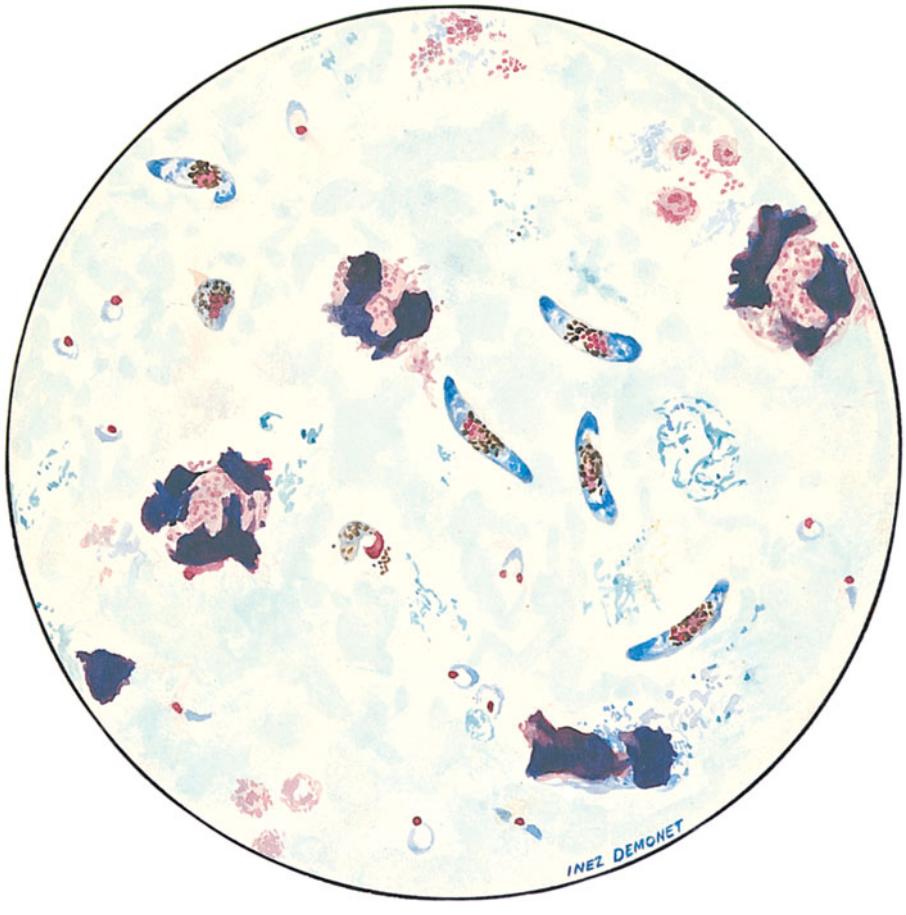

FIGURE 7 *P. falciparum:* morphology in Giemsa-stained thick blood smears. There are multiple small trophozoites (rings) and banana (crescent)-shaped gametocytes. Two gametocytes with variant shapes are present at 10 o'clock. Outside areas of endemicity, parasites on a thick film are normally fewer than in this figure. (Reproduced from reference 85.)

TABLE 3 Alternative methods for diagnosis of malaria

Principle	Method	Comments	Advantages	Disadvantages	Reference(s)
Giemsa stain	Thick film	Gold standard for detection	Screens large volume of blood	Species identification sometimes difficult	16
	Thin film	Traditional method for species identification	Preserves morphology of parasite in erythrocyte	Less sensitive than thick film examination	25
Fluorescent DNA/RNA stains	Acridine orange-stained films	Requires fluorescent microscope	Good sensitivity	May be difficult to read	27, 47
	Centrifugation/AO (QBC)[a]	Requires fluorescent microscope	Rapid	Species identification difficult	46, 63, 72
	Flow cytometry		Automated	Poor sensitivity	80
Hemozoin detection	Dark-field microscopy	Abundant pigment in macrophages suggests poor prognosis		Poor sensitivity	38
	Automated blood analyzers	Detection in unsuspected cases	Automated	Poor sensitivity	31
Nucleic acid detection	DNA/RNA hybridization	First nucleic acid-based method		Poor sensitivity, technically difficult	5, 23
	PCR	Care required to prevent contamination/ false-positive results	Sensitivity comparable to or better than thick film; species identification; best approach to detect mixed infections	Expensive, lengthy procedure	20, 70, 76, 83
Antigen detection	Detection of HRP-2 (Parasight-F, ICT Malaria Pf, PATH Falciparum Malaria IC Test)	Immunochromatographic dipstick, *P. falciparum* only	Convenient, rapid, minimal training required	Expensive, cannot be used to monitor therapy, detects only *P. falciparum*	6, 44, 77, 78, 86
	Detection of HRP-2 and aldolase (ICT Pf/Pv, Binax Now ICT Malaria Test)	Immunochromatographic dipstick, *P. falciparum* and non-*P. falciparum*	Convenient, rapid, minimal training required	Expensive, cannot be used to monitor therapy	19, 78, 87
	Detection of parasite LDH (OptiMAL)	Immunochromatographic dipstick, *P. falciparum* and non-*P. falciparum*	Convenient, rapid, minimal training required	Expensive	24, 37, 56, 61

[a] QBC, Quantitative Buffy Coat techinique.

Special Considerations in Areas of Intense Malaria Transmission

For returning travelers or residents of areas of low to moderate malaria transmission, it is generally safe to conclude that a positive malaria smear confirms the diagnosis of clinical malaria. In areas of intense transmission, however, such as much of sub-Saharan Africa or some areas in Southeast Asia, diagnosis of clinical malaria on the basis of a positive peripheral smear is difficult. In such areas both nonmalarial fevers and asymptomatic parasitemia are common; indeed, the large majority of individuals may harbor *P. falciparum.* Therefore, fever due to nonmalarial causes may frequently coincide with parasitemia. At a population level it is possible to estimate the fraction of fevers attributable to malaria (29), but this does not help in individual diagnosis. Since high parasitemias are more likely to be associated with fever than low parasitemias, it is tempting to create definitions of clinical malaria based on fever and parasitemia above a specified cutoff. Unfortunately, in many areas of endemicity no cutoff is satisfactory. For example, in Northern Ghana the pretest probability that a child with fever has clinical malaria is 60%. Finding a positive malaria smear raises that probability only to 70%. To obtain a posttest probability of 80% that the fever is due to malaria requires a parasitemia threshold of 20,000 parasites/μl and leads to a sensitivity in the clinical definition of only 55% (64a). In such situations it may be entirely reasonable not to perform a malaria smear and to treat all fevers as malaria empirically. Whether or not it is

cost-effective to attempt to make a laboratory diagnosis of malaria in a given area of endemicity depends on a complex interaction between the local attributable fraction of fevers due to malaria, the cost and side effect profile of recommended first-line antimalarial agents, and the cost and accuracy of available diagnostic methods.

Treatment and Prevention

Prophylaxis and therapy of malaria have been recently reviewed (17, 18, 48). *P. falciparum* resistant to chloroquine is present in all areas of endemicity with the exception of Central America and the Caribbean. In addition, resistance to other drugs including sulfadoxine-pyramethamine (Fansidar) and mefloquine is present in many areas and is expanding rapidly. Distribution of drug resistance in *P. falciparum* as of June 2005 is summarized in Table 4. Current information on the distribution of drug-resistant *P. falciparum* can be obtained from the Centers for Disease Control and Prevention, Malaria Hotline, in Atlanta, Ga. (phone: 770-488-7788). In vitro susceptibility testing of *P. falciparum* has been described (64) but is not available for clinical use. The combinations of quinine or quinidine and doxycycline or of atovaquone and proguanil remain effective against most strains of *P. falciparum.* In Africa, the combination of an artemisinin derivative with a variety of antimalarials including lumefantrine, sulfadoxine-pyramethamine, or amodiaquine has shown promising results and is replacing chloroquine as the first-line therapy for outpatient malaria recommended by many African Ministries of Health. None of the artemisinin derivatives, however, is licensed in the United States. Therapy of chloroquine-resistant *P. falciparum* is a complex and rapidly evolving field, and consultation with an infectious diseases specialist is essential. Chloroquine-resistant *P. vivax* emerged in a few areas in the 1990s (3, 54, 60, 67) and has continued to spread (2). More-detailed information on specific antimalarial agents and on specialized in vitro susceptibility test methods can be found in chapters 150 and 152, respectively.

Drug and Vaccine Development

In the face of rapidly developing drug resistance, development of new antimalarial drugs and, ultimately, an effective malaria vaccine is a high priority. The sequencing of the *P. falciparum* genome (26) and subsequent characterization of the transcriptome and proteome (30) have helped identify a number of potential new drug targets. Even before completion of the *P. falciparum* genome sequence, data mining of the unassembled sequence data led to identification of inhibitors of an isoprenoid biosynthesis pathway with in vitro and in vivo activity against *Plasmodium* (39). Since completion of the genome sequence, analysis of metabolic pathways has led to identification of additional drug targets in several pathways including serine proteases involved in hemoglobin degradation in the food vacuole; protein, DNA, and fatty acid synthesis in the apicoplast; and electron transport in the mitochondrion. These and other advances in antimalarial drug development have been recently reviewed (65, 90).

There remain many difficult obstacles to overcome in malaria vaccine development. *P. falciparum* is a complex, multistage pathogen that uses a variety of strategies to evade the human immune response, including stage-specific antigen expression, antigenic variation, and widespread allelic diversity of immune targets. Nonetheless, two lines of evidence suggest that a malaria vaccine may be attainable. First, residents of areas of endemicity who do not succumb to malaria in early childhood develop a limited, clinical immunity that greatly reduces their risk of severe disease and death when they become infected. This immunity is largely mediated by antibodies directed against antigens expressed on the merozoite stage (66). Second, human volunteers immunized with radiation-attenuated sporozoites develop solid sterile immunity to sporozoite challenge (13). Immunity induced with irradiated sporozoites is apparently mediated by T-cell responses directed against infected hepatocytes (15). A number of candidate malaria vaccines have been tested in humans including synthetic peptide vaccines (55, 57, 79), recombinant viral particle vaccines (73), DNA vaccines (82), and heterologous prime-boost combinations of DNA and recombinant viral vaccines (52). Although these vaccines have induced immune responses and, in some cases, short-term, partial protection (1, 73), much work remains before an effective vaccine can be deployed.

BABESIA

Introduction

The genus *Babesia* includes approximately 100 species that are transmitted by ticks of the genus *Ixodes* and infect a variety of wild and domestic animals (35). The *Babesia* species are grouped loosely into small *Babesia* (trophozoites measuring 1.0 to 2.5 μm), including *B. microti* and *B. gibsoni,* and the large *Babesia* (trophozoites measuring 2.5 to 5.0 μm), including *B. bovis* and *B. canis.* This morphological division is generally supported by molecular phylogenetic analysis, except that *B. divergens,* which has small trophozoites, groups with the large babesias (35). In the United States, *B. microti* and several recently described, unnamed species, WA1 (62), CA1 (58), and MO1 (32), infect humans. In Europe, the bovine parasites *B. bovis* and *B. divergens* have been isolated from human

TABLE 4 Distribution of drug-resistant *P. falciparum*[a]

Region	Chloroquine resistance	Resistance to second line antimalarials
Caribbean, Central America	No	No
South America	Yes	Sulfadoxine-pyramethamine (Amazon Basin), mefloquine (Amazon Basin)
West Africa	Yes	Sulfadoxine-pyramethamine, mefloquine
East Africa	Yes	Sulfadoxine-pyramethamine
Central Asia	Yes	Sulfadoxine-pyramethamine
Southeast Asia	Yes	Sulfadoxine-pyramethamine, mefloquine, halofantrine, quinine

[a] Based on information from U.S. Centers for Disease Control and Prevention (http://www.cdc.gov/ncidod/emergplan/box23.htm) as of 11 August 2001 and updated with information from the World Health Organization Roll Back Malaria Department (http://www.who.int/malaria/resistance.html) as of 24 June 2005.

patients. These geographic ranges are not strict; recently, infection by *B. microti* has been reported from both Europe (33, 50) and Japan (84), and infection with a *B. divergens*-like organism was reported in the northwest United States (34).

Life Cycle

While the life cycle of *Babesia* is roughly similar to that of *Plasmodium,* there are a number of important differences (Fig. 8). First, no exoerythrocytic stage has been described for *Babesia;* sporozoites injected by the bite of an infected tick invade erythrocytes directly. Within the erythrocyte, the trophozoites reproduce by binary fission rather than schizogony. While gametocytes presumably exist, they have not been morphologically distinguished from trophozoites. As in *Plasmodium,* fertilization of gametes occurs in the insect intestine within the blood meal and the zygotes pass through the intestinal epithelium to the hemolymph. In *Plasmodium,* sporogony takes place in oocysts attached to the transluminal aspect of the intestine and sporozoites released from oocysts migrate to the salivary glands; in *Babesia,* fertilized gametes migrate through the intestinal wall, through the hemolymph, and on to the salivary glands, where they develop into sporoblasts. The final production of sporozoites from sporoblasts occurs only when the tick begins to take a blood meal; the resulting sporozoites are injected into the host during the final hours of attachment and feeding.

