Rickettsia and *Orientia*

DAVID H. WALKER AND DONALD H. BOUYER

66

TAXONOMY

The family *Rickettsiaceae* comprises two genera of small, obligately intracellular bacteria that reside free within the cytosol, namely, *Rickettsia* and *Orientia*. Although the number and diversity of strains in each genus are similar, the practices of species designation differ remarkably. The second edition of *Bergey's Manual of Systematic Bacteriology* lists 20 validated names of *Rickettsia* species, and others have been proposed (84). *Orientia tsutsugamushi*, the single species of the genus, has 0.8% divergence of the *rrs* (16S rRNA) gene. Similarly, other obligately intracellular bacteria have 0.5% *rrs* divergence within a species (e.g., *Ehrlichia chaffeensis, Coxiella burnetii,* and *Chlamydia trachomatis*). A recent proposal of criteria for the limits of divergence of *Rickettsia* species would allow different species to be as closely related as 0.2% divergence for *rrs*, 0.8% for citrate synthetase *(gltA)*, 1.2% for outer membrane protein A *(ompA)*, 0.8% for outer membrane protein B *(ompB)*, and 0.7% for surface protein 4 *(sca4)* (15). There are no common or universal concepts that can be utilized to delineate prokaryotic species as there are with eukaryotes.

The typhus group (TG) and spotted fever group (SFG), defined originally by their distinctive lipopolysaccharide antigens, constitute the genus along with other ancestral species such as *R. bellii* and *R. canadensis*. The TG consists of only two members, *R. prowazekii* and *R. typhi*, whereas the SFG contains bacteria that are generally recognized as human pathogens *(R. rickettsii, R. akari, R. conorii, R. africae*, *R. sibirica, R. japonica, R. honei, R. felis, R. parkeri, R. slovaca*, *R. aeschlimannii,* and *R. australis)* as well as a steadily growing list of organisms identified only in arthropods (3, 50, 55, 84). Most of these species of undetermined pathogenicity, including *R. montanensis, R. bellii, R. peacockii,* and *R. rhipicephali,* are much more prevalent in U.S. ticks than is pathogenic *R. rickettsii*. In Europe, *R. helvetica* and *R. massiliae* have been proposed as human-infecting species based on limited evidence (5, 14). SFG isolates from Israel and the Astrakhan region of Russia, which have wider geographic distributions, are genetic variants of *R. conorii.* Similarly, SFG isolates recovered from *Hyalomma* ticks in Inner Mongolia and Africa and from patients in France and Africa have been designated the mongolotimonae strain of *R. sibirica*.

Orientia tsutsugamushi diverges from *Rickettsia* by approximately 10% in the *rrs* gene and differs greatly in its cell wall structure, containing completely unrelated proteins and lacking lipopolysaccharide and peptidoglycan (Table 1). Phylogeny using *groEL* reveals similar genetic diversity for the unispecies genus *Orientia* as for the *Rickettsia* genus, for which some believe that too many species have been created (Fig. 1) (35). *O. tsutsugamushi*, originally classified serologically, has subsequently been analyzed genetically (51). In each geographic area there are several genetic variants, and they differ from the genetic variants in other regions. Clonal evolutionary divergence has produced an enormous number of genotypes. Genetic variants of *O. tsutsugamushi* correspond to particular arthropod hosts in which divergence most likely occurred.

DESCRIPTION OF GENERA

Species of *Rickettsia* are small (0.3 to 0.5 μm by 1 to 2 μm), obligately intracellular bacteria of the α-*Proteobacteria* with a gram-negative cell wall structure that contains lipopolysaccharide, peptidoglycan, a major 135-kDa S-layer protein (OmpB), a 17-kDa lipoprotein, and for SFG rickettsiae a surface-exposed protein (OmpA) containing a variable number of nearly identical tandem repeat units (71). *Rickettsia* organisms have small (1.11 to 1.27 Mb), A+T-rich genomes resulting from reductive evolution with a high proportion (19 to 24%) of noncoding sequence and remarkable synteny (39). The lack of genes for enzymes for sugar metabolism, lipid biosynthesis, nucleotide synthesis, and amino acid synthesis and the presence of genes encoding enzymes for the complete tricarboxylic acid cycle and several copies of ATP/ADP translocase suggest both independent synthesis of ATP and acquisition of host ATP and rickettsial utilization of host sources for nutrition and building blocks. Rickettsiae adhere to the host cell receptor Ku70 by OmpB (and also by OmpA to an unknown receptor for SFG rickettsiae), trigger signaling pathways leading to recruitment and activation of induced phagocytosis, and escape from the phagosome by membranolytic activities of rickettsial phospholipase D and TlyC (36, 37, 82). *O. tsutsugamushi* (0.3 to 0.5 μm by 0.8 to 1.5 μm) has a major surface protein of 54 to 58 kDa as well as 110-, 80-, 47-, 42-, 35-, 28-, and 25-kDa surface proteins but lacks muramic acid, glucosamine, 2-keto-3-deoctulonic acid, and hydroxy fatty acids, suggesting the absence of lipopolysaccharide and peptidoglycan. Compared with *Rickettsia* spp., *Orientia* has a more plastic gram-negative

TABLE 1 Characteristics of *Rickettsia* spp. and *Orientia tsutsugamushi*[a]

cell wall with a thicker outer leaflet and thinner inner leaflet of the outer envelope and does not have a slime layer.

EPIDEMIOLOGY AND TRANSMISSION

Rickettsia spp. reside in an arthropod host (tick, mite, louse, flea, or other insect) for at least a part of their life cycle, during which they are maintained by transovarian transmission and/or cycles involving horizontal transmission to mammalian hosts (38) (Table 2). *Orientia* resides free in the cytosol and is maintained in nature by transovarian transmission in trombiculid mites, which transmit the infection to humans during feeding as the larval stage (Table 2).

CLINICAL SIGNIFICANCE

In addition to Rocky Mountain spotted fever (RMSF), rickettsialpox, murine typhus, flying squirrel-associated *R. prowazekii* infection, flea-borne spotted fever, and *R. parkeri* infection, which are indigenous to the United States, the potential for imported cases is significant for African tick bite fever, boutonneuse fever, murine typhus, and scrub typhus (Table 2) (10, 27, 28, 48, 54, 62, 75, 80). Other rickettsioses, either because of their geographic distribution and the infrequency of travelers' exposure to them or because of their incidence, are unlikely to be imported. RMSF, louse-borne typhus, and scrub typhus are life-threatening illnesses even for young, previously healthy persons. Murine typhus, boutonneuse fever, and North Asian tick typhus can have a fatal outcome in patients who are elderly or have underlying diseases or other risk factors. Although *R. felis, R. africae,* and *R. parkeri* cause milder, usually nonfatal rickettsioses, their importance has increased, with diagnoses over a wide geographic distribution (18, 45, 47, 85).

An average of 7 days after tick bite inoculation of rickettsiae, patients with RMSF develop fever, severe headache, malaise, and myalgia, frequently accompanied by nausea, vomiting, and abdominal pain and sometimes cough (27). A rash typically appears only after 3 to 5 days of illness. Rickettsiae infect endothelial cells, frequently leading to increased vascular permeability and focal hemorrhages (21). In severe cases, noncardiogenic pulmonary edema and rickettsial encephalitis

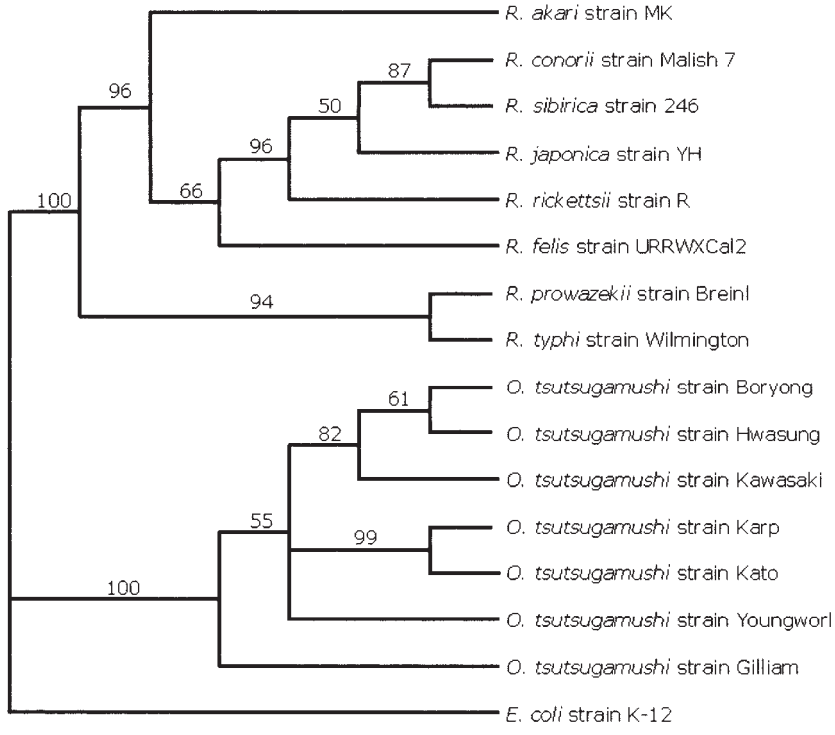

FIGURE 1 Phylogeny of *Rickettsia* and *Orientia* as determined by unweighted maximum parsimony analyses of *groEL* gene sequences prepared by PAUP 4.0 software with *Escherichia coli* as the outgroup. Numerical values on the branches represent the quantity of genetic divergence from the nearest node.

TABLE 2 Etiology, epidemiology, and ecology of rickettsial diseases

Organism	Disease	Geographic distribution	Typical mode of transmission to humans	Natural cycle
Spotted fever group				
R. rickettsii	Rocky Mountain spotted fever	Western Hemisphere	Tick bite	Transovarian in ticks and rodent-tick cycles
R. akari	Rickettsialpox	United States, Ukraine, Croatia, Korea	Mite bite	Transovarian in mites and mite-mouse cycles
R. conorii	Boutonneuse fever	Southern Europe, Africa, Middle East	Tick bite	Transovarian in ticks
R. africae	African tick bite fever	Sub-Saharan Africa, Caribbean	Tick bite	Transovarian in ticks
R. parkeri	American tick bite fever	North and South America	Tick bite	Transovarian in ticks
R. sibirica	North Asian tick typhus	Asia, Europe, Africa	Tick bite	Transovarian in ticks
R. japonica	Japanese spotted fever	Japan	Tick bite	Ticks
R. australis	Queensland tick typhus	Australia	Tick bite	Ticks
R. honei	Flinders Island spotted fever	Australia, Thailand	Tick bite	Transovarian in ticks
R. slovaca	Tick-borne lymphadenopathy	Eurasia	Tick bite	Unknown
R. felis	Flea-borne spotted fever	North and South America, Europe, Africa	Not known	Transovarian in cat fleas
Typhus group				
R. prowazekii	Primary louse-borne typhus	Worldwide	Infected louse feces rubbed into broken skin or mucous membranes or inhaled as aerosol	Human-louse cycle; flying squirrel-flea and/or louse cycle
R. prowazekii	Brill-Zinsser disease	Worldwide	Recrudescence years after primary attack of louse-borne typhus	
R. typhi	Murine typhus	Worldwide	Infected flea feces rubbed into broken skin or mucous membranes or inhaled as an aerosol	Rat-flea cycle; opossum-flea cycle
Scrub typhus group				
O. tsutsugamushi	Scrub typhus	Japan, eastern Asia, northern Australia, west and southwest Pacific	Chigger bite	Transovarian in mites

with coma and seizures are grave conditions that often presage death (74).

Rickettsialpox has been recognized mainly as a nonfatal urban disease with disseminated vesicular rash and an eschar at the location of rickettsial inoculation by the feeding mite (28, 31). The complete spectrum of clinical manifestations of *R. felis* infections has yet to be determined. This disease suffers from diagnostic neglect despite its widening recognized geographic distribution and the prevalence of cat flea exposure (62, 85).

Murine typhus causes a rash in only slightly more than one-half of patients, cough and chest radiographic infiltrates suggesting pneumonia in many patients, and severe illness with seizures, coma, and renal and respiratory failure necessitating intensive care unit admission in 10% of hospitalized cases (10).

Travelers who have returned from Africa and develop fever, one or more eschars, and in some cases regional lymphadenopathy and a maculopapular or vesicular rash are very likely infected with *R. africae* (54).

Rickettsia prowazekii, R. rickettsii, R. typhi, and *R. conorii* are bioterror threats via aerosol exposure to organisms that are stable and infectious at a low dose (72).

Scrub typhus caused by *O. tsutsugamushi* occurs in the geographic area that is bordered by Japan, Korea, and Russia on the north, Australia on the south, Pakistan and Afghanistan on the east, and the Philippines and Micronesia on the west (51, 63, 67). Clinical symptoms of the disease include fever, headache, maculopapular rash, eschar, lymphadenopathy, and central nervous system involvement (24, 58, 65). Without treatment, mortality can reach up to 30% (24).

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

Blood should be collected as early as possible in the course of illness. For the isolation of rickettsiae, blood should be obtained in a sterile heparin-containing vial prior to the administration of antimicrobial agents that are active against rickettsiae (27, 33). For isolation and immunocytologic diagnosis, blood should be stored temporarily at 4°C and processed as promptly as possible. If inoculation of cell culture or animals must be delayed for more than 24 h, plasma, buffy coat, whole blood, or biopsied tissue should be frozen rapidly and stored at −70°C or in liquid nitrogen. EDTA- or sodium

citrate-anticoagulated blood collected in the acute state has been used effectively for the diagnosis of murine typhus, epidemic typhus, Japanese spotted fever, scrub typhus and, with lower sensitivity, RMSF and African tick bite fever, by PCR (17, 54, 61, 62, 64, 68, 69). PCR provides a higher diagnostic yield when applied to biopsy specimens of rickettsia-infected lesions, particularly eschars (44, 45). If whole blood, plasma, buffy coat, or tissue cannot be processed for PCR within several days, it should be stored at −20°C or lower.

For serologic diagnosis, blood is collected as early in the course of disease as possible, a second sample is collected after 1 or 2 weeks, and, if a fourfold rise in antibodies has not occurred, a third sample is collected 3 or 4 weeks after onset. The serum may be stored for several days at 4°C but should be stored frozen at −20°C or lower for longer periods to avoid degradation of the antibodies. However, blood samples collected by fingerstick on appropriate blotting paper in remote areas and sent by ordinary mail can be eluted for serologic diagnosis (13).

A 3-mm-diameter punch biopsy specimen of a skin lesion, preferably a maculopapule containing a petechia or the margin of an eschar, should be collected as soon as possible (41, 73). Although treatment should not be delayed, it is best to perform the biopsy prior to the completion of 24 h of treatment with a tetracycline or chloramphenicol. For immunohistologic detection of SFG or TG rickettsiae, the specimen can be snap-frozen for frozen sectioning or fixed in formaldehyde for the preparation of paraffin-embedded sections (21, 28, 41, 73–75, 77). The former approach yields an answer more rapidly, but freezing artifacts distorts the architecture of the tissue, and fixed tissue is more convenient for shipping to a reference laboratory (44). Aseptically collected autopsy tissues, e.g., spleen and lung, are useful for rickettsial isolation, ideally inoculated fresh, or held for 24 h at 4°C or stored frozen at −70°C for longer periods, if the specimen must be shipped to a public health or reference laboratory. Autopsy tissues can also be examined for rickettsiae by immunohistochemistry or PCR.

Body lice *(Pediculus humanus corporis)* removed from patients suspected of having epidemic typhus can be examined for the presence of rickettsiae. Body lice acquire rickettsiae and remain infected for life, thus providing a useful specimen for PCR diagnosis even after a prolonged period of shipping at ambient temperature and humidity, which do not ensure survival of the lice (60).

ISOLATION PROCEDURES

Due to their high infectivity and low dose capability, rickettsial isolation is performed in biosafety level 3 laboratories. Cumbersome historic methods such as inoculation of adult male guinea pigs, mice, or the yolk sac of embryonated chicken eggs have been supplanted by cell culture methods, except for isolation of *O. tsutsugamushi,* which is achieved by intraperitoneal inoculation of mice (27, 33). Vero, L-929, HEL, and MRC5 cells have been used in antibiotic-free media to isolate rickettsiae. The best results reported are achieved with heparin-anticoagulated plasma, buffy coat, or skin lesion biopsy specimen collected prior to administration of antirickettsial therapy.

Samples containing 0.5 ml of triturated clinical material mixed with 0.5 ml of tissue culture medium are inoculated as promptly as possible onto 3.7-ml shell vials with 12-mm-diameter round coverslips having a confluent layer of cells and centrifuged at 700 × *g* for 1 h at room temperature to enhance attachment and entry of rickettsiae into host cells (2, 33). After removal of the inoculum, the shell vials are washed with phosphate-buffered saline and incubated with minimal essential medium containing 10% fetal calf serum in an atmosphere containing 5% CO_2 at 34°C. At 48 and 72 h, a coverslip is examined by Giemsa or Gimenez stain or by immunofluorescence with antibodies against SFG and TG rickettsiae. Detection of four or more organisms is interpreted as a positive result. This method has yielded a diagnosis in 59% of samples from patients with boutonneuse fever who had neither been treated nor developed antibodies to *R. conorii* prior to collection of the sample (33). Rickettsiae were detected at 48 h of growth in 82% of the positive samples. Universal precautions should be exercised, and work should be performed in a laminar flow biosafety hood with use of gloves and gown. Although the quantity of rickettsiae in the cell culture is relatively low, avoidance of aerosol, internal, or contact exposure should be taken as for mycobacteria, fungi, and viruses.

IDENTIFICATION OF *RICKETTSIA* AND *ORIENTIA* ISOLATES

Rickettsiae isolated in cell culture can be identified by indirect immunofluorescence with group-, species-, and strain-specific monoclonal antibodies. In an increasing number of laboratories, rickettsial isolates are identified by molecular methods such as PCR amplification of genes that are genus specific (17-kDa protein, citrate synthase, or OmpB) or SFG specific (OmpA) (57). Determination of DNA sequences identifies unique isolates. *O. tsutsugamushi,* being more distantly related to *Rickettsia* spp., lacks the above cell wall genes but can be identified by PCR of the gene encoding the major immunodominant 56-kDa surface protein.

Identifying the species of rickettsial isolates by microimmunofluorescence serotyping requires intravenous inoculation of mice with rickettsiae on days 0 and 7 and collection of sera on day 10 (49). These high-titer antibodies react with conformational species-specific epitopes of OmpA and OmpB. Antibodies against group-specific lipopolysaccharide develop later in the murine immune response to *Rickettsia*. This rather cumbersome and expensive method requires propagation of large quantities of the isolate and of the prototype strains for immunofluorescence titration as well as for development of the typing sera. Genetic analysis of a larger portion of the genome is currently favored for identification of isolates. An isolate that is known to be a *Rickettsia* should be identified in a biosafety level 3 laboratory, and isolates of *R. rickettsii* and *R. prowazekii* must be handled as required by U.S. federal regulations for select agents.

DIRECT DETECTION OF THE ETIOLOGIC AGENT IN CLINICAL SAMPLES BY IMMUNOLOGIC AND GENETIC METHODS

The diagnoses of RMSF, boutonneuse fever, murine typhus, louse-borne typhus, and rickettsialpox have been established by immunohistochemical detection of rickettsiae in formalin-fixed, paraffin-embedded sections of biopsy specimens of rash and eschar lesions (21, 27, 28, 41, 73, 75, 77) (Fig. 2, left). Monoclonal antibodies that are specific for lipopolysaccharides of either SFG or TG rickettsiae have been used to detect rickettsiae by immunoperoxidase staining (Fig. 2, right). There is no antibody commercially available (75, 76). The sensitivity and specificity of immunohistochemical detection of *R. rickettsii* in cutaneous biopsy specimens are 70 and 100%, respectively (27, 73). Eschar biopsies yield

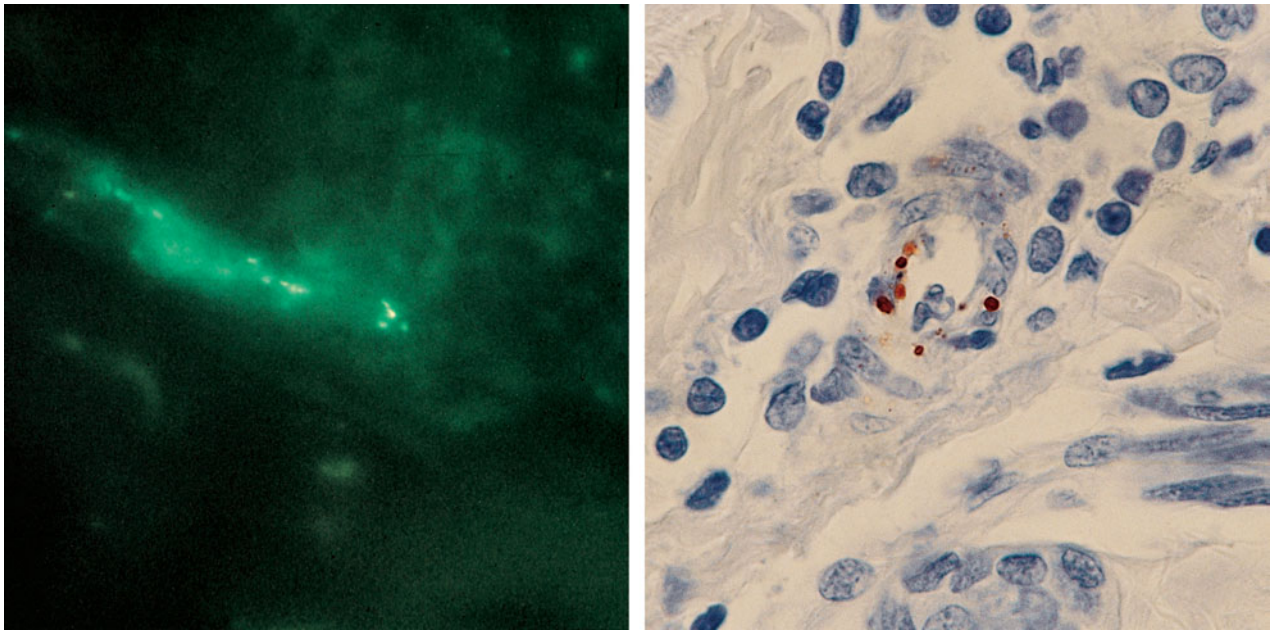

FIGURE 2 (Left) Direct immunofluorescence staining of skin biopsy specimens with anti-SFG *Rickettsia* antibodies facilitates rapid diagnosis. Rickettsiae are present in the vessel wall. (Right) Demonstration of rickettsial organisms in the microvasculature of the dermis in a patient with a history of Rocky Mountain spotted fever. Rickettsiae are seen in the vessel wall. An immunoperoxidase stain, using monoclonal antibodies directed against spotted fever group lipopolysaccharide, was used. Skin biopsy magnification, ×800.

sensitive specimens for the diagnosis of SFG rickettsioses that manifest that lesion and should be considered for diagnostic evaluation in patients suspected to have rickettsialpox, boutonneuse fever, or African tick bite fever.

Immunocytochemical detection of *R. conorii* in circulating endothelial cells has been accomplished by capture of the endothelial cells from blood samples using magnetic beads coated with a monoclonal antibody to a human endothelial cell surface antigen followed by immunofluorescent staining of the intracellular rickettsiae (33). This method has a sensitivity of 50% and a specificity of 94%. Rickettsiae are detected in 56% of untreated patients and in 29% of patients receiving antirickettsial treatment. *O. tsutsugamushi* has been identified using immunohistochemistry in human endothelial cells, macrophages, and cardiac myocytes (42). In situ hybridization has not been reported for the detection of rickettsiae in tissue samples.

PCR has been applied to the amplification of the DNA of *R. rickettsii*, *R. conorii*, *R. japonica*, *R. typhi*, *R. prowazekii*, *R. africae*, *R. felis*, *R. akari*, *R. slovaca*, and *O. tsutsugamushi*, usually from peripheral blood, buffy coat, or plasma, but occasionally from fresh, frozen, or paraffin-embedded tissue or arthropod vectors from patients (8, 12, 17, 44, 54, 59-62, 64, 66, 68–70). Nested PCR applied to skin biopsy specimens, particularly of eschars prior to treatment, has a sensitivity of 78% (16). For all pathogenic *Rickettsia* spp., the 17-kDa lipoprotein gene is the principal target, employing the primers CATTACTTGGTTCTCAATTCGGT and GTTTTATTAGTGGTTACGTAACC, which amplify a 231-bp DNA fragment (62). The *glt*A, *rrs*, and *omp*A genes have also been amplified diagnostically, with the *Rickettsia* being identified through either restriction fragment length polymorphism analysis using AluI and XbaI or sequencing of the PCR product (62). The availability of rickettsial genome sequences offers the possible design of an enormous number of primer sets. The approach of using primer sets on a single occasion to reduce the chances of amplicon contamination and false-positive results seems impractical. With batch processing being done annually, the delay in laboratory results reduces the clinical value (16). The single use of primers requires that their utility and sensitivity be unknown. The potential for amplicon contamination originating from a positive patient sample remains even if there is no positive control. Recent advances in technology such as real-time PCR allow for increased sensitivity in the detection of rickettsiae (12, 32, 43, 59, 70). The advantage of real-time PCR is detection of rickettsial organisms during the early or acute phase of disease before the generation of antibody. The targets for primer design have ranged from housekeeping genes (*glt*A) to antigen genes (*omp*A and *omp*B). The sensitivities for detection vary among primer sets. For example, real-time assays utilizing primer set RR.190.547F (CCTGCCGATAATTATACAGGTTTA) and RR.190.701R (GTTCCGTTAATGGCAGCAT), which generates a product of 154 bp, can detect five copies of rickettsial DNA (12). The primer set CS-5 and CS-6 detects 1 copy of *R. rickettsii* DNA and 10 copies of *R. bellii* DNA. Perhaps the best potential demonstration of real-time PCR as a diagnostic assay was observed in the primers targeting *ompB* and an *ompB* probe (70). For *O. tsutsugamushi*, the 56-kDa protein gene is the usual target of diagnostic PCR (68). The nested 56-kDa gene PCR assay is highly sensitive for the diagnosis of *O. tsutsugamushi* infections during the acute phase of the disease (61). PCR amplification of DNA from blood samples, using primers p34 (TCAAGCTTATTGCTAGTGCAATGTCTGC) and p55 (AGGGATCCCTGCTGCTGTGCTTGCTGCG), which generate a 1,003-bp product, followed by nested PCR with primers p10 (GATCAAGCTTC-

CTCAGCCTACTATAATGCC) and p11 (CTAGGGATCC-CGACAGATGCACTATTAGGC), amplifies a 483-bp product. This assay detects 10 prototype strains of *O. tsutsugamushi* and does not amplify *R. typhi* or *R. honei*. A duplex PCR assay using the *groEL* gene identifies both SFG rickettsiae and *O. tsutsugamushi* (46). Real-time PCR assays utilizing the *Orientia htrA* gene have been applied to diagnosis with clinical samples (24, 66).

Molecular and immunohistochemical diagnostic testing, the most useful methods for establishing a diagnosis during the acute stage of illness when therapeutic decisions are critical, are available at this time, to the best of our knowledge, in only a few reference laboratories including ours. Individual cases for immunohistochemistry may be referred to the following laboratories after contacting the directors for consultation: David H. Walker, M.D., Department of Pathology, University of Texas Medical Branch, 301 University Blvd., Keiller Building, Room 1.116, Galveston, TX 77555-0609, telephone (409) 772-3989, fax (409) 772-1850, e-mail dwalker@utmb.edu; J. Stephen Dumler, M.D., Division of Medical Microbiology, Department of Pathology, The Johns Hopkins Medical Institutions, Meyer B1-193, 600 North Wolfe Street, Baltimore, MD 21287, telephone (410) 955-5077, fax (410) 614-8087, e-mail sdumler@jhmi.edu; and Sherif Zaki, M.D., Ph.D., Department of Pathology, Centers for Disease Control and Prevention, 1600 Clifton Road Mail Stop G32, CDC, Atlanta, GA 30333, telephone (404) 639-3133, e-mail sxz1@cdc.gov.

SEROLOGIC TESTS

For most clinical microbiology laboratories, assays for antibodies to rickettsiae are the only tests performed. This situation is unfortunate for the patient with a life-threatening, acutely incapacitating rickettsial disease because these assays are useful principally for serologic confirmation of the diagnosis in convalescence and usually do not provide information that is helpful in making critical therapeutic decisions during the acute stages of illness. Patients who died of rickettsioses usually had received many antibiotics, none of which had antirickettsial activity owing in part to the lack of laboratory data providing clinical guidance for a rickettsial diagnosis. The earlier a diagnosis is established, the shorter the course of rickettsial illness after an appropriate antirickettsial antibiotic is administered.

Serologic assays for the diagnosis of rickettsial infections include the "gold standard" indirect immunofluorescence assay (IFA), indirect immunoperoxidase assay, latex agglutination, enzyme immunoassay (EIA), *Proteus vulgaris* OX-19 and OX-2 and *Proteus mirabilis* OX-K strain agglutination, line blot, Western immunoblotting, and rapid flow assays (4, 7, 9–11, 19, 22, 25–30, 52, 73, 81, 83). Only a portion of these assays are available as commercial kits or as assays performed in reference laboratories for some, but not all, rickettsial diseases. Other serologic tests such as indirect hemagglutination, microagglutination, and complement fixation are no longer in general use.

The IFA contains all the rickettsial heat-labile protein antigens and group-shared lipopolysaccharide antigen and, thus, provides group-reactive serology. IFA reagents are available commercially for SFG and TG rickettsiae from Panbio, Inc., Baltimore, Md.; Focus Technologies, Cypress, Calif., and bioMerieux, Durham, N.C.; they are also available for *O. tsutsugamushi* from Panbio, Inc. In cases of RMSF, IFA detects antibodies at a diagnostic titer of ≥64, usually in the second week of illness. Effective antirickettsial treatment of RMSF must be initiated by day 5 of illness to avoid a potentially fatal outcome. For boutonneuse fever, a diagnostic IFA titer of ≥40 occurs in 46% of patients between days 5 and 9 of illness, in 90% of patients between 20 and 29 days, and in 100% of patients thereafter. In murine typhus, diagnostic IFA titers are present in 50% of cases by the end of the first week of illness and in nearly all cases by 15 days after onset (10). In areas where particular rickettsial diseases are endemic, a higher diagnostic cutoff titer is required. For example, for the IFA diagnosis of scrub typhus in patients residing in zones of endemicity, an IFA titer to *O. tsutsugamushi* of ≥400 is 96% specific and 48% sensitive, with sensitivity rising from 29% in the first week to 56% in the second week (4). Lowering the diagnostic cutoff titer to 100 raises the sensitivity only to 84% and reduces the specificity to 78%. These considerations are not as important when testing patients who have visited regions of endemicity for only a short period. Each laboratory performing the test should establish its own cutoff titers for the patient population, the microscope and reagents used, and the laboratorian's judgment of the minimal positive signal.

Indirect immunoperoxidase assays for scrub typhus, murine typhus, boutonneuse fever, and presumably other rickettsioses yield results similar to those of IFA when the immunoglobulin G (IgG) diagnostic titer is set at 128 and that of IgM is set at 32 (29). Advantages include the use of a light microscope rather than a fluorescent microscope and the production of a permanent slide result.

Latex agglutination test reagents are available commercially from Panbio, Inc., only for RMSF in the United States. Latex beads coated with an extracted rickettsial protein-carbohydrate complex containing rickettsial lipopolysaccharide are agglutinated mainly by IgM antibodies, with reports of a sensitivity of 71 to 94% and a specificity of 96 to 99% (19). A diagnostic titer of 128 is often detected early in the second week of illness.

EIAs have been developed in various formats including antigens coating microtiter wells or immobilized on nitrocellulose or other sheets for use in the commercial reference laboratory setting. Dot-EIA kits are commercially available as Dip-S-Ticks from Panbio, Inc., for detecting antibodies against *R. rickettsii, R. conorii, R. typhi*, and *O. tsutsugamushi* (29, 81). No peer-reviewed publications have evaluated the use of the dot-EIA for the diagnosis of RMSF. When compared with an IFA titer of ≥64 for the diagnosis of murine typhus, the dot-EIA showed a sensitivity of 88% and specificity of 91% (29). The dot-EIA for diagnosis of scrub typhus had sensitivities and specificities of only 80 and 77%, respectively, when compared with an IFA cutoff titer of 64, and 89 and 66%, respectively, at an IFA cutoff titer of 128 (81). These SFG rickettsiae and *R. typhi* kits detect cross-reactive antibodies as demonstrated in an outbreak of African tick bite fever by clinical and epidemiologic data. The dot-EIA of *R. conorii* antigen provided early diagnostic evidence of a SFG rickettsiosis. Subsequent analysis revealed poor specificity with a high rate of false-positive results. These assays are diagnostic tools that do not require expensive, specialized equipment, but they suffer from apparent low specificity. Standard EIAs for detecting IgG or IgM antibodies against SFG rickettsiae or *O. tsutsugamushi* are also available from Panbio. The utilization of these tests for paired sera from populations with clinical (fever, headache, or rash) and epidemiologic (tick exposure) features consistent with rickettsiosis would most likely yield useful information. A multitest Dip-S-Ticks EIA for scrub typhus, murine typhus, and leptospirosis was not useful in Thailand, where nearly all patients had

antibodies to more than one agent and others had antibodies against an agent that was not the cause of the illness (79). The diagnosis of scrub typhus by detection of antibodies in clinical samples in an IgM capture enzyme-linked immunosorbent assay can be utilized for single serum samples from early-stage infections (22). The performance values of this assay are a sensitivity of 96.3% and a specificity of 99%. A comparison of serologic methods for scrub typhus revealed that EIA containing recombinant p56 of Karp, Kato, and Gilliam strains was most sensitive (100%) and rapid lateral flow assay of antibodies against recombinant Karp p56 had a sensitivity of 86% (22). The latter, which is especially useful in situations with limited laboratory facilities and a low number of specimens, is available from Panbio Ltd., Brisbane, Australia.

The assays that have been most widely used for the diagnosis of rickettsial diseases are agglutination of the OX-19 and OX-2 strains of *Proteus vulgaris* for rickettsioses and the OX-K strain of *Proteus mirabilis* for *O. tsutsugamushi* infections. These assays have poor sensitivity and specificity (26, 73). They should be replaced by more accurate serologic methods such as IFA or EIA. However, there are situations in developing countries where the choice is between the *Proteus* agglutination tests and none at all for the detection of important public health problems such as outbreaks of louse-borne typhus. In fact, the evidence leading to the discovery of Japanese spotted fever and Flinders Island spotted fever included *Proteus* agglutinating antibodies.

Shared antigens of OmpA, OmpB, and group-specific lipopolysaccharide impede establishment of a species-specific diagnosis by serologic methods. The criterion of a fourfold or greater difference in IFA titers between the two suspected agents distinguished infections by *R. prowazekii* and *R. typhi* in only 34% of cases and infections by *R. africae* from those by *R. conorii* in only 26% (34, 54). Western immunoblotting detection of antibodies against OmpA or OmpB of only one *Rickettsia* species has also been proposed as a criterion for species-specific diagnosis. However, it was effective in distinguishing *R. prowazekii* and *R. typhi* infections or *R. africae* and *R. conorii* infections in only one-half of the cases (23, 34, 54). Cumbersome, expensive cross-absorption of sera prior to IFA or Western immunoblotting is more effective in establishing a species-specific diagnosis. However, interpretation of these results requires careful evaluation of the performance of valid controls, the quality and quantity of each antigen preparation, and the potential for the occurrence of infection by an untested, even as yet unrecognized, agent. In the past, knowledge of the geographic origin of the case sufficed to designate the specific diagnosis. However, the increasing number and geographic overlap of rickettsioses challenge the old assumptions.

ANTIMICROBIAL SUSCEPTIBILITY TESTING

Data supporting the use of doxycycline or another tetracycline antibiotic as the drug of choice for the treatment of infections caused by *Rickettsia* spp. and *O. tsutsugamushi* and the use of chloramphenicol as an alternative drug have been derived principally by empiric experience and retrospective case studies (20). In addition to historic studies of the activity of antimicrobial agents against these obligately intracellular bacteria in infected animals and embryonated eggs, studies of the effects of antimicrobial agents in cell culture have supported the consideration of alternative drugs such as fluoroquinolones, josamycin, azithromycin, and clarithromycin. Indeed, several fluoroquinolones, josamycin, and azithromycin have been used successfully for the treatment of boutonneuse fever under certain circumstances but cannot be recommended for more pathogenic rickettsioses (1, 6, 40, 53, 56). Except for cases of scrub typhus in Thailand which have not responded to doxycycline or chloramphenicol but for which azithromycin may be effective, there is little concern regarding rickettsial development of antimicrobial resistance (53, 78). During pregnancy, chloramphenicol has been used to treat RMSF and josamycin for boutonneuse fever. Antimicrobial susceptibility studies of rickettsiae are not routinely performed clinical laboratory tests.