Epidemiology

Babesiosis is transmitted by the bite of infected *Ixodes scapularis* ticks, and outbreaks of human infection have been described in the Northeast, Midwest, and West Coast of the United States; in Europe; and, recently, in Japan (84). Relatively few cases of babesiosis have been reported in the United States: 10 to 12 cases per year in New York and Nantucket over the past 30 years (35). However, because babesiosis is a mild and self-limiting infection in most persons,

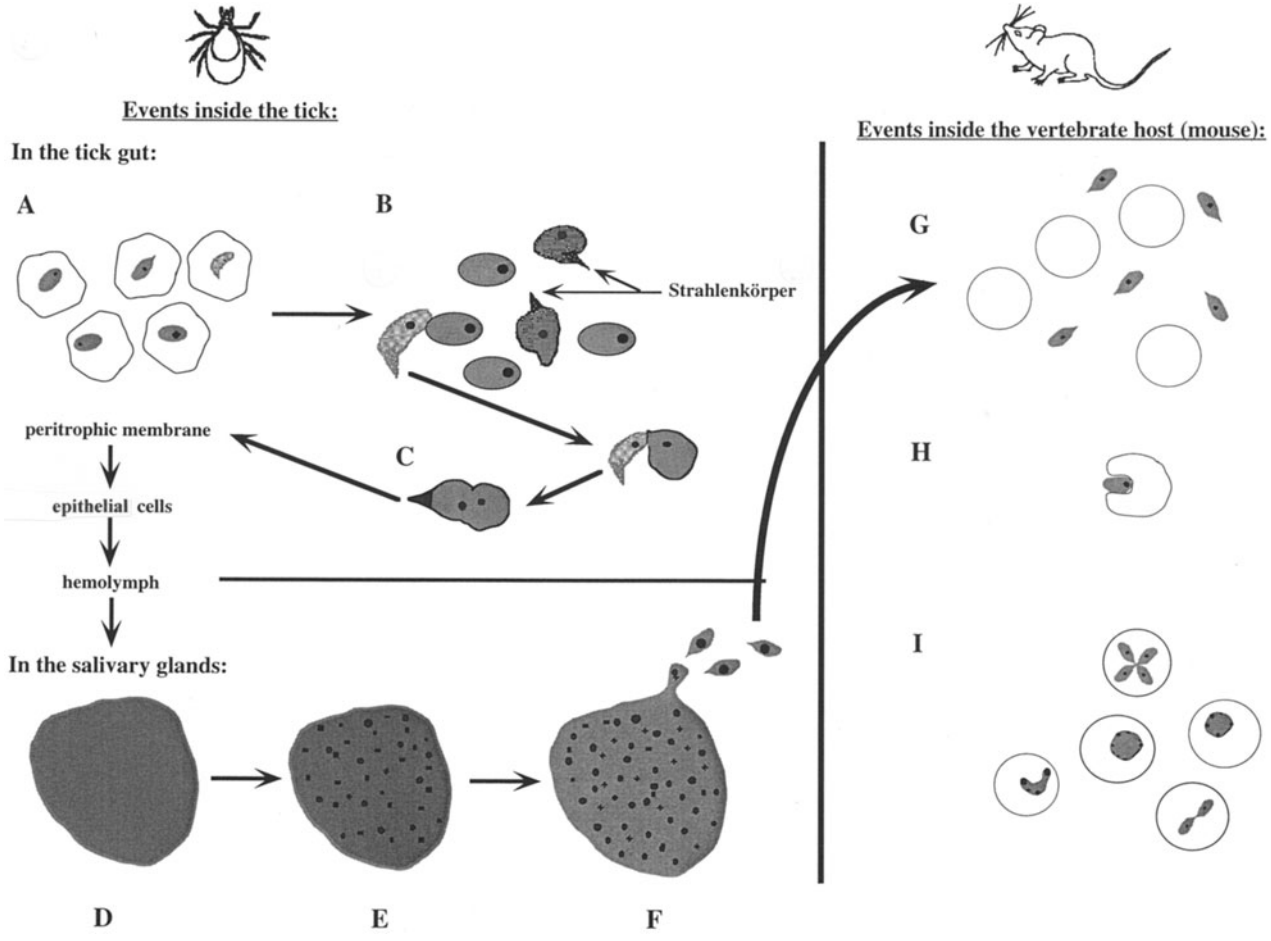

FIGURE 8 Life cycle of *Babesia.* Events in the tick begin with the parasites still visible in consumed erythrocytes. Some are beginning to develop Strahlenkörper forms (specialized apical organelles) (A). The released gametes begin to fuse (B). The zygote then goes on to infect and move through other tissues within the tick (C) to the salivary glands. Once a parasite has infected the salivary acini, a multinucleate but undifferentiated sporoblast is formed (D). After the tick begins to feed, the specialized organelles of the future sporozoites form (E). Finally, mature sporozoites bud off the sporoblast (F). As the tick feeds on its vertebrate host, these sporozoites are inoculated into the host (G). Sporozoites (or merozoites) contact a host erythrocyte and begin the process of infection by invagination (H). The parasites become trophozoites and can divide by binary fission within the host erythrocyte, creating the various ring forms and crosses seen on stained blood smears (I). Illustrations are not to scale. (Reproduced with permission from reference 35).

the number of unreported infections may be much higher. Indeed, serological surveys of blood donors have shown a seroprevalence of 3 to 8% for antibodies to *B. microti* (35). With the exception of a few cases attributed to newly described *Babesia* spp. (32, 34, 58, 62), babesiosis in the United States results from infection with *B. microti.* In Europe, only about 30 cases of babesiosis have been reported, principally infections of splenectomized individuals with *B. divergens;* however, these infections are clinically serious, with a mortality rate of 42% (28). A handful of cases of transfusion-associated babesiosis, usually involving transmission of *B. microti* from an asymptomatic donor, have been reported from the United States.

The host ranges of *B. microti* and *B. divergens* are wide, and virtually any mammal that serves as a host for *I. scapularis* ticks can be a reservoir of infection. *Babesia* spp. share both vectors and animal reservoirs, i.e., *Ixodes* ticks and white-footed mice, with several other tick-borne pathogens, including the agents of Lyme disease and human granulocytic ehrlichosis. Not surprisingly, there have been reports of coinfection with *B. microti* and *Borrelia burgdorferi,* and approximately 10% of Lyme disease patients in areas where babesias are endemic may be infected with *B. microti.* Lyme disease patients coinfected with *B. microti* experienced more-severe symptoms than those infected with either agent alone (41).

Clinical Disease

There is a wide range of clinical presentations of babesiosis, from mild or asymptomatic infection through a fulminant illness clinically similar to malaria and characterized by high fever, myalgias, malaise, fatigue, hepatosplenomegaly, and anemia. In general, infection with *B. microti* in the United States tends to occur in nonsplenectomized individuals and to be relatively mild. Infection with the more recently described babesias from the United States and with *B. divergens* in Europe tends to occur in splenectomized or immunocompromised individuals and to be clinically more severe. Overall, mortality among clinically apparent cases of *B. microti* infection in the United States is 5%, while that in *B. divergens* infection in Europe is 40%. In both the United States and Europe, risk factors for severe disease include increasing age, splenectomy, and immunocompromise.

Diagnosis

The diagnosis of babesiosis should be considered for a patient with the appropriate clinical symptoms and a history of travel to areas of endemicity, exposure to ticks, or recent blood transfusion. Examination of Giemsa-stained thin blood smears is the most direct approach to diagnosis. The appearance of *Babesia* in thin films is shown in Fig. 9. Although the trophozoites of *Babesia* can be confused with

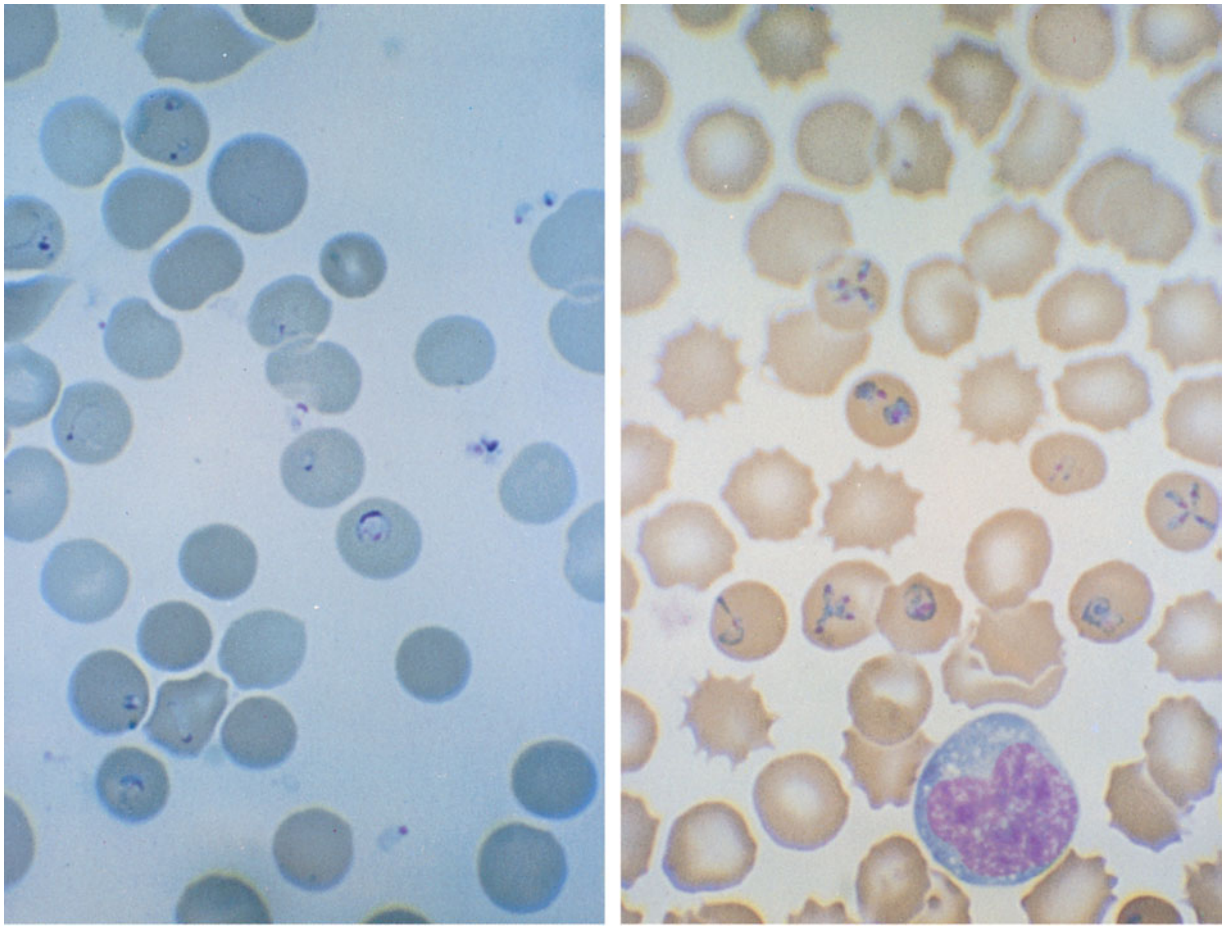

FIGURE 9 *Babesia* spp. in thin blood films. (Left) *B. microti* in human blood: parasites in erythrocytes and extracellular parasites; (right) *Babesia* sp. in classic Maltese cross (tetrad) configuration, a form diagnostic for babesiosis but rare in slides from humans infected with *B. microti.*

Plasmodium rings, particularly the small ring trophozoites of *P. falciparum, Babesia* can be distinguished from *P. falciparum* by several criteria. *Babesia* trophozoites are quite variable in size (1 to 5 μm), and the smallest are smaller than *P. falciparum* rings. Extracellular trophozoites and multiply infected erythrocytes are more common in *Babesia*. The cytoplasm of the larger *Babesia* trophozoites frequently contains a clear vacuole, which is rare or absent in *P. falciparum*. Finally, diagnostic tetrads, the Maltese cross, though rare in clinical specimens, may be present in *Babesia*. Parasitemias may be very low, particularly in chronic infections in nonsplenectomized patients; in such cases diagnosis may require serologic testing (12), hamster inoculation (8), or PCR amplification (59).

Treatment and Prevention

Mild cases of infection with *B. microti* usually resolve spontaneously. In more serious cases treatment with clindamycin and quinine or with atovaquone and azithromycin is standard. In very severe cases of *B. microti* infection and in *B. divergens* infection in splenectomized or immunosuppressed patients, antimicrobial therapy may be supplemented with exchange transfusion. Appropriate personal protective measures including use of long pants, long-sleeved shirts, and insect repellent may reduce the risk of infection when outdoors in areas of endemicity.

Leishmania and *Trypanosoma*

DAVID A. BRUCKNER AND JAIME A. LABARCA

137

Leishmania spp. and *Trypanosoma* spp. are protozoa belonging to the family *Trypanosomatidae.* Leishmaniasis is principally a zoonosis, and the organisms are obligate intracellular parasites transmitted to humans by bites from an infected female sand fly. For *Leishmania* in the Old World, there is only one subgenus, *Leishmania;* however, in the New World, the genus has been split into subgenera *(Leishmania* and *Viannia)* according to the development of the organism in the digestive tract (peripylarian or suprapylarian) of the sand fly (30). Depending on the geographic area, many different species can infect humans, producing a variety of diseases (cutaneous, diffuse cutaneous, mucocutaneous, and visceral diseases) (Table 1). The spectrum of clinical presentation is dependent on the host's cell-mediated immune response (68).

Trypanosoma spp. are hemoflagellate protozoa that live in the blood and tissue of the human host. American trypanosomiasis (Chagas' disease) is produced by *Trypanosoma cruzi,* which belongs to the family *Schizotrypanum* and is confined to the American continent. *Trypanosoma rangeli* belongs to the family *Tejaria,* produces an asymptomatic infection, and is also present only on the American continent. African trypanosomiasis (sleeping sickness) is caused by *T. brucei gambiense* and *T. brucei rhodesiense* species belonging to the family *Trypanozoon* and is confined to the central belt of Africa. African trypanosomes and *T. rangeli* are transmitted directly into the bite wound by salivary secretions from the insect vector, whereas *T. cruzi* is transmitted through contamination of the bite wound with the feces from the reduviid bug (Table 2). The first documented case of human trypanosomiasis caused by *T. evansi* was detected in India (78).

LEISHMANIA SPP.

Recent estimates suggest that there are approximately 350 million people at risk of acquiring leishmaniasis, with 112 million currently infected. More than 400,000 new cases are reported annually (33). New species of *Leishmania,* particularly in the New World, are being detected frequently. The taxonomy of leishmaniasis is controversial and in a state of dynamic flux. Species differentiation is currently based on molecular techniques rather than geographical distribution and clinical presentation (18, 24, 51).

Life Cycle and Morphology

The parasite has two distinct phases in its life cycle (amastigote and promastigote) (Fig. 1). The amastigote stage (Leishman-Donovan body) is found in reticuloendothelial cells of the mammalian host. The amastigote form is small, is round or oval, measures 3 to 5 μm, and contains a large nucleus and small kinetoplast (Fig. 1 and 2). This stage undergoes multiplication within the reticuloendothelial cells of the host.