INTERPRETATION AND REPORTING OF RESULTS

When reporting the results of an assay for antibodies in a single serum sample, the laboratorian seldom knows the duration of illness and whether the serum sample is from the acute or the convalescent phase of the disease. For sera that are nonreactive by dot-EIA, by IFA at a dilution of 1:64, by indirect immunoperoxidase assay at a dilution of 1:128, by latex agglutination at a dilution of 1:64, or by Weil Felix *Proteus* agglutination at a titer of 1:160, the laboratory report should state that no antibodies were detected at the particular cutoff dilution, which may differ among some laboratories and some patient populations, that negative results are expected in the acute stage of rickettsial illness, and that a second sample should be submitted to evaluate the possibility of seroconversion if no alternative diagnosis has been established. If paired acute- and convalescent-phase sera separated by an appropriate interval are available, they should be tested simultaneously. It is wise to test for all the rickettsial and ehrlichial agents to which the patient is likely to have been exposed in the United States. SFG rickettsiae, *Ehrlichia chaffeensis*, *Anaplasma phagocytophilum*, and *R. typhi* are the likely agents unless travel to an area where scrub typhus is endemic has occurred. If the paired sera are negative, the report should state that the results do not support the diagnosis of rickettsial infection, but that occasionally antibody synthesis is delayed, particularly in cases with early antirickettsial therapy. If a single serum sample contains an IFA antibody titer of $\geq$64, an IgM-IFA titer of $\geq$1:32, an indirect immunoperoxidase antibody titer of $\geq$128, a latex agglutination titer of $\geq$64, or a Weil Felix titer of $\geq$1:320, the laboratory report should state that antibodies reactive with the particular rickettsial antigen were detected at the measured titer, that the result provides supportive evidence for the diagnosis of the rickettsial disease, and that a convalescent-phase sample should be submitted to assess the possibility of seroconversion. If paired sera measured simultaneously show a fourfold or greater rise in titer, the interpretation is stated that the results strongly support the rickettsial diagnosis indicated by the tested antigen. If a significant titer was detected in the acute-phase sample, but no rise or only a single doubling dilution rise was measured, it should be stated that an additional later sample should be tested to evaluate a fourfold rise or fall in titer. The concept that recrudescent typhus could be distinguished from primary louse-borne typhus by the absence of IgM antibodies to *R. prowazekii* and of *Proteus* OX-19 agglutinating antibodies has been challenged (11). The manufacturers of the dot-EIA have recommended the interpretation that strongly reactive samples (three or four dots) may indicate the presence of a specific antibody response and that weakly reactive samples (one or two dots) are infrequent but possible in normal populations. Retesting 2 to 3 weeks later would establish the diagnosis if three or four dots develop in the convalescent serology and should always be performed.

Isolation of a rickettsia from blood or tissue may be interpreted as indicating an etiologic role. The level of identification of the isolate should be stated, whether identified only as to a group containing particular organisms or to the species level.

Immunohistologic and immunocytologic diagnostic interpretation states the method, reactivity of the method (e.g., antibody reactive with SFG rickettsiae), and location of the antigen (e.g., in vascular endothelium and frequently adjacent vascular smooth muscle for *R. rickettsii*). Detection of three or more rickettsiae in vascular endothelium in biopsy specimens or four or more rickettsiae in captured circulating endothelial cells is diagnostic of rickettsial infection.

Interpretation of PCR results should state the target gene, the organisms that would be detected, and the presence or absence of a DNA product of a particular size. If a specific oligonucleotide probe or DNA sequencing confirmed the specificity of the identification, this result should be stated. For negative immunohistologic, immunocytologic, and PCR results, it should always be stated that the failure to detect the agent does not exclude the diagnosis along with data regarding the sensitivity and specificity of the assay in the particular laboratory and the effects of antirickettsial treatment on the sensitivity.

Special efforts should be made to establish the diagnosis of fatal cases including rickettsial isolation, immunohistology, PCR, and serology on samples collected at necropsy.

Ehrlichia, Anaplasma, and Related Intracellular Bacteria*

JUAN P. OLANO AND MARIA E. AGUERO-ROSENFELD

67

TAXONOMY

Members of the genus *Ehrlichia* and *Anaplasma* have become important agents of human disease. Together with a number of other pathogens in several genera, they are obligate intracellular bacteria currently placed in the *Proteobacteria* phylum, section alpha, order *Rickettsiales* and family *Anaplasmataceae*. While most closely related to the genera *Rickettsia* and *Orientia,* organisms classically considered ehrlichiae could be divided into four major clades. Taxonomic classification of this group of bacteria (Fig. 1) is largely based upon sequence analysis of 16S rRNA genes and *groESL* operons (50). This classification has been further supported by sequence analysis of the citrate synthase (*gltA*), the β-subunit of RNA polymerase (*rpoB*), FtsZ protein (*ftsZ*), and rRNA genes (73–75, 83, 94, 132). The phylogenetic approach is further supported by serologic cross-reactions, comparisons among major immunodominant surface proteins, and the cellular tropisms of these bacteria (46, 77). All members of the tribes *Ehrlichieae* and *Wolbachieae* are included in the family *Anaplasmataceae* with elimination of the tribe structure of the family *Rickettsiaceae*. Current and former denominations of these bacteria associated with human and veterinary infections are found in Table 1. All tick-borne bacteria of *Anaplasmataceae* are grouped within two closely related genera, *Ehrlichia* and *Anaplasma*. The former members of the *Ehrlichia phagocytophila* group that include the species *Ehrlichia equi* and the bacterium formerly known as human granulocytic ehrlichiosis (HGE) agent were merged into a single species within the genus *Anaplasma* as *A. phagocytophilum*. Although minor sequence differences in the 16S rRNA gene exist between the former members of the *E. phagocytophila* group, it seems that such differences are related to their biological and ecological differences (34, 95, 128). Genetic variants of *A. phagocytophilum* have been reported in ticks and mammals in the Northeast United States and Europe (95, 128). Recently, a new agent closely related to *Ehrlichia ruminantium* has been found in *Ixodes ricinus* ticks removed from asymptomatic individuals in Northern Italy. This agent has been proposed as "*Candidatus* Ehrlichia walkerii" (27, 82, 123).

While *Ehrlichia* species infect predominantly leukocytes of humans and other mammals, *Anaplasma* species infect bone marrow-derived cells of all lineages in different animal hosts. *Neorickettsia* species infect predominantly mononuclear phagocytes and occasionally enterocytes in mammalian hosts. The genus *Aegyptianella* is currently listed as incerta sedis. *Wolbachia* spp. are "endocytosymbionts" of insects and helminths that are transmitted only by transovarial and transstadial (between stages of development) passage.

DESCRIPTION OF THE GENERA

Ehrlichia and *Anaplasma* spp. are obligate intracellular gram-negative bacteria that propagate and reside in cytoplasmic membrane-lined vacuoles in bone marrow-derived cells including granulocytes, monocytes, erythrocytes, and platelets, and for *E. ruminantium*, also within endothelial cells (118, 137, 141). Infection of endothelial cells is not surprising since both hematopoietic and endothelial cells are derived from a common ancestor, the hemangioblast that gives rise to angioblasts (endothelial precursor cells) and the hematopoietic stem cells. In fact, angioblasts share several cell surface markers with the hematopoietic stem cells and some of those markers are retained down to the endothelial differentiation (116).

For the genera *Ehrlichia* and *Anaplasma*, organisms are transmitted by tick bite, whereas organisms in the genera *Wolbachia* and *Neorickettsia* are not. Individual small (0.2- to 0.4-μm) dense forms of bacterial cells resembling chlamydial elementary bodies have been described, as have larger forms (0.8 to 1.5 μm) resembling reticulate bodies (113). Both are capable of binary fission, and a developmental cycle has not been demonstrated. After a few days, the elementary bodies dividing in the phagosome form an initial pleomorphic inclusion that matures into a microscopic colony known as a morula. *Neorickettsia sennetsu* grows as bacterial cells that may maintain their individual vacuolar membranes when they undergo binary fission, and thus an intracellular inclusion may not be identified by light microscopy. Cell lysis is a feature of the infectious process and leads to the release of cell-free bacteria that can infect other competent cells (22). Unlike *Rickettsia,* members of the genera *Ehrlichia* and *Anaplasma* do not show thickening of either leaflet of the outer membrane and the outer membrane appears to be more ruffled in *A. phagocytophilum* than in *N. sennetsu* or *Ehrlichia chaffeensis* (118). By transmission electron microscopy, *Ehrlichia* and *Anaplasma* spp. do not appear to contain significant amounts of peptidoglycan, a fact confirmed by the absence of genes

*This chapter contains information presented in chapter 65 by Maria E. Aguero-Rosenfeld and J. Stephen Dumler in the eighth edition of this Manual.

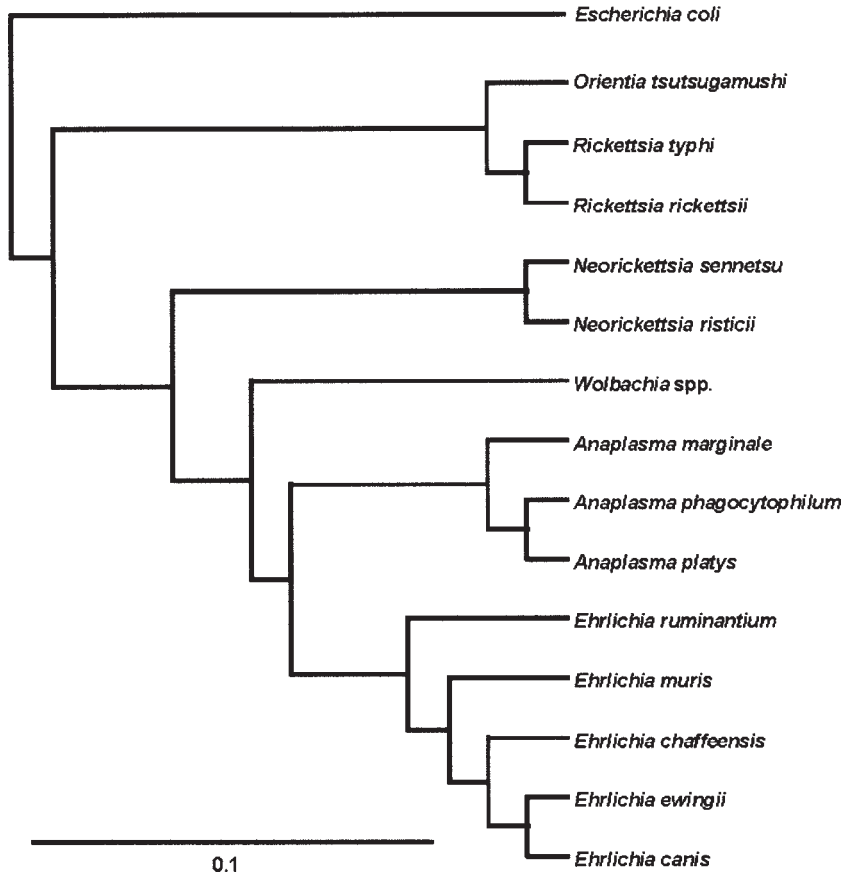

FIGURE 1 Neighbor-joining phylogenetic tree inferred from 16S ribosomal RNA gene sequences of selected *Ehrlichia, Anaplasma, Neorickettsia,* and *Wolbachia* spp. *Escherichia coli* is used as an outgroup. The bar represents the estimated number of substitutions per site.

necessary for the synthesis of this cell wall component on the full genome sequences currently available for *Anaplasma marginale* and *E. ruminantium* (20, 40). The genome size of *N. sennetsu* is approximately 800 kb, whereas those of *E. chaffeensis* and *E. ruminantium* are 1,200 kb, and those of *A. phagocytophilum* and *A. marginale* are 1,500 and 1,200 kb, respectively. With the availability of five full genomic sequences (*A. marginale* and *E. ruminantium, E. chaffeensis, Ehrlichia canis,* and *A. phagocytophilum),* certain themes have emerged including the low G+C content seen in other endosymbionts (*A. marginale* is the exception; it contains more G+C than any other intracellular bacterium) and a large proportion of noncoding sequences that have resulted from both reductive evolution due to their intracellular niche and ongoing sequence duplication events. Many of the genes for the glycolytic pathway are absent (142). Carbon sources are proline and glutamate. All enzymes for Krebs cycle are present, as well as the enzymes necessary for purine and pyrimidine metabolism, in contrast to rickettsiae, which lack such enzymes. ATP synthesis is possible since they possess the ATP synthase complex and other enzymes of the aerobic respiration chain. However, ATP/ADP translocases are not present, in contrast to the *Rickettsia* genus. Genes for type IV secretion systems are present as in other α-proteobacteria and most likely represent virulence genes (100). A surprising feature of the genomes is the presence of a large number of pseudogenes that are the product of sequence duplication events rather than reductive evolution seen in other intracellular bacteria (20). The active duplication of tandemly repeated sequences probably counteracts the reductive evolution to create new genes and therefore increase antigenic diversity as a mechanism of survival.

A. marginale and *Aegyptianella* spp. are intraerythrocytic bacteria of ruminants and birds, amphibians, or reptiles, respectively. These organisms also reside in small membrane-bound inclusions (18) and are not known to be associated with human disease.

EPIDEMIOLOGY AND TRANSMISSION

Ehrlichia and *Anaplasma* spp. are zoonotic agents that are transmitted to animals and humans most frequently after a tick bite or possibly by ingestion of fish infested by *Neorickettsia*-infected flukes. *Wolbachia* spp. are symbionts of a broad range of arthropods and helminths. Thus, most species have the potential for vertebrate and invertebrate life stages (Table 1). Based on a recent publication, transovarial transmission in ticks does not appear to occur, and thus, *Ehrlichia* and *Anaplasma* species depend upon high levels of bacteremia and in some cases persistent infection for enzootic maintenance (86). Transstadial and interstadial transmission in ticks allows ehrlichiae to be acquired from blood meals on naturally infected animals by the immature stages of ticks (larvae and nymphs), which can transmit the ehrlichiae to other mammalian hosts after molting to the next stage (nymph or adult).

TABLE 1 Selected features of *Ehrlichia, Anaplasma, Neorickettsia,* and *Aegyptianella* species of human and veterinary interest

Organism name	Former denomination(s)	Vector	Disease[a]	Hosts developing disease	Infected cells	Reservoir host
Anaplasma phagocytophilum	*Ehrlichia equi*	*Ixodes persulcatus* group	EGE	Horses	Granulocytes	Deer, sheep
	Ehrlichia phagocytophila HGE agent		Tick-borne fever HGA	Ruminants Humans, dogs		White-footed mice
Anaplasma marginale, A. centrale, A. ovis		Several tick species	Ruminant anaplasmosis	Cattle (sheep, goats)	Erythrocytes	Ruminants, wild cervids?
Anaplasma platys	*Ehrlichia platys*	*Rhipicephalus sanguineus?* *Amblyomma* spp.?	Canine cyclic thrombocytopenia	Dogs	Platelets	Ruminants?
Anaplasma bovis	*Ehrlichia bovis*	*Rhipicephalus appendiculatus* *Amblyomma variegatum*	Bovine ehrlichiosis	Cattle	Mononuclear leukocytes	Ruminants? Rabbits?
Ehrlichia chaffeensis		*Amblyomma americanum* *Dermacentor variabilis*	HME	Humans Dogs	Mononuclear leukocytes	White-tailed deer Domestic dogs Others?
Ehrlichia ewingii		*Amblyomma americanum*	CGE Ehrlichiosis ewingii	Dogs Humans	Granulocytes	Canids?
Ehrlichia canis		*Rhipicephalus sanguineus*	CME	Dogs Humans?	Mononuclear leukocytes	Canids
Ehrlichia ruminantium	*Cowdria ruminantium*	*Amblyomma* species	Cowdriosis (heartwater)	Domestic and wild ruminants	Granulocytes Endothelial cells	Ruminants
Ehrlichia muris		*Haemaphysalis flava*	Not named	Laboratory mice	Mononuclear leukocytes	Not known
Neorickettsia sennetsu	*Ehrlichia sennetsu*	Unknown; possibly acquired by ingestion	Sennetsu fever	Humans	Mononuclear leukocytes	Fluke-infested fish?
Neorickettsia risticii	*Ehrlichia risticii*	Ingestion of fluke-infested insects	Potomac horse fever	Horses	Mononuclear leukocytes	*Juga* spp. flukes
Neorickettsia helminthoeca		Ingestion of fluke-infested salmonid fish	Salmon poisoning disease	Dogs, bears	Mononuclear leukocytes	Fluke-infested fish
Aegyptianella spp. (genus and species incertae sedis)		*Amblyomma* spp.	Not known	Birds, amphibians, reptiles	Erythrocytes	Not known

[a] EGE, equine granulocytic ehrlichiosis (anaplasmosis); CGE, canine granulocytic ehrlichiosis; CME, canine monocytic ehrlichiosis.

Humans are only inadvertently infected and represent an end stage host for ehrlichiae. Natural maintenance of tick-borne ehrlichiae depends on the presence of appropriate tick vectors and mammalian hosts in the local environment (6, 87, 117, 135).

Natural reservoirs that are known to exist for *E. chaffeensis* involve both white-tailed deer *(Odocoileus virginianus)* and domestic dogs, and perhaps other animals that host *Ambylomma americanum* ticks (43, 85). Other minor reservoirs include opossums, raccoons, voles, coyotes, and goats (104). White-tailed deer also serve as a reservoir of *Ehrlichia ewingii* and of another ehrlichial agent closely related to *Anaplasma platys,* the white-tailed deer agent, which has not yet been associated with human disease (8). The identities of the major reservoirs for *A. phagocytophilum* are incompletely investigated, although small mammals, especially the white-footed mouse *(Peromyscus leucopus)* in the eastern United States, and other small mammals such as chipmunks *(Tamias striatus)* and voles *(Clethrionomys gapperi)* are naturally infected and are frequent hosts of the immature stages of *Ixodes scapularis* (135, 139). The role of white-footed mice as a reservoir of *A. phagocytophilum* in nature has been questioned, since immunity that develops after infection may render them temporarily host incompetent (84). Persistent or prolonged infection of animal reservoirs is essential for maintenance of zoonotic pathogens. Mice infected with *Borrelia burgdorferi* remain infected for many months, essential for continuous transmission to different stages of developing *I. scapularis* ticks (56). In Europe, red deer, sheep, cattle, and goats are persistently infected and serve as reservoirs of *A. phagocytophilum*. The reservoir for *N. sennetsu* is not known; however, epidemiological data suggest that consumption of raw fish was associated with sennetsu fever. Other species of *Neorickettsia* seem to have a complex transmission process involving trematode stages. *Neorickettsia risticii*, the agent of Potomac horse fever, appears to be transmitted to horses by accidental ingestion of insects carrying *N. risticii*-infected cercariae (89). Similarly, *Neorickettsia helminthoeca* infects dogs through ingestion of trematode-infested fish.

Over 20 species of ticks have been identified in the transmission of *A. marginale* worldwide (81). Other modes of transmission such as accidental inoculation of infected erythrocytes or blood-sucking insects have also been reported for *A. marginale.* Tick vectors also appear to be important in the transmission of members of the genus *Aegyptianella* to birds and amphibians (71).

CLINICAL SIGNIFICANCE

Human Diseases

HME

The causative agent of human monocytotropic ehrlichiosis (HME) is *E. chaffeensis,* a monocytotropic ehrlichia that was first identified as a human pathogen in a patient with a severe febrile illness after tick bites in 1986 (91). More than 1,300 cases of HME have been identified by the CDC between 1999 and 2004 (32, 33, 59); however, serologic data compiled at a major commercial laboratory that performs serologic testing for *E. chaffeensis* comprise more than 722 diagnostic serologic results between 1992 and 1995 alone, suggesting that HME occurs much more frequently than is reported (137). In another study based on a commercial laboratory, between 1997 and 1998, a total of 486 cases were diagnosed serologically (101). Passive and active case identification has revealed that clinically apparent HME occurs as frequently as or more frequently than Rocky Mountain spotted fever in Oklahoma, Georgia, Maryland, Tennessee, and North Carolina (127, 137). In fact, a 3-year prospective study conducted in Cape Girardeau, Mo., revealed an incidence between 2 and 4.7 per 100,000 population, a figure that is almost 1 order of magnitude higher than the one obtained by passive surveillance (102). Most cases are identified in the south central and southeastern United States, but increasingly infections have been identified in the mid-Atlantic region as well. Prospective evaluation of individuals with high rates of tick exposure shows that approximately 75% of seroconversions with antibody to *E. chaffeensis* are subclinical (57). Recent reports from Latin America, Africa, Europe, and Asia seem to indicate that *E. chaffeensis,* or closely related microorganisms, is also found in those localities (24, 39, 60, 120, 143). *E. chaffeensis* nucleotide sequences were found in different tick species from different regions of China, using PCR to amplify ehrlichial 16S rRNA genes (30).

The median incubation period for HME is 9 days, and two of every three patients are males; the median age is 44 years (57, 104). Patients typically present with high fever (97%), headache (81%), malaise (84%), and myalgia (40 to 60%), usually without other specific physical findings. Manifestations of gastrointestinal involvement (nausea, vomiting, and diarrhea), respiratory involvement (cough or pulmonary infiltrates), and joint pain are rare. Central nervous system involvement (stiff neck, confusion) and meningitis have been described (127). Rash patterns are variable in character, distribution, and temporal appearance. It could be petechial, macular, maculopapular, and erythematous (103, 104). Rash frequency is higher in the pediatric population and is present in up to 67% of cases (124). In spite of the nonspecific clinical symptoms and signs, laboratory findings are abnormal in at least 86% of patients, including leukopenia (60 to 74%) with lymphopenia and neutropenia, thrombocytopenia (70 to 90%), and increased serum aspartate transaminase activities (80 to 90%). Severe complications include a toxic shock-like syndrome with multiorgan failure, meningoencephalitis, diffuse alveolar damage associated with adult respiratory distress syndrome, and fulminant infections in patients immunocompromised by human immunodeficiency virus (HIV), high-dose corticosteroids, or organ transplantation (55, 93, 106, 107, 122). The case fatality rate of approximately 2 to 3% would be higher if effective antimicrobial therapy were not available. Fatal disease has been described most frequently in males, older patients, and those immunocompromised and with debilitating illnesses.

HGA, Formerly Known as Human Granulocytic Ehrlichiosis

The causative agent of human granulocytotropic anaplasmosis (HGA) is *A. phagocytophilum,* causing an illness identical to that of the formerly named *E. equi* and *E. phagocytophila* in horses and ruminants, respectively (58, 90). HGA was first identified in 1990 in a patient from Wisconsin after tick bites in an area where *E. chaffeensis* and its tick vector do not exist (11). Although the most frequent mode of transmission is through the bite of an infected *Ixodes* tick, other modalities of infection are likely to exist; perinatal transmission has been reported (68). Transmission by accidental inoculation of infected blood or by transfusion is probably rare but should also be considered.

As for HME, HGA is not a reportable illness in most states; thus, the true incidence and prevalence of the infection are unknown. However, prospective passive case collection in

northwestern Wisconsin during 1990 through 1995 revealed a yearly incidence rate of 16 cases per 100,000 population, with peak rates identified as high as 58 cases per 100,000 population in some counties in 1995 (13). Between 1999 and 2004 over 2,000 cases have been reported nationwide (32, 33, 59). The highest annual incidence rates were in the Northeast and upper Midwest states. Infected patients have been identified in many other states as well as in several European and Asian countries (9, 17, 21, 23, 41, 65, 79, 110, 112, 115, 137). Subclinical infection is probably the norm, as nearly 14 and 11% of the population assessed in northwestern Wisconsin and Westchester County, N.Y., respectively, have antibodies indicative of prior infection (2, 12). The tick vectors for HME and HGA coexist in the mid-Atlantic, southern New England states, and in the southern Midwest. Thus, both diseases can occur in these areas (41). Furthermore, human ehrlichioses, including HME, HGA, and *E. ewingii* infections, are clinically undistinguishable.

HGA has a median incubation period of 5 to 11 days after *Ixodes* spp. tick bites and occurs in patients with a median age of 43 to 60 years (1, 3, 13). Twice as many men as women have the illness (14). Patients present with high fever, myalgias, headache, and malaise, with gastrointestinal, respiratory, musculoskeletal, or central nervous system involvement in fewer patients. Rash is observed in less than 11% of patients. Leukopenia with lymphopenia, thrombocytopenia, and increased serum aspartate transaminase activities are present in most patients during early stages of the disease. The hematological abnormalities may normalize before antimicrobial treatment, and lymphocytosis with atypical lymphocytes has been observed after the first week of infection (14, 70). Severe complications of HGA include a septic shock-like illness with multiorgan failure, adult respiratory distress syndrome, and opportunistic infections (13, 62, 70, 138); meningitis has not been documented with HGA. At least six deaths have been associated with HGA; at least three of those patients had opportunistic infections including *Candida* esophagitis, *Cryptococcus* pneumonia, invasive pulmonary aspergillosis, and herpes esophagitis (13, 62, 138).

Ehrlichiosis Ewingii

The association of *E. ewingii* with human disease was first demonstrated by detection of its DNA in the blood of patients presenting with clinical and routine laboratory findings indistinguishable from HME in Missouri (29). The main vector is also the Lone star tick (*A. americanum*), and therefore, the distribution of the disease is similar to that of HME. Evidence of *E. ewingii* in *Dermacentor variabilis* ticks has also been documented (145, 149). White-tailed deer are also reservoirs for this bacterium, and recent epidemiological studies suggest that dogs might also play a role as such (8, 149). Ehrlichiosis ewingii seems to affect mostly immunosuppressed patients including patients with HIV. Although clinical descriptions exist for only a few patients, it has not been reported as a cause of death and patients coinfected with HIV and *E. ewingii* seem to have a milder disease than those patients coinfected with HIV and *E. chaffeensis* (29, 105). In dogs, *E. ewingii* is responsible for canine granulocytotropic ehrlichiosis.

Sennetsu Ehrlichiosis (Neorickettsiosis)

Named after the Japanese term for glandular fever, *N. sennetsu* was first isolated from patients with suspected infectious mononucleosis in 1953 (97). Rarely identified now, patients develop a self-limited febrile illness with chills, headache, malaise, sore throat, anorexia, and generalized lymphadenopathy. Cases were identified only in Japan and possibly Malaysia. Laboratory findings include early leukopenia and atypical lymphocytes in the peripheral blood during early convalescence. No fatalities or severe complications have been reported.

Other Human Ehrlichioses

In 1996, an *E. canis*-like agent was isolated from the blood of an asymptomatic man from Venezuela who had morulae in peripheral blood monocytes. Serological investigations in children with febrile illness and healthy adults exposed to dogs with canine ehrlichiosis in that geographic area showed antibodies in two healthy individuals reacting with the Venezuelan agent (Venezuelan human ehrlichia), *E. chaffeensis*, *E. canis,* and *Ehrlichia muris*. Comparison of the 16S rRNA gene of the Venezuelan human ehrlichia agent with two strains of *E. canis* showed one or two base differences (111). Two additional cases were identified by real-time PCR in patients from Cape Girardeau, Mo., as part of a prospective study performed between 1997 and 1999. In fact, one of the cases was a dual infection caused by *E. chaffeensis* and *E. canis* (J. P. Olano and J. W. McBride, unpublished data).

While *Wolbachia* spp. are not known to be directly pathogenic for humans or animals, emerging experimental evidence indicates a potential role for the intracellular bacterial components ("symbionts") of such helminths as *Brugia malayi*, *Onchocerca volvulus*, and *Wuchereria bancrofti* as potentiators of the inflammatory reactions that are considered significant parts of the pathogenesis of the parasite infection (66, 134).

Animal Diseases

Members of *Ehrlichia, Anaplasma, Neorickettsia,* and *Aegyptianella* and related genera were known as veterinary pathogens long before they were recognized as human pathogens. Work in this area by dedicated veterinary microbiologists has contributed tremendously to the recognition and understanding of the diseases they cause in humans.

Canine Ehrlichiosis

Several agents produce infections in dogs, as shown in Table 1, which include canine monocytic ehrlichiosis caused by *E. canis* and *E. chaffeensis,* granulocytic ehrlichiosis caused by *E. ewingii,* granulocytic anaplasmosis caused by *A. phagocytophilum,* and canine cyclic thrombocytopenia caused by *A. platys* (53, 54, 118, 129). *Neorickettsia helminthoeca,* agent of salmon poisoning disease, also causes infection in dogs; it infects mononuclear cells and is acquired after ingesting salmonid fish encysted with a fluke harboring the organism (118).

Equine Ehrlichiosis

Potomac horse fever is a febrile gastrointestinal disease of horses caused by *N. risticii,* which infects monocytes (67), and is acquired through a complex aquatic ecosystem where infected insects seem to be implicated (89).

Equine granulocytic ehrlichiosis caused by *A. phagocytophilum,* formerly *E. equi,* is a seasonal disease first described in 1969. Although it has been described as occurring mostly in the foothills of Northern California (88), it also occurs in other regions of the United States and Europe. It causes a self-limiting disease in horses, which is similar to HGA in humans (15) and appears to be transmitted in California through the bite of infected *Ixodes pacificus* ticks. Tick-borne fever of ruminants is caused by the granulocytotropic *A. phagocytophilum,* formerly *E. phagocytophila,* and is transmitted via the bite of infected *I. ricinus* ticks in Europe (58).

Anaplasmosis of Ruminants

A. marginale is the etiologic agent of bovine anaplasmosis, the most prevalent tick-borne disease of cattle worldwide. Mechanical transmission by biting flies and other insects may also occur. Organisms develop as an intraerythrocytic inclusion and can produce severe anemia, weight loss, abortion, and sometimes death. A feature of this infection is the persistent low-level bacteremia even after clinical recovery; therefore, infected animals become a reservoir for transmission to other animals. This feature is shared with the related *A. phagocytophilum* infections of deer and *A. platys* infection of dogs. Antigenic variation has been postulated to play a role in the persistence of *A. marginale* infection and transmission (108).

Aegyptianella Infection of Birds and Amphibians

Members of the genus *Aegyptianella* infect erythrocytes of different animal species throughout the world. The type species is *Aegyptianella pullorum* of birds. Other species such as *A. bacterifera* have been associated with infections in amphibians. *A. botuliformis,* which infects helmeted guineafowls in Africa, appears to be transmitted through the bite of infected *Amblyomma* species (71). Based on 16S rRNA and *groEL* gene sequencing, *A. pullorum* is most closely related to *Anaplasma* spp.

Heartwater (Cowdriosis)

Ehrlichia (Cowdria) ruminantium is an intracellular bacterium that infects neutrophils and endothelial cells of cattle, sheep, goats, and certain wildlife species (118). Heartwater is an acute disease that can cause mortality rates up to 90% in susceptible ruminants. It occurs most frequently in sub-Saharan Africa and in the islands of the Atlantic and Indian Oceans and the Caribbean Sea and is transmitted by *Amblyomma* tick vectors.

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

EDTA- or acid-citrate-dextrose-anticoagulated blood or cerebrospinal fluid (CSF) and serum should be obtained for diagnosis or confirmation of HME or HGA. Currently, there are three methods for diagnosis during the acute phase of illness, when ehrlichiae are likely to be present in circulating peripheral blood or CSF leukocytes: PCR amplification of *Ehrlichia* or *Anaplasma* species nucleic acids, detection of morulae in the cytoplasm of infected leukocytes by nonspecific Romanowsky stains (e.g., Giemsa or Wright) or by specific immunocytologic or immunohistologic stains using *E. chaffeensis* or *A. phagocytophilum* antibodies, and culture of *Ehrlichia* or *Anaplasma* species from blood or CSF. EDTA-anticoagulated blood is the most useful specimen for most tests and should be obtained during the acute phase of illness (1, 61, 103).

Samples for PCR should be tested promptly, but if the blood is maintained at 4°C, it may still be possible to amplify nucleic acids several days to a week or more later. If delays beyond several days are anticipated, the blood should be frozen at –20°C until used. There is less experience with collection and storage of CSF for PCR, but it is expected that similar conditions will yield appropriate results. PCR using serum or plasma is far less sensitive than PCR using samples that contain infected leukocytes.

Peripheral blood buffy coat smears or cytocentrifuged preparations of CSF cells should be prepared within several hours of obtaining the samples since leukocytes degenerate rapidly. Once prepared, air-dried blood smears and cytocentrifuged CSF preparations are stable at room temperature for months or years.

The culture conditions for *Ehrlichia* and *Anaplasma* species are still being optimized. Currently the preferred specimen for culture is peripheral blood. Samples should be obtained by sterile venipuncture or lumbar puncture and submitted as soon as possible to the laboratory that is to attempt culture. Usually, this requires overnight courier service since culture is currently performed only in a few public health and research laboratories. Samples to be cultured should be maintained at approximately 4°C during shipping; it is important to avoid freezing, which is likely to reduce the content of viable ehrlichiae. Success rates in culturing *A. phagocytophilum* are far better than those for *E. chaffeensis*. The time elapsed between collection of the blood sample and inoculation in cell lines appears to be especially critical for *E. chaffeensis* isolation. EDTA-anticoagulated blood stored for up to 18 days at 4°C has also been successfully used to culture *A. phagocytophilum* in vitro (78). After cultivation, ehrlichia-infected cells may be stored in a frozen state at −80°C for several months or in liquid nitrogen for longer periods. Storage of infected cells is best accomplished when more than 50 to 90% of the host cells are infected and is achieved by suspension of at least 10^6 cells per ml in tissue culture medium that contains 10% dimethyl sulfoxide (DMSO) and at least 30% fetal bovine serum.

LABORATORY CONFIRMATION OF *EHRLICHIA CHAFFEENSIS*

Direct Examination

Microscopy by Romanowsky Staining of Peripheral Blood

Patients with suspected HME should have Romanowsky-stained (Giemsa or Wright stain) peripheral blood or buffy coat leukocytes examined for the presence of ehrlichial morulae. This method is very insensitive, identifying up to 29% (2 of 7) of culture-confirmed *E. chaffeensis*-infected patients (127). Ordinarily *E. chaffeensis* organisms are detected predominantly in monocytes, and their detection seems to correlate with severity of infection. When present, ehrlichial morulae are small (1- to 3-μm diameter) round-to-oval clusters of bacteria that stain basophilic to amphophilic with Romanowsky stains (Fig. 4). These clusters are present in the cytoplasm and have a stippled appearance owing to individual bacteria within the vacuole. Detection of morulae is more common in immunocompromised patients. Numbers of infected cells range from 0.2 to 10%, suggesting that up to 500 cells should be examined in suspicious cases.

Antigen Detection by Immunohistology

Immunohistologic methods may be used to identify *E. chaffeensis* within human tissues, including bone marrow, liver, and spleen. An immunohistologic study of bone marrow, however, detected *E. chaffeensis* in only 40% of specimens obtained during the active infection (48). Most immunohistologic studies have been performed using polyclonal antibodies that react with other *Ehrlichia* species. A monoclonal antibody may specifically detect *E. chaffeensis* in human tissues (150). Unfortunately, commercial sources for direct immunohistologic detection of *E. chaffeensis* are not currently available.

Nucleic Acid Detection Techniques

The most widely used nucleic acid amplification test is PCR amplification of *E. chaffeensis* nucleic acids from clinical samples by using the HE1/HE3 primer set (7, 52, 126). This primer pair amplifies a 389-bp fragment of the 16S rRNA gene

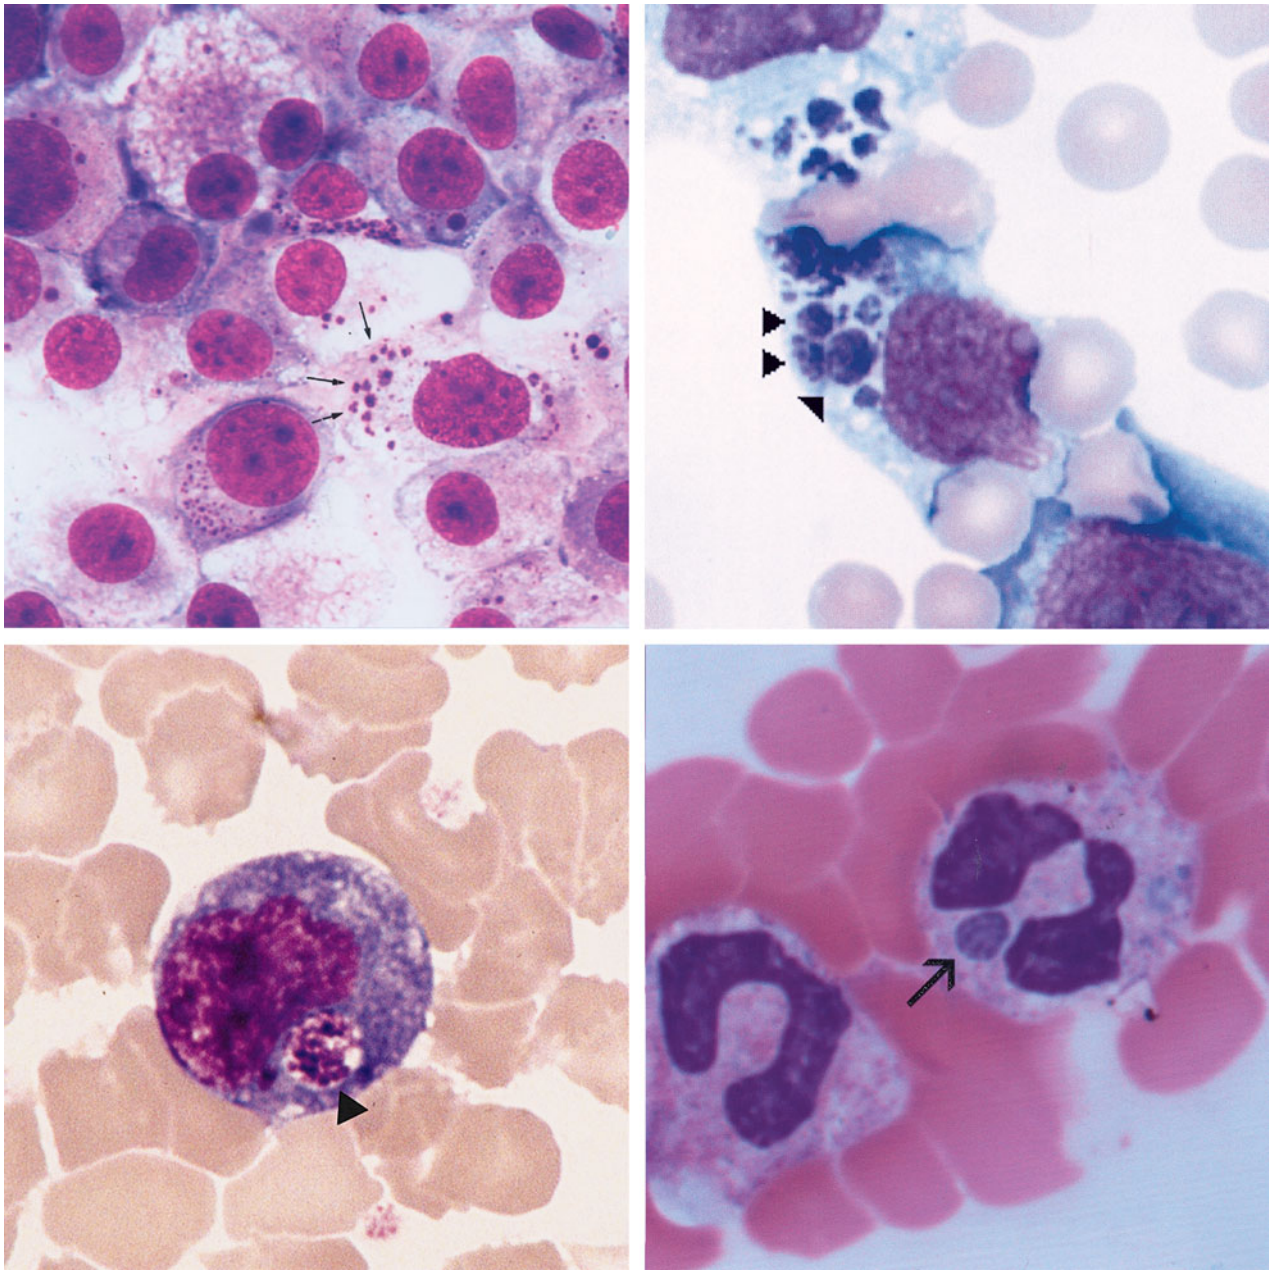

FIGURE 2 (top left) *E. chaffeensis* cultured in the canine histiocyte cell line, DH82. Note the presence of basophilic, stippled, intracytoplasmic inclusions approximately 2 to 3 μm in diameter (arrows). The smaller intracytoplasmic granules may also be ehrlichial morulae (Romanowsky [Leukostat] stain; original magnification, ×1,000).