Upon ingestion during a blood meal by the insect vector (sand fly), the amastigote transforms into the promastigote stage (Fig. 3). Promastigotes multiply in the gut of the insect, transform to metacyclic promastigotes, and migrate to the hypostome of the sand fly, where they are released when the next blood meal is taken. The complete life cycle in the sand fly is from 4 to 18 days. Upon inoculation into the bite site, the promastigote changes to the amastigote form after being engulfed by tissue macrophages. This form change helps to defeat the host's immune response. Changes in the parasite's surface molecules play an important role in macrophage attachment and evading the host's immune response, including manipulating the macrophage's signaling pathways (58, 68, 77).

The life cycles of *Leishmania* organisms are similar for cutaneous, mucocutaneous, and visceral leishmaniasis, except that infected reticuloendothelial cells can be found throughout the body in visceral leishmaniasis.

Epidemiology

All adult female sand flies transmitting leishmaniasis belong to the genus *Phlebotomus* in the Old World and *Lutzomyia* in the New World. There are >30 species of sand flies that can transmit leishmaniasis. The disease is considered primarily a zoonosis, with natural reservoirs including rodents, opossums, anteaters, sloths, and dogs. In certain areas of the world where the disease is endemic, the infection can be transmitted by a human-vector-human cycle. The infection may also be transmitted by direct contact with an infected lesion or mechanically through bites by stable or dog flies. Greater than 90% of cutaneous leishmaniasis cases occur in Afghanistan, Algeria, Brazil, Iran, Iraq, Peru, Saudi Arabia, and Syria. There has been an increase in the number of cases among military personnel deployed in Afghanistan, Iraq, and

Kuwait (19). Most of the diagnosed cases of mucocutaneous leishmaniasis are from Bolivia, Brazil, and Peru.

Visceral leishmaniasis may exist as an endemic, epidemic, and sporadic disease. The disease is a zoonosis except in India, where kala azar is an anthroponosis. The nature reservoirs are wild *Canidae* and various rodents for *L. donovani;* dogs, other *Canidae,* and rats for *L. infantum;* and *Canidae* and cats for *L. infantum (L. chagasi)* in the Americas. Individuals with post-kala azar dermal leishmaniasis may be very important reservoirs for maintaining the infection during interendemic cycles. More than 90% of the cases of visceral leishmaniasis are found in Bangladesh, Brazil, India, Nepal, and Sudan.

Clinical Disease

Depending on the species involved, infection with *Leishmania* spp. can result in cutaneous, diffuse cutaneous, mucocutaneous, or visceral disease (Table 1) (48). A large number of disease variations have been described, which makes classical disease categories confusing (18). In areas of endemicity, leishmania coinfection with human immunodeficiency virus (HIV)-positive patients is common. If coinfected patients remain severely immunocompromised, approximately one-quarter will die within the first month of being diagnosed with leishmaniasis. The leishmanial infection will manifest itself like an opportunistic infection, and parasites will be detected in atypical sites (42).

The first sign of cutaneous disease is the appearance of a firm, painless papule at or near the insect bite site. The incubation period may be as short as 2 weeks *(L. major)* or as long as several months to 3 years *(L. tropica* and *L. aethiopica)*. Papules may be intensely pruritic and will grow to 2 cm or more in diameter. Lesions may progress from a simple papule or erythematous macule to a nodule and ulcerate within days to weeks. In simple cutaneous leishmaniasis, the infection remains localized at the insect bite site where a definite self-limiting granulomatous response develops. Lesions have been mistaken for basal cell carcinoma, tropical pyoderma, sporotrichosis, or cutaneous mycobacterial infections.

Mucocutaneous leishmaniasis is produced most often by the *L. braziliensis* complex. The primary lesions are similar to those found in other infections of cutaneous leishmaniasis. Untreated primary lesions may develop into the mucocutaneous form in up to 80% of the cases. Metastatic spread to the nasal or oral mucosa may occur in the presence of the active

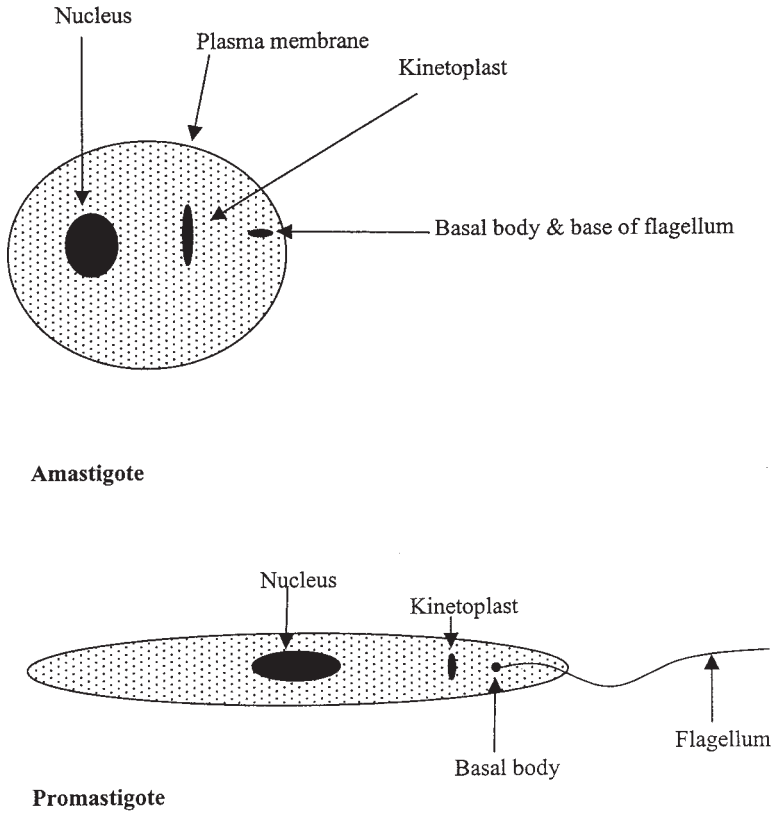

FIGURE 1 Life cycle stages of *Leishmania* spp.

primary lesion or many years later after the primary lesion has healed. Mucosal lesions do not heal spontaneously, and secondary bacterial infections are frequent and may be fatal. A small number of mucocutaneous leishmaniasis cases have been reported with *L. donovani* and *L. aethiopica*. Differential diagnosis has included lymphoma, midline granuloma, Wegener's granulomatosis, paracoccidioidomycosis, histoplasmosis, cutaneous mycobacterial infection, and leprosy.

Clinical features of the visceral disease vary from asymptomatic, self-resolving infections to frank visceral leishmaniasis. The incubation period may be as short as 10 days and as long as 2 years; usually it is within 2 to 4 months. Common symptoms include fever, anorexia, malaise, weight loss, and, frequently, diarrhea. Individuals coinfected with HIV may not elicit common symptoms seen in immunocompetent individuals, whereas the leukopenia will be unusually severe (42). Common clinical signs include nontender hepatomegaly and splenomegaly, lymphadenopathy, and occasional acute abdominal pain; darkening of facial, hand, foot, and abdominal skin (kala azar) is often seen in light-skinned persons in India. Anemia, cachexia, and marked enlargement of liver and spleen are noted as the disease progresses. Death may ensue after a few weeks, or after 2 to 3 years in chronic cases. The majority of infected individuals will be asymptomatic or have very few or minor symptoms that will resolve without therapy. Differential diagnosis in the acute stage will include amebic liver abscess, Chagas' disease, malaria, typhoid, typhus, and schistosomiasis. Subacute or chronic disease has been confused with bacteremia, brucellosis, histoplasmosis, leukemia, lymphoma, malaria, mononucleosis, and schistosomiasis.

Postdermal leishmaniasis or post-kala azar dermal leishmaniasis is a condition seen in India and the Sudan in some patients unsuccessfully treated for visceral leishmaniasis. This syndrome is rarely seen in Latin America but has been reported to occur in patients coinfected with HIV. The macular or hypopigmented dermal lesions are associated with few parasites, whereas erythematous and nodular lesions are associated with abundant parasites. This condition must be differentiated from leprosy, syphilis, and yaws.

Diagnosis

In areas where the disease is endemic, the diagnosis may be made on clinical grounds. Prolonged fever, progressive weight loss, anemia, leukopenia, hypergammaglobulinemia, and pronounced hepatomegaly and splenomegaly are highly suggestive of visceral leishmaniasis. The development of one or more chronic skin lesions with a history of exposure in an area of endemicity is suggestive of cutaneous leishmaniasis. Definitive diagnosis depends on detecting either the amastigotes in clinical specimens or the promastigotes in culture. All cutaneous lesions should be thoroughly cleaned with 70% alcohol, and extraneous debris, the eschar and exudates, should be removed. After debridement, with precautions being taken to prevent bleeding, the base of the ulcer can be scraped with a scapel blade to obtain an exudate for slide preparation, culture, or PCR. Specimens can be collected from the margin of the lesion by aspiration, scraping, or punch biopsy or by making a slit with a scalpel blade. Material scraped from the wall of the slit should be smeared onto a number of slides. Laboratorians may want to contact

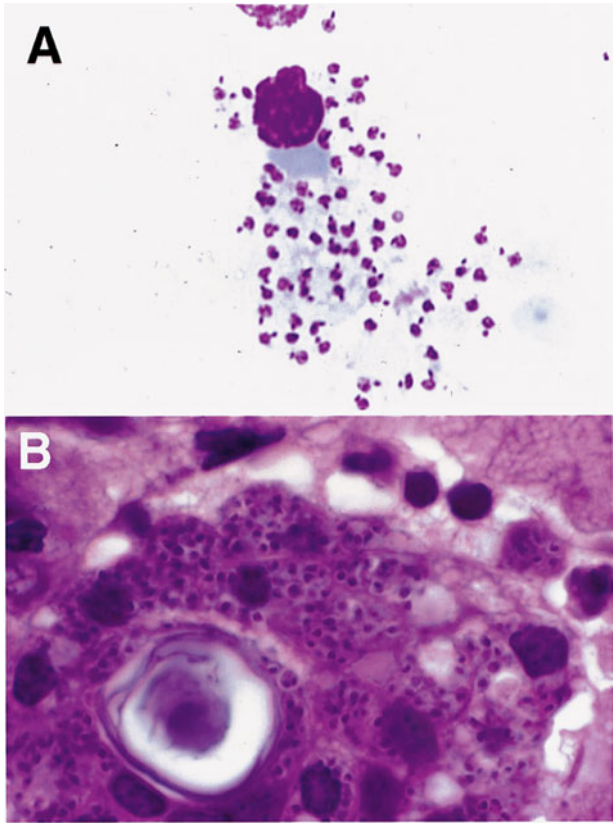

FIGURE 2 (A) *Leishmania donovani* amastigotes from splenic press preparation (Giemsa stain); (B) *Leishmania donovani* amastigotes in liver (hematoxylin and eosin stain).

their state public health laboratory or the Centers for Disease Control and Prevention (CDC) for diagnostic information and help in specimen selection and available tests.

The core of tissue from a punch biopsy can be used to make imprints or touch preparations on a slide. This core can also be submitted for histological examination. Recognition of amastigotes in tissues is more difficult than in smears or imprints because the organisms tend to be crowded within the cells, appear smaller, and are cut at various angles. Fine-needle aspiration can also be performed by using a sterile syringe containing sterile preservative-free buffered saline (0.1 ml) and a 26-gauge needle. The needle is inserted under the outer border of the lesion, the needle is rotated several times, and tissue fluid is aspirated into the needle. Tissue obtained by splenic puncture yields the highest rate of positive specimens; however, this procedure carries significant risk to the patient, particularly those with coagulation disorders. Other specimens for the detection of visceral leishmaniasis include lymph node aspirates, liver biopsy, sternal aspirates, iliac crest bone marrow, and buffy coat preparations of venous blood. Amastigotes with reticuloendothelial cells have been detected in bronchoalveolar lavage fluid, pleural effusions, and biopsy specimens collected from the gastrointestinal tract and oropharynx of HIV-positive patients (42). Individuals with post-kala azar dermal leishmaniasis have large numbers of parasites in the skin, particularly those with erythematous and nodular lesions (43).

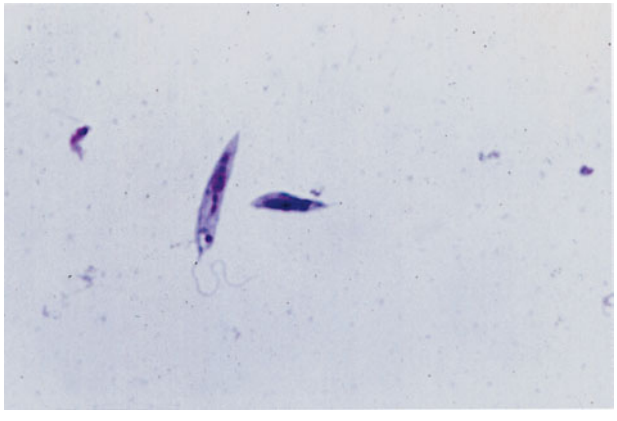

FIGURE 3 *Leishmania donovani* promastigotes (Giemsa stain).

Amastigote stages will be found within macrophages or close to disrupted cells (Fig. 2). This stage can be recognized by its shape, size, staining characteristics, and especially the presence of an intracytoplasmic kinetoplast. The cytoplasm will stain light blue, and the nucleus and kinetoplast will stain red or purple with Giemsa stain. Molecular techniques (none are FDA approved) for the detection of leishmanial DNA or RNA have been used for diagnosis, prognosis, and species identification. These methods are considered to be more sensitive than slide examination or culture, particularly for the detection of mucocutaneous leishmaniasis (3, 30, 33, 35, 37, 49, 57, 59, 62, 71, 75, 79). Generally, organisms in mucocutaneous lesions are scant and difficult to detect microscopically. Because infections caused by *Leishmania* subgenus *Viannia* are considered to be more aggressive and are more likely to result in treatment failure, molecular techniques to identify the organism to the species level can be very important (41, 44, 76).

If material is to be cultured, it must be collected aseptically. Tissues should be minced prior to culture. Culture media successfully employed to recover organisms include Novy, MacNeal, and Nicolle's medium (NNN) and Schneider's Drosophila medium supplemented with 30% fetal bovine serum. Cultures, incubated at 25°C, should be examined twice weekly for the first 2 weeks and once a week thereafter for up to 4 weeks before the culture is declared negative. Promastigote stages can be detected microscopically in wet mounts and then stained with Giemsa to observe their morphology.