FIGURE 3 (top right) *A. phagocytophilum* cultured in the human promyelocytic cell line HL-60 from the blood of an infected patient. Note the presence of multiple basophilic, stippled, intracytoplasmic inclusions (arrowheads) in an HL-60 cell (Wright stain; original magnification, ×1,000).

FIGURE 4 (bottom) *E. chaffeensis* (A [left]) and *A. phagocytophilum* (B [right]) in peripheral blood leukocytes. Note that the *E. chaffeensis* morula (arrowhead) is present in a monocyte (A) and that *A. phagocytophilum* morula (arrow) is present in a neutrophil (B) (Wright stain; original magnification, ×1,000).

sequences. The product may be detected by simple nucleic acid staining (e.g., ethidium bromide) after agarose gel electrophoresis or by Southern hybridization of the amplified products, using an internal probe that is reported to increase analytical sensitivity (38). A clinical evaluation of *E. chaffeensis* PCR using the HE1/HE3 system showed a sensitivity of 79 to 100% compared with detection of *E. chaffeensis* or *E. canis* antibodies in convalescence; however, *E. chaffeensis* nucleic acids were frequently detected in patients who never developed antibodies, a finding of uncertain significance given the high degree of analytical specificity demonstrated with this system (7, 126). Similar results occur when using a nested PCR that employs broad-range "*Ehrlichia* genus" primers in an initial step followed by PCR with the HE1/HE3 primer pair (80). A nested PCR assay with broad-range 16S rRNA primers (8F and 1448R) followed by a second (nested) reaction with primers 15F and 208R on whole blood yielded similar results to culture in another study (127). Other targets for PCR that have not been fully evaluated for clinical sensitivity or specificity include the *groESL* operon, a variable-length PCR target of unknown significance that is present in *E. chaffeensis* (105, 127, 131), the 120-kDa antigen gene that encodes an immunodominant antigen with tandemly repeated subunits that may vary among *E. chaffeensis* isolates, the quinolinate synthase A gene, *nadA,* and the p28 multigene family (105, 136, 152, 153). In a prospective study, the overall PCR sensitivity and specificity were 56 and 100%, respectively, using the 16S rRNA subunit, *nadA,* and 120-kDa protein genes (102). However, in this study several blood samples had high titers of antiehrlichial antibodies by indirect fluorescent-antibody (IFA) and were in the late phases of the disease, suggesting that the sensitivity was decreased due to lower numbers of circulating ehrlichiae. When sensitivity was calculated based on seroconversion rates, it increased to 84%. Posttest probabilities for a positive and negative PCR result were 96 and 11.1%, respectively. Posttest probabilities take into account a clinical case definition and therefore are most useful when used in the appropriate clinical setting (102).

Real-time multicolor PCR and real-time multiplex reverse transcriptase PCR assays have been developed recently with extremely high analytical sensitivity and specificity comparable to that of nested PCR assays (45, 125). Advantages of this technique include a lower risk of contamination, greater speed, lower cost, and a multicolor and multiplexing format allowing detection of multiple ehrlichial pathogens at the same time.

Isolation Procedures

E. chaffeensis has been isolated from peripheral blood of more than 30 patients with HME, and an *E. canis*-like organism was isolated only once from an asymptomatic human (42, 107, 111, 127). The most frequently used cell for primary isolation is the canine histiocytic cell line, DH82; however, *E. chaffeensis* has been successfully cultivated in other cells including the human macrophage-like THP-1 cells, the fibroblast-like HEL-22 cells, Vero cells, and HL-60 cells (human promyelocytic cell line differentiated to monocytic pathway), among others (63). Isolation may be successful even when infected leukocytes are not observed on examination of peripheral blood (127). The usual format for isolation involves direct inoculation of leukocyte fractions or, less optimally, whole blood into flasks with a confluent layer of adherent cells or into flasks that contain approximately 2×10^5 to 1×10^6 nonadherent cells per ml of tissue culture medium. Macrophage-like cells that are highly phagocytic may be adversely affected by the presence of numerous erythrocytes; thus, it is recommended that either (i) leukocytes be fractionated from erythrocytes by density gradient centrifugation (e.g., Ficoll-Paque), (ii) leukocytes be harvested after erythrocyte lysis (hypotonic lysis, $NHCl_4$ lysis, etc.), or (iii) cell confluency be reestablished after cultivation with erythrocyte-containing samples by addition of uninfected host cells. Since *E. chaffeensis* may be present in a very small proportion of peripheral blood leukocytes, it is usually advisable to inoculate cultures with as many peripheral blood leukocytes as possible. This may be difficult owing to leukopenia that often accompanies HME. A method using 2 to 3 ml of EDTA-anticoagulated blood, diluted in 2 volumes of sterile Hanks' balanced salt solution, followed by Histopaque (Sigma, St. Louis, Mo.) gradient separation of leukocytes gave a high yield of isolation in a study of the use of culture to diagnose HME (127).

The blood mononuclear cells are resuspended in a 2-ml volume of tissue culture medium supplemented with 5% fetal bovine serum and allowed to interact with adherent host cells in a 25-cm^2 flask for 3 h, usually enhanced by incubation with rocking at 37°C in 5% CO_2. The inoculum is removed if significant erythrocyte contamination is present and the monolayer is replenished with 5 ml of fresh tissue culture medium. Since *Ehrlichia* species are bacteria, antibiotics in the medium must be avoided. The generation time of *E. chaffeensis* is approximately 19 h (19), and thus, cultures must be maintained to allow a slow logarithmic or stable growth phase to avoid the host cells outgrowing the ehrlichiae.

Identification

The presence of infected cells is determined by sampling the medium (DH82 cells and THP-1 cells) or by lightly scraping part of the monolayer. Aliquots of the culture are cytocentrifuged, followed by Romanowsky or immunofluorescent stains, and cells are examined for the presence of intracytoplasmic morulae or *E. chaffeensis* antigen (Fig. 2). Culture may require 1 month or more but has been achieved in as short a time as a few days (42, 47, 127). Confirmation of the infectious agent is currently best achieved by PCR amplification using species-specific primers (5).

Serologic Tests

The majority of cases of HME are diagnosed by retrospective serologic confirmation, and serology is the most sensitive method for diagnostic confirmation. The most widely used test is the IFA test, which utilizes ehrlichia-infected cells fixed to glass slides. Ehrlichial antigens may be difficult to prepare and are available mostly through public health and research laboratories, although commercial production and distribution are now available. Commercial sources of IFA serodiagnostic kits include Focus Technologies (Cypress, Calif.) and PanBio Diagnostics (Columbia, Md.). Immunoblot procedures are becoming increasingly popular because of the perception of increased specificity (25, 35, 146).

Currently, there is little standardization for any method of ehrlichial serology, and cutoff titers are dependent on validation in individual laboratories that perform these assays. The algorithm for serologic testing by IFA includes an initial screen at a dilution of 1:64 or 1:80 for antibodies to *E. chaffeensis*. Reactive samples are then titrated.

Ehrlichia chaffeensis IFA

E. chaffeensis antibodies are detected by IFA using *E. chaffeensis* Arkansas strain-infected DH82 canine macrophage-like cells. Sera are serially diluted starting at a dilution of 1:64. The presence of antibodies is detected after incubation with fluorescein isothiocyanate-conjugated anti-human immunoglobulins. A positive reaction is detected by the fluorescent

demonstration of typical intracytoplasmic ehrlichial morula morphology. It is important to identify the appropriate proportion of infected cells as determined by a positive control serum and the appropriate morphology for each antigen preparation to preclude false-positive interpretations. Prescreening for autoantibodies or routine removal of rheumatoid factors lessens the risk of misinterpretation due to antibodies reactive with cellular components including nuclear or cytoplasmic antigens. A fourfold increase or decrease in antibody titer, with a peak titer or a single convalescent titer of ≥64 for a patient with a consistent clinical history, supports the diagnosis of HME. Antibody titers may be detected in a small proportion of subjects without HME owing to the presence of antigens that are highly conserved among bacterial species, including heat shock proteins (44, 146). Acute-phase sera should be obtained at the time of presentation with acute illness, and convalescent sera are best obtained 3 to 6 weeks later (44).

The sensitivity and specificity of the IFA for *E. chaffeensis* infections in the convalescent phase are not known but are assumed to be high because of a high degree of correlation of the presence of *E. chaffeensis* antibodies and characteristic clinical findings (57). In the early phases of the disease, IFA testing is not sensitive when compared to PCR (37). A systematic evaluation of the usefulness of immunoglobulin M (IgM) testing is not available, although a preliminary evaluation based on nine culture-confirmed cases suggests that it might be slightly more sensitive than IgG for the diagnosis of HME during the acute phase (37). Previously, the serologically cross-reactive *E. canis* was used as a surrogate antigen; however, this serodiagnostic assay has a lower sensitivity than that obtained using *E. chaffeensis,* and its use should be discouraged (7). The role of immunoblots in diagnosis is not well established; however, many patients with *E. chaffeensis* infection can be differentiated from patients with HGA by the demonstration of antibodies reactive with one or more of the 22-, 28-, 29-, 46-, 54-, or 120-kDa antigens of *E. chaffeensis* (25, 35). A recombinant 120-kDa protein that has been applied in a dot blot method appears to offer a sensitive and specific serologic confirmation tool (151). Antibodies to *E. chaffeensis* have also been detected in patients diagnosed with Rocky Mountain spotted fever, Q fever, brucellosis, Lyme disease, and Epstein-Barr virus infections, suggesting that false-positive reactions do occur (44, 146). Antigenic diversity among isolates of *E. chaffeensis* is well described (36) but may not affect the detection of the polyclonal antibody response that is generated with human infection. Several reports have characterized patients with HME without antibody responses, even long after onset (52, 121, 127). However, in the few cases in which *E. chaffeensis* infection has been most clearly proven by cultivation of the agent, most patients who survived developed clear serologic reactions detected by IFA methods in convalescence (36, 42, 47, 105, 127). Hypothetical reasons for false-negative results include infection by antigenically diverse strains (unproven) and abrogation of antibody response by early therapy (127).

LABORATORY CONFIRMATION OF *ANAPLASMA PHAGOCYTOPHILUM*

Direct Examination

Microscopy by Romanowsky Staining of Peripheral Blood

Examination of Romanowsky-stained (Giemsa or Wright stain) peripheral blood or buffy coat leukocytes for the presence of ehrlichial morulae is highly valuable in the diagnosis of HGA. Usually, 800 to 1,000 granulocytes are examined under ×500 to ×1,000 magnification for the presence of morulae (1, 3, 13). Since most patients presenting with positive smears have less than 1% of infected granulocytes and usually have leukopenia, buffy coat preparations have a higher yield than peripheral smears. Infection rates as high as 40% of peripheral granulocytes have been described (11). As for HME, the presence of detectable infected granulocytes in peripheral blood seems to correlate with the severity of infection (3, 11, 13). The sensitivity of the buffy coat smear examination in the acute phase of HGA is approximately 60% (14). When present, ehrlichial morulae are small (1- to 3-μm diameter) round-to-oval clusters of bacteria that stain basophilic to amphophilic with Romanowsky stains (Fig. 4). These clusters are present in the cytoplasm of neutrophils or eosinophils and have a stippled appearance owing to individual bacteria within the vacuole.

Immunohistology for Antigen Detection

Immunohistologic methods may also be used to identify *A. phagocytophilum* within human tissues, including bone marrow, liver, and spleen.

Nucleic Acid Detection Techniques

Multiple PCR assays for detection of *A. phagocytophilum* nucleic acids have been published (51, 96, 130). Most utilize regions of the 16S rRNA gene that are relatively specific as targets for amplification. The most frequently applied and evaluated method employs the primer set ge9f and ge10r, which amplifies a 919-bp fragment, most often used as a single stage reaction, with or without a hybridization probe to enhance sensitivity (34, 51). A popular alternative is the use of nested PCR with an outer set of primers that anneal to and amplify eubacterial 16S rRNA genes, followed by an internal PCR with *A. phagocytophilum*-specific primers (96, 126). PCR amplification of the *groESL* region by use of a nested reaction has also been useful to detect ehrlichial DNA in blood during the acute phase. Primers HS1 and HS6 are used in the primary reaction followed by primers HS43 and HS45. The size of the amplified product distinguishes *E. chaffeensis* from *A. phagocytophilum* (528 versus 480 bp, respectively) (130). The analytical sensitivity and specificity of several published primer sets were evaluated by Massung and Slater (96) by using DNA extracted from serial dilutions of *A. phagocytophilum*-infected HL-60 cells. Specificity was evaluated using DNA extracted from cultures of *E. chaffeensis, Rickettsia rickettsii,* and *Bartonella henselae*. The primer sets with the greatest sensitivity and specificity were those used in a nested reaction to amplify the 16S RNA gene, ge3a-ge10 and ge9-ge2, and those amplifying the *msp2* gene, msp2-3f-msp2-3r (96). Both PCR assays detected as few as 0.25 infected HL-60 cell. Most recently a multiplex assay to detect *Ehrlichia* and *Anaplasma* spp. by real-time reverse transcriptase-PCR was developed and evaluated in peripheral blood of dogs suspected of ehrlichiosis (125). The assay has a sensitivity of 100 16S rRNA transcripts, which corresponds to about one infected cell in a test sample, can detect single or multiple infections, and has the potential for automation.

Isolation Procedures

A. phagocytophilum has been successfully cultivated more often from human patients than has *E. chaffeensis, E. canis,* or *N. sennetsu* owing to the higher quantity of organisms that are present in peripheral blood in many infected patients (1). More than 65 isolates have been cultured from infected patients at a single medical center in the United States. Although HGA has

been described in Europe and Asia, no human isolates of *A. phagocytophilum* have been reported yet in any locality outside the United States. Few animal isolates, however, have been cultured in Europe (16, 144). Isolation is best achieved in the human promyelocytic cell line HL-60 (61) and has also been accomplished when ehrlichiae are not observed in peripheral blood smears. The optimal conditions for recovery of these bacteria have not been conclusively determined, but cultivation in HL-60 cells has been achieved with or without the presence of granulocyte-differentiating chemicals (e.g., DMSO or retinoic acid) (64). Because erythrocytes do not adversely affect the HL-60 cells, direct inoculation of EDTA-anticoagulated blood is effective. Fractionation of blood into leukocytes by preparation of buffy coat or by isolation of granulocyte fractions by density gradient centrifugation is also effective (119). Ordinarily, approximately 100 to 500 μl of EDTA-anticoagulated blood containing approximately between 10^2 and 10^4 infected granulocytes is inoculated into a total of approximately 100-fold more uninfected HL-60 cells that are in the exponential growth phase and are subsequently maintained at a concentration between 2×10^5 and 1×10^6 cells per ml of tissue culture medium.

Identification

Cultures are examined every 2 to 3 days by Romanowsky staining of cytocentrifuged preparations of 20 to 50 μl of culture suspensions. Ehrlichial morulae appear as small aggregates of basophilic bacteria in the cytoplasm of the HL-60 cells (Fig. 3). Since HL-60 cells may contain a variety of cytoplasmic granules, immunocytology can be very helpful for the inexperienced laboratorian. Unfortunately, immunohistological reagents are currently not commercially available. Cultures usually require between 5 and 10 days of cultivation before morulae are clearly identified, but infected cells may be detected as early as 3 days postinoculation. Time to detection of organisms in culture correlates with the amount of bacteria present in blood at the time of culture inoculation (78). Definitive identification is achieved by PCR amplification using species-specific primers (34, 60, 109) or by sequence analysis of 16S rRNA genes that have been amplified by universal eubacterial PCR (34). The exact length of incubation before cultures are considered negative is still unknown, but they should be kept for at least 14 days, with the cell density being maintained at about 2×10^5/ml.

Serologic Tests

A. phagocytophilum IFA

A. phagocytophilum is a single species that now includes three previously distinct organisms, *E. phagocytophila, E. equi,* and the former HGE agent (15, 34, 61). Thus, IFA serologic testing is performed using any of these antigens (46, 72, 140). Previously, most testing was performed using neutrophils obtained from the blood of animals experimentally infected with *E. phagocytophila* or *E. equi* (11, 46, 90). Currently, the preferred method for testing human sera is the use of a human isolate propagated in the human HL-60 promyelocyte cell line (4, 41, 72, 114). It is now well demonstrated that antigenic diversity exists among *A. phagocytophilum* isolates, but it is unlikely that such diversity affects detection under clinical circumstances (10, 140). Interpretation of immunofluorescent patterns is similar to that for *E. chaffeensis* and requires an experienced microscopist. IFA kits are currently available from Focus Technologies and PanBio Diagnostics.

Sera should be screened at a single dilution (1:64 or 1:80), and the presence of antibodies is determined after incubation with fluorescein isothiocyanate-conjugated anti-human IgG/IgM. If specimens test reactive, they are serially diluted to determine the end point titer. A serologic confirmation of the diagnosis is achieved when a fourfold rise in titer is demonstrated in convalescence with a minimum titer of 80, or when a single antibody titer of ≥80 is demonstrated in a patient with typical clinical features of HGA (3, 13). Approximately 25 to 45% of infected patients have antibodies at the time of presentation (3, 4, 13); however, up to 11 to 14% of the population possesses antibodies in some highly endemic regions, rendering this early serologic information less useful (2, 12). The typical response during acute infection is a rapid rise (within 2 weeks of onset) in antibody levels reaching high titers (≥640) within the first month (4). In a treated cohort of patients whose diagnosis of HGA was confirmed by culture, the antibody titers declined gradually over the next few months and about one-half of the patients had detectable antibodies by IFA 1 year after infection (4). However, many patients have antibodies detectable for months to years after initial infection (14).

The sensitivity and specificity of the HGA serologic tests are both believed to be high because of good correlation between typical clinical cases and serologic reactions to *A. phagocytophilum* group antigens (3, 4, 13). HGA serology had a sensitivity of 91.3% in a group of 24 culture-confirmed patients (4) and a median sensitivity of 95% among a group of 28 patients diagnosed by culture, PCR, or the presence of morulae in blood smears (140). IgM testing appears to be a useful tool for identification of recent infection, although the sensitivity may not be as high as that for IgG testing (140). Although enzyme-linked immunosorbent assays (ELISA) and immunoblots have been described (46, 114), they are not routinely used in the serology of HGA. Immunoblots may be used to differentiate among *A. phagocytophilum* and *E. chaffeensis* infections by demonstration of a major *A. phagocytophilum* antigen of approximately 44 kDa in sera of HGA patients (46, 72, 146). Cross-reactivity between *E. chaffeensis* and *A. phagocytophilum* group has been observed in IFA. Under those circumstances, testing with both antigens often shows higher titers with antigens of the homologous infecting agent (3, 140).

False-positive reactions have been observed in patients with other rickettsial infections, Q fever, and Epstein-Barr virus infections. Many patients with HGA develop antibodies that react with *B. burgdorferi* by ELISA and demonstrate diagnostic IgG or IgM immunoblots (148). Although some patients have been confirmed by culture to have concurrent infection with *A. phagocytophilum* and *B. burgdorferi,* the statistical probability that this mechanism accounts for most of these concurrent positive serologic results is very low (99, 146). Another explanation is the exposure to the various tick-borne agents at different times rather than by a single tick bite. The most frequent scenario is the presence of antibodies to the various agents in individuals living in areas of high endemicity (12, 92). Autoantibodies to platelets and other leukocyte components can cause false-positive IFA tests (147).

Other immunoassays employing recombinant p44 antigens have been developed and show promise as alternative tests to IFA (133, 154). Antigens of 42 to 49 kDa are immunodominant in *A. phagocytophilum* infection and are encoded by a multigene family (31, 98) similar to the major surface proteins *(msp)* of *A. marginale* (108).

ANTIMICROBIAL SUSCEPTIBILITIES

Routine antimicrobial susceptibility testing of *Ehrlichia* or *Anaplasma* species isolates is unnecessary. These bacteria are maintained enzootically by transmission among ticks and

feral mammalian reservoir hosts (6, 85, 109, 135, 139). The level of exposure of such vertebrate and invertebrate hosts to antimicrobial selection factors is very low, and thus antimicrobial resistance is very unlikely. Most patients with either HME or HGA become afebrile and have clinical improvement within 48 h of therapy with a tetracycline antibiotic, including doxycycline, the drug of choice (13, 57). Retrospective analysis of patients with HME has shown a significant degree of efficacy for tetracyclines or chloramphenicol compared with other broad-spectrum antimicrobials (57). With in vitro studies, tetracycline antibiotics are uniformly bactericidal for *Ehrlichia* and *Anaplasma* species, whereas the MICs of chloramphenicol cannot be safely achieved in humans with HME or HGA (26, 69, 80). In contrast, the most frequently used antibiotics for patients who have had recent tick bites, amoxicillin and ceftriaxone, and broad-spectrum antibiotics that might be prescribed for undifferentiated fever such as other cephalosporins, aminoglycosides, and macrolides are not effective for inhibition of ehrlichial growth in vitro. The rifamycins (rifampin and rifabutin) can achieve effective inhibition or killing of *Ehrlichia* and *Anaplasma* species in vitro, and the fluoroquinolones (ofloxacin, levofloxacin, and trovafloxacin) have very low MICs for human isolates of *A. phagocytophilum* (69, 80). Rifampin has been successfully used to treat HGA during pregnancy and appears to be a useful alternative for patients who cannot receive tetracyclines (28). A recent publication describes a method to evaluate in vitro susceptibility testing by real-time PCR, showing *E. chaffeensis* to be susceptible to doxycycline and rifampin and to have partial susceptibility to the fluoroquinolones. Resistance to macrolides, cotrimoxazole, and beta-lactam compounds was confirmed (19).

Whereas persistent infections with *Ehrlichia* and *Anaplasma* species may occur frequently in naturally and experimentally infected animals even after treatment with tetracycline (58, 76), persistence of ehrlichiae in humans has rarely been documented (49, 121). Therapy is usually highly effective at eliminating ehrlichiae from the blood of infected humans.

INTERPRETATION AND REPORTING OF RESULTS

The current algorithm for identification and confirmation of infections by *Ehrlichia* and *Anaplasma* species requires a complete evaluation of the history, physical examination, and laboratory results that will suggest the diagnosis. Before specific tests for etiologic determination are attempted, a decision concerning therapy should be made since delays may lead to increased morbidity and perhaps mortality. At the time of acute illness and prior to institution of antiehrlichial therapy, EDTA-anticoagulated blood should be obtained for PCR amplification of *E. chaffeensis* and *A. phagocytophilum* and considered for the possibility of in vitro cultivation. A peripheral blood or buffy coat smear should be examined for the presence of morulae that would confirm the presumptive diagnosis. Serum should be obtained and tested for antibodies to *E. chaffeensis* or *A. phagocytophilum*, with an aliquot saved for repeat testing when a convalescent serum is obtained 2 to 4 weeks later.

The presence of intracytoplasmic inclusions within a leukocyte in peripheral blood might be due to the presence of overlying platelets, Döhle bodies, toxic granulations, nuclear fragments, Auer rods in blasts, other bacteria, yeasts, inorganic materials, or granules of normal large granular lymphocytes or granulocytes. If the typical morphology of an *Ehrlichia* or *Anaplasma* spp. morula is observed, an assessment as to the hematopoietic lineage and the percentage of cells that contain morulae should be made and reported.

A positive PCR result should be reported as such, indicating the presence of *E. chaffeensis* or *A. phagocytophilum* DNA present, and it should be made clear that a positive PCR is not equivalent to the culture of ehrlichiae from blood. Laboratories that use a broad-range PCR to identify *Ehrlichia* or *Anaplasma* spp. DNA in blood may also detect *E. ewingii* infection that may mimic either HME or HGA (29).

IFA serologic results should be reported as the titer of antibodies determined to be reactive with *E. chaffeensis* or *A. phagocytophilum,* including the positive cutoff values determined in the laboratory. An interpretation should indicate whether the titers are considered "significant" or "positive" based upon a fourfold increase or decrease or as single high-titered serum. It should be remembered that infections with *E. ewingii* would yield serologic patterns considered diagnostic of *E. chaffeensis* that are difficult to differentiate even with immunoblot methods. Immunoblot analyses should provide information about antibodies that react with specific antigens considered unique or diagnostic of infection with a single species of *Ehrlichia* or *Anaplasma*.

Human ehrlichioses became nationally notifiable in 1999, but not all states report these diseases. For the purpose of surveillance, the Council of State and Territorial Epidemiologists (CSTE) and the CDC developed a case definition that was amended in 2000 to include ehrlichioses other than HME and HGA (http://www.cste.org/ps/2000/2000-id-03.htm). According to this definition, a case presenting with compatible clinical and routine laboratory abnormalities described above could be classified as confirmed or probable based on specific laboratory findings. A confirmed HME or HGA case is supported by (i) a fourfold change in antibody titer to *E. chaffeensis* or *A. phagocytophilum* antigen, respectively, by IFA in paired serum samples; or (ii) positive PCR and confirmation of *E. chaffeensis* or *A. phagocytophilum* DNA, respectively; or (iii) identification of morulae in leukocytes, and a positive IFA titer to *E. chaffeensis* or *A. phagocytophilum* antigen, respectively (based on a cutoff established by the laboratory performing the assay); or (iv) immunostaining of *E. chaffeensis* or *A. phagocytophilum* antigen, respectively, in a biopsy or autopsy sample; or (v) culture of *E. chaffeensis* or *A. phagocytophilum,* respectively, from a clinical sample. The diagnosis of other human ehrlichiosis or ehrlichiosis caused by an unspecified agent is supported by (i) demonstration of a fourfold change in antibody titer to more than one *Ehrlichia* or *Anaplasma* sp. by IFA in paired serum samples, in which the dominant reactivity cannot be determined; or (ii) identification of an *Ehrlichia* or *Anaplasma* sp. other than *E. chaffeensis* or *A. phagocytophilum* by PCR, immunostaining, or culture. According to the CSTE case definition, a probable HME or HGA case is that with a clinically compatible illness with either a single positive IFA titer (based on the cutoff established by the laboratory performing the assay) or the visualization of morulae in leukocytes.

Coxiella

PHILIPPE BROUQUI, THOMAS MARRIE, AND DIDIER RAOULT

68

TAXONOMY

Coxiella burnetii is the only species of the genus and has been placed in the γ subdivision of the class *Proteobacteria,* close to *Rickettsiella grylli, Legionella* spp., and *Francisella* spp., on the basis of comparison of the 16S rRNA-encoding gene sequences.

DESCRIPTION OF THE GENUS

C. burnetii, the organism responsible for Q fever, is a pleomorphic coccobacillus with a gram-negative cell wall (4). It is an obligate intracellular microorganism measuring 0.2 by 0.7 μm. It does not stain with Gram stain but does stain with Gimenez stain. *C. burnetii* undergoes a developmental cycle in which there is a large-cell and a small-cell variant (59). The small-cell variant attaches to the host cell (usually a macrophage) and is ingested. *C. burnetii* develops within the phagolysosome, where the acid pH activates its metabolic enzymes. Following maturation to the large-cell variant, sporogenesis begins (59). Spore formation explains why *C. burnetii* is so successful as a pathogen. It can survive for up to 10 months at 15 to 20°C, for more than 1 month on meat in cold storage, and for more than 40 months in skim milk at room temperature (12). *C. burnetii* was shown to survive in free-living amoebae, suggesting a possible mechanism to explain the survival and resistance of the pathogen in the environment (Fig. 1) (47).

C. burnetii undergoes phase variation akin to the smooth-to-rough transition of lipopolysaccharides (LPS) of gram-negative bacteria (91). In nature and in laboratory animals, it exists in the phase I state, in which the organisms react with late-convalescent-phase (45 days) guinea pig sera and only slightly with early-convalescent-phase (21 days) sera (91). Apparently phase II LPS is a deletion mutant of phase I LPS (96), of which the fitness, in vitro, is superior to that of phase I. After numerous passages in cell culture or embryonated eggs, truncation of the LPS occurs, yielding the antigenic form, phase II.

EPIDEMIOLOGY AND TRANSMISSION

Q fever is a worldwide zoonosis. *C. burnetii* has been identified in arthropods, fish, birds, rodents, marsupials, and livestock (3). Indeed, it naturally infects more than 40 species (including 12 genera) of ticks on five continents (4). Lice, mites, and parasitic flukes are also infected (64). Bandicoots, rats, rabbits, mice, porcupines, hedgehogs, tortoises, cattle, sheep, goats, dogs, swine, cats, camels, buffaloes, baboons, leopards, hyenas, chickens, ducks, geese, turkeys, pigeons, bats, and shrews have all been infected with this microorganism (43, 64).

The extreme infectivity of *C. burnetii* results in large outbreaks and makes it a potential bioweapon. The major route of transmission of Q fever to humans is by inhalation of dust particles contaminated with parturient fluids. The organism can stick on wool and dust and can be spread by the wind to distant places. Cases of Q fever have occurred miles away from the lambing site in the direction in which the winds blew (8, 93, 95). Ingestion of milk and milk products is a risk factor for transmission of Q fever (25). Raw milk from cows was considered a risk factor for Q fever in California, and the decrease in the prevalence of Q fever in this state could be partly related to cessation of the practice of drinking raw milk. However, the consumption of goat cheese made from raw as well as pasteurized milk was reported as a risk factor (25, 35). In experimental animal models, the route of infection (aerosol or intraperitoneal) has been shown to determine the specific organs that are involved (lung and liver, respectively) (45). Sexually transmitted Q fever has been suggested, but this route needs to be confirmed (61).

The current understanding of the natural history of Q fever is that a nonimmune patient comes into contact with *C. burnetii*, which causes a primary infection that could be asymptomatic or symptomatic (76). The symptomatic primary infection is acute Q fever. The spontaneous evolution of acute infection is usually a complete recovery in the normal host. In immunocompromised hosts, *C. burnetii* can multiply despite an antibody response following primary infection (symptomatic or not). In these cases, because the immune system is unable to control the infection, chronic infection develops. This hypothesis is supported by all available data from human beings as well as from animal models (75). Preliminary data support that the inoculum size, the route of infection, host factors, and the specific strain all contribute to the clinical expression (e.g., pneumonia versus hepatitis) of acute infection (75, 88).

The immune control of Q fever is T-cell dependent, but it does not lead to *C. burnetii* eradication, and immunosuppression can induce relapse of infection in apparently cured patients or laboratory animals (85, 86). *C. burnetii* DNA can be found in apparently cured people as well as in the dental pulp of experimentally infected and cured guinea pigs (1).

Therefore, patients with acute Q fever who become immunocompromised or who have cardiac valve lesions are particularly at risk to develop chronic infection and especially endocarditis (19, 77).

Following primary infection, 60% of patients seroconvert without clinical manifestations and only 2% need to be hospitalized. A chronic infection develops in less than 1% of acutely infected patients and is often associated with a subtle and unique immune defect (58). Interleukin 10 (IL-10) seems to play a key role in the evolution of chronic infection (36).

Among children with Q fever, boys and girls are equally represented whereas men are 2.45 times more frequently infected than women (54). This has been suggested to be related to occupational exposure, although the protective role of 17β estradiol has been clearly demonstrated in a mouse model (48).

Since 30 to 50% of patients with Q fever and a valve lesion may develop Q fever endocarditis in the 2 years postinfection (19), echocardiography is recommended to detect such lesions as bicuspid aortic valve and minimal valvular leaks in all patients with acute Q fever (18).

CLINICAL SIGNIFICANCE

Acute Q Fever

The onset is usually abrupt, and patients present with high fever (91%), headaches (51%), myalgias (37%), arthralgias

(29%), and cough (34%), less frequently a rash (11%) or a meningeal syndrome (4%). Laboratory investigations show thrombocytopenia (35%), elevated liver enzymes (62%), and an elevated erythrocyte sedimentation rate (55%). The chest radiograph is abnormal in 27% of patients (77). The clinical presentation varies from country to country without clear explanation as to which one of the three major manifestations, i.e., isolated fever, hepatitis, or pneumonia, dominates.

Clinically isolated fever, without pneumonia or hepatitis, is usually associated with severe headache, and in some patients it persists long enough to meet the criteria for fever of unknown etiology. Pneumonia is the major clinical presentation of Q fever in Nova Scotia (Canada), the Basque country (Spain), and in the United Kingdom. Hepatitis is the most common form worldwide including France and Australia. Usually, increased liver enzymes suggest hepatitis; however, a few patients present with jaundice and/or hepatomegaly. Liver biopsy shows inflammatory granulomas, typically organized in the form of a "doughnut"; i.e., the granuloma contains a central lipid vacuole surrounded by a fibrinoid ring (58) (Fig. 2). Neurological manifestations of Q fever occur in 2% or more of cases and include meningitis, meningoencephalitis, peripheral neuropathy, and myelitis (5). Cardiac involvement occurs in 2% of acutely ill patients. This includes myocarditis (29), which led to death in two of the eight patients reported to date (29), and pericarditis, which is frequent but nonspecific (50). Among 204 patients with pericardial effusions, 10 (5%) were diagnosed as having Q fever by systematic testing (49). Other atypical presentations of acute Q fever have been reported such as acute acalculous cholecystitis (81) and isolated lymphadenitis from which *C. burnetii* has been cultured (26). Moreover, as *C. burnetii* occurs worldwide, it has been reported as a cause of fever in travelers returning from tropical countries (65) and may be associated with concurrent malaria (10).

Chronic fatigue following acute Q fever has been described in Australia and the United Kingdom (2, 66). It was reported that 20% of patients with post-Q-fever fatigue syndrome have moderate cytokine dysregulation (66). Q fever in immunocompromised hosts has been reported in patients with cancer (68) as well as in those with human immunodeficiency virus infection (52, 74). Q fever, when contracted during pregnancy, can result in abortion or neonatal death and in premature birth or low birth weight (71). About 4% of parturients in an area where Q fever is endemic have evidence of previous exposure to *C. burnetii,* and this correlates with adverse pregnancy outcomes (44). Twenty-three cases of Q fever during pregnancy have been reported (90). Most of these patients had complications including fetal or newborn death (11 cases) and premature birth (7 cases); only five patients had a normal pregnancy. One-half of the patients develop a serological profile of chronic Q fever during pregnancy, and, as in other mammals, *C. burnetii* can be isolated from the milk, the placenta, and the vaginal discharge. Multiple premature births have been reported in such cases (90), and these patients are subject to relapses during subsequent pregnancies. Patients with a valve lesion, an arterial aneurysm, or a prosthesis who have an episode of acute Q fever are at very high risk for chronic infection (77). Of acutely infected patients with a preexisting valvulopathy, 38% develop endocarditis within 2 years (19). In Greek children acute Q fever accounts for 3% of fever with unknown etiology (53). Children are less frequently symptomatic than adults and have milder disease, mostly pneumonitis (54). Chronic infection has rarely been reported, and when it occurs it manifests as endocarditis and osteomyelitis (11).

Chronic Q Fever

The major clinical form of chronic Q fever is endocarditis. At least 800 cases have been reported since 1949. In France, Q fever causes 5% of endocarditis cases with an estimated prevalence of $1/10^6$ inhabitants per year, which is close to what has been observed in Israel and Switzerland. In the largest published series of blood-culture-negative endocarditis, Q fever represented one-half (48%) of the etiologies, another 28% being due to *Bartonella* spp. and only 1% due to other fastidious growing microbes (38). The clinical presentation of patients with Q fever endocarditis varies according to the delays in diagnosis (70). A better knowledge of the disease has led to a significant reduction in this delay, explaining the decrease in the prevalence of heart failure, hepatomegaly, and abnormal liver function tests in this group of patients (37). Patients are usually afebrile or have low-grade intermittent fever.

Echocardiography is frequently inconclusive and fails to identify vegetations so that the diagnosis of endocarditis can easily be missed. A clue to the diagnosis is the presence of a known valve lesion and unexplained illness (fever, hepatitis, weakness, digital clubbing, weight loss, stroke, or renal insufficiency), an elevated erythrocyte sedimentation rate, increased serum transaminase levels, or thrombocytopenia. In such cases, positive Q fever serology complements the diagnosis made using modified Duke Criteria (27). Vascular infection is the second most commonly identified site of chronic Q fever. We have diagnosed 25 cases in our laboratory (28, 77), and 6 more were reported from other centers including England, the United States, Switzerland, and Australia (16, 17, 21, 60). Other manifestations of chronic Q fever include osteomyelitis (13), chronic hepatitis diagnosed in patients with alcoholism (77), pseudotumor of the spleen, pseudotumor of the lung, and infection of a ventriculoperitoneal drain (51). Recently, a case of vasculitis and pulmonary amyloidosis (41) following acute Q fever and resulting in the death of the patient was reported.