Animals such as the golden hamster can be inoculated with patient material. Animals are inoculated intranasally for cutaneous and mucocutaneous leishmaniasis and intraperitoneally for visceral leishmaniasis. It may take 2 to 3 months before an animal becomes positive. A combination of tissue smears, culture, and animal inoculation may be needed to optimize the laboratory diagnosis of the infection. PCR testing, if available, can be used as a supplemental diagnostic procedure (62, 65).

The leishmanin (Montenegro) test (not available in Canada or the United States), a delayed-hypersensitivity reaction, is useful for epidemiological surveys of a population to identify groups at risk of infection. Positive reactions are usually seen in cutaneous and mucocutaneous leishmaniasis; however, patients with active visceral and diffuse cutaneous leishmaniasis exhibit negative reactions. Post-kala azar patients may also exhibit a negative reaction. This test is of no value for the diagnosis of visceral leishmaniasis.

Serologies (none are FDA approved) are available for research or epidemiologic purposes; however, they are not very useful for the diagnosis of mucocutaneous and visceral

leishmaniasis. In kala azar, there is a large increase in gamma globulins, both immunoglobulin G (IgG) and IgM. This is the basis for the aldehyde or formol-gel test, which has been used as a screening test in areas of endemicity (55). The addition of 1 drop of formalin to 1 ml of serum promotes the precipitation of immunoglobulins. A number of serologies including indirect fluorescent antibody (IFA), enzyme-linked immunoassay (ELISA), and immunoblot tests have been developed for diagnostic purposes; however, they are not widely available except in areas of endemicity (10, 13, 64). An ELISA and dipstick test using *L. infantum/L chagasi* recombinant k39 antigen has good sensitivity and specificity in diagnosing visceral leishmaniasis in immunocompetent people (12, 74). Visceral leishmaniasis patients coinfected with HIV may have no detectable antileishmania antibodies (11, 42). Serologic testing is available at some referral laboratories and the CDC. The detection of urinary antigens has been used for the diagnosis of visceral leishmaniasis (5).

Treatment and Prevention

Lesions in simple cutaneous leishmaniasis generally heal spontaneously. Treatment options have included cryotherapy, heat, surgical excision of lesions, and chemotherapy. Although the optimal treatment for cutaneous leishmaniasis is unknown, standard therapy consists of injections of antimonial compounds. Response to therapy varies depending on the species of *Leishmania* and the type of disease (70); therefore, it is important to identify the species of *Leishmania* causing the infection (79). Antimonial therapy has been given intralesionally and parenterally. The two commonly used pentavalent antimonials are sodium stibogluconate (Pentostam) and a meglumine antimoniate (Glucantime). The drug of choice for treatment of kala azar is sodium stibogluconate (Pentostam). Pentamidine isethionate is an alternative therapy for treatment of kala azar. Amphotericin B and liposomal amphotericin B can be used when the disease does not respond to antimonial or pentamidine therapy. Allopurinol, either alone or in combination with antimonials, has been effective in treating cutaneous leishmaniasis. Hexadecylphosphocholine (miltefosine) is an oral alkylphosphocholine analogue that has proven to be effective in treating cutaneous and visceral leishmaniasis even with patients coinfected with HIV (67). The risk of relapse is quite high within the first 6 to 12 months posttherapy. It is possible that macrophages may harbor quiescent parasites for life (54). Frequent relapses have been noted to occur in immunocompromised and HIV-positive patients and in patients unable to complete therapy due to drug toxicity (46). Patients clinically cured of *L. (V.) braziliensis,* which is noted for its chronicity, latency, and metastasis with mucosal membrane involvement, have been found to be PCR positive up to 11 years posttherapy (52). To ensure that treatment has been effective, follow-up smears and cultures should be done 1 to 2 weeks posttherapy. PCR testing has been used to monitor the progress of therapy (52, 61).

In areas where leishmaniasis is endemic, vaccination is still a major goal for eliminating leishmaniasis. This has been practiced by inoculating the serous exudate from naturally acquired lesions of cutaneous leishmaniasis into an inconspicuous area of the body of a nonimmune person. Vaccines against other forms of leishmaniasis have not been effective. Other possible prevention methods include spraying dwellings with residual insecticides and applying insect repellents to the skin. Fine-mesh bed netting, including insecticide-treated nets, may also be used and is an alternative to household spraying. Reservoir control has been unsuccessful in most areas, although in areas where canines may be a reservoir host, pyrethroid-impregnated collars are being used to prevent infections. Individuals with lesions should be warned to protect the lesion from insect bites with some type of covering. Patients should also be educated about the possibility of autoinoculation or infection.

AMERICAN TRYPANOSOMIASIS

■ *Trypanosoma cruzi*

American trypanosomiasis (Chagas' disease) is a zoonosis caused by *Trypanosoma cruzi.* There are 100 million persons at risk of infection in 18 Latin American countries, and 16 to 18 million persons are actually infected (42). Patients can present with either acute or chronic disease. Chagas' disease was considered a disease of rural areas; however, it is now ubiquitous due to social pattern changes of rural to urban migration. A very serious problem is disease acquisition through blood transfusion (50). A large number of patients with positive serology can remain asymptomatic.

Life Cycle and Morphology

Trypomastigotes (Fig. 4 and 5) are ingested by the reduviid bug (triatomids, kissing bugs, or conenose bugs) as it obtains a blood meal. The trypomastigotes transform into epimastigotes (Fig. 4 and 6) that multiply in the posterior portion of the midgut. After 8 to 10 days, metacyclic trypomastigotes develop from the epimastigotes. These metacyclic trypomastigotes are passed in the feces.

Humans contract Chagas' disease when the reduviid bug defecates while taking a blood meal and metacyclic trypomastigotes in the feces are rubbed or scratched into the bite wound or onto mucosal surfaces. In humans, *T. cruzi* can be found in two forms, as amastigotes and trypomastigotes (Fig. 4, 6, and 7). The trypomastigote form is present in the blood and infects the host cells. The amastigote form multiplies within the cell, eventually destroying the cell, and both amastigotes and trypomastigotes are released into the blood.

The trypomastigote is spindle shaped and approximately 20 μm long and characteristically assumes a C or U shape in stained blood films (Fig. 6). Trypomastigotes occur in the blood in two forms, a long, slender form and a short, stubby one. The nucleus is situated in the center of the body, with a large, oval kinetoplast located at the posterior end. A flagellum arises from the basal body and extends along the outer edge of an undulating membrane until it reaches the anterior end of the body, where it projects as a free flagellum. When the trypomastigotes are stained with Giemsa stain, the cytoplasm stains blue and the nucleus, kinetoplast, and flagellum stain red or violet.

The amastigote (2 to 6 μm in diameter) is indistinguishable from those found in leishmanial infections. It contains a large nucleus and a rod-shaped kinetoplast that stains red or violet with Giemsa stain, and the cytoplasm stains blue (Fig. 2 and 7).

Epidemiology

Chagas' disease is a zoonosis occurring throughout the American continent, including Central and South America, Texas, and California (56). It involves reduviid bugs living in close association with reservoirs (dogs, cats, armadillos, opossums, raccoons, and rodents). Human infections occur mainly in rural areas where poor sanitary and socioeconomic conditions and poor housing provide excellent breeding places for reduviid bugs. Chagas' disease is found in 18 countries in

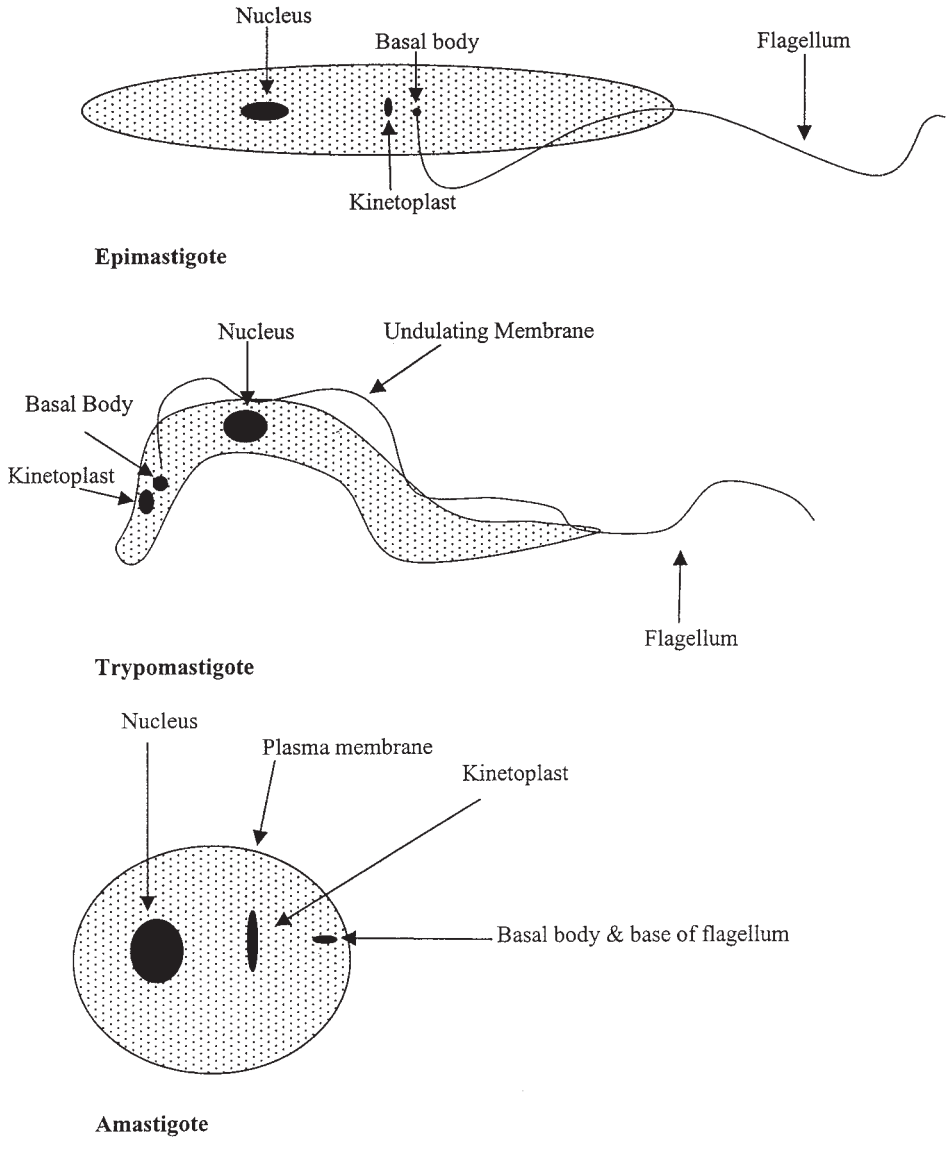

FIGURE 4 Life cycle stages of trypanosomes.

Central and South America. The disease distribution has been broken into two ecological zones: the Southern Cone, where the reduviid vector lives inside the human home, and the Northern South America, Central America, and Mexico zone, where the reduviid lives inside and outside the home. Strains of *T. cruzi* have large differences in infectivity of potential vectors, antigenicity, histotropism, pathogenicity, and response to therapy (4, 6, 7, 16). Most human infections may be due to *T. cruzi* subgroup II (34). Transmission by blood transfusion is a serious concern in areas of endemicity, and serologic screening of blood donors can be used, whereas in areas where the disease is not endemic questionnaires may be used to defer prospective donors from areas of endemicity (63, 73).

Clinical Disease

In addition to contracting *T. cruzi* infections through the insect's bite wound or exposed mucous membranes, one can be infected by blood transfusion, placental transfer, organ transplant, and accidental ingestion of parasitized reduviid bugs (73). A localized inflammatory reaction may ensue at the infection site with development of a chagoma (erythematous subcutaneous nodule) or Romaña's sign (edema of the eyelids and conjunctivitis).

Acute systemic signs occur around the second to third week of infection and are characterized by high fevers; hepatosplenomegaly; myalgia; erythematous rash; acute myocarditis; lymphadenopathy; and subcutaneous edema of face, legs, and feet. The acute phase of Chagas' disease in immunosuppressive patients is manifested as acute myocarditis or acute encephalitis with a high mortality rate. Most acute cases resolve over a period of 2 to 3 months into an asymptomatic chronic stage. Approximately 30% of these individuals develop myocarditis or symptoms associated with denervation of the digestive tract (31).

Chronic Chagas' disease is diagnosed more commonly than the acute phase. Symptoms of the chronic phase are related to the damage sustained during the acute phase of the disease.

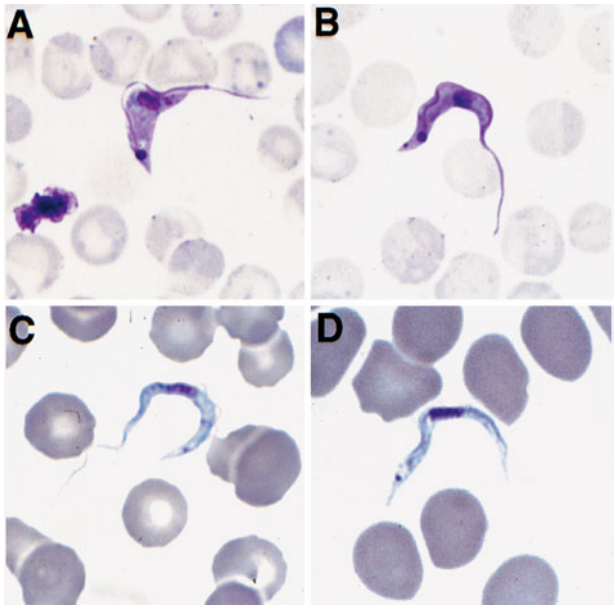

FIGURE 5 (A and B) *Trypanosoma cruzi* trypomastigotes; (C and D) *Trypanosoma brucei gambiense* trypomastigotes.

Chronic Chagas' disease may develop years or decades after undetected infection or after the diagnosis of acute disease. The most frequent clinical sign of chronic Chagas' disease is cardiomyopathy manifested by cardiomegaly and conduction changes. Some patients are more likely to have megaesophagus or megacolon. The "mega" condition has been associated with the destruction of ganglion cells, resulting in dysmotility causing dysphagia, aspiration, and regurgitation in patients with megaesophagus and severe constipation in megacolon. In chronic Chagas' disease, autoimmunity may also be responsible for tissue destruction in addition to the tissue destruction caused by the parasite. Reactivation of Chagas' disease in HIV-positive patients usually leads to very high parasitemia (25). Central nervous system (CNS) involvement is seldom observed, but in HIV-coinfected individuals, CNS involvement is frequently noted, and acute fatal meningoencephalitis and granulomatous encephalitis have been described for these patients (42). Congenital transmission can occur in both acute and chronic phases of the disease. Infants of seropositive mothers should be monitored for up to a year after birth to rule out infection.