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

Biosafety level 2 practice and facilities are recommended for nonpropagative laboratory procedures including serological examination and staining of impression smears. Biosafety level 3 practice and facilities are recommended for activities involving inoculation, incubation, and harvesting of cell cultures, the necropsy of infected animals, and the manipulation of infected tissues (14). Although *C. burnetii* can be isolated from blood and a variety of tissues, this biosafety level is not feasible in most laboratories. Since the organism can withstand very harsh environmental conditions, it is unlikely that it will die during transport to a suitable laboratory. Blood should be collected in tubes containing EDTA or sodium citrate (heparin interferes with PCR), and the leukocyte layer should be saved for PCR. Solid specimens should be frozen at −80°C until they are cultured. Most laboratories depend on serological techniques to diagnose *C. burnetii* infection. For the diagnosis of acute Q fever, it is best that acute- and convalescent-phase serum samples collected 2 to 4 weeks apart be tested. Serum samples from patients with Q fever present no hazard to laboratory workers when handled using standard biosafety level 2 precautions.

LABORATORY DIAGNOSIS

Direct Examination

Antigen Detection

C. burnetii can be identified in tissues by a direct immunofluorescence technique. This is of limited utility for the routine diagnosis of C. *burnetii* since, with the exception of heart valve tissue from patients with Q fever endocarditis (9), tissue specimens from patients with acute Q fever are not generally submitted to the laboratory. The main reason for this is that the illness is mild to moderate in severity and death is extremely unusual. However, patients with Q fever endocarditis do have large numbers of C. *burnetii* organisms in the affected valvular tissue. These can be demonstrated by direct immunofluorescence (73) or electron microscopy. Other techniques that can be used to detect C. *burnetii* in tissues include immunohistology (9) (Fig. 3) and capture enzyme-linked immunosorbent assays (ELISAs) or enzyme-linked immunofluorescence assays (92).

Nucleic Acid Detection Techniques

PCR has successfully been used to detect DNA in cell cultures and clinical samples (89). Several genes have then been used to generate specific primers including 16S rRNA, 23S rRNA genes, superoxide dismutase, plasmid-based sequences, and the transposase encoding IS*111* multicopy insertion sequence gene (30). LightCycler nested PCR (LCN-PCR) using the IS*111* multicopy gene has been reported to be very sensitive. Because this is a closed glass capillary system, it does not pose more contamination risk than standard real-time PCR. It allows molecular detection of C. *burnetii* in sera from patients with Q fever endocarditis or vascular infection as well as in acute-phase sera of patients with acute Q fever (10, 20). LCN-PCR is particularly useful for early seronegative acute Q fever patients, but lacks sensitivity after 4 weeks of disease evolution. Thus, it is suggested that this test be added to serology in the first 2 weeks after the onset of symptoms to improve early diagnosis and in the 2 weeks following the onset of symptoms in the remaining seronegative patients only if suspicion of Q fever is high (31). Consequently, a positive PCR in a late-convalescent-phase serum should be carefully interpreted with the help of other conventional diagnostic methods and clinical data (84). LCN-PCR is also valuable for patients with phase I antibody titers between 800 and 6,400. In this range a positive PCR is correlated with chronic infection. For patients with chronic infection who have a higher level of antibody, the PCR is usually negative. Identification of C. *burnetii* at the strain level has been made possible with the use of a multispacer typing method allowing definition of three monophyletic groups among 158 isolates from all over the world (33). More recently a LightCycler PCR assay using hydrolysis probes has been used to detect C. *burnetii* in sera from patients with malaria (10).

Isolation Procedures and Identification

Isolation of C. *burnetii* must be done only in a biosafety level 3 containment facility due to its extreme infectivity. This microorganism can be isolated by inoculation of specimens into conventional cell cultures (e.g., Vero cells) (69), embryonated egg yolk sacs (63), or laboratory animals, such as mice or guinea pigs (39). The spleen of the inoculated animal is the most useful organ for the recovery of C. *burnetii.* Ground spleen extracts (0.2 to 0.5 ml of a 10% suspension) should be inoculated into embryonated eggs, which die 7 to 9 days later. These methods are used infrequently, but inoculation of animals remains helpful when the organism must be isolated from tissues contaminated with multiple bacteria or in order to obtain phase I C. *burnetii* antigens from phase II cells. The adaptation of a viral shell vial culture system using a human embryonic lung fibroblast (HEL cells) has improved the isolation of intracellular bacteria, especially C. *burnetii* (55, 69, 78). Plasma and buffy coat layers from heparinized blood are diluted 1:2 with Eagle's minimal essential medium (EMEM). Tissue specimens are homogenized in sterile phosphate-buffered saline (PBS) and diluted 1:2 in EMEM. Shell vials containing 12-mm-diameter round glass coverslips are seeded with 50,000 human embryonic lung cells in 1 ml of EMEM containing 10% fetal calf serum. The cells are incubated for 3 days at 37°C in an atmosphere containing 5% CO_2 until the monolayer is confluent. Then 1 ml of each homogenized specimen is placed into each of three shell vials. A 1-h centrifugation step (700 × *g* at 23°C) enhances the attachment and penetration of the bacteria into the cells. The supernatant is removed, and the monolayer is washed twice with PBS. Then 1 ml of EMEM containing 10% fetal calf serum is added to each vial. After an incubation period of 6 days, C. *burnetii* organisms are visualized as short rods by microscopic examination after staining with the Gimenez stain. Briefly, the infected cell smear is covered with carbol basic fuchsin (100 ml of 10% [wt/vol] basic fuchsin in 95% ethanol added to 250 ml of 4% [vol/vol] aqueous phenol and to 650 ml of distilled water) and allowed to stand 1 to 2 min. The smear is then washed in tap water and covered with malachite green solution (0.8% aqueous malachite green oxalate) for 6 to 9 s, washed again, and air dried (32). Confirmation of the presence of C. *burnetii* within the cells is performed by an indirect immunofluorescence assay with polyclonal or monoclonal anti-C. *burnetii* antibodies (Fig. 4) (69, 78). Positive cultures are passaged in cells several times to establish the isolated strain.

Serologic Tests

The microagglutination test (24, 64), the complement fixation test (22), the indirect immunofluorescent antibody (IFA) test (22, 62), and ELISA (97) have been used for the serological diagnosis of C. *burnetii* infection. With experimentally infected guinea pigs, ELISA is more sensitive than the IFA test. Antibodies against phase I whole cells are detected by day 9 with ELISA, by day 16 with the IFA test, and by day 20 with the complement fixation test. A commercial ELISA test (PanBio *Coxiella burnetii* immunoglobulin M [IgM] ELISA; QFM-200, Brisbane, Australia) has also been used for the serological diagnosis of acute Q fever, especially for the detection of IgM antibodies (23). However, the ELISA for the diagnosis of Q fever has not been standardized, rendering comparison of titers from laboratory to laboratory impossible. There are no accepted criteria for the diagnosis of acute versus chronic Q fever by this test. The complement fixation test is not as sensitive as the IFA test. Serum samples from about 20% of patients with acute Q fever are anticomplementary. A prozone phenomenon may be present in serum samples from some patients with chronic Q fever. This could result in a false-negative test result unless the laboratory is aware of this possibility.

The IFA test is the serological test of choice for the diagnosis of both acute and chronic Q fever. It is carried out by the procedure of Philip et al. (67) with purified whole-cell antigens at a concentration of 200 μg/ml. Both phase I and phase II antigens are used. Each antigen (phase I and II cells) is spotted onto slides, air dried, and fixed in acetone

for 15 min at room temperature (approximately 20°C). Serum dilutions are added to each antigen spot and incubated in a moist chamber for 1 h at room temperature. Slides are then rinsed three times with PBS before being incubated with a fluorescein isothiocyanate-conjugated anti-human polyvalent (α, γ, or μ chain-specific) immunoglobulin or anti-IgG-, anti-IgA-, or anti-IgM-specific immunoglobulin and incubated for 30 min at 37°C in a moist chamber. The slides are then washed in PBS, rinsed in distilled water, and dried. Coverslips are mounted onto the slides with glycerol mounting medium. The slides are immediately read using a microscope with a UV light source at a magnification of ×400. The end point is the highest dilution showing whole-cell fluorescence. This method can be used to determine IgG, IgM, and IgA antibody fractions to phase I and phase II. However, test results can be confounded by the presence of rheumatoid factor. Thus, rheumatoid factor absorbent is used to remove IgG before the determination of IgM and IgA (94). The choice of negative cutoff titer depends upon the source and purity of the antigen and the amount of background antigen stimulation in the population to be studied. We use 1:50 dilution as our first positive dilution (94). Others have used a 1:8 dilution. An IFA diagnostic kit (Q Fever IFA IgG, Focus Diagnostics, Inc., Cypress, Calif.) is commercially available.

The antigenic variation of *C. burnetii* is extremely useful in differentiating acute and chronic illness. In acute Q fever, antibodies to phase II antigens predominate, and their titer is higher than the phase I antibody titer. IgM antibodies appear usually at about the same time as IgG. On the other hand, in chronic forms of the disease, such as endocarditis, high-titer anti-phase I antibodies are detected uniformly. For the diagnosis of acute Q fever, cutoff values of anti-phase II IgG antibody of 200 or greater and of anti-phase II IgM antibody of 50 or greater are mandatory. For the diagnosis of chronic Q fever endocarditis, a titer of anti-phase I IgG of 800 or greater has been shown to raise the posttest probability to 98% (94).

ANTIMICROBIAL SUSCEPTIBILITIES

Antibiotic susceptibility testing of *C. burnetii* is difficult since this organism cannot be grown in axenic medium and methods are not standardized; therefore, susceptibility testing should be conducted only in appropriately experienced laboratories. Three models of infection have been used: animals, chick embryos, and cell culture; but only the last system is used today.

A shell vial assay with HEL cells for assessment of the bacteriostatic effects of antibiotics against *C. burnetii* has been developed (78). With this system, amikacin and amoxicillin were not effective and ceftriaxone and fusidic acid were inconsistently active, while cotrimoxazole, rifampin, doxycycline, tetracycline, minocycline, and clarithromycin (58) as well as sparfloxacin and the quinolones PD 127,391 and PD 131,628 (40) were bacteriostatic. By the same technique, moxifloxacin demonstrated better activity than ofloxacin and pefloxacin (82), and telithromycin showed better activity than erythromycin, with MICs of 1 μg/ml and 8 μg/ml, respectively (83). When $P388D_1$ and L929 cell multiplication was inhibited with cycloheximide during antibiotic challenges, pefloxacin, rifampin, and doxycycline (69) as well as clarithromycin (58) were bacteriostatic.

Lack of bactericidal activity was related to antibiotic inactivation by the low pH of the phagolysosomes in which *C. burnetii* multiplied. It has been subsequently shown that the addition of chloroquine, a lysosomotropic alkalinizing agent, to antibiotics improved the activities of doxycycline and pefloxacin, which then became bactericidal (57). Real-time quantitative PCR has been reported to be a faster and reliable technique for antimicrobial susceptibility testing of *C. burnetii*-infected cells (6, 7).

INTERPRETATION AND REPORTING OF RESULTS

The diagnosis of Q fever is currently based on serology. In acute Q fever, seroconversion usually is detected 7 to 15 days after the onset of clinical symptoms. Approximately 90% of patients have detectable antibodies by the third week. IFA antibody titers reach their maximum levels 4 to 8 weeks after the onset of disease and then decrease gradually during the ensuing 12 months (34). IgM titers declined to undetectable levels after 10 to 17 weeks (15, 22). In blood culture-negative endocarditis, the sensitivity and the posttest probability of having Q fever in a single-step serological assay with an 800-titer cutoff were 100 and 99.5%, respectively (80). Thus, in chronic Q fever a single serum sample is diagnostic. Consequently it has been suggested to modify the Duke criteria for the diagnosis of endocarditis and proposed that a single-serum *C. burnetii* phase I IgG antibody titer of 800 or a single positive blood culture for *C. burnetii* be considered major criteria for endocarditis (27). Serum samples from patients with Q fever endocarditis may cross-react with *Bartonella* spp., but cross-reaction is weak and differences in titers allow easy differentiation (46). For patients with a serological diagnosis of *Bartonella* endocarditis, the patient's sera should also be assayed for *C. burnetii* antibodies. Cross-reaction with other antigens is distinctly unusual.

The persistence of high levels of anti-phase I antibodies despite appropriate treatment, or the reappearance of such antibodies, should raise the suspicion of possible chronic Q fever. Patients with valvular or vascular abnormalities, those who are immunocompromised, and pregnant women should have repeated *C. burnetii* serology tests if they have a medical history of acute Q fever or a prolonged and unexplained febrile episode. In uncertain cases, a PCR performed with blood may help to determine if the patient is convalescent (negative) or infected (positive).

The follow-up of patients treated for chronic Q fever also should be done serologically. During therapy, serologic testing should be performed once monthly for 6 months and every 3 months thereafter. The levels of antibodies decrease very slowly, but this decrease correlates with the serum doxycycline level and a 2-dilution decrease for anti-phase I IgG and IgA is associated with cure. When the antibodies are initially present, IgM antibodies disappear first, and then IgA antibodies disappear; but IgG titers remain positive for years (79). Antimicrobial treatment can be stopped after 18 months to 3 years if the anti-phase I IgG titer by IFA is below 400 and IgA anti-phase I is undetectable (72).

Tropheryma

DIDIER RAOULT, FLORENCE FENOLLAR, AND DAVID RELMAN

69

Tropheryma whipplei is the bacterial agent of Whipple's disease and was described for the first time in 1907 by an American pathologist, George Hoyt Whipple (44). The clinical manifestations of this disease are diverse, protean, and nonspecific (19, 33). Due to the varied manifestations of the disease, the differential diagnosis is large, sometimes leading to a delayed diagnosis. Without treatment, the natural evolution of the disease is always fatal. The recent isolation of *T. whipplei* has opened new perspectives for the management of the disease (36).

TAXONOMY

In 1991, Wilson et al. sequenced a fragment of 16S rRNA gene from tissue of a patient with Whipple's disease (45). This partial sequence suggested a bacterium related to the *Actinomyces* clade. In 1992, Relman et al. described a nearly complete bacterial 16S rRNA gene sequence that was detected in five patients with Whipple's disease but not in a group of controls (39). The inferred phylogeny of the presumed causative agent suggested that the organism is an actinomycete and a member of the phylum *Actinobacteria*. The bacterium was originally named "*Tropheryma whippelii,*" but this was subsequently revised to *Tropheryma whipplei*, following its cultivation and phenotypic characterization, in order to accommodate the nomenclature rules of the International Society of Systematic Bacteriology (25).

DESCRIPTION OF THE GENOME

The entire genomes of two different strains of *T. whipplei* have been sequenced (2, 38). Sequencing of *T. whipplei* Twist revealed a 927,303-bp genome which carries 808 predicted protein-coding genes and with a GC content of 47% (38). Sequencing of *T. whipplei* TW08/27 revealed a 925,938-bp genome which carries 784 predicted protein-coding genes and with a GC content of 46.3% (2). *T. whipplei* possesses a unique circular chromosome and is the only known reduced-genome species (<1 Mb) within the *Actinobacteria* (2, 38). The genomic sequences of the two strains are nearly (>99%) identical at the nucleotide sequence level, encoding quasi-identical gene complements. This specific genome includes apparent deficiencies in energy metabolism and amino acids synthesis, suggesting a requirement of external nutrients. Alignment of the two genome sequences reveals a large chromosomal inversion, the extremities of which are located within two paralogous genes (2). These genes belong to a large family of predicted cell surface proteins defined by the presence of a common repeat highly conserved at the nucleotide level. The repeats appear to trigger genome fragment rearrangements in *T. whipplei*, potentially resulting in the expression of different subsets of cell surface proteins (2). This phenomenon might represent a new mechanism for evasion of the host's immune response during the course of this chronic disease.

NATURAL HABITAT

The source of *T. whipplei* and its transmission are presently unknown. The bacterium seems to be present in the environment. Studies based on PCR have shown the presence of *T. whipplei* DNA in effluent from sewage plants (30) and in human stools and saliva (10, 11, 23), and it has been speculated that *T. whipplei* is acquired via the oral route (19). Different studies have been performed to establish the presence of *T. whipplei* DNA in people without Whipple's disease in saliva, duodenal biopsy specimens, gastric liquids, and stools (11, 12, 41). However, the data should be analyzed with caution because they are based on "home-brew PCR" and have not been independently confirmed (10, 15, 31). It has been suggested that *T. whipplei* may have a specific geographic and racial distribution, with a predominance in Caucasians and in Central Europe (10).

CLINICAL FEATURES OF WHIPPLE'S DISEASE

The most common clinical presentation of Whipple's disease is an association of diarrhea, arthralgias, and lymphadenopathy, but all organs may be affected (17, 33). Many cases are associated with long-standing, relapsing and remitting arthralgias. As many as 15% of patients lack gastrointestinal symptoms throughout their illness (42), and small-bowel biopsies may be normal (34). It is therefore not surprising that in many of these atypical cases the diagnosis may not be made for some time and may be entirely missed until it is demonstrated at necropsy. The main clinical manifestations of Whipple's disease are summarized in Table 1.

TABLE 1 Clinical manifestations of Whipple's disease

Manifestations
Classic manifestations
Diarrhea
Arthralgias
Weight loss
Abdominal pain
Lymphadenopathy
Cutaneous pigmentation
Fever of unknown origin
CNS involvements
Cognitive impairment
Ophthalmoplegia
Myoclonic signs
Hypothalamic involvement
Cerebellar involvement
Abnormal ocular movements
Ophthalmologic manifestations
Uveitis
Cardiovascular manifestations
Blood culture-negative endocarditis
Pericarditis
Myocarditis

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

When Whipple's disease is suspected, saliva and stools for PCR and blood for PCR and immunohistochemistry are easy to sample and test. Saliva and stools are not considered useful samples by some authors (11, 12, 41). However, we have never obtained a positive PCR assay from these samples from people without a final diagnosis of Whipple's disease, except in one case (our unpublished data) (15). Small-bowel endoscopic biopsies should also be sampled systematically in suspected cases of Whipple's disease, even in the absence of intestinal symptoms. Several biopsies must be sampled from the duodenum and jejunum because the lesions can be focal and sparse (19). In cases of suspected Whipple's endocarditis, the excised cardiac valve should be tested by periodic acid-Schiff (PAS) staining, PCR, and immunohistochemistry. In cases of suspected neurologic Whipple's disease, cerebrospinal fluid (CSF) should be sampled as well as saliva, stools, blood, and small-bowel mucosa. If these investigations are not diagnostic, another disease site should be sampled based on associated signs and symptoms (lymph node, synovial biopsy, liver, cardiac valve, or vitreous fluid). If all these examinations are negative and accessible lesions are observed on brain magnetic resonance imaging, a stereotaxic biopsy should be performed for PCR and immunohistochemistry. Finally, if a diagnosis of Whipple's disease is established, even in the absence of neurologic signs, CSF should be systematically sampled and tested by PCR due to the common, subclinical involvement of the central nervous system (CNS) in this disease (6, 43). For PCR and culture, fresh samples should be frozen at −80°C and transported in dry ice. For PAS staining and immunohistochemistry, all the samples should be fixed in 10% formalin and transported at room temperature.

DIRECT EXAMINATION

Electronic Microscopy

Electron microscopy has been reported to demonstrate typical bacteria in macrophages from all kinds of tissues (Table 2) (19). Electron microscopy is not a practical tool for the diagnosis of the disease.

PAS Staining

The histological study of small-bowel biopsy specimens by use of PAS staining was the first tool for the diagnosis of Whipple's disease and is still considered an important and sometimes definitive diagnostic criterion (Table 2). The criterion is based on the observation of (i) diastase-resistant, magenta-stained inclusions within macrophages of the lamina propria and (ii) lymphatic dilatation. This PAS staining pattern, which has long been considered pathognomonic of Whipple's disease, is found in other diseases (19, 33). The presence of noncaseous granulomas composed of epithelioid cells may be observed in lymphatic tissues, the gastrointestinal tract, liver, or lung in Whipple's disease. These granulomas are often PAS negative (10, 19, 33). Depending on clinical manifestations, other tissues may be appropriate for PAS staining to establish the diagnosis of Whipple's disease, such as lymph node, synovium, cardiac valve, brain, or CSF (10, 19, 33).

Immunohistochemistry

The culture of *T. whipplei* has made possible the generation of polyclonal antibodies directed against the bacterium (27, 29) and an immunohistochemical diagnosis of Whipple's

TABLE 2 Diagnostic tools for the diagnosis of Whipple's disease

Technique	Sample(s)	Advantage	Disadvantage
Electron microscopy	Small-bowel tissue; all other kinds of tissues; body fluids	None	Not available in all laboratories; laborious
PAS staining	Small-bowel tissue; all other kinds of tissues; body fluids	Available in all laboratories; can be used on archival samples	Low specificity
Nucleic acid amplification	Blood; saliva; stools; small-bowel tissue; all other kinds of tissues; body fluids	Available in some laboratories	Specificity variable depending on sample type and laboratory
Immunodetection	Blood; small-bowel tissue; all other kinds of tissues; body fluids	Good specificity; can be used on archival samples	Noncommercialized antibodies
Culture	Blood; small-bowel tissue; all other kinds of tissues; body fluids	New strain isolation	Specific technology; long time required for the primary isolation
Serology	Serum	Simple procedure	Presently experimental

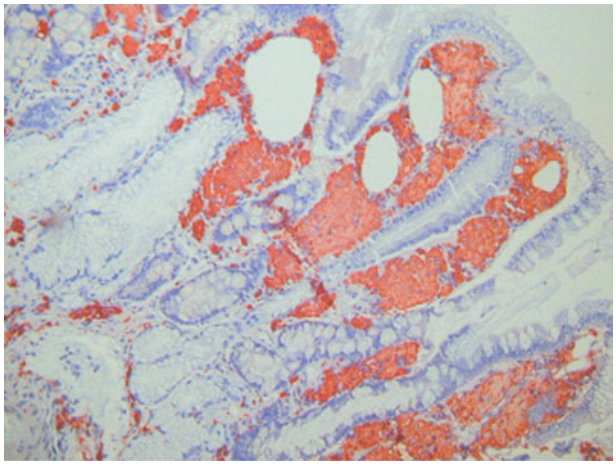

FIGURE 1 Immunohistochemistry performed on duodenal biopsies using rabbit polyclonal antibodies specifically directed against *Tropheryma whipplei*. Original magnification, ×100. Courtesy of Hubert Lepidi.

disease (26–28, 37). This technique has been performed on various kinds of tissues (duodenum, lymph node, brain, and cardiac valve), on body fluids such as aqueous humor, and on blood monocytes (1, 8, 9, 26, 27, 36, 37). This technique provides direct visualization of the bacilli in macrophages (Fig. 1) and offers increased sensitivity and specificity over the traditional PAS staining method (Table 2). It can also be used retrospectively on fixed samples (9).

Molecular Detection

PCR assays can be performed with a variety of tissue types (e.g., intestinal mucosa, lymph nodes, cardiac valves, and brain) and body fluids (CSF, blood, and saliva [Table 2]) (18). DNA extraction is a key step: different protocols have been proposed, involving phenol-chloroform-ethanol purification, chaotropic lysis, Chelex suspension, or a QIAamp DNA binding column (18). Some authors have also used digestion buffer before DNA extraction (18). These protocols can be applied to paraffin-embedded samples, as well as fresh samples. PCR amplification of the 16S rRNA gene was the first molecular tool for the diagnosis of Whipple's disease (39). As with all PCR assays, it is critical to include positive and negative controls (including water and DNA extracted from controls tissues). For each assay, the positive and negative controls must be, respectively, positive and negative to validate the results. Recently, a PCR assay targeting the 16S-23S intergenic region by using a real-time PCR apparatus has been successful for the diagnosis of Whipple's disease (15). This technique offers the advantages of reduced time for PCR analysis and lowered risk of contamination. The availability of the genome has also offered the possibility of selecting DNA targets in a more rational and informed manner. A real-time PCR assay targeting repeated sequences of *T. whipplei* significantly enhanced PCR assay sensitivity without altering its specificity, when compared to regular PCR (16). When amplified product is detected, the identification of the *T. whipplei* sequence should be confirmed by sequencing or hybridization. A problem with nonstandardized PCR assays is DNA contamination. In addition to general recommendations for avoiding contamination, we believe that when positive results from PAS staining or immunohistochemistry are not obtained in parallel with a positive PCR result (especially from blood, CSF, saliva, and stools), it is imperative to obtain confirmation of the diagnosis by using a different sample type tested with a different procedure (e.g., using a different DNA target to reduce the likelihood of false-positive PCR results).

Isolation Procedure

The cultivation of *T. whipplei* from various samples can be achieved with cell culture techniques and human fibroblasts (Table 2) (8, 14, 25, 32, 36, 37). Based on this technique, isolates have been obtained from cardiac valve, duodenal biopsy tissue, blood, aqueous humor, CSF, adenopathy, and synovial fluid (14, 32). Among them, 17 isolates (1 from a duodenal biopsy, 2 from cardiac valves, 7 from CSF, 4 from a blood sample, 2 from lymph node, and 1 from synovial fluid) have been established in serial cultures (2, 14, 32) (our unpublished data). In our experience, the delay before primary detection of *T. whipplei* from clinical samples is approximately 30 days (14), but it may be shorter (32). The cultivation of *T. whipplei* from contaminated specimen types such as intestinal biopsy specimens requires the use of drugs such as colistin, amphotericin B, cephalothin, or ciprofloxacin. *T. whipplei* genome analysis indicates deficiencies in amino acid biosynthetic pathways. As a consequence, the missing amino acids must be obtained from the environment. This information has allowed the design of a medium supplemented with amino acids, in which *T. whipplei* grows axenically (40). By use of this technique, two strains of *T. whipplei* from CSF, two strains from blood, one strain from synovial fluid, one strain from adenopathy, and one strain from cardiac valve have been isolated and established in parallel to cell culture (our unpublished data).

Identification

Every 15 days for 180 days of culture, the culture medium is changed, and before the medium is replaced 100 μl of the supernatant is obtained for centrifugation and stained by immunofluorescence using anti-*T. whipplei* polyclonal rabbit antibodies to detect bacterial growth. In parallel, a PCR assay is performed to confirm the growth and the identification. Confirmation of isolates as *T. whipplei* must be systematically obtained by specific PCR assay and amplicon sequencing or hybridization.

SEROLOGIC TESTING

The culture of *T. whipplei* has led to the development of serologic tests for this disease. However, serologic testing for Whipple's disease is not currently available (Table 2) (33, 35, 36).

ANTIMICROBIAL SUSCEPTIBILITIES

A study of the susceptibilities of three strains of *T. whipplei* to antibiotics in cell culture has indicated that doxycycline, macrolides, ketolides, aminoglycosides, penicillin, rifampin, teicoplanin, chloramphenicol, and trimethoprim-sulfamethoxazole are active against this organism, with MICs ranging from 0.25 to 2 μg/ml (4). Vancomycin was somewhat active with a MIC of 10 μg/ml. Cephalosporins (including ceftriaxone), colimycin, aztreonam, and fluoroquinolones are not active. Variability in the susceptibility of imipenem is also observed. A combination of doxycycline and hydroxychloroquine has been shown to be bactericidal in vitro because *T. whipplei* resides in acidic vacuoles of host cells (4, 22). The antibiotic susceptibilities of these three

TABLE 3 Strategy for interpretation of results depending on sample type and diagnostic technique[a]

Sample(s)	PAS	IHC	PCR	Confirmed diagnosis
Small bowel	+	− or NA	− or NA	No
Lymph nodes,	+	NA	+	Yes
cardiac valve, brain,	− or NA	+	+	Yes
other biopsy	− or NA	− or NA	+	Yes (?)
specimens	− or NA	+	− or NA	Yes (?)
CSF, blood	+	− or NA	− or NA	No
	+	− or NA	+	Yes
	− or NA	+	+	Yes
	− or NA	− or NA	+	?[b]
Saliva, stools	NA	NA	+	Predictive value depending on the laboratory

[a] Abbreviations and symbols: IHC, immunohistochemistry; NA, not available; −, negative; +, positive.
[b] Needs to be confirmed on a second sample, using a second DNA target if possible.

strains grown in axenic medium have also been studied (3). The active compounds on axenic medium are sulfamethoxazole, doxycycline, macrolides, penicillin G, streptomycin, rifampin, chloramphenicol, thiamphenicol, teicoplanin, vancomycin, amoxicillin, gentamicin, aztreonam, levofloxacin, and ceftriaxone, with MICs ranging from 0.06 to 1 μg/ml. Trimethoprim is not effective in vitro as predicted from genomic analysis (5).

INTERPRETATION OF RESULTS

A strategy for interpretation of diagnostic test results based on sample type and technique is summarized in Table 3. When a patient presents with "typical" features of Whipple's disease, including diarrhea, malabsorption, lymphadenopathy, and/or arthralgias, the diagnosis should be suspected. For cases of Whipple's disease without intestinal symptoms, such as Whipple's disease endocarditis and isolated neurologic disease, the diagnosis is more difficult. One of the main problems is the interpretation of an isolated positive PCR. These results must always be confirmed with a second specimen, such as blood or CSF, ideally using a different procedure and/or different DNA target. In these cases, the presence of a positive PCR from saliva or stool may be useful in confirming the diagnosis of Whipple's disease.

TREATMENT

Presently, the recommended treatment is an oral regimen of trimethoprim and sulfamethoxazole administered from 1 to 2 years. Many recommend that this regimen be preceded with treatment for 14 days consisting of intramuscular streptomycin and intravenous benzyl penicillin (penicillin G) (7, 13, 20, 21, 24). Based on recent data from in vitro assays, a therapeutic regimen that includes a combination of doxycycline and hydroxychloroquine to eradicate intracellular organisms is now suggested. Moreover, high doses of sulfamethoxazole in association with doxycycline and hydroxychloroquine may improve the treatment of CNS disease and reduce the likelihood of relapse. Clinical trials are now needed to confirm this strategy.

Antibacterial Agents

JOSEPH D. C. YAO AND ROBERT C. MOELLERING, JR.

70

Antimicrobial chemotherapy has played a vital role in the treatment of human infectious diseases in the 20th century. Since the discovery of penicillin in the 1920s, literally hundreds of antimicrobial agents have been developed or synthesized, and dozens of these are currently available for clinical use. While the broad number and variety of agents available provide a great deal of flexibility for the clinician in the use of these agents, the sheer numbers available and the continuing development of agents make it difficult for clinicians to keep up with progress in the field. Similarly, this variety presents significant challenges for the clinical microbiologist, who must decide which agents are appropriate for inclusion in routine and specialized susceptibility testing.

This chapter provides an overview of the antibacterial agents currently marketed in the United States, with major emphasis on their mechanisms of action, spectra of activity, important pharmacological parameters, and toxicities. Antibiotics that have fallen into disuse or remained investigational are mentioned only briefly.

PENICILLINS

The penicillins (Table 1) are a group of natural and semisynthetic antibiotics containing the chemical nucleus 6-aminopenicillanic acid, which consists of a β-lactam ring fused to a thiazolidine ring (Fig. 1a). The naturally occurring compounds are produced by a number of *Penicillium* spp. The penicillins differ from one another in the substitution at position 6, where changes in the side chain may modify the pharmacokinetic and antibacterial properties of the drug.

Mechanism of Action

The major antibacterial action of penicillins is derived from their ability to inhibit a number of bacterial enzymes, namely, penicillin-binding proteins (PBPs), that are essential for peptidoglycan synthesis (358). This ability to inhibit bacterial cell wall enzymes such as the transpeptidases usually confers on the penicillins bactericidal activity against gram-positive bacteria. The bactericidal activity of the penicillins is often related to their ability to trigger membrane-associated autolytic enzymes that destroy the cell wall. Other minor mechanisms of action include inhibition of bacterial endopeptidase and glycosidase, enzymes involved in bacterial cell growth. There is also recent evidence suggesting that penicillins may inhibit RNA synthesis in some bacteria, causing death without cell lysis, but the significance of these observations remains to be proven (223).

Pharmacology

Oral absorption differs markedly among the penicillins. As a natural congener of penicillin G, penicillin V resists gastric acid inactivation and is better absorbed from the gastrointestinal tract than is penicillin G. Amoxicillin is a semisynthetic analog of ampicillin and has greater gastrointestinal absorption than ampicillin (95 versus 40% absorption). Bacampicillin is an ampicillin ester that is absorbed considerably better from the gastrointestinal tract than is ampicillin or amoxicillin. This ester is inactive until naturally occurring esterases in the intestinal mucosa and serum hydrolyze them to release the parent compound, ampicillin, into the serum. The isoxazolyl penicillins, such as oxacillin, cloxacillin, dicloxacillin, and nafcillin, are acid stable and are also absorbed from the gastrointestinal tract (140), in contradistinction to certain other antistaphylococcal penicillins, such as methicillin, which are not acid resistant and cannot be given via the oral route.

Repository forms of penicillin G, available in procaine or benzathine, delay absorption from an intramuscular depot. Procaine penicillin G provides detectable levels for 12 to 24 h, suitable for treatment of uncomplicated pneumococcal pneumonia and gonorrhea due to fully susceptible organisms. Benzathine penicillin G achieves very low levels in blood for prolonged periods (3 to 4 weeks) and is useful for the therapy of syphilis and for prophylaxis of streptococcal pharyngitis and rheumatic fever.

Penicillins are well distributed to many body compartments, including the lungs, liver, kidneys, muscle, bone, and placenta. Penetration into the eye, brain, cerebrospinal fluid (CSF), and prostate is poor in the absence of inflammation. These drugs are metabolized to a small degree and are rapidly excreted, essentially unchanged, via the kidneys. With average half-lives of 0.5 to 1.5 h, they are usually administered every 4 to 6 h to maintain effective levels in blood. The renal tubular excretion of penicillins can be blocked by probenecid, thus prolonging their half-lives in serum.

Dosage reduction of most penicillins is necessary only in severe renal insufficiency (creatinine clearance of ≤10 ml/min). Dosages of all penicillins except nafcillin and the isoxazolyl penicillins are adjusted for hemodialysis. Peritoneal dialysis requires dosage reduction for carbenicillin and ticarcillin.

TABLE 1 Penicillins

- Natural
  - Benzylpenicillin (penicillin G)
  - Phenoxymethyl penicillin (penicillin V)
- Semisynthetic
  - Penicillinase resistant
    - Methicillin
    - Nafcillin
    - Cloxacillin
    - Dicloxacillin
    - Oxacillin
  - Extended spectrum
    - Aminopenicillins
      - Ampicillin
      - Amoxicillin
      - Bacampicillin
      - Pivampicillin
    - Carboxypenicillins
      - Carbenicillin
      - Ticarcillin
    - Ureidopenicillins
      - Azlocillin
      - Mezlocillin
      - Piperacillin
- Penicillin + β-lactamase inhibitor combinations
  - Ampicillin-sulbactam
  - Ticarcillin-clavulanate
  - Amoxicillin-clavulanate
  - Piperacillin-tazobactam

Spectrum of Activity

The penicillins have activity against most gram-positive and many gram-negative and anaerobic organisms. Penicillin G is very effective against penicillin-susceptible *Staphylococcus aureus, Streptococcus pneumoniae, Streptococcus pyogenes,* viridans group streptococci, *Streptococcus bovis, Neisseria gonorrhoeae, Neisseria meningitidis, Pasteurella multocida,* anaerobic cocci, *Clostridium* spp., *Fusobacterium* spp., *Prevotella* spp., and *Porphyromonas* spp. However, the occurrence of penicillin-resistant pneumococci has recently been increasing worldwide (190). Penicillin is the drug of choice for syphilis and *Actinomyces* infections. Penicillin V has a spectrum of activity similar to that of penicillin G except that it is less active against *N. gonorrhoeae.* Penicillinase-resistant penicillins, of which methicillin is the prototype, are primarily effective against penicillinase-producing staphylococci (115). The agents are at least 25 times more active than other penicillins against penicillinase-positive staphylococci. Although they are also active against *S. pneumoniae* and *S. pyogenes,* their MICs for these organisms are higher than those of penicillin G. They are not active against enterococci, members of the family *Enterobacteriaceae, Pseudomonas* spp., or members of the *Bacteroides fragilis* group.

Ampicillin and amoxicillin have spectra of activity similar to that of penicillin G, but they are more active against enterococci and *Listeria monocytogenes.* Although they are also more active against *Haemophilus influenzae* and *Haemophilus parainfluenzae,* up to 35% of *H. influenzae* isolates are resistant, usually because of β-lactamase production. *Salmonella* and *Shigella* spp., including *Salmonella enterica* serovar Typhi, and many strains of *Escherichia coli* and *Proteus mirabilis* are susceptible to these agents. Ampicillin is more effective against shigellae, whereas amoxicillin is more effective against salmonellae. Both of these agents are degraded by β-lactamase and are inactive against many *Enterobacteriaceae* and *Pseudomonas* spp.

The carboxypenicillins and ureidopenicillins have increased activity against gram-negative bacteria that are resistant to ampicillin. Although these drugs are susceptible to staphylococcal penicillinase, they are more stable against hydrolysis by the β-lactamases of *Enterobacteriaceae* and *Pseudomonas aeruginosa.* Carbenicillin and ticarcillin are relatively active against streptococci as well as against *Haemophilus* spp., *Neisseria* spp., and a variety of anaerobes (124). They inhibit *Enterobacteriaceae* but are inactive against *Klebsiella* spp. Although carboxypenicillins are not particularly active against the enterococci, they may act synergistically with aminoglycosides against these organisms.