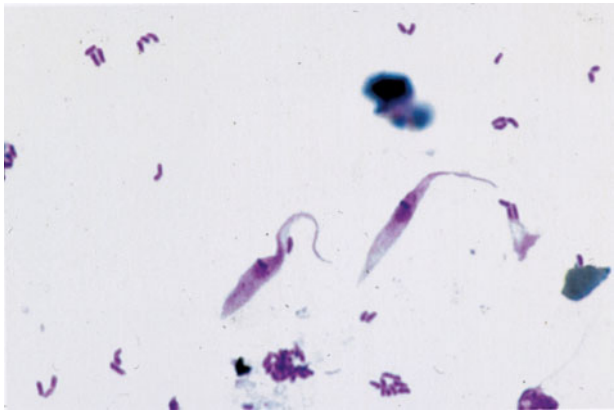

FIGURE 6 *Trypanosoma cruzi* epimastigotes (Giemsa stain).

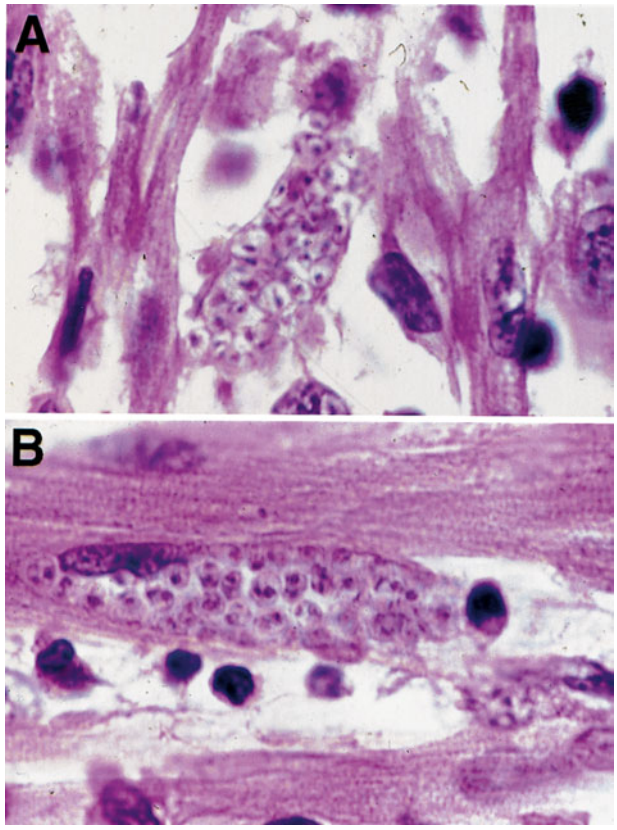

FIGURE 7 (A and B) *Trypanosoma cruzi* amastigotes in heart muscle (hematoxylin and eosin stain).

Diagnosis

Health care personnel working with specimens from patients suspected of having Chagas' disease should follow the blood-borne pathogen guidelines. Trypomastigotes are highly infectious.

The definitive diagnosis depends on demonstration of trypomastigotes in the blood, amastigote stages in tissues, or positive PCR and serologic tests. Aspirates from chagomas and enlarged lymph nodes can be examined for amastigotes and trypomastigotes. Histological examination of biopsy specimens may also be done. Trypomastigotes may be easily detected in the blood in acute disease; however, in chronic disease, this stage is rare or absent, except during febrile episodes. Trypomastigotes appear in the blood about 10 days after infection and persist through the acute phase. Laboratorians may want to contact their state public health laboratory or the CDC for diagnostic information and help in specimen selection and available tests.

Trypomastigotes may be detected in blood by using thin and thick blood films or the buffy coat concentration technique (72). The stain of choice is Giemsa for both amastigote and trypomastigote stages. Although not routinely available except in specialized centers, PCR (not FDA approved) has been used to detect as few as one trypomastigote in 20 ml of blood and has been useful in treatment follow-up (14, 21, 50). In areas where kala azar occurs, amastigote stages look

similar and infections of *L. donovani* and *T. cruzi* must be differentiated by either PCR, immunoassay, culture (epimastigote in *T. cruzi* versus promastigote in *L. donovani*), serologic tests, animal inoculation, or xenodiagnosis techniques (21). Patient history, including geographic and/or travel history, and confirmation of organisms in striated muscle rather than reticuloendothelial tissues are very strong evidence for *T. cruzi* rather than *L. donovani* as the causative agent.

Aspirates, blood, and tissues can also be cultured. The medium of choice is NNN. Cultures, incubated at 25°C, should be examined for epimastigote stages twice weekly during the first 2 weeks and once per week thereafter for up to 4 weeks before they are considered negative. If available, laboratory animals (rats or mice) can be inoculated and the blood can be observed for trypomastigotes.

Although xenodiagnosis is used less frequently for clinical diagnosis in areas of endemicity, trypanosome-free reduviid bugs are allowed to feed on individuals suspected of having Chagas' disease. The feces, hemolymph, hindgut, and salivary glands can be examined microscopically for flagellated forms over a period of 3 months, or PCR methods can be used to detect infected bugs. Xenodiagnosis is positive in less than 50% of the seropositive patients. Some patients may develop a severe anaphylactic reaction to the reduviid bug's salivary secretion.

Serological tests (none are FDA approved) using blood and saliva for the diagnosis of Chagas' disease include complement fixation (Guerreiro-Machado test), chemiluminescence, IFA, indirect hemagglutination, and ELISA. Most of these tests use an epimastigote antigen, and cross-reactions have been noted for patients infected with *Trypanosoma rangeli, Leishmania* spp., *Toxoplasma gondii*, and hepatitis (23, 33). Most lack sensitivity and specificity, and the WHO recommends testing with two conventional assays before accepting a positive result (40). The use of synthetic peptides and recombinant proteins has improved the sensitivity and specificity of the serodiagnostic techniques (1, 15, 28, 29, 38, 63). Due to the lack of sensitivity and specificity of serologic tests, it is recommended that at least two different serologic test methods be used to screen blood donor populations (60). Follow-up blood specimens should be reexamined 1 to 2 months after therapy by the techniques described above. Serologic testing is available at referral laboratories and the CDC.

Treatment and Prevention

Nifurtimox (Lampit) and benznidazole (Radamil) reduce the severity of acute Chagas' disease, but they have little impact on the progression of chronic Chagas' disease. Other drugs, allopurinol, fluconazole, itraconazole, and ketoconazole, have been used to treat a limited number of patients. Surgery has been successfully used to treat cases of chagasic heart disease, megaesophagus, and megacolon.

Until recently, control of Chagas' disease has been mainly through the use of insecticides to eliminate the reduviid vector. Construction of reduviid-proof dwellings and health education are essential for effective control programs. Bed nets are also effective in preventing infections. Serologic screening of blood products for transfusion from areas in which the disease is endemic is highly recommended. An alternative approach to serologic testing for blood donors is the use of questionnaires to defer prospective donors from areas of endemicity.

■ *Trypanosoma rangeli*

T. rangeli infects humans and other vertebrates in both Central and South America and is often found in areas where *T. cruzi* is also present (26, 39). Human infections are asymptomatic, and trypomastigotes have been noted to persist in the blood for longer than a year. *T. rangeli* and *T. cruzi* can use the same triatomid vector to transmit infections. *T. rangeli* infections can be transmitted by inoculation of triatomid saliva during feeding or by the vector's feces (27). In some areas, *T. rangeli* infections are five to six times more frequent than infections with *T. cruzi*. Trypomastigotes can be detected from the blood of infected patients by using thin and thick blood smears and buffy coat concentration techniques. The parasites can be stained with Giemsa or Wright stains. Microscopically, the trypomastigote cannot be differentiated from African trypanosomes, which do not occur in the Americas. PCR methods have been used to detect infections in humans and vectors (22, 27). Infections can also be detected by xenodiagnosis. In addition, blood can be cultured (Tobies medium or NNN) or injected into laboratory animals (mice) and examined for epimastigotes and trypomastigotes, respectively. Although there are no serologic tests to detect *T. rangeli* infections, serologic cross-reactions have been noted to occur with tests for *T. cruzi* (2). There are no treatment recommendations for *T. rangeli* infections.

AFRICAN TRYPANOSOMIASIS

African trypanosomiasis is limited to the tsetse fly belt of Central Africa, where there are over 60 million people at risk for African trypanosomiasis (20). The West African (Gambian) form of sleeping sickness, noted for its chronicity and responsible for 99% of the sleeping sickness cases, is caused by *T. brucei gambiense,* whereas the East African (Rhodesian) form, noted for its acute morbidity and mortality, is caused by *T. brucei rhodesiense* (66). *T. brucei gambiense* infections can last for months to years with slow CNS involvement. In some areas of endemicity, civil strife has disrupted both the health care infrastructure and vector control, which has led to a resurgence of this disease.

Life Cycle and Morphology

T. brucei rhodesiense and *T. brucei gambiense* are closely related and morphologically indistinguishable. In the past, differentiation was based on clinical signs and geographic area; however, differentiation can now be accomplished using isoenzyme characteristics and DNA and RNA methods.

The trypomastigote forms (Fig. 4 and 6) in the blood range from long, slender-bodied organisms with a long flagellum to short, fat, stumpy forms without a free flagellum (14 to 33 μm long and 1.5 to 3.5 μm wide). The short, stumpy forms are the infective stage for the tsetse fly.

Using Giemsa or Wright stains, the granular cytoplasm stains pale blue and contains dark blue granules and possibly vacuoles. The centrally located nucleus stains reddish. The kinetoplast is located at the organism's posterior end and stains reddish; the remaining intracytoplasmic flagellum (axoneme) may not be visible. The flagellum arises from the kinetoplast, as does the undulating membrane. The flagellum runs along the edge of the undulating membrane until the undulating membrane merges with the trypanosome body at the organism's anterior end. At this point the flagellum becomes free to extend beyond the body. Trypanosomal forms are ingested by the tsetse fly when a blood meal is taken and transform to epimastigotes (Fig. 4). The organisms multiply in the gut of the fly, and after approximately 2 weeks, the organisms migrate back to the salivary glands. Humans are infected when metacyclic forms from the salivary glands are introduced into the bite site when the blood meal is taken. The trypomastigote has the ability to change the surface coat of the

outer membrane, helping the organism evade the host's humoral immune response (32).

Epidemiology

The development cycle in the tsetse fly varies from 12 to 30 days and averages 20 days. Fewer than 10% of the tsetse flies become infective after obtaining blood from infected patients. Both female and male tsetse flies can transmit the infection.

Although there is no evidence of animal-to-human transmission of *T. brucei gambiense,* trypanosomal strains isolated from hartebeest, kob, chickens, dogs, cows, and domestic pigs in West Africa are identical to those isolated from humans in the same area. Evidence suggests that transmission may be entirely interhuman. The tsetse fly vectors of Rhodesian trypanosomiasis are game feeders that may transmit the disease from human to human or from animal to human.

Clinical Disease

After a bite by an infected tsetse fly, a local inflammatory reaction that resolves spontaneously within 1 to 2 weeks can be detected at the bite site. The trypomastigotes gain entrance to the bloodstream, causing a symptom-free low-grade parasitemia that may continue for months. The infection may selfcure during this period without development of symptoms or lymph node invasion. Chancres may be confused with insect bites and bacterial skin infections.

The clinical course and disease progression are more acute with *T. brucei rhodesiense* than with *T. brucei gambiense* infections. Diagnostic symptoms include irregular fever, lymph node enlargement (particularly those of the posterior triangle of the neck, known as Winterbottom's sign, which is prominent in *T. brucei gambiense* infections), delayed sensation to pain (Kerandel's sign), and erythematous skin rashes. In addition to lymph node involvement, the spleen and liver become enlarged. With Gambian trypanosomiasis, the blood-lymphatic stage (stage I) may last for years before the sleeping sickness syndrome occurs (CNS involvement, stage II).

Laboratory findings include anemia, granulocytopenia, increased sedimentation rate, and marked increases in serum IgM. The sustained high IgM levels are a result of the parasite producing variable antigen types to evade the patient's defense system (32). In an immunocompetent host, the lack of elevated serum IgM rules out African trypanosomiasis. Diagnostic differential may include brucellosis, malaria, relapsing fever, and typhoid.

Upon trypomastigote invasion of the CNS, the sleeping-sickness stage of the infection is initiated (stage II). Gambian trypanosomiasis is characterized by steady progressive meningoencephalitis, behavioral changes, apathy, confusion, coordination loss, and somnolence. *T. brucei rhodesiense* produces a more rapid, fulminating disease, and death may occur before there is extensive CNS involvement. In the terminal phase of the disease, the patient becomes emaciated, leading to profound coma and death, usually from secondary infections. Cerebrospinal fluid (CSF) findings include increased protein and IgM levels, lymphocytosis, and morular cells of Mott. Morular (mulberry) cells are altered plasma cells whose cytoplasm is filled with proteinaceous droplets. Morular cells are not seen in all patients; however, they are characteristic of African trypanosomiasis. The diagnostic differential may include cryptococcosis, HIV, meningitis, Parkinson's disease, psychiatric disorders, and space-occupying lesions.

Diagnosis

Definitive diagnosis depends upon demonstration of trypomastigotes in blood, lymph node aspirate, sternum bone marrow, and CSF. Trypomastigotes can be more readily detected in body fluids in infections due to *T. brucei rhodesiense* than in those due to *T. brucei gambiense* because of higher parasitemias. Due to periodicity, parasite numbers in the blood vary, and a number of techniques must be used to detect the trypomastigotes. Laboratorians may want to contact their state public health laboratory or the CDC for diagnostic information and help with specimen selection and available tests.

Trypomastigotes are highly infectious, and health care personnel must be cautious and adhere to bloodborne-pathogen precautions when handling blood, CSF, or aspirates. Blood can be collected from either finger stick or venipuncture. Venous blood should be collected in a tube containing EDTA. Multiple blood exams should be performed before trypanosomiasis is ruled out. Parasites are found in high numbers in the blood during the febrile period and in low numbers in the afebrile periods. If CSF is examined, a volume greater than 1 ml, preferably 5 ml or more, should be collected. In addition to thin and thick blood films, a buffy coat concentration method is recommended to detect the parasites. Parasites can be detected on thick blood smears when numbers are greater than 2,000/ml, with hematocrit capillary tube concentration when numbers are greater than 100/ml, and on an anion-exchange column when numbers are greater than 4/ml. Unfortunately, anion-exchange is not easily adapted to clinical laboratories or field studies (20). In suspected and confirmed cases of trypanosomiasis, a lumbar puncture is mandatory to rule out CNS involvement (stage II). CSF examination must be conducted by using centrifuged sediments (17). The CSF should be examined immediately because the trypomastigotes begin to autolyse within 10 min. Detection of trypomastogotes in the CSF allows immediate classification of stage II illness (CNS involvement). In cases in which trypomastigotes are in undetectable numbers in the blood, they may be seen in aspirates of inflamed lymph nodes; however, attempts to demonstrate them in tissue are not practical. Blood and CSF specimens should be examined during therapy to evaluate the clinical response and 1 to 2 months after therapy. ELISA has been used to detect antigen in serum and CSF. This method could also be used for clinical staging of the disease to determine whether there was CNS infection and as a follow-up to therapy. Referral laboratories have used molecular methods (PCR, not FDA approved) to detect infections and differentiate species, but these methods are not routinely used in the field (9, 20, 46).

Serologic techniques (not FDA approved) that have been used for epidemiologic screening include IFA, ELISA, indirect hemagglutination assay, the card agglutination trypanosomiasis test (CATT), and LATEX/*T. b. gambiense*. CATT is effective in screening the population for suspected cases of *T. brucei gambiense* but not *T. brucei rhodesiense*. Major serodiagnostic problems with CATT include false-positive results due to malarial infections and the fact that many in the population have elevated antibody levels due to exposure to animal trypanosomes that are noninfectious to humans. CATT does not differentiate between current and past infections (20, 36, 69). Both CATT and LATEX/*T. b. gambiense* have good negative predictive values (20). Markedly elevated serum and CSF IgM concentrations are of diagnostic value. CSF antibody titers should be interpreted with caution because of the lack of reference values and the possibility of CSF containing serum due to a traumatic tap. Intrathecal production of immunoglobulins can be found in a number of neuroinflammatory diseases. LATEX/IgM has been developed for field use to measure CSF concentrations of IgM (20).

Antibodies to galactocerebrosides and neurofilaments as well as elevated concentrations of interleukin-10 may be

markers for CNS involvement, all of which have been used to monitor CNS infections (20, 47).

Small laboratory animals (rat and guinea pig) have been used to detect infections. *T. brucei rhodesiense* is more adaptable to cultivation and animal infection than *T. brucei gambiense;* however, cultivation is not practical for most diagnostic laboratories.

Treatment and Prevention

Suramin (Bayer 205, Naphuride, Antrypol) is the drug of choice for treating the early blood or lymphatic stage of *T. brucei rhodesiense* infections, whereas pentamidine isethionate (Lomidine) is the drug of choice for treating the early stages of *T. brucei gambiense* infections (8, 45, 66). Both drugs require parenteral administration, and side effects can be quite severe. Suramin and pentamidine isethionate do not cross the blood-brain barrier; therefore, melarsoprol (mel B, Arsobal) is the drug of choice when CNS involvement is suspected. A major complication of melarsoprol is reactive encephalitis, occurring in 5 to 15% of the patients, for whom there is a 50% mortality rate. A new 10-day course with reduced dosage has been found to be effective in treating *T. brucei gambiense* infections (45, 66).

Difluoromethyornithine (DFMO, Eflornithine, Ornidyl) is a cytostatic drug effective against the acute and late stages of *T. brucei gambiense* infections. It is less effective in late-stage disease in patients coinfected with HIV, and patients were more likely to relapse after treatment (42). Therapy failure rates have reached as high as 50% (53). The effectiveness of therapy can be judged microscopically by the absence of trypomastigotes in the blood, lymph fluid, or CSF and by a decrease in CSF white blood cells. CSF antibodies (IgM) decrease, as do levels of interleukin-10, after successful therapy (47). Any individual treated for African trypanosomiasis should be monitored for 2 to 3 years after completion of therapy. About 2% of the patients treated for CNS disease experience relapses.

Population-screening programs have been used to control *T. brucei gambiense* infections. The use of vector control measures has met with limited success. The release of sterile male flies to mate with females has had some success in eliminating vectors (7). The most effective control measures include an integrated approach to reduce the human reservoir of infection and the use of insecticide and fly traps; however, economic resources are limited and effective programs cannot be sustained. Persons visiting areas in which the infection is endemic should wear protective clothing (long-sleeved shirts and long trousers). Other measures include reduction in vegetation around human settlements, insect repellents, bed netting, and screens. Chemoprophylaxis is not recommended due to drug toxicity. Vaccines are not available.

OTHER TRYPANOSOMES INFECTING HUMANS

Trypanosoma evansi

The first human case of *T. evansi* was diagnosed in India (78). This organism is normally considered to be a parasite of animals (buffalo, camels, cattle, horses, and rats) and has a very wide geographic distribution (Africa, Asia, and Central and South America). The infection is transmitted mechanically by blood-sucking insects such as stable or horse flies. In animals, the incubation period is 5 to 60 days and the severity of the disease varies from no symptoms to weakness, weight loss, anemia, abortions, and death. In the above-mentioned human case, the patient complained of transient fevers and sensory disorders. Fever peaks were noted every 7 to 10 days, and large numbers of parasites were detected in the blood at the time of fevers. No parasites were observed in the CSF. The patient was treated with suramin. Laboratory diagnosis is usually done by examination of blood and lymph node aspirates or biopsy specimens. *T. evansi* cannot be differentiated from *T. brucei gambiense, T. brucei rhodesiense,* or *T. rangeli* microscopically.

Toxoplasma

MARIANNA WILSON, JEFFERY L. JONES, AND JAMES B. McAULEY

138

TAXONOMY

Phylum Apicomplexa, Class Conoidasida, Subclass Coccidiasina, Order Eucoccidiorida, Suborder Eimeriorina, Family Sarcocystidae, (*Sarcocystis*), Subfamily Toxoplasmatinae, Genus *Toxoplasma*

LIFE CYCLE

Toxoplasma gondii is a protozoan parasite that infects most species of warm-blooded animals, including humans. Members of the cat family Felidae are the only known definitive hosts for the sexual stages of *T. gondii* and thus are the main reservoirs of infection. The three stages of this obligate intracellular parasite are (i) tachyzoites (trophozoites), which rapidly proliferate and destroy infected cells during acute infection; (ii) bradyzoites, which slowly multiply in tissue cysts; and (iii) sporozoites in oocysts (Fig. 1). Tachyzoites and bradyzoites occur in body tissues; oocysts are excreted in cat feces. Cats become infected with *T. gondii* by carnivorism or by ingestion of oocysts. Cats that are allowed to roam outside are much more likely to become infected than domestic cats that are confined indoors. After tissue cysts or oocysts are ingested by the cat, viable organisms are released and invade epithelial cells of the small intestine, where they undergo an asexual cycle followed by a sexual cycle and then form oocysts, which are then excreted. The unsporulated (i.e., uninfective) oocyst takes 1 to 5 days after excretion to become sporulated (infective). Although cats shed oocysts for only 1 to 2 weeks, large numbers may be shed, often exceeding 100,000 per g of feces. Oocysts can survive in the environment for several months to more than a year and are remarkably resistant to disinfectants, freezing, and drying but are killed by heating to 70°C for 10 min.

EPIDEMIOLOGY AND TRANSMISSION

Serologic prevalence data indicate that toxoplasmosis is one of the most common infections of humans throughout the world. Because *T. gondii* organisms are rarely detected in humans with toxoplasmosis, serologic examination is used to indicate the presence of the infection by detecting *Toxoplasma*-specific antibodies. The prevalence of positive serologic titers increases with age. Infection is more common in warm climates and at lower altitudes than in cold climates and mountainous regions. This distribution is probably related to conditions favoring the sporulation and survival of oocysts. Variations in the prevalence of infection between geographic areas and between population groups within the same locale are also probably due to differences in exposure. A high prevalence of infection in France (65 to 85%) has been related to a preference for eating raw or undercooked meat. However, a high prevalence in Central America has been related to the frequency of stray cats in a climate favoring the survival of oocysts. Among U.S. military recruits in 1962, seroprevalence rates of up to 30% were found in people living along the sea coast, with rates of less than 1% in the Rocky Mountains and the desert Southwest. More recent data comparing antibody prevalence in U.S. military recruits in 1962 and 1989 indicated a one-third decrease in seropositivity (80). The overall seroprevalence in the United States as determined with specimens collected by the Third National Health and Nutritional Assessment Survey (NHANES III) between 1988 and 1994 among persons 12 or more years of age was found to be 22.5%, with seroprevalence among women of childbearing age (15 to 44 years) of 15% (43). No statistically significant differences were found in *T. gondii* antibody prevalence between NHANES III and NHANES 1999–2000 samples (42).

Human infection may be acquired in several ways: (i) ingestion of undercooked infected meat containing *T. gondii* cysts; (ii) ingestion of the oocyst from fecally contaminated hands, food, or water; (iii) organ transplantation or blood transfusion; (iv) transplacental transmission; and (v) accidental inoculation of tachyzoites. The two major routes of transmission of *Toxoplasma* to humans are oral and congenital. In humans, ingesting either the tissue cyst or the oocyst results in the rupture of the cyst wall, which releases organisms that invade the intestinal epithelium, disseminate throughout the body, and multiply intracellularly. The host cell dies and releases tachyzoites, which invade adjacent cells and continue the process. The tachyzoites are pressured by the host's immune response to transform into bradyzoites and form tissue cysts, most commonly in skeletal muscle, myocardium, and brain; these cysts may remain throughout the life of the host. Recrudescence of clinical disease may occur if the host becomes immunosuppressed and the cysts rupture, releasing the parasites.

Prevention

Risk factors for *T. gondii* infection identified in epidemiologic studies include eating raw or undercooked pork, mutton, lamb, beef, mincemeat products, or wild game meat; cleaning

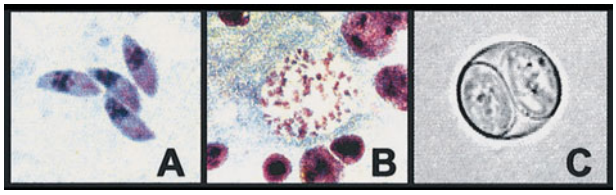

FIGURE 1 Three life stages of *T. gondii*. (A) Tachyzoites, Giemsa stain. (B) Cyst with bradyzoites in brain tissue, Giemsa stain. (C) Sporulated oocysts, unstained. (Photographs courtesy of J. P. Dubey, U.S. Department of Agriculture, Beltsville, Md.)

the cat litter box; contact with soil (gardening and yard work); and eating raw or unwashed vegetables or fruits (44). Recommendations for prevention of toxoplasmosis in pregnant women were discussed at a conference at the Centers for Disease Control and Prevention and published (5). These recommendations included the following: (i) food should be cooked to safe temperatures (beef, lamb, and veal roasts and steaks to at least 145°F; pork, ground meat, and wild game to 160°F; poultry to 180°F); (ii) fruits and vegetables should be peeled or washed thoroughly before eating; (iii) cutting boards, dishes, counters, utensils, and hands should always be washed with hot, soapy water after they have contacted raw meat, poultry, seafood, or unwashed fruits or vegetables; (iv) pregnant women should wear gloves when gardening and during any contact with soil or sand because cat waste might be in soil or sand, and they should wash their hands afterwards; (v) pregnant women should avoid changing cat litter if possible. If no one else is available to change the cat litter, pregnant women should use gloves and then wash their hands thoroughly. The litter box should be changed daily because *T. gondii* oocysts require more than one day to become infectious. Pregnant women should be encouraged to keep their cats inside and not adopt or handle stray cats. Cats should be fed only canned or dried commercial food or well-cooked table food, not raw or undercooked meats.

CLINICAL SIGNIFICANCE

Toxoplasmosis can be categorized into four groups: (i) acquired in the immunocompetent patient; (ii) acquired or reactivated in the immunodeficient patient; (iii) congenital; and (iv) ocular. Methods of diagnosis and their interpretations may differ for each clinical category.

Acquired infection with *Toxoplasma* in immunocompetent individuals is generally an asymptomatic infection. However, 10 to 20% of patients with acute infection may develop cervical lymphadenopathy and/or a flu-like illness. The clinical course is benign and self-limited; symptoms usually resolve within weeks to months.

Immunodeficient patients often have central nervous system (CNS) disease but may have myocarditis or pneumonitis. In patients with AIDS, toxoplasmic encephalitis is the most common cause of intracerebral mass lesions and is thought to be due to reactivation of chronic infection. Toxoplasmosis in patients being treated with immunosuppressive drugs may be due to either newly acquired or reactivated latent infection.

Congenital toxoplasmosis results from an acute primary infection acquired by the mother during pregnancy. The incidence and severity of congenital toxoplasmosis vary with the trimester during which infection was acquired. Because treatment of the mother may reduce the severity of symptoms in the infant due to congenital infection, prompt and accurate diagnosis is extremely important. Many infants with subclinical infection at birth will subsequently develop signs or symptoms of congenital toxoplasmosis; however, treatment may help prevent subsequent symptoms.

Ocular toxoplasmosis, an important cause of chorioretinitis in the United States, may be the result of congenital or acquired infection. Acquired infection is now thought to be more common than congenital infection. Congenitally infected patients are often asymptomatic until the second or third decade of life, when lesions develop in the eye presumably due to cyst rupture and subsequent release of tachyzoites and bradyzoites. Chorioretinitis is characteristically bilateral in patients with congenital infection but is often unilateral in individuals with acute acquired *T. gondii* infection.