The ureidopenicillins have greater in vitro activity against streptococci and enterococci than do the carboxypenicillins, and they inhibit more than 75% of *Klebsiella* spp. (87, 343). They have excellent activity against many *Enterobacteriaceae* and anaerobic bacteria, including members of the *B. fragilis* group. On a weight basis, their activities in decreasing order of potency against *P. aeruginosa* are as follows: piperacillin, azlocillin > mezlocillin, ticarcillin > carbenicillin (66). These agents also act synergistically with aminoglycosides against *P. aeruginosa.*

Adverse Effects

Common reactions to penicillins include allergic skin rashes, diarrhea, and drug fever. Severe anaphylactic reactions, which can be fatal, may occur in previously sensitized patients rechallenged with penicillins, but fortunately, such reactions are quite rare. At high doses (usually $>30 \times 10^6$ U/day), penicillin G can cause myoclonic twitching and seizures due to central nervous system toxicity. All of the penicillins may cause interstitial nephritis on an allergic basis, but methicillin is more likely than the other penicillins to cause this complication. Hepatitis has been associated with prolonged use of oxacillin. High-dose carbenicillin can result in sodium overload and hypokalemia. Neutropenia may occur with any of the penicillins. Thrombocytopenia and Coombs-positive hemolytic anemia are rare complications of penicillin therapy. Bleeding tendencies due to interference with platelet function can occur with the use of carboxypenicillins and ureidopenicillins (105). Although pseudomembranous colitis has been associated with all the penicillins, it occurs more frequently with ampicillin (19).

CEPHALOSPORINS

Cephalosporins are derivatives of the fermentation products of *Cephalosporium acremonium* (also designated *Acremonium chrysogenum*). They contain a 7-aminocephalosporanic acid nucleus, which consists of a β-lactam ring fused to a dihydrothiazine ring (Fig. lb). Various substitutions at positions 3 and 7 alter their antibacterial activities and pharmacokinetic properties. The addition of a methoxy group at position 7 of the β-lactam ring results in a new group of compounds called cephamycins, which are highly resistant to a variety of β-lactamases.

Mechanism of Action

Similar to the penicillins, cephalosporins act by binding to PBPs of susceptible organisms, thereby interfering with

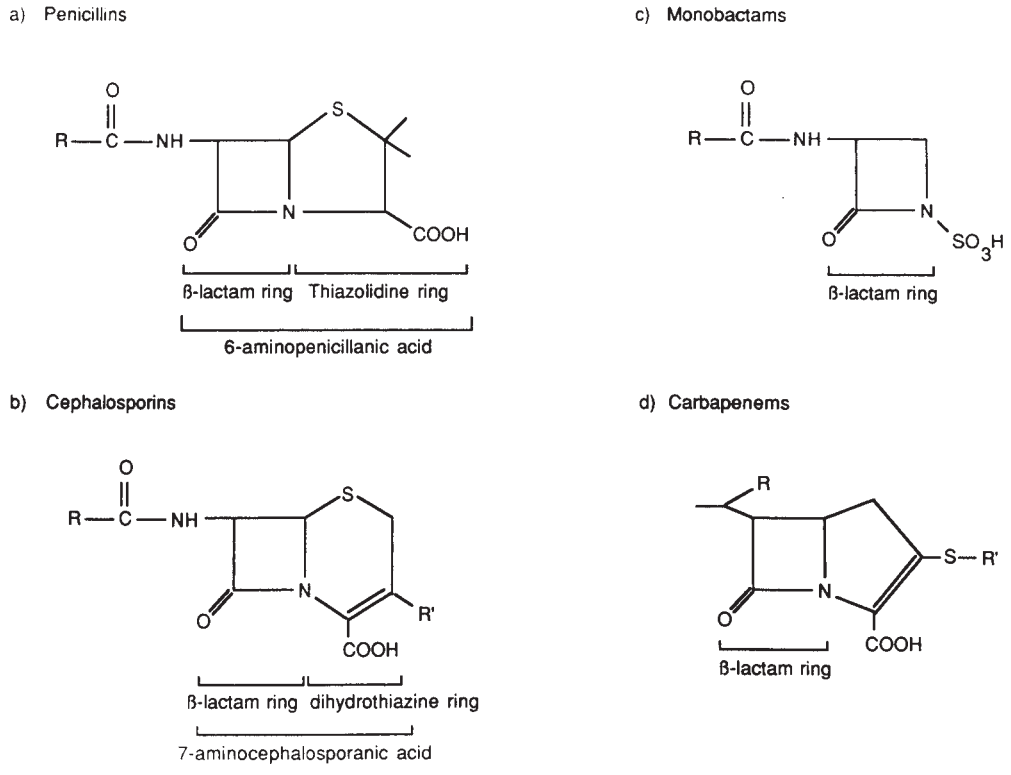

FIGURE 1 Chemical structures of β-lactam antibiotics.

synthesis of peptidoglycan of the bacterial cell wall. In addition, these β-lactam agents may produce bactericidal effects by triggering autolytic enzymes in the cell envelope (358).

Pharmacology

Most cephalosporins require parenteral administration, but a growing number are available in oral form. Cephalexin, cephradine, cefadroxil, cefaclor, cefuroxime axetil, cefprozil, loracarbef, cefdinir, cefditoren pivoxil, cefixime, cefpodoxime proxetil, and ceftibuten are given orally and have good gastrointestinal absorption (60 to 90% of the oral dose). Cefuroxime axetil is an acetoxyethyl ester of cefuroxime, and it is deesterified at the intestinal mucosa and absorbed into the bloodstream as cefuroxime. Cefditoren pivoxil and cefpodoxime proxetil are prodrugs that are absorbed and hydrolyzed by esterases in vivo to release the active drugs, cefditoren and cefpodoxime, respectively. Relatively high concentrations of these agents are attained across the placenta and in synovial, pleural, pericardial, and peritoneal fluids. Levels in bile are usually high, especially with cefoperazone, which is excreted mainly in the bile. Ceftizoxime, cefotaxime, ceftriaxone, cefoperazone, moxalactam, and cefepime enter well into the CSF and are useful for the treatment of meningitis. Cefuroxime penetrates inflamed meninges, but levels in CSF are inadequate in providing bactericidal activity against susceptible bacteria.

Cephalothin, cephapirin, and cefotaxime are converted to the desacetyl forms before excretion. All cephalosporins except cefoperazone are excreted primarily by the kidneys, and for these drugs, dosage adjustments are necessary in patients with renal insufficiency (creatinine clearance of <50 ml/min). Like that of the penicillins, the renal excretion of cephalosporins, except for ceftriaxone, is impeded by probenecid. In general, these agents are removed by hemodialysis but not by peritoneal dialysis. Of the cephalosporins, cefonicid and ceftriaxone have the longest elimination half-lives, at 4.5 and 8 h, respectively, permitting once- or twice-daily drug administration in the treatment of serious infections.

Spectrum of Activity

Cephalosporins are classified by a well-accepted but somewhat arbitrary scheme of grouping by generations based on general features of their antibacterial activity (Table 2). The first-generation (narrow-spectrum) drugs, exemplified by cephalothin and cefazolin, have good activity against gram-positive organisms and relatively modest activity against gram-negative organisms. They are active against penicillin-susceptible and -resistant *S. aureus* as well as *S. pneumoniae, S. pyogenes,* and other aerobic and anaerobic streptococci. Methicillin-resistant *S. aureus, Staphylococcus epidermidis,* and enterococci are resistant. Some *Enterobacteriaceae,* including many strains of *E. coli, Klebsiella* spp., and *P. mirabilis,* are susceptible. *Pseudomonas* spp. (including *P. aeruginosa),* many *Proteus* spp., and *Serratia* and *Enterobacter* spp. are resistant. These agents are active against penicillin-susceptible anaerobes except members of the *B. fragilis* group. They have only modest activity against *H. influenzae.*

The second-generation (expanded-spectrum) cephalosporins are stable against certain β-lactamases found in gram-negative bacteria and, as a result, have increased activity against gram-negative organisms. The agents are more active than narrow-spectrum drugs against *E. coli, Klebsiella* spp., and *Proteus* spp. Their activity also extends to cover some *Enterobacter* and *Serratia* strains, and they have good activity against *Haemophilus* spp., *Neisseria* spp., and many anaerobes.

TABLE 2 Cephalosporins

Narrow spectrum (first generation)
Cefadroxil
Cefazolin
Cephalexin
Cephaloridine
Cephalothin
Cephapirin
Cephradine
Expanded spectrum (second generation)
Cefaclor
Cefamandole
Cefonicid
Ceforanide
Cefuroxime
Cefprozil
Loracarbef
Cefmetazole
Cefotetan
Cefoxitin
Broad spectrum (third generation)
Cefdinir
Cefditoren
Cefixime
Cefoperazone
Cefotaxime
Cefpodoxime
Ceftazidime
Ceftibuten
Ceftizoxime
Ceftriaxone
Extended spectrum (fourth generation)
Cefepime
Cefpirome

Cefaclor, cefuroxime, cefamandole, cefonicid, and cefprozil are active against ampicillin-resistant *H. influenzae* and *Moraxella catarrhalis* (334). However, cefamandole exhibits a significant inoculum effect and is not suitable for treating life-threatening infections due to *H. influenzae.* Ceforanide and cefonicid have spectra of antibacterial activities similar to that of cefamandole, but they are less active than cefamandole against gram-positive cocci. Loracarbef belongs to a new class of cephalosporin derivatives known as carbacephems in which the sulfur atom of the dihydrothiazine ring is replaced by a methylene group to form a tetrahydropyridine ring (67). Since this structural modification of the cephalosporin nucleus is minor, loracarbef is considered a cephalosporin. Its spectrum of antibacterial activity is very similar to those of cefaclor, cefuroxime, and cefprozil. None of the expanded-spectrum agents is active against *Pseudomonas* spp.

Cefoxitin, cefotetan, and cefmetazole belong to a unique group of expanded-spectrum cephalosporins that have marked activity against anaerobes, including members of the *B. fragilis* group (175, 364). Cefotetan is two to four times less active than cefoxitin and cefmetazole against gram-positive cocci, but it is more potent than these two drugs against susceptible *Enterobacteriaceae.* The three drugs are equally active against *H. influenzae, M. catarrhalis,* and *N. gonorrhoeae,* including penicillin-resistant strains. While these drugs are comparable in their activities against the *B. fragilis* group, cefoxitin is the most active against *Prevotella* spp., *Porphyromonas* spp., and gram-positive anaerobic cocci. Cefotetan and cefmetazole have the advantage of more prolonged half-lives in serum.

Third-generation (broad-spectrum) cephalosporins are generally less active than the narrow-spectrum agents against gram-positive cocci, but they are much more active against the *Enterobacteriaceae* and *P. aeruginosa.* Their potent broad spectra of activity against gram-negative organisms are due to their stability against β-lactamases and their ability to pass through the outer cell envelopes of gram-negative rods (104, 254). There are two subgroups among these agents: those with potent activity against *P. aeruginosa* (ceftazidime and cefoperazone) and those without such activity (ceftizoxime, cefotaxime, and ceftriaxone).

Cefotaxime inhibits more than 90% of strains of *Enterobacteriaceae,* including those resistant to aminoglycosides. The MIC_{90}s for strains of *E. coli, Proteus* spp., and *Klebsiella* spp. tested are <0.5 μg/ml. Its activity against strains of *Serratia marcescens, Enterobacter cloacae,* and *Acinetobacter* spp. is variable, and it is inactive against *P. aeruginosa.* It has moderate activity against anaerobes but is inferior to cefoxitin and cefotetan against most of these isolates.

Ceftizoxime and ceftriaxone have spectra of activity similar to that of cefotaxime, with a few exceptions. Ceftriaxone is the most active agent against penicillinase-positive or -negative strains of *N. gonorrhoeae* (108). It is effective as single-dose therapy for infections caused by these organisms (51). Because of its long half-life in serum (the longest of the currently available cephalosporins), ceftriaxone is used frequently in outpatient antibiotic therapy of serious infections, including Lyme disease (229).

Cefoperazone is less active than cefotaxime against many *Enterobacteriaceae* and gram-positive cocci. However, it has activity against *P. aeruginosa,* with an MIC_{50} of ≤ 16 μg/ml. Its activity against anaerobes is similar to that of cefotaxime (177). Ceftazidime has potent activity against *P. aeruginosa,* with an MIC_{90} of <8 μg/ml (248). It is more active than the ureidopenicillins against these strains. This agent has activity similar to that of cefotaxime against the *Enterobacteriaceae* but is not as active against gram-positive cocci. It has little activity against gram-negative anaerobes.

Cefdinir (63), cefditoren (173, 178), cefixime (15), cefpodoxime (116, 298), and ceftibuten (177, 376) are extended-spectrum oral cephalosporins that are more stable than the narrow- and expanded-spectrum oral cephalosporins against gram-negative bacterial β-lactamases. Compared with the earlier cephalosporins, the newer drugs are equally active against streptococci (MIC_{90}s $\leq$ 0.06 μg/ml) but less active against methicillin-susceptible staphylococci (MIC_{90}s $=$ 2 μg/ml). While they have potent activities similar to that of ceftizoxime against many *Enterobacteriaceae, H. influenzae, M. catarrhalis,* and *N. gonorrhoeae* (including β-lactamase-producing strains), they are inactive against *Pseudomonas, Enterobacter, Serratia,* and *Morganella* spp. and anaerobes. None of the currently available cephalosporins is clinically useful against enterococci.

Cefepime is a so-called fourth-generation (extended-spectrum) cephalosporin approved for clinical use in the United States. Cefepime and cefpirome (formerly HR 810), which is currently undergoing clinical evaluations, have the unique features of reduced affinity for and increased stability against the Bush class I β-lactamases. Therefore, these agents are active against stably derepressed class I β-lactamase mutants of *Enterobacteriaceae* and *P. aeruginosa.* In addition, cefepime and cefpirome penetrate well through the outer membrane of gram-negative bacteria, due to a quaternary

nitrogen substitution that makes them zwitterions (net neutral charge). They are more active in vitro than cefotaxime and ceftriaxone against some *Enterobacteriaceae, Proteus, Providencia, Morganella,* and *Citrobacter* (MIC_{90}s ≤ 0.1 μg/ml) (126, 180, 301). Cefepime has activity comparable to that of ceftazidime against *P. aeruginosa,* with MIC_{90}s of ≤4 μg/ml, and it is active against some ceftazidime-resistant strains (279). Against staphylococci (MIC_{90}s ≤ 2 μg/ml) and streptococci (MIC_{90}s ≤ 0.12 μg/ml), the activities of this group of drugs are comparable to those of the narrow-spectrum cephalosporins (126, 180). However, they are not active clinically against enterococci or anaerobes.

Adverse Effects

Cephalosporins are generally very well tolerated. The most common side effects are diarrhea and hypersensitivity reactions such as rash, drug fever, and serum sickness. Cross-reactions with these drugs occur in only 3 to 7% of penicillin-allergic patients (186). Other infrequent side effects include pseudomembranous colitis, elevated serum creatinine and transaminase levels, leukopenia, thrombocytopenia, and Coombs-positive hemolytic anemia. These abnormalities are usually mild and reversible. Prolonged use of ceftriaxone has been associated with formation of gallbladder sludge, which usually resolves after the drug is discontinued (304), and, rarely, cholecystitis.

Disulfiram-like reactions have been described to occur in patients receiving cefamandole, cefotetan, and cefoperazone. This reaction is attributed to the *N*-methylthiotetrazole side chains of these antibiotics, which are similar to the chemical structure of disulfiram. Hypoprothrombinemia and bleeding tendencies have been observed with these cephalosporins. Causes of the coagulopathy included (i) alteration to healthy gut flora by the antibiotics, thus inhibiting the synthesis of vitamin K and its precursors, and (ii) the *N*-methylthiotetrazole side chain, which inhibits the vitamin K-dependent carboxylase enzyme responsible for converting clotting factors II, VII, IX, and X to their active forms and also prevents regeneration of active vitamin K from its inactive form (302).

OTHER β-LACTAM ANTIBIOTICS

■ Monobactams

Aztreonam is the only monobactam antibiotic currently in clinical use. The monobactams are β-lactams with various side chains affixed to a monocyclic nucleus (Fig. 1c).

Mechanism of Action

Aztreonam binds primarily to PBP 3 of gram-negative aerobes, including *P. aeruginosa,* thereby disrupting bacterial cell wall synthesis. It is not hydrolyzed by most commonly occurring plasmid-mediated and chromosomally mediated β-lactamases, and it does not induce the production of these enzymes (42).

Pharmacology

Given intravenously, aztreonam is widely distributed to body tissues and fluids. Average serum drug concentrations exceed the MIC_{90}s for most *Enterobacteriaceae* four to eight times for 8 h and are inhibitory to *P. aeruginosa* for 4 h. Aztreonam crosses inflamed meninges in sufficient amount to be potentially therapeutic for meningitis caused by susceptible organisms. Its half-life in serum is about 1.7 h, and it is excreted mainly unchanged by the kidney. Dosage modification is necessary for patients with renal failure. The drug is removed by both hemodialysis and peritoneal dialysis.

Spectrum of Activity

The antibacterial activity of aztreonam is limited to aerobic gram-negative rods, inhibiting most *Enterobacteriaceae, Neisseria* spp., and *Haemophilus* spp., with MIC_{90}s of ≤0.5 μg/ml (17, 332). It has significant activity against *Enterobacter* spp. and *S. marcescens,* with most strains being inhibited at ≤16 μg/ml. However, many *Acinetobacter* spp., *Burkholderia cepacia,* and *Stenotrophomonas maltophilia* are resistant. It shows in vitro synergism when combined with aminoglycosides against 30 to 60% of aztreonam-susceptible organisms, including *P. aeruginosa* and aminoglycoside-resistant gram-negative rods (41). Bacterial tolerance and inoculum effect are generally not seen with this agent. Aztreonam is not active against gram-positive bacteria or anaerobes.

Adverse Effects

Aztreonam is generally a safe agent, with a toxicity profile similar to those of other β-lactam drugs. Nausea, diarrhea, skin rash, eosinophilia, mild elevation of serum transaminase levels, and transiently elevated serum creatinine levels have occurred. It has minimal cross-reactivity with other β-lactams and can be used safely in patients allergic to penicillins or cephalosporins (303). Hematologic abnormalities have not been reported.

■ Carbapenems

Carbapenems are a unique class of β-lactam agents with the widest spectrum of antibacterial activity of the currently available antibiotics. Structurally, they differ from other β-lactams in having a hydroxyethyl side chain in *trans* configuration at position 6 and lacking a sulfur or oxygen atom in the bicyclic nucleus (Fig. 1d). The unique stereochemistry of the hydroxyethyl side chain confers stability against β-lactamases. Imipenem (*N*-formimidoyl thienamycin), a semisynthetic derivative of thienamycin produced by *Streptomyces* spp., meropenem, and ertapenem are the carbapenems currently available for clinical use (20, 259). Other members of this class currently undergoing preclinical evaluation or clinical trials include biapenem, doripenem, faropenem, and panipenem.

Mechanism of Action

Carbapenems bind to PBP 1 and PBP 2 of gram-negative and gram-positive bacteria, causing cell elongation and lysis (318). They are stable against most plasmid-mediated or chromosomally mediated β-lactamases except those produced by *S. maltophilia* and some strains of *B. fragilis* (249). Bacterial resistance arises from production of carbapenemases (metallo-β-lactamases) capable of hydrolyzing the carbapenem nucleus and from alteration of the porin channels in the bacterial cell wall, reducing the permeability of the drugs.

Pharmacology

After intravenous administration, the carbapenems distribute widely in the body but undergo no significant biliary excretion. Imipenem is metabolized and inactivated in the kidneys by a dehydropeptidase I (DHP-I) enzyme found in the brush border of proximal renal tubular cells. To achieve adequate concentrations in serum and urine, a DHP inhibitor, cilastatin, was developed; it is combined with imipenem in a 1:1 dosage ratio for clinical use. Cilastatin has no antibacterial activity, nor does it alter the activity of imipenem. It has a renal protective effect by preventing excessive accumulation of potentially toxic imipenem metabolites in the renal tubular cells. Meropenem, ertapenem, faropenem, and biapenem contain a β-methyl group substitution at position C-1 of the bicyclic nucleus

resulting in increased stability against inactivation by human renal DHP-I. These agents do not require concomitant administration of a DHP-I inhibitor.

The pharmacokinetics of imipenem and meropenem are very similar, with elimination half-lives in serum of about 1 h. Peak concentrations of the drugs in serum are about 25 to 35 μg/ml and 55 to 70 μg/ml following 0.5- and 1-g doses, respectively. These drugs penetrate inflamed meninges well, with drug levels of 0.5 to 6 μg/ml in the CSF (68, 259). Ertapenem is highly (>95%) bound to human plasma proteins, with poor penetration into the CSF. Its relatively long plasma half-life of 4 h allows for once-daily dosing frequency. The peak concentration in serum of 155 μg/ml is reached following a single intravenous dose of 1 g (256). Dosage adjustment of these carbapenem drugs is necessary for creatinine clearance of ≤30 ml/min. These agents, including cilastatin, are effectively removed by hemodialysis.

Spectrum of Activity

In general, all the carbapenems have similar antibacterial potencies, with minor differences. They have excellent in vitro activity against aerobic gram-positive species: staphylococci (penicillin-susceptible and -resistant isolates); viridans group streptococci; group A, B, C, and G streptococci; *Bacillus* spp.; and *L. monocytogenes.* Imipenem is two to four times more active than meropenem and ertapenem against streptococci and staphylococci, but methicillin-resistant staphylococci are usually resistant to all carbapenems. Although the MICs of carbapenems for penicillin-resistant pneumococci are elevated (MIC_{90}s of 0.25 to 2 μg/ml), many strains remain susceptible to these drugs, with imipenem being most potent (265). Ertapenem has poor activity against *Enterococcus faecalis,* but these isolates are inhibited by other carbapenems at ≤4 μg/ml. However, *Enterococcus faecium* strains are usually resistant.

More than 90% of *Enterobacteriaceae,* including those resistant to other β-lactams and aminoglycosides (254), are susceptible to carbapenems, with the following decreasing order of activity: doripenem, ertapenem, meropenem > biapenem > faropenem, imipenem (89, 97, 124, 157, 179, 215, 259, 362). These agents are highly active against clinical isolates of extended-spectrum β-lactamase-producing *Klebsiella pneumoniae* and *E. coli,* with MIC_{90}s of 0.015 to 0.125 μg/ml (193, 205). Most *Enterobacter* spp., *Citrobacter* spp., and *Serratia* spp. are inhibited by ≤2 μg/ml. Although ertapenem is inactive against *Acinetobacter* and *Pseudomonas,* it is 5- to 10-fold more active than other carbapenems against fastidious gram-negative bacteria such as *Haemophilus, Moraxella, Neisseria,* and *Pasteurella.* Most strains of *P. aeruginosa* are inhibited by other carbapenems at 4 to 8 μg/ml, with meropenem as the most potent agent, including against imipenem-resistant strains (123, 157, 204, 275). While they inhibit *B. cepacia* and *Pseudomonas stutzeri,* carbapenems are inactive against *S. maltophilia* (83). Emergence of resistant *Pseudomonas* spp. has been observed during therapy with imipenem (373). The drug may show in vitro antagonism when combined with broad-spectrum cephalosporins or extended-spectrum penicillins as a result of its ability to induce class I β-lactamase production (249).

Carbapenems are the most potent β-lactams against anaerobes, with activities comparable to those of clindamycin and metronidazole. The MIC_{90}s for anaerobic gram-positive cocci, *Clostridium,* the *B. fragilis* group, *Fusobacterium, Porphyromonas,* and *Prevotella* are ≤4 μg/ml (133, 214, 275, 363, 366, 368). This class of drugs is also active in vitro against *Actinomyces, Nocardia,* and atypical mycobacteria (25, 72, 84, 97, 133).

Adverse Effects

The side effects of carbapenems are similar to those of other β-lactam antibiotics. Nausea, vomiting, and diarrhea occur in up to 5% of patients, usually associated with parenteral administration of ertapenem and imipenem. Pseudomembranous colitis can occur with carbapenems. Allergic reactions such as drug fever, skin rashes, and urticaria are seen in about 3% of patients. Cross-reactivity with other β-lactam agents is possible but has not been fully studied. Seizures of unclear etiology have occurred in up to 1% of patients receiving ertapenem and imipenem, particularly in the elderly age group and in patients with renal insufficiency or underlying neurologic disorders. Meropenem has not been associated with seizures. Reversible elevation of serum transaminases, leukopenia, and thrombocytopenia have been described for carbapenems, but no coagulopathy has been reported.

β-LACTAMASE INHIBITORS

Clavulanic Acid

Clavulanic acid is a naturally occurring, weak antimicrobial agent found initially in cultures of *Streptomyces clavuligerus* (252). It inhibits β-lactamases from staphylococci and many gram-negative bacteria. This agent acts primarily as a "suicide inhibitor" by forming an irreversible acyl enzyme complex with the β-lactamase, leading to loss of activity of the enzyme.

Clavulanic acid acts synergistically with various penicillins and cephalosporins against β-lactamase-producing staphylococci, klebsiellae, *H. influenzae, M. catarrhalis, N. gonorrhoeae, E. coli, Proteus* spp., the *B. fragilis* group, *Prevotella* spp., and *Porphyromonas* spp. (12, 114, 124). Plasmid-mediated TEM β-lactamases present in ceftazidime-resistant strains of *K. pneumoniae* and *E. coli* are inactivated by this drug (169). However, the inducible β-lactamases (chromosomal class I) of *Enterobacter, Citrobacter, Proteus, Acinetobacter, Serratia,* and *Pseudomonas* spp. are not inhibited by clavulanic acid (191). The combination of clavulanic acid with ampicillin, amoxicillin, or ticarcillin is active in vitro against *Mycobacterium tuberculosis,* which is known to produce β-lactamases (73, 380).

In the United States, clavulanic acid is available for clinical use in combination with oral amoxicillin at dosage ratios of 1:2, 1:4, 1:7, and 1:16 and in a 1:15 or 1:30 parenteral combination with ticarcillin. Intravenous combinations of clavulanic acid and amoxicillin at ratios of 1:5 and 1:10 are also used outside of North America. The pharmacological parameters of amoxicillin and ticarcillin are not significantly altered when either drug is combined with clavulanic acid. Amoxicillin-clavulanate is moderately well absorbed from the gastrointestinal tract, with a half-life in serum of about 1 h for each component. One-third of a dose is metabolized, while the remainder is excreted unchanged in the urine. The drug is widely distributed to various body tissues and fluids, but it penetrates uninflamed meninges very poorly.

Adverse reactions are similar to those reported for amoxicillin or ticarcillin used alone. Nausea, vomiting, abdominal cramps, and diarrhea occur in 5 to 10% of patients taking amoxicillin-clavulanate. The incidence of allergic skin reactions is similar to that with ampicillin alone.

Sulbactam

Sulbactam is a semisynthetic 6-desaminopenicillin sulfone with weak antibacterial activity (5). It functions as an effective

inhibitor of certain plasmid-mediated and chromosomally mediated β-lactamases of *S. aureus,* many *Enterobacteriaceae, H. influenzae, M. catarrhalis, Neisseria* spp., *Legionella* spp., the *B. fragilis* group, *Prevotella* spp., *Porphyromonas* spp., and *Mycobacterium* spp. (122, 237). Sulbactam alone is active against *N. gonorrhoeae, N. meningitidis,* some *Acinetobacter* spp., and *B. cepacia* (170, 239). It acts synergistically with penicillins and cephalosporins against organisms that are otherwise resistant to the β-lactam drugs because of the production of β-lactamases. A combination of sulbactam (8 μg/ml) and ampicillin (16 μg/ml) inhibits most strains of staphylococci, *Klebsiella* spp., *E. coli, H. influenzae, M. catarrhalis, Neisseria* spp., the *B. fragilis* group, *Prevotella* spp., and *Porphyromonas* spp. that are ampicillin resistant (284, 365). Like clavulanic acid, sulbactam does not inhibit the β-lactamases of *Enterobacter, Citrobacter, Providencia,* indole-positive *Proteus, Pseudomonas* spp., or *S. maltophilia.*

For clinical use, sulbactam is combined with ampicillin as a parenteral preparation in a 1:2 ratio. The pharmacological properties of the drugs are not affected by each other in this combination. Ampicillin-sulbactam penetrates well into body tissues and fluids, including peritoneal and blister fluids. It enters the CSF in the presence of inflamed meninges. Like ampicillin, sulbactam has a half-life in serum of 1 h, and 85% of the drug is excreted unchanged via the kidneys. Since clearances of sulbactam and ampicillin are affected similarly in patients with impaired renal function, dosage adjustments are similar for the two drugs.

The most common side effects of the ampicillin-sulbactam combination have been nausea, diarrhea, and skin rash. Transient eosinophilia and transaminasemia have been reported. Adverse reactions attributed to ampicillin may also occur with the use of ampicillin-sulbactam.

Tazobactam

Tazobactam (formerly YTR 830) is a penicillanic acid sulfone derivative structurally related to sulbactam. Like clavulanic acid and sulbactam, tazobactam acts as a suicidal β-lactamase inhibitor and binds to bacterial PBP 1 or PBP 2 (239). Despite having very poor intrinsic antibacterial activity by itself, it is comparable to clavulanate and sulbactam in lowering the MICs up to 20-fold for many organisms when combined with various β-lactams against β-lactamase-producing organisms. Tazobactam actively inhibits the β-lactamases of staphylococci, *H. influenzae, N. gonorrhoeae, E. coli,* the *B. fragilis* group, *Prevotella* spp., and *Porphyromonas* spp. (3, 145, 194). It also has activity against the class I β-lactamases of *Acinetobacter, Citrobacter, Proteus, Providencia*, and *Morganella* spp., but it remains inactive against those of *Enterobacter* spp., *Pseudomonas* spp., *S. maltophilia,* and some *Klebsiella* spp. (191, 194, 239). Of the penicillin–β-lactamase inhibitor combinations, piperacillin-tazobactam is the one most active (two- to eightfold-lower MICs) against β-lactamase-producing aerobic and anaerobic gram-negative rods (99, 194).

Available as a 1:8 ratio dosage combination with piperacillin, tazobactam is administered parenterally. The two drugs do not affect each other's metabolism or pharmacokinetics. High concentrations of both agents are achieved in the intestinal mucosa, lungs, and skin, with relatively poor distribution to muscle, fat, the prostate, and CSF (in the absence of inflamed meninges). With a half-life in serum of about 1 h, elimination of tazobactam is mainly via the renal route and is not affected by hepatic failure (316). Major adverse effects of the piperacillin-tazobactam combination are similar to those of piperacillin alone, such as diarrhea, skin rash, and allergic reactions. Mild elevation in serum transaminase levels may be encountered in about 10% of patients.

AMINOGLYCOSIDES AND AMINOCYCLITOLS

Since the first aminoglycoside (aminoglycosidic aminocyclitol), streptomycin, was introduced in 1944, this class of antibiotic has played a vital role in the treatment of serious infections with gram-negative organisms. Among the unique features of the aminoglycosides is the bactericidal activity against aerobic gram-negative rods (including *Pseudomonas* spp.), activity against *M. tuberculosis*, and relatively low incidence of bacterial resistance. The currently available aminoglycosides are derived from *Micromonospora* spp. (gentamicin, sisomicin, and netilmicin) or from *Streptomyces* spp. (streptomycin, neomycin, kanamycin, tobramycin, and paromomycin). The difference in origin of these compounds accounts for the differences of their suffixes, "micin" versus "mycin." Streptomycin, neomycin, kanamycin, tobramycin, and gentamicin are naturally occurring aminoglycosides, whereas amikacin and netilmicin are semisynthetic derivatives of kanamycin and sisomicin, respectively. Structurally, each of these aminoglycosides contains two or more amino sugars linked by glycosidic bonds to an aminocyclitol ring nucleus.

Spectinomycin is an aminocyclitol antibiotic isolated from *Streptomyces spectabilis*. Although it contains an aminocyclitol nucleus, it is not strictly an aminoglycoside because it does not contain an amino sugar or a glycosidic bond.

Mechanism of Action

Aminoglycosides are bactericidal agents that inhibit bacterial protein synthesis by binding irreversibly to the bacterial 30S ribosomal subunit. The aminoglycoside-bound bacterial ribosomes then become unavailable for translation of mRNA during protein synthesis, thereby leading to cell death (79). The aminoglycosides also cause misreading of the genetic code, with resultant production of nonsense proteins. To reach the intracellular ribosomal binding targets, an aerobic energy-dependent process is necessary to enable successful penetration of the bacterial inner cell membrane by the aminoglycosides. Bacterial uptake of these agents is facilitated by inhibitors of bacterial cell wall synthesis such as β-lactams and vancomycin. This interaction forms the basis of antibacterial synergism between aminoglycosides and β-lactam antibiotics (81, 130). There are three known mechanisms of bacterial resistance to aminoglycosides: (i) decreased intracellular accumulation of the antibiotic by altering the outer membrane permeability, decreasing inner membrane transport, or active efflux; (ii) modification of the target site by mutation in the ribosomal proteins or 16S RNA; and (iii) enzymatic modification of the drug (the most common mechanism present).

Spectinomycin acts similarly to the aminoglycosides by binding to the 30S ribosomal subunits and inhibiting protein synthesis. However, it does not cause misreading of the mRNA and is not bactericidal.

Pharmacology

All aminoglycosides have similar pharmacological properties. Gastrointestinal absorption of these agents is unpredictable and always low. Because of its severe toxicity with systemic administration, neomycin is available only for oral and topical use. After intravenous administration, aminoglycosides are freely distributed in the extracellular space but

penetrate poorly into the CSF, vitreous fluid of the eye, biliary tract, prostate, and tracheobronchial secretions, even in the presence of inflammation.

In adults with normal renal function, the aminoglycosides have half-lives in serum of about 2 to 3 h. They are primarily excreted, essentially unchanged, via the kidneys. There is considerable variation in the elimination of aminoglycosides among individuals, especially in patients with impaired renal function. Monitoring of serum aminoglycoside levels in these patients is essential for providing adequate therapy and reducing toxicity. With their features of concentration-dependent killing and prolonged postantibiotic effect, aminoglycosides may be administered once daily to achieve maximum bactericidal activity at high concentrations in serum without increased risk of toxicities (21). In renal failure, the drugs accumulate and dosage reductions are necessary. Aminoglycosides are substantially removed by hemodialysis and to a lesser extent by peritoneal dialysis.

Spectrum of Activity

Aminoglycoside antibiotics are active primarily against aerobic gram-negative rods and *S. aureus*. As a group, they are particularly potent against the *Enterobacteriaceae, P. aeruginosa,* and *Acinetobacter* spp. Certain differences in antimicrobial spectra among the various aminoglycosides do exist. Kanamycin is limited in its spectrum because of the common resistance of *P. aeruginosa* and frequent occurrence of plasmid-mediated inactivating enzymes among other gram-negative bacilli (79). It is now used occasionally as a "second-line" drug in combination with other antibiotics for the therapy of mycobacterial infections (350, 351). Similarly, widespread resistance among *Enterobacteriaceae* has limited the usefulness of streptomycin. As a single agent, streptomycin is used in the therapy of infections due to *Francisella tularensis* (tularemia) and *Yersinia pestis* (plague) (219). It is often used in conjunction with tetracycline for the treatment of brucellosis. It has the greatest in vitro activity of the aminoglycosides against *M. tuberculosis*. It may also be used in combination with penicillin or vancomycin for the treatment of infective endocarditis due to viridans group streptococci or enterococci, provided that the organisms do not possess high-level ribosomal or enzymatic resistance to streptomycin (356, 357, 371, 372).

Although gentamicin and tobramycin have very similar antibacterial activity profiles, gentamicin is more active in vitro against *Serratia* spp., whereas tobramycin is more active against *P. aeruginosa* (247). However, these minor differences have not been correlated with greater efficacy of one agent over the other. For the most part, gentamicin and tobramycin are susceptible to inactivation by the same modifying enzymes produced by resistant bacteria, except that in contrast to gentamicin, tobramycin can be inactivated by 6-acetyltransferase and 4′-adenyltransferase and has variable susceptibility to 3-acetyltransferase. Netilmicin and amikacin are resistant to many of these aminoglycoside-modifying enzymes and therefore are active against most *Enterobacteriaceae* that are resistant to gentamicin and tobramycin (242). Netilmicin is intrinsically less active than gentamicin and tobramycin against *P. aeruginosa*, and most gentamicin-resistant *Serratia*, *Proteus, Providencia*, and *Pseudomonas* isolates are also usually resistant to netilmicin (121). Amikacin is often used as the aminoglycoside of choice when gentamicin and tobramycin resistances are prevalent. In addition, amikacin is active against many *Mycobacterium* spp. (350, 351). Aminoglycosides are only moderately active against *Haemophilus* and *Neisseria* spp. Of the agents active against *Bartonella* spp., aminoglycosides are the only drugs consistently bactericidal toward this group of organisms (218, 219).

Although active against staphylococci, aminoglycosides are not recommended as single agents for the treatment of staphylococcal infections. Gentamicin is often combined with a penicillin or vancomycin for synergy in the treatment of serious infections due to staphylococci, enterococci, or viridans group streptococci (356, 357, 371). The aminoglycosides are not active against anaerobes.

Paromomycin is an aminoglycoside notable for its amebicidal and antihelminthic effects, and it is used clinically for the treatment of intestinal amebiasis and tapeworm infections (228). It has modest antibacterial activity against gram-positive cocci and *Enterobacteriaceae*, but *P. aeruginosa* isolates are generally resistant.

Spectinomycin is used primarily for uncomplicated anogenital infections due to *N. gonorrhoeae* (354), including β-lactamase-producing strains, and gonococci are rarely resistant to this drug (108). It is useful in patients with penicillin allergy. Spectinomycin is ineffective for pharyngeal gonococcal infections, syphilis, or chlamydial infections.

Adverse Effects

Considerable intrinsic toxicity, mainly in the form of nephrotoxicity and auditory or vestibular toxicity, is characteristic of all of the aminoglycosides. The nephrotoxic potential varies among the aminoglycosides, with neomycin being the most toxic and streptomycin the least. This effect is usually reversible when the drug is discontinued. The presence of hypotension, prolonged duration of therapy, preexisting renal insufficiency, and possibly excessive trough serum aminoglycoside concentrations increase the risk of nephrotoxicity.

All aminoglycosides are capable of causing damage to the eighth cranial nerve in humans. Vestibular toxicity is more frequently associated with streptomycin, gentamicin, and tobramycin, whereas auditory toxicity is more typical of kanamycin and amikacin. This frequently irreversible side effect may occur even after discontinuation of the drug and is cumulative with repeated courses of the agent. The ototoxicity is a result of selective destruction of the hair cells in the cochlea. Clinically detectable auditory and vestibular dysfunction has been reported to occur in 3 to 5% of patients receiving gentamicin, tobramycin, or amikacin who underwent audiometric testing (106).

Neuromuscular paralysis, which is usually reversible, can occur after rapid intravenous infusion of aminoglycosides. This phenomenon occurs particularly in the setting of myasthenia gravis or concurrent use of succinylcholine during anesthesia. Other minor adverse reactions include local pain and allergic skin rashes. No known serious adverse reactions have been reported for spectinomycin.

QUINOLONES

Quinolones belong to a group of potent antibiotics biochemically related to nalidixic acid, which was developed initially as a urinary antiseptic. Nalidixic acid and its early analogs, oxolinic acid and cinoxacin, have limited clinical applications as a result of the widespread emergence of bacterial resistance. Newer quinolones have been synthesized by modifying the original two-ring quinolone (or naphthyridone) nucleus with different side chain substitutions (10). These new agents, also known as fluoroquinolones, each contain a fluorine atom attached to the nucleus at position 6. Cinoxacin, enoxacin, norfloxacin, lomefloxacin, ciprofloxacin, ofloxacin, levofloxacin, sparfloxacin, trovafloxacin, gatifloxacin, gemifloxacin, and

moxifloxacin are currently available for clinical use in the United States. Temafloxacin and grepafloxacin have been withdrawn from clinical use due to toxicities. Garenoxacin and sitafloxacin are currently undergoing clinical investigation in the United States. Several closely related fluoroquinolones (enrofloxacin and sarafloxacin) are approved for agricultural and veterinary use in the United States and elsewhere.

Mechanism of Action

The primary bacterial target of the quinolones is DNA gyrase, a type II DNA topoisomerase enzyme essential for DNA replication, recombination, and repair (150). Newer fluoroquinolones also inhibit DNA topoisomerase IV. The DNA gyrase A subunit is the main target of quinolones in gram-negative bacteria, whereas topoisomerase IV is the primary target in gram-positive bacteria. Inhibition of these bacterial enzyme targets causes relaxation or decatenation of the supercoiled DNA, leading to termination of chromosomal replication and interference with cell division and gene expression. By inhibiting bacterial DNA synthesis, these agents are bactericidal. However, the antibacterial activity of quinolones is reduced in the presence of low pH, urine, and divalent cations (Mg^{2+} and Ca^{2+}).

Bacterial resistance to quinolones may occur by one or more of the following mechanisms: single-step chromosomal mutations in the structural genes for DNA gyrase and topoisomerase IV, mutations in the regulatory genes governing bacterial outer membrane permeability to the drug, and expression or overexpression of energy-dependent efflux pumps that can actively remove drugs from the bacterial cell (148, 267). Transferable plasmid-mediated resistance to nalidixic acid and fluoroquinolones can also occur in *Enterobacteriaceae* by acquisition of a resistance gene encoding a protein which inhibits the binding of quinolones to bacterial DNA gyrase (168, 234, 258). In addition, a transferable aminoglycoside acetyltransferase [AAC(6′).1B] has been shown to confer low-level resistance to ciprofloxacin (284a).

Pharmacology

Fluoroquinolones are generally well absorbed from the gastrointestinal tract, with the exception of norfloxacin. The oral bioavailability varies from 60 to 95% for the various fluoroquinolones (325, 375). After oral administration, concentrations in serum peak in 1 to 2 h. The presence of food does not significantly alter the absorption of these drugs. However, coadministration with iron- or zinc-containing multivitamins or with antacids containing aluminum, magnesium, or calcium substantially reduces the gastrointestinal absorption and subsequent peak concentrations of quinolones in serum. The degree of serum protein binding is generally low, ranging from 8% for ofloxacin to 75% for trovafloxacin. The prolonged elimination half-lives of fluoroquinolones, ranging from 3.5 h for ciprofloxacin to 20 h for sparfloxacin, allow for twice- or once-daily dosing (139, 237, 338). Ciprofloxacin, ofloxacin, levofloxacin, trovafloxacin, gatifloxacin, and moxifloxacin are also available for intravenous use. The intravenous formulation of trovafloxacin is prepared as alatrofloxacin mesylate, which is a prodrug of trovafloxacin and is rapidly hydrolyzed in vivo to yield the active drug.

Quinolones have good penetration into the lungs, kidneys, muscle, bone, intestinal wall, and extravascular body fluids. Concentrations in the prostate are about twice those in the serum, and concentrations 25 to 100 times above peak concentrations in serum are achieved in the urine. In the presence of meningeal inflammation, only ofloxacin, levofloxacin, trovafloxacin, gatifloxacin, and moxifloxacin achieve concentrations of >1 μg/ml in the CSF (212, 222). Quinolones penetrate well into phagocytes, such that concentrations within neutrophils and macrophages are as high as 14 times those in serum (340). This feature accounts for their excellent in vivo activity against such intracellular pathogens as *Brucella, Listeria, Salmonella,* and *Mycobacterium* spp.

Trovafloxacin and pefloxacin are metabolized mainly by the liver to form glucuronide conjugates, and pefloxacin is converted into norfloxacin in vivo. Ofloxacin exhibits little or no in vivo metabolism, and it is excreted mainly (90%) via the kidneys. The other quinolones are cleared by both the hepatic and renal routes in various proportions, with elimination primarily via the kidneys. This renal elimination is blocked by probenecid. Small amounts of these drugs are also excreted in the bile.

Hepatic insufficiency prolongs the elimination half-lives of pefloxacin and trovafloxacin, whereas the clearance of other fluoroquinolones is significantly diminished in the presence of renal failure. All of these drugs are only partially removed by hemodialysis (<15%) and are minimally affected by peritoneal dialysis because of their marked extravascular penetration, as reflected in their very large volumes of distribution.

Spectrum of Activity

Quinolones may be categorized into groups with similar spectra of antibacterial activity (Table 3), analogous to the classification of cephalosporins (10). The narrow-spectrum quinolones are inactive against gram-positive cocci, and their clinical utility is limited by widespread prevalence and rapid emergence of bacterial resistance. Broad-spectrum (second-generation) fluoroquinolones are active against both gram-positive and gram-negative bacteria (237, 335,

TABLE 3 Quinolones

346, 378). Increased activity against gram-positive cocci and favorable pharmacodynamic properties (high ratios of area under the curve from 0 to 24 h to MIC) are major features of the newer fluoroquinolones (third and fourth generations), with potencies two- to eightfold greater than those of broad-spectrum agents (9, 23, 37, 62, 64, 75, 82, 217, 271). MIC_{90}s for methicillin-susceptible and -resistant *S. aureus* and coagulase-negative staphylococci are in the range of 0.03 to 1 μg/ml, while methicillin-resistant staphylococci are becoming increasingly resistant to these agents. Although potency against enterococci is lower, gatifloxacin is two- to fourfold (MIC_{90}s of 0.25 to 0.5 μg/ml) and gemifloxacin and moxifloxacin are four- to eightfold (MIC_{90}s of 0.03 to 0.25 μg/ml) more active than levofloxacin against multidrug-resistant *S. pneumoniae*.

In contrast to earlier drugs of this class, many of the expanded- and extended-spectrum quinolones possess potent activity against anaerobes, including members of the *B. fragilis* group and *Clostridium difficile* (57, 95, 257, 317). The relative activities of these newer drugs against all anaerobes in decreasing order of potency are as follows: sitafloxacin > garenoxacin > gatifloxacin, trovafloxacin > moxifloxacin, tosufloxacin. The more active of these agents inhibit *the B. fragilis* group, *Prevotella, Porphyromonas, Fusobacterium, Clostridium,* and anaerobic gram-positive cocci at concentrations of 0.06 to 2 μg/ml. However, increasing fluoroquinolone resistance has emerged among *Bacteroides* spp. since the introduction of the newer drugs (28, 131, 314).

The fluoroquinolones possess excellent activity in vivo against *Enterobacteriaceae, P. aeruginosa, Citrobacter* spp., *Serratia* spp., *Acinetobacter* spp., *H. influenzae*, and gram-negative cocci such as *N. gonorrhoeae, N. meningitidis*, and *M. catarrhalis* (23, 27, 29, 62, 64, 82, 217, 344). Enteropathogenic gram-negative rods such as *Salmonella*, *Shigella*, *Yersinia enterocolitica, Vibrio* spp., *Aeromonas* spp., *Plesiomonas* spp., *Campylobacter jejuni,* and enteroinvasive and enterotoxigenic *E. coli* are all susceptible to the quinolones (98, 378). Clinical studies have shown these drugs to be effective in the prophylaxis and treatment of infectious diarrheas. However, reduced susceptibility and resistance to quinolones have emerged in clinical isolates of *Salmonella, Shigella,* and *Campylobacter* spp. (100, 163). *Legionella* spp. are susceptible to these agents, with MICs of most fluoroquinolones of 0.12 to 1.0 μg/ml for these organisms (29, 37, 82, 94). Fluoroquinolones are the first class of oral antibiotics with outstanding potency against *P. aeruginosa*. Ciprofloxacin and trovafloxacin are the most active among these drugs against *P. aeruginosa,* with MIC_{90}s of 0.5 to 1 μg/ml. However, *Burkholderia* spp. and *S. maltophilia* are variably resistant to quinolones (344)

The fluoroquinolones, especially ciprofloxacin, levofloxacin, ofloxacin, and sparfloxacin, are active in vitro against *M. tuberculosis,* the *Mycobacterium fortuitum* group, *Mycobacterium chelonae*, *Mycobacterium kansasii*, and *Mycobacterium xenopi* (80, 335, 383). Their activity against *Mycobacterium avium* complex is fair to poor. They also exhibit activity against *Chlamydia trachomatis, Chlamydophila pneumoniae,* and *Mycoplasma hominis*, with MIC_{90}s of 0.1 to 1 μg/ml, but are less potent against *Ureaplasma urealyticum* (98, 187). Ciprofloxacin and pefloxacin have been shown to inhibit *Rickettsia conorii*, *Rickettsia rickettsii*, and *Coxiella burnetii* (281, 282, 382). The broad-spectrum fluoroquinolones also possess potent activity against *Bartonella* spp. (218) and *Brucella melitensis* (101). Although quinolones possess in vitro activity against *Plasmodium falciparum* at achievable concentrations in serum, they are relatively ineffective when used clinically for the treatment of malaria. *Nocardia* spp. are relatively resistant to the quinolones (25, 84).

No significant inoculum effect has been observed among the bacteria susceptible to quinolones. Combinations of quinolones with (β-lactam drugs or aminoglycosides are usually indifferent or additive in their effects against gram-negative and gram-positive bacteria and mycobacteria (378). However, bactericidal activities of quinolones can be antagonized by rifampin or chloramphenicol.

Adverse Effects

Gastrointestinal symptoms, occurring in up to 10% of patients as nausea, vomiting, abdominal discomfort, and diarrhea, are the most common side effects (11, 202, 319). However, *C. difficile* colitis occurs infrequently with the use of quinolones. Headaches, fatigue, insomnia, dizziness, agitation, and, rarely, seizures can occur. These adverse neurologic effects are usually associated with high dosages in elderly patients or concurrent use of nonsteroidal anti-inflammatory drugs.

Allergic reactions are uncommon and often manifest as rash, urticaria, and generalized pruritus. Dose-related photosensitivity occurs most frequently in patients on fleroxacin, sparfloxacin, and lomefloxacin. Prolongation of the QT interval has also occurred with sparfloxacin and grepafloxacin. Rare laboratory abnormalities occurring during fluoroquinolone therapy include elevations in serum transaminases, eosinophilia, leukopenia, and thrombocytopenia. Trovafloxacin is rarely used because it results in rare occurrences of liver dysfunction or failure. Gatifloxacin can cause hypoglycemia and hyperglycemia, and its use is contraindicated in diabetic patients.

Enoxacin and, to a lesser extent, ciprofloxacin and pefloxacin increase the levels of theophylline and caffeine in serum as a result of decreased hepatic clearance (11, 277, 369). Other reported drug interactions include augmentation of the anticoagulant effects of warfarin by ciprofloxacin, norfloxacin, and ofloxacin and an increase in serum cyclosporine levels with ciprofloxacin (277).

Although irreversible cartilage erosions and skeletal abnormalities were observed in studies of quinolone toxicity in animals (11), such effects have not yet been documented clinically. However, quinolones are generally contraindicated for use in patients less than 18 years old and in pregnant or nursing mothers. Tendinitis and tendon rupture, mainly involving the Achilles tendon, have occurred with the use of fluoroquinolones, most frequently with pefloxacin and ciprofloxacin (188).

MACROLIDES

Macrolides have been in use since the early 1950s, with erythromycin as the prototypical antibiotic of this class for over 30 years (355). Their chemical structures consist of a macrocyclic lactone ring attached to two sugar moieties, desosamine and cladinose. They differ from each other in the size (14 to 16 atoms) and substitution pattern of the lactone ring. Erythromycin is a naturally occurring 14-membered-ring macrolide derived from *Streptomyces erythraeus*, and other natural analogs include oleandomycin, spiramycin, and josamycin. Clarithromycin and dirithromycin are 14-membered-ring semisynthetic macrolides, while azithromycin is a 15-membered-ring derivative also known as an azalide, with a nitrogen atom incorporated in its lactone ring. These new macrolides offer significant advantages over

erythromycin because of expanded antimicrobial spectra, improved pharmacokinetic parameters, and less frequent adverse effects and drug interactions. Roxithromycin, flurithromycin, and rokitamycin are new macrolides available for clinical use currently in Europe, Asia, and South America (189).

Mechanism of Action

Macrolides are generally bacteriostatic agents that inhibit bacterial RNA-dependent protein synthesis. They may be bactericidal at high drug concentrations and against a small inoculum of bacteria. They bind reversibly to the 23S rRNA of the 50S ribosomal subunits of susceptible organisms, thereby blocking the translocation reaction of polypeptide chain elongation (342). The presence of *erm* gene-encoded rRNA methylases that modify the 23S rRNA target-binding site is the primary mechanism of macrolide resistance and confers macrolide-lincosamide-streptogramin B (MLS_B) coresistance (93). Other less common mechanisms of resistance to macrolides include production of macrolide-inactivating enzymes (esterases, phosphorylases, and glycosidases), *mef* gene-encoded active efflux of drug, and mutations in 23S rRNA and ribosomal proteins (197).

Pharmacology

Erythromycin is available in various topical, parenteral (lactobionate and gluceptate), and oral (base stearate, ethylsuccinate, and estolate) preparations. While clarithromycin and dirithromycin are available only in oral forms, azithromycin is formulated for oral and intravenous administration. When administered orally, erythromycin base is rapidly inactivated by gastric acid, whereas the newer macrolides are stable against acid degradation. Intestinal absorption of erythromycin (except for the estolate form) and azithromycin is reduced up to 50% in the presence of food. Peak levels in serum of 2 to 3, 1 to 2, 0.2 to 0.6, and 0.4 μg/ml are reached at 3 h after oral doses of erythromycin (500 mg), clarithromycin (250 mg), dirithromycin (500 mg), and azithromycin (500 mg), respectively. Much higher concentrations of erythromycin are achieved with intravenous infusion. Tissue distributions of macrolides are excellent, with concentrations in various tissues 10- to 100-fold higher than that in serum (370). The high concentrations reached rapidly within neutrophils and macrophages account for their potent activity against intracellular pathogens (305). They penetrate poorly into the brain and CSF, but they do cross the placenta and are excreted in breast milk.

Erythromycin, clarithromycin, and dirithromycin are metabolized by the liver and primarily excreted in the bile. Azithromycin is excreted largely unchanged in the bile. Clarithromycin exhibits first-pass metabolism, producing a microbiologically active 14-hydroxy derivative that is two to four times more potent than the parent drug against some organisms. Following gastrointestinal absorption, dirithromycin is rapidly converted by nonenzymatic hydrolysis to erythromycylamine, an active derivative with microbiological activity similar to that of its parent compound. Erythromycin, clarithromycin, 14-hydroxy clarithromycin, azithromycin, and dirithromycin have terminal half-lives in serum of 1.5, 5, 8.5, 41, and 44 h, respectively. Because of its exceptionally high tissue penetration, azithromycin has a half-life in tissue of 2 to 4 days (305). Dosage adjustment of clarithromycin is necessary for patients with moderate to severe renal failure (creatinine clearance of <30 ml/min). Except for clarithromycin, macrolides are removed minimally by hemodialysis or peritoneal dialysis.

Spectrum of Activity

Macrolides are relatively broad-spectrum antibiotics, with activity against gram-positive and some gram-negative bacteria, mycoplasmas, chlamydiae, treponemes, and rickettsiae (148, 305, 370). Erythromycin shows good activity against staphylococci and streptococci, including *S. pneumoniae*, but emergence of resistance among these isolates (especially group A streptococci) is a problem in certain parts of the world (55, 190). Erythromycin and dirithromycin exhibit similar in vitro antibacterial activities (22). Clarithromycin is two- to fourfold more active than the other macrolides, and azithromycin is less active than erythromycin against most staphylococci and streptococci (16). These drugs are bactericidal against susceptible strains of streptococci but bacteriostatic toward staphylococci and enterococci. Erythromycin-resistant strains display cross-resistance to these drugs, and methicillin-resistant staphylococci and many enterococci are resistant to all macrolides. These drugs are also active against *Corynebacterium* spp., *L. monocytogenes*, and *Actinomyces israelii* (16).

The antibacterial activity of macrolides against gram-negative rods is influenced by pH, with increasing potency (lower MICs) as the pH rises to 8.5. *H. influenzae* and *M. catarrhalis* are more susceptible to azithromycin (MIC_{90} of 0.5 μg/ml) than to other macrolides (8- to 16-fold-higher MIC_{90}s) (206, 250, 273). However, additive (and possibly synergistic) activity between clarithromycin and its 14-hydroxy metabolite reduces the MIC of clarithromycin for *H. influenzae* two- to fourfold (251). Clarithromycin is the most active drug in this class against *C. pneumoniae* (MIC_{90} of 0.25 μg/ml) and *Legionella* isolates (MIC_{90} of 0.25 μg/ml) (16). All four macrolides are equally potent against *Bordetella pertussis* and *Mycoplasma pneumoniae*, and erythromycin has long been established as the drug of choice for therapy of infections due to these pathogens and *Legionella* spp. Macrolides are active against *Campylobacter* spp., *Helicobacter pylori, P. multocida, N. meningitidis,* and *Borrelia burgdorferi* (16, 225, 273, 341). Unlike other macrolides, azithromycin is also active in vitro against *E. coli, Shigella* spp., *Salmonella* spp., and *Y. enterocolitica* (206, 250).

Macrolide antibiotics are effective in vitro against many pathogens that cause sexually transmitted diseases. *N. gonorrhoeae, Haemophilus ducreyi, C. trachomatis,* and *U. urealyticum* are all susceptible, but only azithromycin is active against *M. hominis* (16, 206). Erythromycin may be used for the treatment of gonorrhea and syphilis in patients who cannot tolerate penicillin G (51), but data on the new macrolides for these indications are limited. Azithromycin is effective as an alternative to tetracyclines for the treatment of genital chlamydial infections (320). As a group, macrolides are among the most potent agents inhibitory toward *Bartonella* spp. (218).

The macrolides have good activity against anaerobic bacteria such as the *B. fragilis* group, *Fusobacterium* spp., *Prevotella* spp., *Porphyromonas* spp., *Propionibacterium acnes,* and anaerobic gram-positive cocci, with MIC_{90}s of 1 to 4 μg/ml (16). Except for dirithromycin, they are active against most *Clostridium* spp., especially *Clostridium perfringens*, with most strains inhibited at ≤ 1 μg/ml. For this reason, erythromycin is commonly used preoperatively with or without neomycin as oral bowel preparations.

Atypical mycobacteria are more susceptible than *M. tuberculosis* to macrolide antibiotics (206, 251). The MIC_{90}s of clarithromycin and azithromycin for *M. avium* complex are in the range of 2 to 4 μg/ml, allowing additive or synergistic killing activity of these organisms within infected macrophages when these drugs are combined with other

antimycobacterial drugs (16). Erythromycin is used occasionally to treat infections due to *Mycobacterium scrofulaceum, M. kansasii,* and *M. chelonae* (236, 350) and in combination with ampicillin against *Nocardia asteroides* (113).

Spiramycin and the new macrolides offer comparable in vitro activity against *Toxoplasma gondii*, and they are effective in the treatment of toxoplasmosis (228). Although spiramycin has been used to treat cryptosporidiosis, the therapeutic efficacy remains to be proven (77).

Adverse Effects

The incidence of serious side effects related to the use of erythromycin is relatively low. Gastrointestinal irritation, such as abdominal cramps, nausea, vomiting, and diarrhea, is common with oral administration and can occur when the drug is given intravenously. These side effects occur less frequently with dirithromycin, clarithromycin, and azithromycin. Thrombophlebitis is associated with intravenous infusion, but it can be avoided by dilution of the dose in a large volume of fluid and by slow infusion. Hypersensitivity reactions may include skin rash, fever, and eosinophilia. Cholestatic hepatitis occurring in adults has frequently been associated with the estolate form but has also been reported with other forms of erythromycin (329) and azithromycin (7). For this reason, erythromycin estolate is no longer recommended for use in adults.

Reversible hearing loss may occur with the use of large doses and very high concentrations of erythromycin in serum (≥4 g/day), usually in elderly patients with renal insufficiency (40, 152). Ototoxicity has also been reported with high doses of clarithromycin and azithromycin used to treat *M. avium* complex infections. Pseudomembranous colitis and superinfection of the gastrointestinal tract or vagina with *Candida* spp. or gram-negative rods occur rarely. Concurrent erythromycin therapy increases the levels of theophylline, cyclosporine, and digoxin in serum by interfering with their hepatic metabolism (345). It also increases the anticoagulant effect of warfarin. To date, no clinically significant interactions have been observed between these drugs and dirithromycin, clarithromycin, or azithromycin. However, cardiac arrhythmias have occurred during concurrent use of terfenadine with erythromycin or clarithromycin.

KETOLIDES

Ketolides are semisynthetic derivatives of erythromycin A, having a ketone group instead of an L-cladinose moiety at the 3 position on the erythronolide A ring. This modification of the chemical structure results in increased stability in acid media, noninducibility of MLS_B resistance, and enhanced activity against gram-positive cocci. The ketolides currently under clinical development also have a substituted carbamate link between carbon atoms 11 and 12 in the macrolide nucleus. This modification enables them to retain activity against bacteria whose ribosomes have been methylated at position A2058 as a result of acquired methylase genes (1). Telithromycin is the first and only ketolide approved for clinical use in the United States. Other ketolides, including cethromycin (ABT-773), are undergoing preclinical and clinical studies.

Mechanism of Action

Like the macrolide antibiotics, ketolides inhibit the translation function in susceptible organisms at the level of the 50S ribosomal subunit. Specifically, ketolides interact with the bacterial 23S rRNA at domains II and V of the peptidyltransferase site (147). These drugs are also able to inhibit the formation of the 30S ribosomal unit. Although ketolides do not induce MLS_B resistance, staphylococci with constitutively expressed MLS_B resistance encoded by *erm* genes are resistant to telithromycin. Although these drugs do not appear to be affected by efflux, mutations occurring in 23S rRNA and ribosomal proteins L4 and L22 can lead to in vitro resistance to ketolides (154). This class of drugs has a low potential to select for resistance or induce cross-resistance among other MLS_B antimicrobials.

Pharmacology

Telithromycin is administered orally as a once-daily dose of 800 mg, with rapid gastrointestinal absorption yielding a mean peak concentration in plasma of 2 μg/ml in 1 to 2 h and steady state in 2 days. A mean trough concentration in plasma of 0.07 μg/ml is attained at 24 h after dosing (246). The oral bioavailability of 57% is unaffected by food ingestion. With about 70% of the drug protein bound, telithromycin exhibits biphasic elimination from plasma with initial and terminal half-lives of 2 to 3 h and 9 to 10 h, respectively. The drug penetrates well into bronchopulmonary, tonsillar, and sinus tissues and middle ear fluid, and it is accumulated by polymorphonuclear neutrophils with an intracellular/plasma concentration ratio of >500 at 24 h. Hepatic metabolism with elimination via feces (~80%) is the main route of excretion, and <15% of the administered dose is eliminated in the urine. Dosage adjustments are not necessary in patients with renal or hepatic impairment (86).

Spectrum of Activity

Ketolides possess a good spectrum of potent activity against respiratory pathogens as well as intracellular bacteria, and telithromycin is designed specifically for the treatment of community-acquired respiratory tract infections. It is more active than macrolides against *S. pneumoniae* isolates, irrespective of penicillin susceptibility, with an MIC_{90} of ≤1 μg/ml for telithromycin, and 90% of penicillin-resistant strains are inhibited at 0.25 μg/ml (102, 110, 183, 210). Almost all macrolide-resistant strains of pneumococci are inhibited at ≤0.5 μg/ml, regardless of the underlying mechanism of macrolide resistance. Telithromycin is more active than erythromycin and clarithromycin and as potent as azithromycin against *H. influenzae* (MIC_{90}s of 2 to 4 μg/ml) and *M. catarrhalis* (MIC_{90}s of 0.06 to 0.125 μg/ml). The activity of telithromycin is unaffected by β-lactamase production in these strains, but the MICs are increased twofold in the presence of 5% CO_2. A significant postantibiotic effect may be observed for up to 9 h with this drug against the major respiratory pathogens (86).

Telithromycin is also active against staphylococci, with MIC_{90}s of 0.125 to 0.25 μg/ml for *S. aureus* and coagulase-negative staphylococci, regardless of the susceptibility to oxacillin. However, isolates harboring the constitutive MLS_B mechanism of resistance are resistant to ketolides. Enterococci without underlying resistance to macrolides and clindamycin are susceptible to telithromycin, with MIC_{90}s of 0.125 μg/ml for *E. faecalis* and *E. faecium*. Higher MIC_{90}s (4 to 8 μg/ml) are observed with erythromycin- or clindamycin-resistant enterococci (306). Telithromycin displays good in vitro activity against beta-hemolytic streptococci and viridans group streptococci, regardless of their susceptibility to penicillin G, with all isolates inhibited at ≤0.5 μg/ml. While streptococcal isolates with the *mef*A gene-mediated drug efflux mechanism of resistance to erythromycin remain susceptible to telithromycin, MICs are higher (2 to 16 μg/ml) among the strains with

inducible or constitutive *erm* gene-mediated resistance to erythromycin. Other gram-positive cocci, such as *Pediococcus, Leuconostoc, Stomatococcus,* and *Rhodococcus equi*, are susceptible to telithromycin, with MIC_{90}s of 0.03 to 0.25 μg/ml.

This drug is also very active against gram-positive rods, inhibiting *Corynebacterium* (including *C. diphtheriae* and *C. jeikeium*), *Listeria, Lactobacillus, Actinomyces,* and *Erysipelothrix* at concentrations of ≤0.125 μg/ml (306). Telithromycin is inhibitory (MIC_{90}s of 0.125 to 0.5 μg/ml) to *Peptostreptococcus* spp., *Prevotella* spp., *Porphyromonas* spp., *Bilophila* spp., and *C. perfringens,* but it is not active against other *Clostridium* spp., *Fusobacterium* spp., or the *B. fragilis* group (367). This drug has poor activity against other gram-negative rods, including the *Enterobacteriaceae, Acinetobacter* spp., *P. aeruginosa,* and *B. burgdorferi* (166).

Intracellular pathogens, such as *Legionella, Mycoplasma, Chlamydia,* and *Chlamydophila* are highly susceptible to telithromycin, with MIC_{90}s of 0.004 to 0.25 μg/ml (110). *Rickettsia* spp., *Bartonella* spp., *C. burnetii,* and *F. tularensis* are also susceptible to this agent. Telithromycin is comparable to the macrolides in its activity against mycobacteria, with an MIC_{90} of 4 μg/ml for *M. chelonae* and *M. avium* complex, and it is not active against *M. tuberculosis, Mycobacterium bovis,* and other atypical mycobacteria (111).

Adverse Effects

Telithromycin is well tolerated by all patient populations, with gastrointestinal symptoms, such as diarrhea (15%), nausea (9%), vomiting, and dizziness, as the most frequent adverse effects (8). Occurrence of *C. difficile*-associated diarrhea has not been reported in clinical trial studies. While elevation of serum transaminase levels is found in <10% of patients, rare cases of severe hepatotoxicity can occur (60). Since ketolides are substrates and inhibitors of the hepatic cytochrome P450 CYP3A4 isoenzyme pathway, their potential to lengthen the QT interval is augmented by concomitant administration of other CYP3A4 inhibitors, such as ketoconazole and itraconazole (24).

TETRACYCLINES AND GLYCYLCYCLINES

Tetracyclines are broad-spectrum bacteriostatic antibiotics with the hydronaphthacene nucleus, which contains four fused rings. The congeners form three groups based on their duration of action. Chlortetracycline, oxytetracycline, and tetracycline are short-acting drugs, demeclocycline and methacycline are intermediate-acting drugs, and doxycycline and minocycline are long-acting drugs. Glycylcyclines are a group of semisynthetic tetracycline derivatives containing a glycylamido substitution at position 9, and tigecycline (formerly GAR-936, and a 9-*t*-butylglycylamido analog of minocycline) is the first in this class of drugs available for clinical use.

Mechanism of Action

Tetracyclines and glycylcyclines act against susceptible microorganisms by inhibiting protein synthesis. They enter bacteria by an energy-dependent process and bind reversibly to the 30S ribosomal subunits, preventing the attachment of aminoacyl-tRNA to the ribosomal acceptor A-site in the RNA-ribosome complex (56). Resistance to tetracyclines occurs among clinical isolates as a result of active efflux of the drug from the cell, an altered ribosomal target site that prevents binding of the drug (ribosomal protection), or production of modifying enzymes that inactivate the drug. With stearic hindrance from the bulky side group at position 9, glycylcyclines are unaffected by bacterial ribosomal protection proteins and evade the efflux pumps present in tetracycline-resistant strains. These drugs also have higher binding affinity for the bacterial ribosomes than tetracyclines. Reduced susceptibility to tigecycline has been found among clinical and laboratory-derived strains of *P. mirabilis, Morganella morganii, Klebsiella pneumoniae, P. aeruginosa,* and *S. aureus* possessing multicomponent efflux pumps (220, 294) and in some *Bacteroides* spp. with the *tet*(X) gene-mediated monooxygenase enzyme that degrades tetracyclines (238).

Pharmacology

Tetracyclines are incompletely absorbed from the gastrointestinal tract, but their absorption is improved in the fasting state. Ingestion of food, especially dairy products, and other substances such as antacids and iron preparations impairs the absorption of these drugs. Less interference with absorption by foods occurs with doxycycline and minocycline. These long-acting tetracyclines are more readily absorbed, and therefore, lower doses are required. Peak concentrations in serum of 3 to 5 μg/ml are reached in 2 h after standard oral dosages. Intravenous preparations are available, and peak concentrations in serum of 10 to 20 μg/ml are reached in 1 h after intravenous administration. Tetracyclines are usually bacteriostatic at these clinically achievable concentrations in serum.

Tissue penetration of these drugs is excellent, but levels in CSF are low even in the presence of meningeal inflammation. Tetracyclines cross the placenta and are incorporated into fetal bone and teeth. They are excreted in high concentrations in human milk. Therefore, tetracyclines are not advised for pregnant or lactating women. Minocycline, the most lipophilic tetracycline at physiological pH, reaches relatively high concentrations in saliva and tears, making it an ideal antibiotic to eradicate the meningococcal carrier state (146, 158).

Tetracyclines are metabolized by the liver and concentrated in the bile. Biliary concentrations of tetracyclines are three to five times higher than concurrent levels in plasma, with significant drug accumulation in the blood of patients with hepatic insufficiency or biliary obstruction. These drugs are excreted primarily in the urine except for doxycycline, which is excreted primarily (90%) as an inactive conjugate via the biliary tract in the feces. Renal failure prolongs the half-lives of the tetracyclines except doxycycline. Therefore, doxycycline is considered the tetracycline of choice for extrarenal infections in the presence of renal failure.

Tigecycline is administered as an intravenous formulation because of limited oral bioavailability. With multiple doses of 50 mg infused every 12 h, the peak concentration in serum is ~0.8 μg/ml (227). Despite having plasma protein binding of 80%, the drug has a rapid and wide distribution into tissues, with highest levels in bone and bone marrow. Although drug levels of >1 μg/ml can be achieved in CSF in a rabbit model of meningitis, penetration into human CSF with or without meningitis remains unknown (260). It is eliminated primarily by the liver via glucuronidation and biliary excretion of unchanged drug, and the mean elimination half-life is 36 h. With <30% of the drug excreted unchanged in the urine, dosage adjustment is not required for renal insufficiency, hemodialysis, or mild to moderate hepatic dysfunction.

Spectrum of Activity

All tetracyclines have similar antimicrobial spectra, with activity against many gram-positive and gram-negative bacteria, mycoplasmas, chlamydiae, rickettsiae, and some protozoa. Many gram-positive aerobic cocci, including *S. aureus, S. pyogenes,* and *S. pneumoniae,* are susceptible at concentrations

achievable in serum. However, tetracycline-resistant strains of *S. pneumoniae* are common (190). Although many *E. coli* isolates are susceptible to tetracyclines, pseudomonads and many *Enterobacteriaceae* are resistant. *Shigella* and *Salmonella* spp. are increasingly resistant to these agents (54). Tetracyclines are used mainly for the treatment of acute, uncomplicated urinary tract infections due to *E. coli* (161) and as effective prophylactic therapy for traveler's diarrhea caused by enterotoxigenic *E. coli* (117). With activity against *Burkholderia pseudomallei, Brucella* spp., *Vibrio* spp., and *Mycobacterium marinum* (351), they have been used successfully in the treatment of infections due to these bacteria. Their efficacy in the therapy of cholera is diminishing owing to the emergence of resistant *Vibrio cholerae* isolates (381). Minocycline is active against *Nocardia* spp. (84). Many anaerobic bacteria, including members of the *B. fragilis* group and *Actinomyces* spp., are susceptible to tetracyclines (265).

These drugs are useful in the treatment of urethritis and acute pelvic inflammatory diseases caused by *N. gonorrhoeae, C. trachomatis, U. urealyticum,* and *M. hominis*. Resistance to tetracyclines among *N. gonorrhoeae* strains is increasing (108). The drugs are effective for the treatment of other chlamydial infections (psittacosis, lymphogranuloma venereum, and trachoma) (51). Other infections responsive to tetracyclines include granuloma inguinale, chancroid, relapsing fever, and tularemia. Tetracyclines are the drugs of choice for treating rickettsial infections (Rocky Mountain spotted fever, endemic and scrub typhus, and Q fever). Many pathogenic spirochetes, including *Treponema pallidum* and *B. burgdorferi,* are susceptible (51, 229, 243). Protozoa such as *P. falciparum* and *Entamoeba histolytica* are also inhibited by these drugs (228, 263).

Due to its potent and wide-spectrum activity against gram-positive, gram-negative, and anaerobic organisms, tigecycline is useful for treatment of complicated skin and skin structure infections, intra-abdominal infections, and nosocomial infections due to multidrug-resistant pathogens except *P. aeruginosa* (32, 119, 156, 167, 260, 264). All staphylococci, including methicillin-resistant and vancomycin-intermediate strains, are inhibited at ≤1 μg/ml. Vancomycin-susceptible and -resistant enterococci typically show MIC_{90}s of 0.25 to 0.5 μg/ml, and *E. faecium* and *E. faecalis* are inhibited equally well by this drug. However, tigecycline exhibits no bactericidal activity (minimum bactericidal concentration at which 90% of strains tested are killed [MBC_{90}] > 32 μg/ml) against staphylococci and enterococci in time-kill studies. Viridans group streptococci, beta-hemolytic streptococci, and multidrug-resistant pneumococci are highly susceptible, with MIC_{90}s ranging from ≤0.25 to 0.5 μg/ml. The drug is also very active against the *Enterobacteriaceae* and nonfermentative gram-negative rods, including strains producing extended-spectrum β-lactamases, with MIC_{90}s of ≤2 μg/ml. Of note is its potent inhibition of multidrug-resistant *Acinetobacter baumannii* and *S. maltophilia* (MIC_{90}s of 2 μg/ml). Among fastidious respiratory tract pathogens, MIC_{90}s are 0.5 and 1 μg/ml for *H. influenzae* and *M. catarrhalis,* respectively. *Proteus, Morganella,* and *Providencia* spp. and *P. aeruginosa* are generally resistant (MIC_{90}s of >16 μg/ml). Tigecycline is also active against most *B. fragilis* group isolates (MIC_{90} = 8 μg/ml), *Peptostreptococcus* spp. (MIC_{90} = 4 μg/ml), *Clostridium* spp. (MIC_{90} = 0.5 μg/ml), *Prevotella* spp., *Propionibacterium* spp., and *Fusobacterium* spp.

Compared to tetracyclines, tigecycline exhibits more potent activity against *M. pneumoniae, M. hominis, C. pneumoniae,* and *C. trachomatis,* with MIC_{90}s in the range of 0.125 to 0.5 μg/ml. It is less active toward *U. urealyticum* and *Legionella* spp., with MIC_{90}s of 8 μg/ml. Rapidly growing mycobacteria, including *Mycobacterium abscessus, M. chelonae,* and the *M. fortuitum* group, are 4- to 11-fold more susceptible (MIC_{90}s of ≤0.25 μg/ml) to this drug than to tetracyclines (347). However, slowly growing nontuberculous mycobacteria, such as *M. kansasii, M. marinum,* and *M. xenopi,* are less susceptible to tigecycline than to minocycline.