In general, physicians treat *T. gondii* infection in four circumstances: (i) pregnant women with acute infection, to prevent fetal infection (11, 24, 28); (ii) congenitally infected infants (31, 51); (iii) immunosuppressed persons, usually with reactivated disease (6, 7, 81); and (iv) acute and recurrent ocular disease (38). Drugs are also prescribed for preventive or suppressive treatment in human immunodeficiency virus (HIV)-infected persons (4). The currently recommended drugs work primarily against the actively dividing tachyzoite form of *T. gondii* and do not eradicate encysted organisms (bradyzoites).

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

Serum, plasma, cerebrospinal fluid (CSF), ocular fluid, and amniotic fluid may be tested for antibodies and/or parasite DNA.

Collection for Determination of Parasite DNA

To determine parasite DNA, blood samples should be collected with an anticoagulant; CSF, ocular fluid, and amniotic fluids do not need an anticoagulant. All samples should be shipped and stored at 4°C prior to testing.

Collection for Antibody Determination

Blood specimens to be tested for the presence of antibodies should be allowed to clot and centrifuged, and the serum should be removed and shipped to a reference laboratory. Hemolysis does not seem to interfere with the antibody reaction in most tests. Serum and CSF specimens may be stored for several days at 4°C or frozen for longer storage. Specimens may be shipped at ambient temperature unless they are to be in transit for more than 1 week or be subjected to temperatures above 30°C. To avoid evaporation of small volumes, ocular fluids should be stored and shipped frozen. CSF and ocular fluid should be tested in parallel with a serum sample drawn on the same date. Long-term storage should take place at –20°C or below.

If the determination of immune status is the reason for testing, a single serum specimen is satisfactory; acute- and convalescent-phase specimens are not necessary. In situations in which determining the time of infection is important, specimens drawn at least 3 weeks apart may or may not be useful. In most cases, detection of an increasing immunoglobulin G (IgG) or IgM titer is not possible because the titers have already reached a plateau by the time the initial sample is drawn. If two specimens are to be compared, they should be tested together. Results from tests done at different times, in different laboratories, or with different procedures should not be compared quantitatively, only qualitatively, as positive or negative.

For tests other than serology, contact a reference laboratory for instructions *before* collecting specimens to ensure proper collection and handling.

DIRECT EXAMINATION

Microscopy

Only very rarely can the diagnosis of toxoplasmosis be documented by the observation of parasites in patient specimens by microscopy. Secretions, excretions, body fluids, and tissues are potential specimens for direct observation of parasites but are generally unrewarding. Fluid specimens such as heparinized blood or CSF should be centrifuged, and the sediment should be smeared on a microscope slide. The slides should be air dried, fixed in methanol, and stained with Giemsa for microscopic examination. Tachyzoites may be observed as free organisms or within host cells such as leukocytes. Well-preserved tachyzoites are crescent shaped and stain well, but degenerating organisms may be oval and stain poorly. Tissue imprints stained with Giemsa may reveal *T. gondii* cysts.

Antigen Detection

Immunologic techniques have been used to identify parasites in tissue sections or tissue cultures; fluorescein isothiocyanate- or peroxidase-labeled antisera may be useful in detecting tachyzoites in tissue sections. Enzyme immunoassay (EIA) antigen detection techniques lack sensitivity for human samples and are not recommended.

Nucleic Acid Detection Techniques

PCR technology for *Toxoplasma* has been used to detect congenital infections, toxoplasmic encephalitis in AIDS patients, and ocular disease with various degrees of success. The most important use of PCR appears to be in the prenatal diagnosis of congenital toxoplasmosis. When maternal serological results indicate potential infection during pregnancy, PCR of amniotic fluid has been shown to be more sensitive for the confirmation of fetal infection than the conventional methods of inoculation of mice and tissue culture cells, and fetal blood testing for IgM (23, 36). PCR technology for *Toxoplasma* is offered at the Toxoplasma Serology Laboratory, Palo Alto, Calif., and by a few commercial laboratories. Commercial kits are not yet available. The requestor should be aware that the reliability of PCR tests may vary widely (32, 67).

ISOLATION PROCEDURES

Parasites can be isolated with limited success by inoculating patient tissue or body fluids into either mice or tissue culture cells. Fresh tissue samples are ground in saline with a mortar and pestle and inoculated into the peritoneum of mice or directly into tissue culture flasks. The mice should be monitored for 4 to 6 weeks; if the organism is virulent for mice, the parasites can often be demonstrated in the peritoneal fluid after 5 to 10 days. However, if the organism is relatively avirulent for mice, as is usually the case, the mice may not be killed by the infection. If they survive for 6 weeks, serum samples should be obtained for testing. If antibodies are present, the mouse brain should be examined for the presence of *T. gondii* cysts. If cysts are not observed, the murine host may not have been the ideal host. Inoculate additional mice with brain homogenate from the initially inoculated mice and observe and recheck after 6 weeks. *T. gondii* grows in a variety of tissue culture cells. A cytopathic effect may be detected on direct examination after 24 to 96 h in culture. Giemsa staining may reveal parasite structure, but parasitized cells may be difficult to detect. Immunofluorescence allows more sensitive detection of the organisms. The following procedure has been used with some success for parasite isolation from amniotic fluids (16). Centrifuge a 10-ml sample of amniotic fluid at 1,000 × *g*. Resuspend the sediment in 8 ml of minimum essential medium. Inoculate 1 ml into coverslip cultures of human embryonic fibroblast cell line MRC5 in 24-well plates. Incubate the cultures for 96 h with one change of medium at 24 h; fix the cultures with cold acetone. Examine the coverslips by indirect immunofluorescence for the presence of *T. gondii.* The use of tissue culture cells for isolation permits a more rapid diagnosis than mouse inoculation; both methods can be useful for diagnosing congenital toxoplasmosis.

SEROLOGIC TESTS

Many tests for the detection of antibodies to *Toxoplasma* have been used since Sabin and Feldman developed the methylene blue dye test (DT) (66). Commercial kits for agglutination tests, indirect fluorescent antibody (IFA) tests, and EIA are available worldwide. Because of difficulties in obtaining specimens from patients with clinically documented toxoplasmosis, commercial kit sensitivity and specificity may not be based on documented case specimens but rather on a comparison of results obtained with another kit. Consequently, the true sensitivity and specificity of a kit are generally not known or determined. The rates stated by the manufacturer or published in articles may vary depending on the samples chosen for testing. Sensitivity and specificity rates determined in prospective studies, when random samples are tested as received for *Toxoplasma* testing, will usually differ from those determined in retrospective studies, when the samples have been chosen as potential problem samples to increase the probability of detecting false-positive or false-negative reactions.

When laboratory personnel decide to initiate *Toxoplasma*-specific antibody testing or when they decide to switch to a different antibody detection kit, the user must carefully review the manufacturer's package insert and published literature for information on the sensitivity and specificity rates. The user should perform an in-laboratory comparison of kits by using positive and negative samples confirmed by a toxoplasmosis reference laboratory. Tables 1 and 2 list commercial kits currently available in the United States and references to published evaluations. However, the test kit industry is in a great deal of flux; company and kit names may change.

In the United States, initial testing for the presence of IgG antibodies in most laboratories is usually performed with an EIA or IFA commercial kit. Results may be stated in international units (based on the WHO international standard reference serum for *Toxoplasma* (68) distributed by the PHLS Reference Unit, Public Health Laboratory, Singleton Hospital, Swansea SA2 8QA, Wales, United Kingdom), as an index (specific to each kit), as an optical density value (specific to each kit), or as a geometric mean titer. Numerical results are not comparable from kit to kit; comparison may be made only qualitatively as negative (nonreactive or not infected) or positive (reactive or infected). Although elevated *Toxoplasma*-specific IgG levels have been suggested as an indicator of recent infection, high levels may last for many years after primary infection and should not be relied upon for this purpose.

To more definitely distinguish acute and chronic infections, detection of *Toxoplasma*-specific IgM antibodies has been used. The most important use of IgM test results is that a negative reaction essentially excludes recent infection. A guide to the general interpretation of *Toxoplasma* IgG and

IgM serology results is presented in Table 3. IFA IgM titers generally increase within 1 week of the onset of symptoms and revert to negative within 6 to 9 months of infection. False-positive reactions caused by rheumatoid factor and false-negative reactions caused by blockage by *Toxoplasma*-specific IgG may occur in IFA IgM and indirect EIA for IgM when whole-serum samples are tested. To decrease the effects of these interfering factors, specimens should be treated to obtain only the IgM fraction for testing.

The IgM capture EIA eliminates potential interference by IgG and other isotypes by binding only IgM antibodies; unbound antibodies are removed by washing, thus eliminating the need for serum fractionation. The most important advantage of the IgM capture EIA compared to IFA is the increased detection of congenital infections: the IgM enzyme-linked immunosorbent assay (ELISA) was positive for 73% of serum samples from newborn infants with proven congenital toxoplasmosis, whereas only 25% of the same serum samples were found positive by an IFA IgM test (59). Although the capture EIA system is more efficient at detecting acute infections, some persons may have undetectable or low-level IgM antibodies, and some persons may have detectable IgM antibodies beyond 2 years postinfection (30). Therefore, determining the relative time of infection is not possible with this system alone. Many commercial companies market an EIA kit for IgM: some use the indirect EIA format with a serum pretreatment step, while others use the IgM capture format. False-positive IgM reactions due to unknown factors may be a problem with commercially available kits (85).

The Toxoplasma IgG avidity test is an additional tool to help rule out that a patient's infection occurred within the prior 4 to 5 months (67). Results are based on the measurement of the avidity of *Toxoplasma*-specific IgG antibodies. Depending on the method used, a high avidity result indicates infection acquired more than 3 to 5 months before. However, a low avidity result does not indicate a recently acquired infection because low avidity antibodies may be detectable for a year postinfection. Commercial kits are not available in the United States but are available in other countries from Ani Labsystems (2), bioMérieux (56), and DiaSorin (62).

Other tests may be of assistance in determining current infection. Assays for *Toxoplasma*-specific IgA antibodies should always be performed in addition to IgM assays for newborns suspected of congenital infection (13, 84). The presence of *Toxoplasma*-specific IgE antibodies may also contribute to the determination of acute infections (22). Immunoblot assays may be useful in determining congenital infections (63) and ocular infections (69). These and other assays (45, 53) are available in the United States at the Toxoplasma Serology Laboratory, Palo Alto Medical Foundation, Palo Alto, Calif. (phone: 650-853-4828) and at many of the Toxoplasma Reference Laboratories in Europe.

A guideline for the clinical use and interpretation of serologic tests for *T. gondii* was published (9) by the Clinical and

TABLE 2 Toxoplasma IgM kits available commercially in the United States

Type of test and company[a]	Kit	Reference(s)
IFA		
GenBio	ImmunoFA Toxoplasma IgM	
Hemagen	VIRGO Toxo IgM	
Inverness	Toxoplasma gondii IgM	
Meridian	Toxoplasma IgM	
EIA		
Abbott Labs	IMx Toxo IgM	15, 35, 46, 50, 85
	AxSYM Toxo IgM	14, 29, 62
Bayer Diagnostics	Immuno1	
	ADVIA Centaur	60
Beckman Coulter	ACCESS Toxo M	14, 15, 20, 48
bioMérieux Vitek	VIDAS Toxo IgM	3, 14, 29, 35, 62, 85
Bio-Rad	Platelia Toxo IgM	15, 35, 47, 62, 85
Biotecx	OptiCoat Toxo IgM	
Biotest Diagnostics	Toxo IgM	
Diagnostic Products Corp.	IMMULITE	21, 83
Diamedix	Toxoplasma IgM	79
DiaSorin	Toxoplasma IgM	
	LIAISON	62
Hemagan	Toxoplasma IgM	
Trinity Biotech	CAPTIA Toxoplasma gondii IgM	
Inverness	Toxo IgM

CLINICAL USE OF IMMUNODIAGNOSTIC TESTS

Determination of Immune Status

An algorithm for serological testing for immune status and acute acquired infection is shown in Fig. 2. Three situations in which baseline information about an individual's immune status would be useful include the following: (i) before conception; (ii) before receiving immunosuppressive therapy; and (iii) after the initial determination of positive HIV-1 status. Screening one serum specimen with a sensitive test for IgG antibodies, such as DT, IFA, or EIA, is sufficient. A negative test result indicates that the patient has not been infected. A positive result of any degree indicates infection with *T. gondii* at some undetermined time.

Diagnosis of Acute Acquired Infections

If an acute acquired infection is suspected, the patient's serum specimen should be tested for the presence of *Toxoplasma*-specific antibodies (Fig. 2). A negative result in DT, IgG IFA test, or IgG EIA essentially excludes the diagnosis of acute *Toxoplasma* infection in an immunocompetent person. Demonstration of seroconversion from a negative titer to a positive titer or of more than a fourfold increase in titer confirms the diagnosis when specimens drawn several weeks apart are tested at the same time with the same test. However, such situations are rare because specimens are usually drawn after titers have peaked, too late to observe titer changes after initial infection. Results of an EIA for IgM and an IgG avidity assay can provide additional evidence for or against acute infection when IgG antibodies are present (72). A negative IgM test essentially rules out infection in the previous 6 months. A positive IgM titer combined with a positive IgG titer may be suggestive of acute infection, due to persistent IgM antibodies, or may be a false-positive reaction. If the patient is pregnant, an IgG avidity test should then be performed. A high avidity result in the first 12 weeks of pregnancy essentially rules out an infection acquired during gestation. A low IgG avidity result cannot be used as an indicator of recent infection, because some individuals have persistent low IgG avidity for many months after infection. Immunodiagnosis of acute infection in a pregnant woman should be confirmed by a toxoplasmosis reference laboratory prior to intervention (45).

The presence of typical lymphadenopathy suggestive of acute toxoplasmosis, the presence of a high DT or IgG IFA titer (≥300 IU/ml or ≥1:1,000), and the presence of specific IgM are indicative of acute infection (54, 57). If the patient has clinical illness compatible with toxoplasmosis but the IgG titer is low, a follow-up test 3 weeks later should show an increase in the antibody titer if the illness is due to acute toxoplasmosis and the host is not severely immunosuppressed.

Diagnosis of Congenital Infection

Diagnosis of congenital toxoplasmosis involves diagnosing acute infection in a pregnant woman, demonstrating infection in the fetus, or documenting infection in the newborn infant (66). Congenital toxoplasmosis occurs when a woman passes the infection to her fetus after acquiring a primary infection during pregnancy or, more rarely, when a pregnant woman is immunocompromised and a previously acquired infection is reactivated. The rate of transmission of infection

TABLE 3 Guide to general interpretation of *Toxoplasma* serology results obtained with IgG and IgM commercial assays

IgG result	IgM result	Report/interpretation for humans except infants
Negative	Negative	No serological evidence of infection with *Toxoplasma*.
Negative	Equivocal	Possible early acute infection or false-positive IgM reaction. Obtain a new specimen for IgG and IgM testing. If results for the second specimen remain the same, the patient is probably not infected with *Toxoplasma*.
Negative	Positive	Possible acute infection or false-positive IgM result. Obtain a new specimen for IgG and IgM testing. If results for the second specimen remain the same, the IgM reaction is probably a false positive.
Equivocal	Negative	Indeterminate: obtain a new specimen for testing or retest this specimen for IgG in a different assay.
Equivocal	Equivocal	Indeterminate: obtain a new specimen for both IgG and IgM testing.
Equivocal	Positive	Possible acute infection with *Toxoplasma*. Obtain a new specimen for IgG and IgM testing. If results for the second specimen remain the same or if the IgG becomes positive, both specimens should be sent to a reference laboratory with experience in the diagnosis of toxoplasmosis for further testing.
Positive	Negative	Infected with *Toxoplasma* for more than 1 year.
Positive	Equivocal	Infected with *Toxoplasma* for probably more than 1 year or false-positive IgM reaction. Obtain a new specimen for IgM testing. If results with the second specimen remain the same, both specimens should be sent to a reference laboratory with experience in the diagnosis of toxoplasmosis for further testing.
Positive	Positive	Possible recent infection within the last 12 months, or false-positive IgM reaction. Send the specimen to a reference laboratory with experience in the diagnosis of toxoplasmosis for further testing.

to the fetus ranges from 11% in the first trimester to 90% in the late third trimester, with an overall transmission rate of approximately 40 to 50%.

In France and Austria, the prevention, diagnosis, and treatment of congenital toxoplasmosis begin with mandatory serologic testing of all women before or soon after conception. Although the cost-effectiveness of adopting this approach for all pregnant women in the United States has not been established, this approach does serve as a model for managing individual pregnant patients (11, 34, 36, 64).

Immunocompetent women who have IgG antibody before conception are considered immune and so at very little risk for transmission of infection to the fetus. Women who are seronegative are considered at risk for infection and in France are tested monthly during pregnancy for IgG antibody. If a woman is first tested after conception and has *Toxoplasma*-specific IgG antibodies, IgM and IgG avidity testing should be done to determine if acute infection has occurred during pregnancy (72) (Fig. 2). When the diagnosis of acute toxoplasmosis has been made for a pregnant woman, she can be treated and the fetus can be tested for evidence of infection. The strategy used by Daffos et al. (11) involved initiating treatment with spiramycin once acute maternal infection was indicated and then obtaining amniotic fluid and fetal blood samples between 20 and 26 weeks of gestation for testing (Fig. 3). Amniotic fluid PCR is the recommended test of choice to establish the intrauterine diagnosis of congenital toxoplasmosis (73, 74, 82). In addition, fetal ultrasound examinations were performed every 2 to 4 weeks until delivery to search for several nonspecific signs of infection: cerebral or hepatic calcifications, hydrocephalus, hepatomegaly, or ascites.

If collected, fetal blood should be tested for *Toxoplasma*-specific IgG, IgM, and IgA antibodies. Clotted blood should be inoculated into mice or tissue culture cells to demonstrate parasitemia. Nonspecific markers of infection should be tested for; these include leukocytes, eosinophils, platelets, total IgM, gamma-glutamyltransferase, and lactate dehydrogenase. Most infected fetuses have one or more abnormal nonspecific tests, most commonly an elevated total IgM level or an elevated gamma-glutamyltransferase level (11, 34, 64). Demonstrating *Toxoplasma*-specific IgM or IgA antibodies in fetal serum or isolating the parasite from fetal leukocytes is a definitive diagnosis of fetal infection.

Diagnosis of Infection in the Newborn

Diagnosis of *Toxoplasma* infection in the newborn is made through a combination of serologic testing, parasite isolation, and nonspecific findings (51, 58, 63, 64, 71). An attempt should be made to isolate *T. gondii* from the placenta, amniotic fluid, and cord blood if the diagnosis has not already been established (Fig. 4). *T. gondii* has been isolated from 95% of the placentas of congenitally infected newborns when the mother has not been treated and from approximately 81% when the mother has been treated. However, *T. gondii* can be isolated from the placentas of uninfected newborns as well. The child's serum should be tested for total IgG and IgM antibody levels and *Toxoplasma*-specific IgG, IgM, and IgA antibodies. CSF should be analyzed for cells, glucose, protein, total IgG antibody, and *Toxoplasma*-specific IgG and IgM antibodies and should be directly examined for *T. gondii* tachyzoites. A child suspected of having congenital toxoplasmosis should have a thorough general, neurologic, and ophthalmologic examination and a computed tomographic scan of the head (magnetic resonance imaging does not demonstrate calcifications). Because the diagnosis can take several months to confirm, clinicians may have to treat patients based upon early signs, symptoms, and serology while awaiting definitive confirmation. Although the complexity of diagnosing congenital infection necessitates the use of multiple costly laboratory tests, the benefit of early diagnosis and treatment and the cost of unnecessary treatment justify establishing the correct diagnosis.

Persistent or increasing IgG antibody levels in the infant compared with the mother as measured by the DT or IFA test, and/or positive result for *Toxoplasma*-specific IgM or IgA are diagnostic of congenital infection. Demonstration by immunoblotting that the newborn has serum antibodies that are directed against unique *Toxoplasma* epitopes not found in the mother's serum is also evidence of congenital infection (67, 70).

Placental leak can occasionally lead to false-positive IgM measurements in the newborn. However, because the half-life of IgM is 3 to 5 days, repeat testing at 1 week should

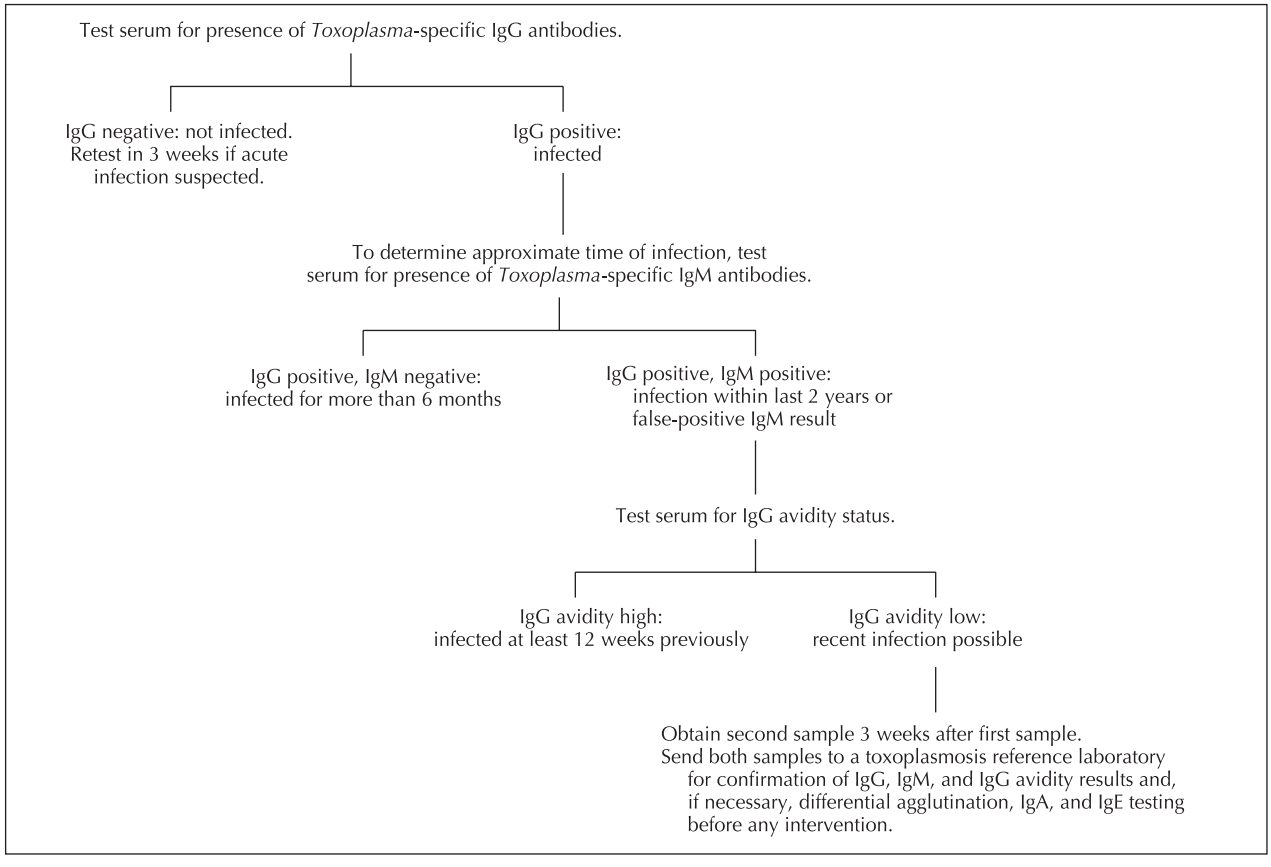

FIGURE 2 Algorithm for the serodiagnosis of toxoplasmosis in people greater than 1 year of age.

show a significant reduction in antibody titer if the child is not infected. Passively transferred maternal IgG has a half-life of approximately 1 month. Maternal antibodies can be detected for several months and have been reported up to 1 year of age. The untreated congenitally infected newborn will begin to produce *Toxoplasma*-specific IgG antibody within approximately 3 months. Treatment of the infected child may delay antibody production until 9 months of age and on rare occasion may prevent production altogether. Persistence of a positive IgG result for a child 12 months old confirms infection. Demonstration of a decrease in antibody load (*Toxoplasma*-specific IgG antibody divided by total IgG) can be helpful in differentiating maternal antibody from fetal antibody.

Although rarely performed, demonstration of IgM antibody or local *Toxoplasma*-specific IgG antibody production in CSF not contaminated with peripheral blood can help to confirm the diagnosis of congenital toxoplasmosis. The calculation is

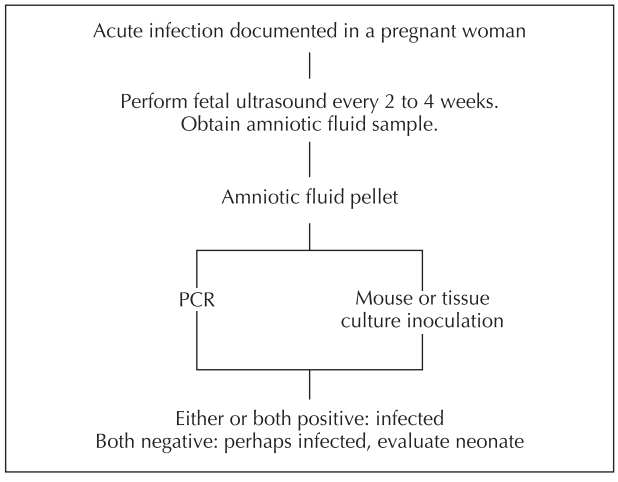

FIGURE 3 Algorithm for the diagnosis of antenatal congenital toxoplasmosis.

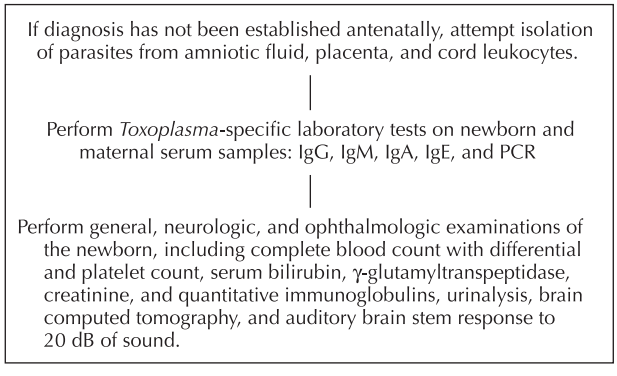

FIGURE 4 Algorithm for the diagnosis of neonatal toxoplasmosis.

made by dividing the *Toxoplasma*-specific antibody titer in the body fluid by the *Toxoplasma*-specific antibody titer in the serum and multiplying the result by the concentration of gamma globulin in serum divided by the concentration of gamma globulin in the body fluid. A result of four or greater corresponds to significant antibody production.

A long-term prospective study is currently under way in the United States to define optimal therapeutic regimens for the treatment of congenital toxoplasmosis (1, 51). Clinicians should contact Rima McLeod, University of Chicago Hospitals, Chicago, Ill. (phone: 773-834-4152), regarding the treatment of infected children.

Diagnosis of Ocular Infection

Toxoplasma chorioretinitis results from both acute infection and congenital infection (37, 38). In addition to demonstrating IgG antibody to *Toxoplasma* in the serum of a person with compatible eye lesions, demonstration of the local production of antibody and detection of parasite DNA in aqueous humor have been used to document active ocular toxoplasmosis (26). When the antibody load formula described in "Diagnosis of Infection in the Newborn" above is used to calculate results obtained in eye fluids and with results obtained in serum, a value of 8 or greater suggests acute ocular toxoplasmosis. If the serum DT titer is greater than 1:1,000, it is usually not possible to calculate local antibody production.

Diagnosis of Infection in the Immunocompromised Host

A wide variety of immunosuppressed hosts, including patients with lymphoma, leukemia, multiple myeloma, carcinoma, neuroblastoma, thymoma, systemic lupus erythematosus, scleroderma, and autoimmune hemolytic anemia and patients with kidney, liver, and heart transplants, have been described as having severe, often fatal, toxoplasmosis. The disease is most often related to reactivation of latent infection and commonly involves the CNS, although a wide spectrum of clinical manifestations have been reported. Diagnosis can be very difficult for these patients, as IgM antibody is usually not detectable and the presence of IgG antibody only confirms chronic infection. In the absence of serologic evidence of acute infection, diagnosis can be confirmed by demonstration of the organism histologically or cytologically as replicating within tissue or by isolation or identification of its nucleic acids in a site such as amniotic fluid, CSF, bronchoalveolar fluid, or placenta, in which the encysted organism would not be present as part of a latent infection.