Susceptibility testing with tigecycline should be done using freshly prepared media or media containing a biocatalytic oxygen-reducing reagent (e.g., Oxyrase), because the drug is prone to oxidative degradation. Testing using aged broth media (prepared >12 h prior to inoculation) yielded MIC results that are generally 1 to 2 dilutions higher than those obtained using fresh media (34, 162).

Adverse Effects

Tetracyclines have irritative effects on the upper gastrointestinal tract, producing esophageal ulcerations, nausea, vomiting, and epigastric distress. Alterations in the enteric flora occur with the use of tetracyclines, often resulting in diarrhea, and pseudomembranous colitis can develop with prolonged use. Hypersensitivity reactions are unusual, generally manifesting themselves as urticaria, fixed drug eruptions, morbilliform rashes, and anaphylaxis. Cross-reactivity among tetracyclines is the rule. Photosensitivity reactions consist of an erythematous rash on areas exposed to sunlight and can occur with all analogs, especially demeclocycline (120).

Minocycline has been known to cause vertigo, and benign intracranial hypertension (pseudotumor cerebri) has been described with many of the analogs (352). Tetracycline can aggravate preexisting renal failure by inhibiting protein synthesis, increasing the azotemia from amino acid metabolism. Tetracyclines cause depression of bone growth, permanent discoloration of the teeth, and enamel hypoplasia when given during tooth and skeletal development (143). Therefore, these drugs are usually avoided in childhood (<8 years of age) and during pregnancy.

Tigecycline is generally well tolerated, with nausea, vomiting, headache, and diarrhea reported as the most common side effects. Due to adverse effects similar to those of tetracyclines on bone and tooth development, use of this drug is contraindicated in pregnant women, nursing mothers, and those <18 years of age. It may also show cross-hypersensitivity to tetracyclines (385).

LINCOSAMIDES

The lincosamide antibiotics include lincomycin, which was initially isolated from *Streptomyces lincolnensis,* and clindamycin, which is a chemical modification of lincomycin. The chemical structure of each drug consists of an amino acid linked to an amino sugar. Compared with lincomycin, clindamycin has increased antibacterial activity and improved absorption after oral administration (224). Both drugs are available for parenteral and oral use, but lincomycin is rarely used now in the United States.

Mechanism of Action

Lincosamides bind to the 50S ribosomal subunits of susceptible bacteria and prevent elongation of peptide chains by interfering with peptidyl transfer, thereby suppressing protein synthesis. The ribosomal binding sites are the same as or closely related to those that bind macrolides, streptogramins, and chloramphenicol (197, 342). Lincosamides can be bactericidal or bacteriostatic, depending on the drug concentration, bacterial species, and inoculum of bacteria.

Pharmacology

About 90% of an oral clindamycin dose is absorbed from the gastrointestinal tract, with no interference from the ingestion of food. A single oral dose of 150 mg yields a peak concentration in serum of 2 to 3 μg/ml in 1 h. Peak levels in serum of 10 to 12 μg/ml are obtained at 1 h after a 600-mg intravenous dose. Therapeutic serum drug levels are maintained for 6 to 9 h after these dosages (199, 224).

Clindamycin distributes well into bone, the lungs, pleural fluid, and bile, but it penetrates poorly into CSF, even with meningitis. It readily crosses the placenta and enters fetal tissues. Clindamycin is actively concentrated in neutrophils and macrophages.

The normal half-life of clindamycin is 2.4 h. Most of the drug is metabolized by the liver and excreted in an inactive form in the urine. Its half-life is prolonged by severe liver dysfunction, necessitating dosage reduction in patients with severe liver disease. Although the serum drug levels are increased in patients with severe renal failure, dose modification is not essential. The drug is not removed significantly by hemodialysis or peritoneal dialysis.

Spectrum of Activity

Lincosamides have a broad spectrum of activity against the aerobic gram-positive cocci and anaerobes. Clindamycin is more potent than lincomycin against methicillin-susceptible *Staphylococcus* spp., *S. pneumoniae,* and group A and viridans group streptococci (199, 224). The MIC_{90}s are in the range of 0.01 to 0.1 μg/ml for these strains. However, resistance to clindamycin has emerged in clinical isolates of these bacteria that are also resistant to erythromycin (55). The prevalence of clindamycin-resistant *S. aureus* may be 15 to 20% in some institutions. Enterococci are uniformly resistant to the lincosamides. All of the *Enterobacteriaceae* are resistant to lincosamides.

Clindamycin is one of the most active antibiotics available against anaerobes, including members of the *B. fragilis* group and *C. perfringens,* with MIC_{90}s of ≤2 μg/ml (18, 199). However, clindamycin resistance (which appears to be increasing) is found in 10 to 15% of *B. fragilis* group organisms, 15 to 20% of *Prevotella* and *Porphyromonas* spp., 10 to 20% of clostridial species, 10% of peptococci, and most *Fusobacterium varium* strains (2, 314). Clindamycin has been used successfully as single-agent therapy for actinomycosis (287), babesiosis (228, 377), and malaria (200). It is also effective in combination with pyrimethamine for toxoplasma encephalitis (76, 286) and in combination with primaquine for *Pneumocystis jirovecii* pneumonia (336).

Adverse Effects

Clindamycin-associated diarrhea occurs in up to 20% of patients, and use of this drug has been associated with pseudomembranous colitis caused by toxin-producing *C. difficile* (19). This complication is not dose related and may occur after oral or parenteral therapy. Prompt cessation of the antibiotic in conjunction with oral vancomycin, metronidazole, or bacitracin therapy is effective in reversing this complication.

Other uncommon side effects include skin rashes, fever, and reversible elevation of serum transaminases. Clindamycin can block neuromuscular transmission and may potentiate the action of neuromuscular blocking agents during anesthesia.

GLYCOPEPTIDES AND LIPOPEPTIDES

Vancomycin, a bactericidal antibiotic obtained from *Streptomyces orientalis*, is the only glycopeptide marketed for clinical use in the United States. Initially introduced for its efficacy against penicillin-resistant staphylococci, it has become most useful against methicillin-resistant staphylococci and in patients allergic to penicillins or cephalosporins. Teicoplanin (formerly teichomycin A), a new complex glycopeptide chemically related to vancomycin (315), is currently available for clinical use in most countries of the world except the United States. Dalbavancin, oritavancin, and telavancin are semisynthetic lipoglycopeptides (glycopeptide derivatives with hydrophobic substituents) currently at various stages of clinical development (185, 262). Daptomycin is a unique, naturally occurring cyclic lipopeptide antibiotic found among the fermentation by-products of *Streptomyces roseosporus* and has potent activity against gram-positive bacteria. Ramoplanin is an investigational semisynthetic lipoglycodepsipeptide with a spectrum of activity similar to those of the glycopeptides (103), but systemic toxicity limits its clinical trials only to oral administration and topical application.

Mechanism of Action

Glycopeptides inhibit peptidoglycan synthesis in the bacterial cell wall by complexing with the D-alanyl-D-alanine portion of the cell wall precursor (244). Resistance to vancomycin and teicoplanin can occur by one of two mechanisms: (i) the presence of a complex series of bacterial cytoplasmic enzymes in vancomycin-resistant enterococci synthesizing abnormal peptidoglycan precursors terminating in D-Ala-D-lactate residues (instead of D-Ala-D-Ala), thereby markedly lowering the binding affinity with the glycopeptides (52), or (ii) increased accumulation of peptidoglycan precursors (murein monomers) resulting in a thickened cell wall with "trapping" of drug molecules, thereby preventing further diffusion of drug into the inner part of cell wall layers of vancomycin-intermediate *S. aureus* (69, 70, 153).

Daptomycin binds irreversibly to the cytoplasmic membrane of susceptible bacteria via a calcium ion-dependent insertion of the hydrophobic tail of the molecule and causes membrane depolarization, resulting in release of potassium ions and disruption of cellular ion concentration gradients (44, 311). The end effect is cell death without cell lysis, providing potent bactericidal activity of this drug. It is unable to penetrate the outer membrane of gram-negative bacteria. Resistance to daptomycin has occurred in enterococci (208, 297) and *S. aureus* (151, 312), possibly due to the physical barrier of a thickened bacterial cell wall similar to those found in vancomycin-intermediate *S. aureus* or to other mechanisms, such as alteration of the charge of the outer cell envelope (71).

Ramoplanin acts by binding to a lipid II intermediate present in the cell membrane of gram-positive organisms and inhibiting bacterial transglycosylase (PBP 1b), an enzyme essential for peptidoglycan synthesis. With this unique mechanism of action, this drug is bactericidal against vancomycin-resistant enterococci and staphylococci.

Pharmacology

Vancomycin and teicoplanin can be administered orally or parenterally. After oral administration, the drugs are poorly absorbed, and high concentrations in stools are achieved, accounting for their efficacy in treating pseudomembranous colitis (109). Desirable peak and trough levels in serum of 20 to 50 μg/ml and 5 to 15 μg/ml, respectively, are obtained after a 1-g intravenous dose of vancomycin every 12 h in healthy subjects (296). Similar serum drug concentrations are reached with intravenous teicoplanin, which has the advantage of a longer serum half-life and which can be administered once daily. Therapeutic levels of both drugs are

achieved in synovial, ascitic, pericardial, and pleural fluids, with variable penetration into the CSF only in the presence of inflamed meninges (144, 234).

Vancomycin and teicoplanin have half-lives in serum of 6 and 45 h, respectively, in patients with healthy renal function, and they are eliminated from the body by glomerular filtration. In severe renal insufficiency, their excretion is prolonged to about 9 days, and they are not removed by hemodialysis or peritoneal dialysis.

Intravenous infusion of daptomycin at 6 mg/kg of body weight results in peak and trough concentrations of 82 and 6 μg/ml, respectively, in serum. About 90% of the drug is bound to plasma proteins, with limited metabolism. Despite its wide distribution into various body sites and tissues, daptomycin shows poor penetration into the CSF and alveolar space, where it is bound by surfactant, precluding its use for the treatment of meningitis and pneumonia (323). Its elimination half-life is 9 h, and 80% of the drug excreted via the kidneys, with two-thirds as intact drug (299). The dosing interval is increased to every 48 h when creatinine clearance is ≤30 ml/min.

Without systemic absorption or intestinal degradation of the drug, ramoplanin administered orally at dosages of 200 and 400 mg twice daily reaches high concentrations in the stool, with mean minimum drug levels of ~460 and ~760 μg/g in the feces, respectively. This feature enables the drug to be developed for clinical trials in treatment of *C. difficile*-associated diarrhea and gastrointestinal decolonization to prevent nosocomial bacteremia due to vancomycin-resistant enterococci.

Spectrum of Activity

Glycopeptides and lipopeptides are active mainly against aerobic and anaerobic gram-positive organisms, including methicillin-susceptible and -resistant staphylococci, streptococci, enterococci, *Corynebacterium* spp., *Bacillus* spp., *L. monocytogenes, Clostridium* spp., and *Actinomyces* spp. The MICs of vancomycin for *S. aureus, S. epidermidis,* streptococci, and enterococci are typically in the range of 0.25 to 2 μg/ml (176). The bactericidal activity varies, with MBCs 20-fold higher than MICs for viridans group streptococci. These agents are essentially bacteriostatic against enterococci and staphylococci. Teicoplanin (138, 141, 211), ramoplanin (65), and daptomycin (14, 211, 374) are two- to fourfold more active than vancomycin against these gram-positive cocci. Resistance to vancomycin has emerged among clinical isolates of enterococci (52) and staphylococci (153). Cross-resistance with teicoplanin is variable in these strains, but most are susceptible to daptomycin and ramoplanin (172), with MICs of ≤2 μg/ml. Other naturally vancomycin-resistant gram-positive organisms, such as *Leuconostoc, Lactobacillus*, and *Pediococcus* spp., are susceptible to ramoplanin (65, 172, 293).

Vancomycin is useful in the prevention and treatment of endocarditis due to gram-positive bacteria in patients who are allergic to penicillin (74, 371). It is the drug of choice for treating *C. jeikeium* infections (128) and is useful for *Chryseobacterium meningosepticum* meningitis (144) and antibiotic-associated *C. difficile* colitis (19, 109).

The glycopeptides and lipopeptides are not active against gram-negative organisms or mycobacteria. They show no cross-resistance with other unrelated antibiotics. They act synergistically with aminoglycosides or rifampin against staphylococci, streptococci, and enterococci (240, 337, 356, 357), and they are bactericidal with aminoglycosides against *Listeria* spp.

Daptomycin exhibits concentration-dependent bactericidal activity in vitro against most gram-positive bacteria in their growing and stationary phases (295). The MIC_{90}s for multidrug-resistant isolates of staphylococci (including vancomycin-intermediate *S. aureus*), pneumococci, and streptococci are ≤1 μg/ml (182, 327, 328). Vancomycin-susceptible and -resistant enterococci are inhibited equally at an MIC_{90} of ≤4 μg/ml (182, 327). The drug is active (MIC_{90}s of ≤2 μg/ml) against *Listeria, Corynebacterium* spp., *Propionibacterium* spp., *C. difficile, C. perfringens,* and peptostreptococci (134). While *Leuconostoc, Pediococcus,* and *Lactobacillus* are susceptible, other *Clostridium* spp., *Actinomyces*, and *Eubacterium* showed MIC_{90}s in the range of 4 to 16 μg/ml. Since optimal in vitro activity of daptomycin depends on the calcium ion concentration in the growth medium, media used for susceptibility testing with this drug should contain the recommended calcium concentration of 50 μg/ml. Current E-test strips of daptomycin used in the drug gradient diffusion method are manufactured with added calcium. Inconsistent results have been observed with the disk diffusion method, and the agar dilution method has not been validated for testing this drug.

Adverse Effects

The most frequent side effects of vancomycin are fever, chills, and phlebitis at the site of infusion. Rapid or bolus infusion of vancomycin causes tingling and flushing of the face, neck, and thorax, known as the red man syndrome, as a result of histamine release by basophils and mast cells (278). This phenomenon is not due to allergic hypersensitivity. Allergic maculopapular or diffuse erythematous rashes can occur in up to 5% of patients. Reversible leukopenia or eosinophilia can rarely develop with glycopeptide use.

Hearing loss due to ototoxicity has been described occasionally for patients in whom serum vancomycin concentrations exceed 50 μg/ml, but it is hard to find unequivocal evidence of vancomycin ototoxicity in humans or animals (40). Vancomycin-induced nephrotoxicity has been rare since the recent availability of highly purified vancomycin preparations. However, the risk of nephrotoxicity increases during combination therapy with vancomycin and aminoglycosides.

Teicoplanin is generally well tolerated and does not produce the red man syndrome or nephrotoxicity. It does cause irritation at the site of intravenous infusion, and ototoxicity has been reported (78).

Common adverse reactions of daptomycin include diarrhea, rash, dizziness, and dyspnea. Elevated serum creatinine phosphokinase levels, myalgias, and reversible myopathy can occur (4, 45), but these adverse effects are significantly reduced with lower dosages and once-daily dosing.

STREPTOGRAMINS

Streptogramins are natural cyclic peptides produced by *Streptomyces* spp. They are a unique class of antibiotics in which each member of the class is a combination of at least two structurally unrelated components, group A and B streptogramins, acting synergistically against susceptible bacteria (269). Group A streptogramins are polyunsaturated macrolactones consisting of lactam and lactone linkages with an oxazole ring, and the main compounds in this group are pristinamycin II_A and pristinamycin II_B. Group B streptogramins are cyclic hexadepsipeptides, with pristinamycin I_A and pristinamycin I_C as the principal compounds. Quinupristin-dalfopristin is the first injectable streptogramin antibiotic combination developed for clinical use in the United States. It is a 30:70 mixture of the semisynthetic streptogramins quinupristin and dalfopristin, which are water-soluble derivatives of pristinamycin I_A and pristinamycin II_A, respectively.

Mechanism of Action

The streptogramins exert a synergistic bactericidal effect on susceptible organisms by inhibiting bacterial protein synthesis. They enter bacterial cells via passive diffusion and then bind specifically and irreversibly to the 50S subunits of the 70S bacterial ribosomes. Binding of group A streptogramins to the ribosome induces a conformational change in the ribosome which increases its affinity for group B compounds. Group A streptogramins prevent peptide bond formation during the chain elongation step, while group B components cause release of the incomplete peptide chains from the 50S ribosomal subunit (342).

Acquired bacterial resistance to the streptogramins, which may be chromosomal or plasmid mediated, is mainly due to modification of the drug target by methylation of the bacterial 23S rRNA, resulting in resistance to all macrolides, lincosamides, and group B streptogramins (MLS_B resistance phenotype), but not to group A streptogramins. Mutations in the L22 ribosomal protein gene (*rplV*), active efflux of group A and B streptogramins, and drug inactivation by streptogramin A acetylase and streptogramin B hydrolase have been described.

Pharmacokinetics

Quinupristin-dalfopristin is administered intravenously, with distribution into most tissues. Both components are highly protein bound (70 to 90%) and rapidly cleared from plasma via biliary excretion by hepatic conjugation processes (209). Less than 20% of the administered drug combination is excreted in the urine. Following intravenous doses of 7.5 mg/kg, peak concentrations in serum of quinupristin and dalfopristin reach 2.7 and 7.2 μg/ml, respectively, with elimination half-lives of 1 and 0.75 h. The two components penetrate and accumulate in macrophages, and the ratio of peak in vitro cellular and extracellular concentrations is 50:35. The drug combination does not cross the noninflamed blood-brain barrier or placenta to any significant degree. Dosage adjustment is needed for patients with renal insufficiency (creatinine clearance of <30 min/min), and the drug combination is removed in modest amounts by dialysis.

Spectrum of Activity

Streptogramins are active mainly against gram-positive bacteria, with modest activities against selected gram-negative and anaerobic pathogens. Quinupristin-dalfopristin has potent bactericidal activity against methicillin-susceptible and -resistant *S. aureus,* coagulase-negative staphylococci, and streptococci, with MIC_{90}s of ≤ 1 μg/ml and MBCs within two- to fourfold of the MICs (31, 112). Staphylococci and streptococci, including *S. pneumoniae,* that are resistant to β-lactam drugs, macrolides, and fluoroquinolones usually remain susceptible to quinupristin-dalfopristin. While most *E. faecium* strains (MIC_{90}s of ≤ 4 μg/ml) are susceptible, *E. faecalis* is intrinsically resistant (MIC_{90}s ≥ 32 μg/ml) to the drug combination because of active efflux of dalfopristin. Although it is not bactericidal against enterococci, quinupristin-dalfopristin inhibits vancomycin-resistant *E. faecium* (VanA or VanB phenotype), including multidrug-resistant strains, at MIC_{90}s of ≤ 2 μg/ml (209). This drug combination has been a significant addition to the current therapeutic options for serious multidrug-resistant gram-positive bacterial infections (195, 201, 235, 270). *N. meningitidis, N. gonorrhoeae, M. pneumoniae, C. pneumoniae,* and *Legionella pneumophila* are all highly susceptible to the drug (MIC_{90}s of ≤ 2 μg/ml). Quinupristin-dalfopristin is also active against *M. catarrhalis* and *H. influenzae*, with MIC_{90}s of ≤ 4 μg/ml. *Enterobacteriaceae* and other nonfermenting gram-negative rods are resistant.

Among the anaerobes, *C. perfringens* and *C. difficile* are the most susceptible (MIC_{90}s of 0.25 μg/ml). Quinupristin-dalfopristin is active against the *B. fragilis* group (MIC_{90} of 4 μg/ml) as well as other anaerobic bacteria, including *Prevotella, Porphyromonas, Fusobacterium, P. acnes, Lactobacillus,* and peptostreptococci, with MIC_{90}s of 2 to 4 μg/ml.

Adverse Effects

Phlebitis at the site of intravenous infusion is the major local adverse reaction, and the incidence and severity are dose and concentration related (209, 292). The most common systemic side effects that may lead to discontinuation of therapy are arthralgias and myalgia, both of which are reversible on discontinuation of the combination (235, 280). Elevated levels of serum transaminases and cutaneous reactions such as itching, burning, and erythema of the face, neck, or upper body have also been reported.

OXAZOLIDINONES

Oxazolidinones are a unique group of synthetic antibiotics originally discovered in the 1970s (216). Linezolid is currently the only oxazolidinone available for clinical use (233), while other analogs are undergoing preclinical development.

Mechanism of Action

The oxazolidinones inhibit bacterial protein synthesis by preventing the formation of a functional initiation complex consisting of $tRNA^{fMet}$, mRNA, initiation factors, and the ribosome (330). Linezolid binds to the domain V region of 23S rRNA in the 50S ribosomal subunit, thereby distorting the binding site for $tRNA^{fMet}$ and inhibiting formation of a functional 70S initiation complex, thus preventing initiation of mRNA translation. In this regard, this class of antibiotics is unique, without cross-resistance with other antibiotics that also inhibit ribosomal protein synthesis. Resistance to linezolid has occurred in clinical isolates of methicillin-resistant *S. aureus,* vancomycin-resistant enterococci, and pneumococci as a result of point mutations in genes encoding the 23S rRNA (30, 231) or L4 ribosomal protein (379). Oxazolidinones are generally inactive against gram-negative bacteria because of endogenous efflux pumps present in these organisms (330).

Pharmacology

Linezolid is available in oral and parenteral forms. Rapid and extensive absorption occurs after oral administration (>95% bioavailability), reaching maximum concentrations in serum of 15 to 20 μg/ml within 2 h after an oral dose of 600 mg. The drug is metabolized primarily in the liver, and the elimination half-life is about 5 h. With 30% of the drug being protein bound, it is well distributed in all body tissues, including the CSF. The drug is eliminated via the kidneys, with 30% being excreted unchanged in the urine. No dose adjustment is necessary in patients with renal insufficiency or mild to moderate hepatic impairment, while 20% of a dose is removed by hemodialysis (213).

Spectrum of Activity

As a group, oxazolidinones have various activities against most gram-positive bacteria and mycobacteria. Linezolid has excellent activity against staphylococci (including methicillin-resistant strains), streptococci, and multidrug-resistant enterococci, with MIC_{90}s ranging from 1 to 4 μg/ml (61, 203,

386). The MIC_{90}s are in the range of 0.5 to 2 μg/ml for pneumococci. Although the antibacterial effect of linezolid is generally bacteriostatic, the drug is bactericidal against most strains of staphylococci and pneumococci. Other bacteria that are inhibited by linezolid include *Actinomyces* spp., *Bacillus cereus, Corynebacterium* spp., *Leuconostoc* spp., *Pediococcus* spp., *R. equi, L. monocytogenes, Clostridium* spp., and gram-positive anaerobic cocci (134). Both slowly and rapidly growing *Mycobacterium* spp. and *Nocardia* spp. are also susceptible to linezolid, with MIC_{90}s of ≤8 μg/ml (38, 39, 348). Linezolid is an important therapeutic option for skin and soft tissue infections (149, 360), respiratory tract infections (290), and infections due to methicillin-resistant staphylococci (309, 326) and vancomycin-resistant enterococci (272, 276).

Adverse Effects

The most common drug-related adverse events (≤5% incidence) are diarrhea, headache, and nausea (118, 291). Prolonged use of linezolid (usually for >28 days) has led to rare optic neuropathy (198), peripheral neuropathy (36), and myelosuppression, including anemia, leukopenia, thrombocytopenia, and pancytopenia that are reversible upon discontinuation of therapy (6, 129). As a mild nonselective inhibitor of monoamine oxidase, linezolid can interact with adrenergic or serotonergic drugs, and rare cases of serotonin syndrome have been reported with concomitant use of selective serotonin reuptake inhibitor drugs (26, 181).

SULFONAMIDES AND TRIMETHOPRIM (TMP)

Sulfonamides were the first effective systemic antimicrobial agents used in the United States during the 1930s. They are derived from sulfanilamide, which shares chemical similarities with *para*-aminobenzoic acid, a factor essential for bacterial folic acid synthesis. Various substitutions at the sulfonyl radical attached to the benzene ring nucleus enhance the antibacterial activity and also determine the pharmacological properties of the drug.

TMP is a pyrimidine analog that inhibits the enzyme dihydrofolate reductase, interfering with folic acid metabolism, subsequent pyrimidine synthesis, and one-carbon fragment metabolism in the bacteria. Since TMP and sulfonamides block the bacterial folic acid metabolic pathway at different sites, they potentiate the antibacterial activity of one another and act synergistically against a wide variety of organisms. Such a combination, TMP-sulfamethoxazole (TMP-SMX), also called co-trimoxazole, was introduced clinically in 1968 and has proven to be very effective in the treatment of many infections (289, 300).

Mechanism of Action

Sulfonamides competitively inhibit bacterial modification of *para*-aminobenzoic acid into dihydrofolate, whereas TMP inhibits bacterial dihydrofolate reductase. This sequential inhibition of folate metabolism ultimately prevents the synthesis of bacterial DNA (155). Since mammalian cells do not synthesize folic acid, human purine synthesis is not affected significantly by sulfonamides or TMP. The antibacterial effect of these agents may be reduced in patients receiving high doses of folinic acid.

Pharmacology

Sulfonamides are usually administered in the oral and topical forms; the intravenous preparations (sulfadiazine and sulfisoxazole) are rarely used. The sulfonamides vary in their durations of action. Thus, sulfamethizole and sulfisoxazole are short-acting compounds, sulfadiazine and SMX are intermediate-acting compounds, and sulfadoxine is a long-acting compound. Mafenide acetate (Sulfamylon cream) and silver sulfadiazine are applied topically to burn patients and have significant percutaneous absorption. Sulfacetamide is available as an ophthalmic preparation, and various combinations of other sulfonamides are available orally (triple sulfa, or trisulfapyrimidine) or as vaginal creams or suppositories.

The orally administered sulfonamides are absorbed rapidly and completely from the gastrointestinal tract. They are metabolized in the liver by acetylation and glucuronidation and are excreted by the kidneys as free drug and inactive metabolites. Sulfonamides compete for bilirubin-binding sites on plasma albumin and increase levels of unconjugated bilirubin in blood. For this reason they should not be given to neonates, in whom increased serum bilirubin levels may cause kernicterus.

Sulfonamides are well distributed throughout the body, with levels in the CSF and synovial, pleural, and peritoneal fluids about 80% of concentrations in serum. They readily cross the placenta and enter the fetal circulation. Sulfonamides may be used in renal failure, but the drugs may accumulate during prolonged therapy as a result of reduced renal excretion.

TMP is available only for oral use and is absorbed almost completely from the gastrointestinal tract. After the usual 100-mg dose, peak levels in serum reach 1 μg/ml in 1 to 4 h. This drug distributes widely in body tissues, including the kidneys, lungs, and prostate, and in body fluids (267). Concentrations in CSF are about 40% of levels in serum. Its half-life in serum is about 10 h in healthy subjects and is prolonged in those with renal insufficiency. Up to 80% of a dose is excreted unchanged in the urine by tubular secretion; the remaining fraction is excreted as inactive metabolites by the kidneys or in the bile.

A fixed combination of TMP-SMX in a dose ratio of 1:5 is available for oral and intravenous use. An intravenous dose of 160 mg of TMP with 800 mg of SMX produces average peak levels in serum of 3.4 and 47.3 μg/ml, respectively, in 1 h. Similar peak levels are reached at 2 to 4 h after the same dose is taken orally. Widely distributed in the body, both drugs reach therapeutic levels in the CSF (40% of levels in serum). Excretion is primarily by the kidneys; dosage reduction is necessary in patients with creatinine clearances of ≤30 ml/min. Both TMP and SMX are removed by hemodialysis and partially by peritoneal dialysis.

Spectrum of Activity

Sulfonamides are inhibitory to a variety of gram-positive and gram-negative bacteria, actinomycetes, chlamydiae, toxoplasmas, and plasmodia. Their in vitro antimicrobial activities are irregular, being strongly influenced by inoculum size and composition of the test media. Susceptibility testing endpoints are often difficult to determine because of the presence of hazy growth within zones of inhibition in disk diffusion tests and because of the phenomenon of "trailing" in dilution tests. Sulfadiazine and sulfisoxazole are effective for rheumatic fever prophylaxis, but they are not useful in treating established group A beta-hemolytic streptococcal pharyngitis. These drugs may be used for prophylaxis of close contacts of patients with meningitis due to sulfonamide-susceptible *N. meningitidis*. Sulfisoxazole can be used to treat chlamydial urethritis, and sulfacetamide ophthalmic solution is effective for trachoma and inclusion conjunctivitis.

Sulfadiazine in combination with pyrimethamine has been used successfully to treat toxoplasmosis, and sulfadoxine combined with pyrimethamine (Fansidar) is effective in the prophylaxis and therapy of *P. falciparum* malaria (228, 230). Sulfonamides are active against *N. asteroides* (84), and they show moderate activity against *M. kansasii,* the *M. fortuitum* group, *M. marinum,* and *M. scrofulaceum* (285). Other uses of sulfonamides include therapy of melioidosis, dermatitis herpetiformis, lymphogranuloma venereum, and chancroid.

Among the gram-negative rods, *E. coli* strains were initially susceptible to the sulfonamides, especially at levels achievable in the urine. Therefore, these drugs have been used primarily in the treatment of first-episode acute urinary tract infections due to *E. coli*. However, increasing bacterial resistance has limited their efficacy in recent years. *S. marcescens, P. aeruginosa,* enterococci, and anaerobes are usually resistant to the sulfonamides.

TMP is active in vitro against many gram-positive cocci and most gram-negative rods. *P. aeruginosa,* most anaerobes, *M. pneumoniae,* and mycobacteria are resistant. The MIC varies considerably with the test media used. Like the sulfonamides, TMP is used primarily in the therapy of uncomplicated and recurrent urinary tract infections due to susceptible organisms (161). However, the prevalence of TMP-resistant *Enterobacteriaceae* is increasing (135).

Combinations of TMP with other agents, such as rifampin, polymyxins, and aminoglycosides, have demonstrated in vitro synergistic activity against various gram-negative rods. TMP combined with dapsone is effective in the treatment of *P. jirovecii* pneumonia in immunocompromised patients.

Many gram-positive cocci, including staphylococci and streptococci, and most gram-negative rods except *P. aeruginosa* are susceptible to TMP-SMX (43). However, 10 to 50% of strains of *S. pneumoniae* are resistant in many parts of the world (190). The drug combination has variable bactericidal effects on enterococci in vitro, depending on the test media used for susceptibility testing (245). Unlike many bacteria that can utilize only thymidine for growth, enterococci can use thymidine, thymine, exogenous folinic acid, dihydrofolate, and tetrahydrofolate, resulting in higher MICs (25- to 50-fold increase) on media containing these compounds (241). This fact also explains the ineffectiveness of TMP-SMX against enterococci in vivo.

With good activity against *M. catarrhalis* and *H. influenzae,* including β-lactamase-producing strains, TMP-SMX is useful for the therapy of acute otitis media, sinusitis, acute bronchitis, and pneumonia. It has shown excellent results in the prophylaxis and therapy of acute and chronic urinary tract infections (161, 321). It is an effective alternative therapy for uncomplicated urogenital gonorrhea, including cases caused by penicillinase-producing *N. gonorrhoeae* (51). It can also be used for the treatment of chancroid, but resistance to TMP-SMX in *H. ducreyi* is increasing. The drug combination is also useful in treating infections due to salmonellae, shigellae, enteropathogenic *E. coli,* and *Y. enterocolitica* (243). It has been used successfully for prophylaxis and treatment of traveler's diarrhea (90), but resistance to TMP-SMX in *Shigella* spp. and *E. coli* now severely limits its usefulness in many parts of the world.

Other microorganisms susceptible to TMP-SMX include *Brucella* spp., *B. pseudomallei, B. cepacia, S. maltophilia, M. kansasii, M. marinum,* and *M. scrofulaceum. M. tuberculosis* and *M. chelonae* are generally resistant. It is a valuable antibiotic for the treatment of *N. asteroides* infections (349), *B. cepacia* and *S. maltophilia* bacteremia, *L. monocytogenes* meningitis, gastroenteritis due to *Isospora belli* and *Cyclospora* spp. (228, 266), and Whipple's disease. In immunocompromised hosts (e.g., those with leukemia or AIDS and organ transplant recipients), TMP-SMX is effective for the prophylaxis and treatment of *P. jirovecii* pneumonia (49, 50, 384).

Adverse Effects

Sulfonamides are known to cause nausea, vomiting, headache, and fever. Hypersensitivity reactions can occur as rashes, vasculitis, erythema nodosum, erythema multiforme, and Stevens-Johnson syndrome (46). Very high doses of less-water-soluble sulfonamides such as sulfadiazine may result in crystalluria, with renal tubular deposits of sulfonamide crystals. Bone marrow toxicity with anemia, leukopenia, or thrombocytopenia can occur. Sulfonamides should be avoided in patients with glucose-6-phosphate dehydrogenase deficiency because of associated hemolytic anemia. Sulfonamides also potentiate the effects of warfarin, phenytoin, and oral hypoglycemic agents.

In general, TMP is well tolerated. With prolonged use, megaloblastic anemia, neutropenia, and thrombocytopenia can develop, especially in folate-deficient patients. Adverse reactions to TMP-SMX due to either the TMP or, more commonly, the SMX component can occur. Mild gastrointestinal symptoms and allergic skin rashes occur in about 3% of patients (196). Megaloblastic bone marrow changes with leukopenia, thrombocytopenia, or granulocytopenia may develop, usually in patients with preexisting folate deficiency. Nephrotoxicity usually occurs in patients with underlying renal dysfunction. Patients with AIDS have a much higher frequency of adverse reactions (as much as 70%) (137).

POLYPEPTIDES

■ Polymyxins

Polymyxins are a group of related cyclic basic polypeptides originally derived from *Bacillus polymyxa.* They have limited spectra of antimicrobial activity and significant toxicity. Only polymyxins B and E (colistin) are available for therapeutic use in humans.

Mechanism of Action

Acting like detergents or surfactants, members of this group of antibiotics interact with the phospholipids of the bacterial cell membrane, thereby increasing cell permeability and disrupting osmotic integrity. This process results in leakage of intracellular constituents, leading to cell death. The bactericidal action is reduced in the presence of calcium, which interferes with the attachment of drugs to the cell membrane.

Pharmacology

The polymyxins are usually administered via the parenteral, oral, or topical route. They are not significantly absorbed when given orally or topically, and intramuscular injections can be painful. Peak concentrations in serum of 5 μg/ml are obtained with a total daily dose of intravenous polymyxin B at 2.5 mg (25,000 U)/kg of body weight. Colistin sulfate is given orally for local antibacterial effect in the gut, while colistimethate sodium, a sulfomethyl derivative of colistin, is used for intravenous or intramuscular injections. The half-life of polymyxin B in serum is about 6 to 7 h, and that of colistin is 2 to 4 h. They do not penetrate well into pleural fluid, synovial fluid, or CSF, even in the presence of inflammation. Excretion is mostly via the kidneys by glomerular

filtration. Levels in serum and toxicity are increased in states of renal insufficiency. These drugs are not removed by hemodialysis, but small amounts can be removed by peritoneal dialysis.

Polymyxin is often used topically as 0.1% polymyxin in combination with bacitracin or neomycin for treatment of skin, mucous membrane, eye, and ear infections. It is poorly absorbed from these surfaces. When the drug is used for irrigation of serous or wound cavities, systemic absorption can be significant enough to produce toxicity.

Spectrum of Activity

Polymyxins are active only against gram-negative rods, especially *Pseudomonas* spp. The MIC_{90}s for *Pseudomonas* spp., including *P. aeruginosa,* are <8 μg/ml. *Proteus, Providencia, Serratia,* and *Neisseria* isolates are usually resistant. Emergence of resistance during therapy is rare, and there is no cross-resistance with other antibiotics. Polymyxins B and E have identical antimicrobial spectra and show complete cross-resistance to one another.

The combination of polymyxins with TMP-SMX may be synergistic in the treatment of serious infection due to multiply resistant *Serratia* spp., *P. aeruginosa, B. cepacia,* and *S. maltophilia* (83, 288). The polymyxins are usually reserved for serious, life-threatening *Pseudomonas* or gram-negative rod infections caused by organisms resistant to all other antibiotics. Aerosolized polymyxins have been used successfully to treat *P. aeruginosa* colonization or respiratory infections in patients with cystic fibrosis or bronchiectasis (107).

Adverse Effects

Neurotoxicity and nephrotoxicity are the two major side effects of polymyxins. Paresthesia with flushing, dizziness, vertigo, ataxia, slurred speech, drowsiness, or mental confusion occurs when levels in serum exceed 1 to 2 μg/ml. Polymyxins also have a curare-like effect that can block neuromuscular transmission. Dose-related renal dysfunction occurs in about 20% of patients receiving appropriate therapeutic dosages. Allergic reactions such as fever and skin rashes are rare, but urticaria and shock after rapid intravenous infusion have occurred.

■ Bacitracin

Originally isolated from *Bacillus licheniformis* (formerly *Bacillus subtilis*), bacitracin is a peptide antibiotic consisting of peptide-linked amino acids. Although it was introduced initially for the systemic treatment of severe staphylococcal infections, it is now mainly restricted to topical use because of its systemic toxicity.

Mechanism of Action

Bacitracin inhibits dephosphorylation of a lipid pyrophosphate, a step essential for bacterial cell wall synthesis. It also disrupts the bacterial cytoplastic membrane.

Pharmacology

Bacitracin is often used in various topical preparations, such as creams, ointments, antibiotic sprays and powders, and solutions for wound irrigation or bladder instillation. When used as a topical antibiotic, no significant amount of bacitracin is absorbed systemically. Large doses used to irrigate serous cavities may be associated with systemic toxicity.

Spectrum of Activity

The drug is active mainly against gram-positive bacteria, especially staphylococci and group A beta-hemolytic streptococci. However, group C and G streptococci are less susceptible, and group B streptococci are resistant (113). *Neisseria* spp. are also susceptible, but gram-negative rods are resistant. Bacitracin is often combined with neomycin, polymyxin B, or both in topical preparations to provide broad-spectrum antibacterial coverage. Orally administered bacitracin is effective in treating antibiotic-associated *C. difficile* colitis (88).

Adverse Effects

Systemic administration of bacitracin results in significant nephrotoxicity. Side effects are rare when the drug is given orally or applied topically. The drug is nonirritating to skin and mucous membranes. Allergic skin sensitization is rare.

CHLORAMPHENICOL

Chloramphenicol is a unique antibiotic originally derived from *Streptomyces venezuelae*. It contains a nitrobenzene ring. It is a highly effective, broad-spectrum antimicrobial agent with specific indications for use in seriously ill patients. Thiamphenicol is an analog of chloramphenicol with a similar spectrum of antimicrobial activity (253). Only chloramphenicol is available for clinical use in the United States.

Mechanism of Action

The drug is a bacteriostatic agent that inhibits protein synthesis by binding reversibly to the peptidyltransferase component of the 50S ribosomal subunit and preventing the transpeptidation process of peptide chain elongation. At therapeutic concentrations achievable in serum, it can be bactericidal against common meningeal pathogens such as *S. pneumoniae, N. meningitidis,* and *H. influenzae* (212, 253). Bacterial resistance occurs with plasmid-mediated, *cat* gene-encoded production of chloramphenicol acetyltransferase enzyme, which inactivates the drug (308).

Pharmacology

Chloramphenicol is available for topical, oral, or parenteral use. It is not absorbed in any significant amount when applied topically, but it is rapidly and completely absorbed from the gastrointestinal tract. After an oral or intravenous dose of 1 g, peak concentrations in serum at 2 h can reach 10 to 15 μg/ml. It diffuses well into many tissues and body fluids, including CSF, where levels are generally 30 to 50% of concentrations in serum even without meningeal inflammation (313). The antibiotic readily crosses the placental barrier and is present in human milk.

Chloramphenicol is metabolized and inactivated by glucuronidation in the liver, with a half-life of 4 h in adults. The active drug (5 to 10%) and its inactive metabolites are excreted by the kidneys. Careful monitoring of serum chloramphenicol levels, maintaining peak concentrations in serum in the therapeutic range of 10 to 20 μg/ml, is useful for ensuring therapeutic efficacy and reduced toxicity. Patients with hepatic failure have high levels of active drug in serum owing to a prolonged half-life. Dosage modification is not necessary in the presence of renal insufficiency, since the metabolites are not as toxic as the active drug. Levels in serum are not affected by hemodialysis or peritoneal dialysis.

Spectrum of Activity

Chloramphenicol is very active against many gram-positive and gram-negative bacteria, chlamydiae, mycoplasmas, and rickettsiae. MIC_{90}s for most gram-positive aerobic and anaerobic cocci are ≤12.5 μg/ml (253). However, the drug is usually inactive against methicillin-resistant *S. aureus* and *S. epidermidis* and is variably active against enterococci. *N.*

meningitidis, H. influenzae (ampicillin-resistant and -susceptible strains), and most *Enterobacteriaceae* are susceptible. Its activity against *Serratia* and *Enterobacter* isolates is variable, and *Pseudomonas* spp. are usually resistant. Salmonellae, including *S. enterica* serovar Typhi, are also susceptible, but resistant isolates are being encountered with increasing frequency (54).

Chloramphenicol has excellent activity against anaerobic bacteria, including members of the *B. fragilis* group. Almost all of these isolates are inhibited at concentrations of ≤10 μg/ml (2, 314). It is also active against *Rickettsia* spp. and *C. burnetii*.

Adverse Effects

Bone marrow toxicity is the major complication of chloramphenicol use. This side effect may occur as either dose-related bone marrow suppression or idiosyncratic aplastic anemia. Reversible bone marrow depression with anemia, leukopenia, and thrombocytopenia occurs as a result of a direct pharmacological effect of the drug on hematopoiesis. High doses (>4 g/day), prolonged therapy, and excessively high levels in serum (>20 μg/ml) predispose patients to develop this type of complication. The second form of bone marrow toxicity is a rare but usually fatal complication that manifests as aplastic anemia. This response is not dose related, and the precise mechanism is unknown. It can occur weeks to months after the use of chloramphenicol, and it can develop after the use of oral, intravenous, or topical preparations.

Gray baby syndrome, characterized by vomiting, abdominal distention, cyanosis, hypothermia, and circulatory collapse, may occur in premature infants and neonates. This toxicity results from the immature hepatic function of neonates, which impairs hepatic inactivation of the drug. Reversible optic neuritis causing decreased visual acuity has been reported for patients receiving prolonged therapy. Chloramphenicol can occasionally cause hypersensitivity reactions, including skin rashes, drug fevers, and anaphylaxis. It potentiates the action of warfarin, phenytoin, and oral hypoglycemic agents by competitive inhibition of hepatic microsomal enzymes.

METRONIDAZOLE

Metronidazole is a 5-nitroimidazole derivative that was first introduced in 1959 for the treatment of *Trichomonas vaginalis* infections. It now has an important therapeutic role in the treatment of infections due to anaerobic bacteria and certain protozoan parasites. Tinidazole, a second-generation 5-nitroimidazole compound, is approved in the United States for treatment of trichomoniasis, giardiasis, and amebiasis.

Mechanism of Action

Metronidazole owes its bactericidal activity to the nitro group of its chemical structure. After the drug gains entry into the cells of susceptible organisms, the nitro group is reduced by a nitroreductase enzyme in the cytoplasm, generating certain short-lived, highly cytotoxic intermediate compounds, free radicals, that disrupt host DNA (96). Resistance to nitroimidazoles may be due to decreased uptake of the drug or inducible production of 5-nitroimidazole reductase enzyme that can scavenge the free-radical intermediates (207).

Pharmacology

Metronidazole can be administered via the topical, oral, or intravenous route. It is absorbed rapidly and almost completely when given orally. Peak levels in serum of 6 μg/ml are obtained 1 h after an oral dose of 250 mg. Intravenous doses of 7.5 mg/kg result in peak concentrations in serum of 20 to 25 μg/ml. The drug has a half-life in serum of 8 h. Therapeutic levels are achieved in all body tissues and fluids, including abscess cavities and CSF, even without meningeal inflammation. The drug crosses the placenta and is secreted in breast milk. It is metabolized mainly in the liver, and 60 to 80% is excreted by the kidneys. With impaired hepatic function, plasma clearance of metronidazole is delayed and dosage adjustments are necessary. The pharmacokinetics are minimally affected by renal insufficiency. Metronidazole and its metabolites are removed completely by dialysis.

Spectrum of Activity

Metronidazole exhibits potent activity against almost all anaerobic bacteria, including the *B. fragilis* group and *Fusobacterium* and *Clostridium* spp. (18). It is the only antimicrobial agent with consistent bactericidal activity against members of the *B. fragilis* group. However, the susceptibility of gram-positive anaerobic cocci is somewhat variable, with MIC_{90}s of 16 μg/ml for these organisms. Most strains of the genera *Actinomyces, Arachnia,* and *Propionibacterium* are resistant. Frequencies of metronidazole-resistant *B. fragilis* group isolates (MICs of >16 μg/ml) in the range of 2 to 5% have been reported from various institutions (2, 314). Tinidazole is somewhat more potent than metronidazole in its antianaerobe activities (58, 174). Nitroimidazoles have no activity against aerobic bacteria, including the *Enterobacteriaceae*.

The drug is effective in the treatment of antibiotic-associated colitis caused by *C. difficile* (19, 53), with efficacy equivalent to that of oral vancomycin for this indication (333). It is also useful in combination with an aminoglycoside for treating polymicrobial soft tissue infections and mixed aerobic-anaerobic intra-abdominal and pelvic infections.

Metronidazole and tinidazole are active against the protozoa *T. vaginalis, Giardia lamblia,* and *E. histolytica*. It is the drug of choice for the treatment of trichomoniasis, giardiasis, and intestinal and invasive amebiasis, including amebic liver abscess (127, 228, 331).

Adverse Effects

Metronidazole is generally well tolerated, and adverse side effects are uncommon. It can cause mild gastrointestinal symptoms such as nausea, abdominal cramps, and diarrhea. An unpleasant, metallic taste may be experienced with oral therapy. Metronidazole can potentiate the effect of warfarin and prolong the prothrombin time.

Although metronidazole is carcinogenic in mice and rats, there is no evidence for carcinogenicity in humans. However, use of this agent in pregnancy, especially during the first trimester, and in nursing mothers should be avoided.

RIFAMYCINS

Rifamycins are a group of macrocyclic compounds produced by the mold *Streptomyces mediterranei.* Rifampin, also known as rifampicin and a semisynthetic antibiotic derived from rifamycin B, was the first of this class of drugs introduced for clinical use in 1968 as an effective antituberculous drug. A closely related compound, rifabutin, a derivative of rifamycin S, is another potent antimycobacterial agent, especially against *M. avium* complex (261). Rifaximin, a derivative of rifampin, possesses an additional pyridoimidazole ring and is a nonabsorbed oral drug used for therapy of uncomplicated traveler's diarrhea.

Mechanism of Action

Rifamycins exert their bactericidal effects by forming a stable complex with bacterial DNA-dependent RNA polymerase, preventing the chain initiation process of DNA transcription (359). Mammalian RNA synthesis is not affected, because the mammalian enzyme is much less sensitive to the drug. Rifampin-resistant isolates possess an altered RNA polymerase enzyme that arises easily from single-step mutations during monotherapy with rifampin.

Pharmacology

Rifampin is well absorbed after oral administration, reaching peak concentrations in serum of 5 to 10 μg/ml in 2 to 4 h following a 600-mg dose. A parenteral preparation is also available. Rifampin is deacetylated in the liver to an active metabolite and excreted in the bile, and it undergoes enterohepatic circulation. The normal half-life in serum varies from 1.5 to 5 h. The drug distributes well to almost all body tissues and fluids, reaching concentrations equal to or exceeding that in serum. Levels in CSF are highest in the presence of inflamed meninges. It is able to enter phagocytes and kill living intracellular organisms (215), and it crosses the placenta. About 30 to 40% of the drug is excreted in the urine, and it does not accumulate in patients with impaired renal function. Hemodialysis and peritoneal dialysis do not eliminate the drug. Dosage adjustments are necessary for patients with severe hepatic dysfunction.

Due to an additional pyridoimidazole ring in its chemical structure, rifaximin is largely unabsorbed after oral administration, with >99% of the drug present in the stool and <1% of an oral dose detectable in plasma of both healthy volunteers and persons with damaged intestinal mucosa (164). Average fecal concentrations of drug reach 8,000 μg/g on the third day of therapy at a dosage of 400 mg orally twice daily (171).

Spectrum of Activity

In addition to its well-known antimycobacterial effects (59), rifampin has a wide spectrum of antimicrobial activity. It is bactericidal against gram-positive cocci such as staphylococci (including methicillin-resistant strains), streptococci, and anaerobic cocci, with MICs in the range of 0.01 to 0.5 μg/ml. It remains an important adjunct in combination therapy of serious and chronic staphylococcal infections (340). However, it is bacteriostatic against enterococci, with usual MICs of <16 μg/ml (240).

N. gonorrhoeae, N. meningitidis, and *H. influenzae,* including β-lactamase-producing strains, are susceptible to rifampin, which is used frequently in the prophylaxis of meningococcal and *H. influenzae* type b meningitis (146). MICs for *Enterobacteriaceae* are ≤12 μg/ml, while MICs for *S. marcescens* and *P. aeruginosa* are higher (240). Besides fluoroquinolones, rifampin is one of the most active agents against *L. pneumophila* and other *Legionella* spp., with MICs of ≤0.03 μg/ml. Because of its ability to enter phagocytes, rifampin inhibits the growth of *Brucella* spp. and *C. burnetii* intracellularly (282), and it is used frequently in combination therapy of infections due to these organisms. Although *Chlamydia* spp. are very susceptible to rifampin in vitro, resistance emerges rapidly when rifampin is used alone.

Rifaximin has broad-spectrum inhibitory activity against enteric bacterial pathogens, including enterotoxigenic and enteroaggregative strains of *E. coli, Aeromonas, Shigella,* and *Salmonella,* with MIC_{90}s ranging from 4 to 16 μg/ml (136, 164, 310). Although it is less active against *C. jejuni* (MIC_{90} of 512 μg/ml), *Y. enterocolitica* (MIC_{90} of 128 μg/ml), *C. difficile* (MIC_{90} of 128 μg/ml), and *H. pylori* (MIC_{50} of 4 μg/ml), concentrations of rifaximin achieved in the intestinal lumen are >10-fold higher than the MICs of the drug for these pathogens. This drug has been used successfully to treat and prevent uncomplicated traveler's diarrhea (91, 92, 324).

Adverse Effects

Rifampin has many side effects, including gastrointestinal discomfort and hypersensitivity reactions, such as drug fever, skin rashes, and eosinophilia. It produces a harmless, orange-red coloration of saliva, tears, urine, and sweat. In up to 20% of patients, an influenza-like syndrome with fever, chills, arthralgias, and myalgias may develop after several months of intermittent therapy (142). This immunologic reaction may be associated with hemolytic anemia, thrombocytopenia, and renal failure. Rifampin-induced hepatitis occurs in <1% of patients and is more frequent during concurrent isoniazid therapy for tuberculosis. As a result of its ability to induce human hepatic cytochrome P450 enzyme, rifampin has clinically significant interactions with many drugs, such as antagonizing the effect of oral contraceptives and diminishing the anticoagulant activity of warfarin.

Headache, nausea, abdominal pain, and fatigue are the most frequent side effects reported for rifaximin. Rare hypersensitivity reactions, including allergic dermatitis, rash, angioneurotic edema, urticaria, and pruritus, can occur with rifaximin, which is contraindicated in those who are allergic to rifampin (164). However, unlike rifampin, rifaximin does not cause clinically relevant interactions with drugs because of the lack of systemic absorption of this drug.

NITROFURANTOIN

Nitrofurantoin belongs to a class of compounds consisting of a primary nitro group joined to a heterocyclic ring. Its role in human therapeutics is limited to treatment of urinary tract infections (161).

Mechanism of Action

The mechanism of action of nitrofurantoin is not fully understood, but highly reactive electrophilic intermediates of the drug activated by bacterial reductases were found to bind nonspecifically to bacterial ribosomal proteins and inhibit inducible synthesis of essential bacterial enzymes, causing complete cessation of protein synthesis and damage to bacterial DNA and RNA (221). However, inhibition of bacterial protein synthesis can occur in the absence of reductive activation of the drug (226). Despite over 30 years of clinical use, there is no emergence of clinically significant bacterial resistance to this drug.

Pharmacology

The drug is available in microcrystalline (Furadantin) and macrocrystalline (Macrodantin) forms. It is administered orally and is well absorbed from the gastrointestinal tract. Very low levels of the drug are achieved in serum and most body tissues after usual oral doses. With a half-life in serum of about 20 min, two-thirds of the drug is rapidly metabolized and inactivated in various tissues. The remaining one-third is excreted unchanged into the urine. An average dose of nitrofurantoin yields a concentration in urine of 50 to 250 μg/ml in patients with healthy renal function. In alkaline urine, more of the drug is dissociated into the ionized form, with lowered antibacterial activity. Nitrofurantoin accumulates in the sera of patients with creatinine clearances of <60 ml/min. The drug is removed by

hemodialysis. The risk of systemic toxicity increases in the presence of severe uremia. It is contraindicated in patients with significant renal impairment and hepatic failure.

Spectrum of Activity

Nitrofurantoin has a broad spectrum of activity against gram-positive and gram-negative bacteria, particularly the common urinary tract pathogens. It is active against gram-positive cocci, such as *S. aureus, S. epidermidis, Staphylococcus saprophyticus,* and *E. faecalis*, with MICs in the range of 4 to 25 μg/ml (159). *S. pneumoniae, S. pyogenes,* and *Corynebacterium* spp. are also susceptible, but they rarely cause urinary tract infections. Over 90% of *E. coli* isolates and many coliform bacteria are susceptible to nitrofurantoin at MICs of <32 μg/ml. However, only one-third of *Enterobacter* and *Klebsiella* isolates are susceptible. *Pseudomonas* and most *Proteus* spp. are resistant. Susceptible organisms rarely become resistant to this drug during therapy.

Adverse Effects

Gastrointestinal irritation, with anorexia, nausea, and vomiting, is the most common side effect. Diarrhea and abdominal cramps may occur. Hypersensitivity reactions, such as drug fever, chills, arthralgia, skin rashes, and a lupus-like syndrome, have been observed (160). Pulmonary reactions are the most common serious side effects associated with nitrofurantoin use. Acute pneumonitis with fever, cough, dyspnea, eosinophilia, and pulmonary infiltrates present on chest radiographs can occur after a few days of therapy (160). This immunologically mediated reaction is more common in elderly patients and is rapidly reversible after cessation of therapy. Chronic pulmonary reactions with interstitial pneumonitis leading to irreversible pulmonary fibrosis can occur in patients on continuous therapy for 6 months or more (232).

Peripheral polyneuropathy is a serious side effect that occurs more often in patients with renal failure. Hemolytic anemia, megaloblastic anemia, and bone marrow suppression with leukopenia can occur. Rare hepatotoxic reactions, such as cholestatic jaundice and chronic active hepatitis, have been reported (307).

FOSFOMYCIN

Fosfomycin, first isolated from cultures of *Streptomyces* spp. in 1969, is a phosphonic acid derivative originally named phosphonomycin (322). In the United States, it is used as single-dose therapy for uncomplicated urinary tract infections due to susceptible organisms (161).

Mechanism of Action

Fosfomycin is bactericidal by inhibiting pyruvyl transferase, a bacterial cytoplasmic enzyme that catalyzes the formation of uridine diphosphate-*N*-acetylmuramic acid during the first step of peptidoglycan synthesis (184). There is little cross-resistance between fosfomycin and other antibacterial agents, most likely because it differs from other agents in its chemical structure and site of action. Rare resistance to fosfomycin can occur by two mechanisms: (i) mutations of the structural or regulatory genes for the bacterial proteins that transport the drug into the cell or (ii) plasmid-mediated production of a drug-inactivating enzyme (255).

Pharmacology

Originally formulated as sodium and calcium salts for oral and intravenous use, fosfomycin is available in the United States as an oral, water-soluble tromethamine salt. Following oral administration, it is rapidly absorbed and converted to the free acid, fosfomycin. With markedly improved oral bioavailability (35 to 40%), fosfomycin has a mean elimination half-life of 5.5 h, and it is primarily excreted unchanged in the urine (268). Following a single oral dose of 3 g, peak concentrations in serum (range, 22 to 32 μg/ml) are achieved within 2 h after administration, with peak urinary concentrations (1,000 to 4,400 μg/ml) occurring within 4 h and remaining high (>128 μg/ml) for 24 to 48 h, sufficient to inhibit most urinary tract pathogens. Peak urinary concentrations are reached later and are lowered when the drug is administered with food or antiperistaltic agents. In patients with renal impairment (creatinine clearance of <30 ml/min), peak serum fosfomycin concentrations are increased, with decreased urinary elimination and reduced urinary concentrations of the drug.

While not bound to plasma protein, it is widely distributed in various body fluids and tissues, including the kidneys, prostate, and seminal vesicles, from which it is cleared slowly. Although it crosses the placental barrier, the drug can be used safely during pregnancy if clearly needed.

Spectrum of Activity

Fosfomycin has a broad spectrum of activity against most gram-positive and gram-negative bacteria isolated from patients with lower urinary tract infections. *E. coli, Serratia, Klebsiella, Citrobacter, Enterobacter, S. aureus,* and enterococci are generally inhibited by fosfomycin at concentrations of <64 μg/ml (13, 268, 322). Fosfomycin is bactericidal at concentrations that are similar to the MICs, at ≤2-fold differences. It is more active than TMP and nalidixic acid, while similar to norfloxacin and co-trimoxazole, in its activity against these organisms (13). At a breakpoint concentration of ≤128 mg/ml, 60, 20, and 80% of isolates of *Pseudomonas* spp., *M. morganii,* and *S. saprophyticus,* respectively, are susceptible to fosfomycin (274). In multiple-dose use, bacterial resistance to fosfomycin emerges rapidly, and it can be chromosomal or, more rarely, plasmid mediated. However, cross-resistance with other antimicrobials has been uncommon (283).

The in vitro activity of fosfomycin is affected by test medium and conditions (268, 274). Fosfomycin has much greater in vitro activity, and closer correlation with in vivo activity, when the test medium is supplemented with glucose-6-phosphate at 25 μg/ml, which is recommended for susceptibility testing with the agar and broth dilution methods. The disk diffusion testing method utilizes disks containing 200 μg of fosfomycin tromethamine and 50 or 100 μg of glucose-6-phosphate.

Adverse Effects

Mild, self-limiting gastrointestinal disturbances, mainly diarrhea, are the most frequent side effects (3 to 5%). Other minor adverse events include headaches, dizziness, rash, and vaginitis.

METHENAMINE

Methenamine is a tertiary amine with properties of a monoacidic base; it is used as a urinary antiseptic. To be activated, it is combined chemically with a poorly metabolized acid and administered as the mandelate (Mandelamine) or hippurate (Hiprex or Urex) salt.

Mechanism of Action

Methenamine has no antibacterial action by itself, but it is converted at acid pH to ammonia and formaldehyde, which provides the antiseptic action. This hydrolytic process occurs

in the urine, and an effective bacteriostatic concentration of formaldehyde is reached at a urine pH of <5.5. Since the serum is at physiological pH, formaldehyde is not released while methenamine circulates in the body.

Pharmacology

The agent is well absorbed from the gastrointestinal tract and is rapidly excreted in the urine. The elimination half-life of methenamine is about 4 h. At a urinary pH of 5.0, about 20% of methenamine excreted in the urine is hydrolyzed to formaldehyde and ammonia. Bactericidal levels (>20 mg/ml) of formaldehyde are generated in the bladder urine at 2 h after oral administration and may be maintained for at least 6 h or until the patient voids (192). The mandelate and hippurate moieties are also rapidly excreted in the urine in active, unchanged forms by glomerular filtration and tubular secretion. The agent is contraindicated in patients with hepatic insufficiency because of the ammonia produced.

Spectrum of Activity

With the liberation of enough formaldehyde into the urine, methenamine is essentially active against all gram-positive and gram-negative bacteria and also against fungi (192). However, it is not effective for treating urinary tract infections due to urea-splitting organisms such as *Proteus* and *Morganella*, which can convert urea to ammonium hydroxide, thereby preventing the hydrolysis of methenamine to formaldehyde. Combination with acetohydroxamic acid, a urease inhibitor, has been suggested for treating these infections by *Proteus* and *Morganella*. Since bacteria and fungi do not become resistant to formaldehyde, emergence of resistance to methenamine is not a problem.

Methenamine is not useful for acute urinary tract infections. It has been used successfully as prophylactic therapy for recurrent bacteriuria, particularly infections caused by highly resistant gram-negative rods or yeasts. It is also effective as prolonged suppressive therapy for chronic bacteriuria in the absence of structural abnormalities of the urinary tract.

Adverse Effects

Methenamine and its acid salts are generally well tolerated. Some patients may develop nausea, vomiting, abdominal cramps, and diarrhea. High doses or prolonged administration of the drug can cause urinary tract irritation by the free formaldehyde, resulting in urinary frequency, dysuria, albuminuria, and hematuria. Skin rashes may also occur. To avoid precipitation of urate crystals in the urine, methenamine salts should not be used in patients with gout or hyperuricemia.

MUPIROCIN

Mupirocin, formerly pseudomonic acid A, is a topical antibacterial agent derived from the fermentation products of *Pseudomonas fluorescens* (125). It contains a unique 9-hydroxynonanoic acid moiety in its chemical structure, and it inhibits isoleucyl-tRNA synthetase, resulting in cessation of bacterial protein synthesis (165). Low-level resistance (MICs of 4 to 256 μg/ml) results from an altered synthetase enzyme due to mutations in the bacterial chromosomal *ileS* gene, whereas high-level, transferable resistance (MIC of ≥512 μg/ml) is mediated by the *mupA* gene, which encodes an entirely different synthetase.

Originally developed for the topical treatment of superficial soft tissue infections, particularly those due to staphylococci, mupirocin is available as a 2% ointment or cream in the United States. After topical application, <1% of the drug is absorbed systemically, with no detectable levels in the urine or feces. Penetration into deeper dermal layers of the skin is increased with traumatized skin or use of occlusive dressings. The drug is highly protein bound (95%), and its activity is lowered in the presence of serum. It is most active at moderately acid pH, with no inoculum effect (353). Mupirocin is slowly metabolized in the skin to the inactive monic acid.

It has excellent in vitro activity, primarily against the gram-positive cocci. *S. aureus*, including methicillin-resistant strains, and coagulase-negative staphylococci are uniformly very susceptible, with MIC_{90}s of <0.5 μg/ml (47). Emergence of resistant strains of staphylococci can occur with widespread use of mupirocin (33, 35, 339). Most streptococci (including *S. pneumoniae*, beta-hemolytic streptococci of groups A, B, C, and G, and viridans group streptococci) are inhibited by concentrations of ≤1 μg/ml. Resistant bacteria include enterococci, *Corynebacterium* spp., *Erysipelothrix* spp., *P. acnes*, gram-positive anaerobes, and most gram-negative bacteria. However, *H. influenzae, N. gonorrhoeae, N. meningitidis, M. catarrhalis, B. pertussis*, and *P. multocida* are quite susceptible, with MICs in the range of 0.02 to 0.025 μg/ml. There is no cross-resistance between mupirocin and other major groups of antibiotics. Clinically, mupirocin is efficacious in the therapy of superficial skin infections, such as impetigo, folliculitis, and burn wound infections, that are caused by staphylococci or streptococci (132). Although this drug has been used successfully to eradicate nasal carriage of *S. aureus*, including methicillin-resistant strains (48, 85), it may not prevent nosocomial *S. aureus* infections (361).

No systemic toxic effects have been reported with mupirocin. Local irritation, such as burning, stinging, itch, and rash, which may be due to the polyethylene glycol base in the vehicle ointment, may occur.

APPENDIX

Approximate Concentrations of Antibacterial Agents in Serum

The concentrations of antimicrobial agents listed below are approximations taken from various reports and publications. Several factors can influence the level of antimicrobial agent in individual patients, including inherent differences in the patients themselves, their physical condition, the dosages, and the routes of administration. The values can also be influenced by the assay methods used to obtain them. Therefore, these concentrations should be used only as approximate values, and clinicians should use their knowledge of the patient and the drugs, the recommendations from U.S. Food and Drug Administration-approved package inserts, or other reputable sources in planning their therapeutic regimens.

Antimicrobial agent	Serum half-life (h)	Unit dose	Average peak level in serum (μg/ml)[a]		
			p.o.	i.m.	i.v.[b]
Amikacin	2–2.5	7.5 mg/kg		15–20	20–40
Amoxicillin	1	500 mg	6–8		
Amoxicillin-clavulanate	1.3 / 1.0	250/125 mg	3.3 (Amox) 1.5 (Clav)

Mechanisms of Resistance to Antibacterial Agents*

LOUIS B. RICE AND ROBERT A. BONOMO

71

GENERAL CONCEPTS, INOCULUM EFFECTS, AND TOLERANCE

In considering the growing problem of antimicrobial resistance in bacteria, it is worth remembering that resistance is neither a new phenomenon nor unexpected in an environment in which potent antimicrobial agents are used. The diversity of the microbial world and the relatively specific activities of our antimicrobial agents virtually ensure widespread resistance among bacteria. In many cases, this resistance is recognized when an antibiotic is first tested for development. For example, it is not considered a problem or threat that *Escherichia coli* is resistant to vancomycin. We simply understand that *E. coli* is not among vancomycin's spectrum of activity and avoid using vancomycin when *E. coli* infection is known or highly suspected (i.e. *E. coli,* has natural or primary resistance to vancomycin). Conversely, the increasing resistance of *E. coli* to ciprofloxacin represents an important problem, since we frequently use the fluoroquinolone class of antimicrobial agents to treat infections in which *E. coli* is likely to be involved. So when we speak of the problem of resistance, we must recognize that most problems result from expression of resistance by bacteria that are intrinsically susceptible to the antibiotic in question (i.e, acquired resistance).

It is also important to recognize that resistance as a clinical entity is essentially a relative phenomenon, in many ways a problem only indirectly related to the microbiologic techniques often used to detect it. For example, it is possible to incorporate enough ticarcillin into an agar plate to inhibit an ampicillin-resistant strain of *Enterococcus faecium* (in many cases this requires about 10,000 μg/ml). So in one sense, ampicillin-resistant *E. faecium* isolates are susceptible to high concentrations of ticarcillin. However, such concentrations cannot be achieved at the site of infection, so ampicillin-resistant *E. faecium* strains are not considered susceptible to ticarcillin. It is the responsibility of the Clinical and Laboratory Standards Institute (formerly the National Committee for Clinical Laboratory Standards), the U.S. Food and Drug Administration, and other standard-setting bodies in different countries to make determinations on susceptible, intermediate, and resistant breakpoints for new antimicrobial agents, considering factors of in vitro susceptibility, pharmacokinetics, and pharmacodynamics. These issues become very important in treating meningitis, in which relatively minor increases in the MIC of penicillin for *Streptococcus pneumoniae* can foil treatment, but in many cases are less relevant in the treatment of simple urinary tract infections, given the tendency of many antibiotics to concentrate in the urine.

The relativity of resistance is no better exemplified than by considerations of susceptibility in bacterial strains that exhibit significant inoculum effects, such as those resistant by virtue of producing β-lactamase. β-Lactamase-mediated resistance results from a chemical interaction in which the β-lactamase molecule binds to the β-lactam antibiotic in a manner that ultimately results in the hydrolysis of the critical β-lactam ring structure (Fig. 1). The rapidity and efficiency with which binding and hydrolysis proceed are dependent upon the affinity with which the β-lactamase molecule binds the antibiotic and the efficiency of the subsequent hydrolysis. High affinity and rapid hydrolysis mean that the cell wall synthesis machinery (penicillin binding proteins, or PBPs) can be defended with few β-lactamase molecules compared to the number of β-lactam molecules likely to be present in the vicinity of the PBPs. Low affinity and slow hydrolysis mean that more β-lactamase molecules are necessary for effective resistance but also that resistance can be more easily overcome by adding more antibiotic molecules. Increasing the inoculum of organisms in a solution with a fixed concentration of β-lactam antibiotic has the effect of increasing the number of β-lactamase molecules and can in some instances result in clinically important levels of resistance. The MIC for a *Klebsiella pneumoniae* strain that produces extended-spectrum β-lactamase TEM-26, for example, may be 1 μg of cefotaxime/ml with a standard inoculum (ca. 10^5 CFU/ml). However, when the inoculum is increased to 10^7 CFU/ml, the MIC increases to greater than 256 μg/ml (210). This type of resistance is likely to be important in treating a large-inoculum infection such as pneumonia. The existence of inoculum effects has led to the common practice of considering all *K. pneumoniae* strains that are resistant to ceftazidime to be resistant to all cephalosporins (excepting the cephamycins), regardless of in vitro susceptibility test results using the standard inoculum.

A second, more amorphous and difficult-to-evaluate concept in considering antimicrobial resistance is that of

* This chapter contains information presented in chapter 68, by Louis B. Rice, Daniel Sahm, and Robert A. Bonomo in the eighth edition of this Manual.

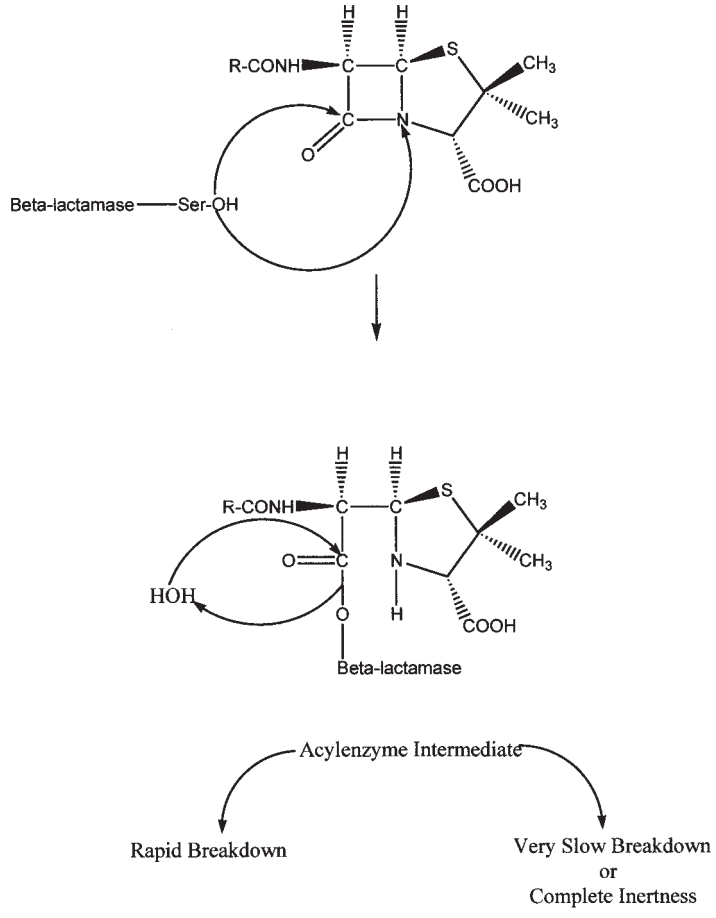

FIGURE 1 Penicillin-interactive, active-site serine peptidases and their reactions with β-lactam carbonyl donors. Modified from reference 87 with permission of Annual Reviews (http://www.annualreviews.org).

tolerance, or resistance to killing at antimicrobial concentrations sufficient to inhibit further growth. Tolerance is an unimportant concept for the treatment of most infections, since for therapeutic success it is usually sufficient to inhibit further growth of bacteria (bacteriostatic activity), allowing the patient's immune defenses to kill the growth-inhibited organisms and clean up the debris. In some instances, however, antimicrobial killing of the bacteria (bactericidal activity) is required to yield a high percentage of treatment success. Instances in which bactericidal activity is preferred include cases of endocarditis, meningitis, and osteomyelitis, in which the immune system has limited access to the infection site. They also include circumstances in which the immune system is severely compromised, such as it is in patients undergoing high-dose chemotherapy for hematologic malignancies. In these instances, antibiotics that are primarily bacteriostatic, such as the tetracyclines and the macrolides, are considered poor choices for therapy whereas β-lactam antibiotics, which are primarily bactericidal, are preferred. Some bacteria are naturally tolerant to β-lactam antibiotics. Bactericidal activity against enterococci, for example, requires two agents, one active against cell wall synthesis and an aminoglycoside (154). Recognition of this bactericidal synergism has raised cure rates for enterococcal endocarditis from about 40 to 70% or greater (207). Unfortunately, expression of aminoglycoside-modifying enzymes (AMEs) negates the synergism and appears to decrease the cure rates for enterococcal endocarditis. Although some level of tolerance to β-lactam antibiotics can be demonstrated for several different bacterial species, the impact on the treatment of clinical infections appears to be less dramatic than for enterococci.

Emergence and Spread of Antibiotic Resistance

The emergence of antimicrobial resistance phenotypes is inevitably linked to the clinical (or other) use of the antimicrobial agent against which resistance is directed. One reason for this association is trivial—we do not generally test for resistance to antibiotics that are not in clinical use. The second reason is that nature abhors a vacuum, so when an effective antibiotic eliminates susceptible flora, resistant varieties soon fill the niche. Once a resistance phenotype has emerged within a previously susceptible species, the rapidity and efficiency with which it spreads are impacted by a host of different factors, including the degree of resistance expressed, the ability of the organism to tolerate the resistance mechanism, linkage to other genes, the site of primary colonization, and others. The rapidity and completeness of resistance gene spread are often unpredictable. For example, the staphylococcal β-lactamase gene (conferring resistance to penicillin) was first described shortly after the introduction of penicillin into clinical use and is now almost universally present within

staphylococci in the hospital and the community. It was not until the early 1980s that this gene was described in *Enterococcus*, and it has never spread widely in this genus. The reverse appears to be true with the vancomycin resistance genes, which are found widely in *E. faecium* but remain exceedingly rare in *Staphylococcus aureus.*

An important cause of the spread of antimicrobial resistance is the failure to adhere to appropriate infection control techniques, both within and outside the hospital. It is well established that strains of methicillin-resistant *S. aureus* (MRSA) within individual hospitals, and even within entire cities, are often clonally related, as determined by genetic techniques such as pulsed-field gel electrophoresis and staphylococcal protein A typing (211). The spread of these problematic pathogens has been attributed to transmission from patient to patient, presumably by transiently or persistently colonized health care workers (228). The primary site of *S. aureus* colonization is the anterior nares. Colonization of the nares facilitates aerosol transmission of the resistant bacteria, particularly during periods of viral upper respiratory infection in the colonized worker. It also facilitates direct transmission, given the frequent contact between hands and noses in many people and the frequently poor hand-washing practices of health care workers. The clinical consequences of patient colonization can be significant. Studies have shown a correlation between patient colonization with MRSA and subsequent infection during periods of high risk, such as the postoperative period (184).

Although antibiotic resistance is predominantly a nosocomial problem, resistant bacteria are also spread in the community setting. Sites in which resistant bacteria have been known to spread include day care centers and nursing homes (1, 274). Penicillin-resistant pneumococci have been found to colonize as many as 25% of a day care center's population. Transmission probably reaches its peak in the winter months, when viral upper respiratory infections are prevalent. The prevalence of viral upper respiratory tract infections works in two ways to increase transmission: (i) it probably increases the inoculum of resistant organisms being spread by those already colonized (see above-mentioned references for *S. aureus* colonization), and (ii) it makes those who are not colonized more likely to become colonized because of the increased likelihood that they will be receiving antimicrobial therapy. Nursing homes are predisposed to resistance for a variety of reasons, including the debilitated state of much of their populations, frequent movement back and forth to tertiary care hospitals, and frequent use of antimicrobial agents in an effort to ward off infections that will necessitate hospital admissions.

A final important source for the emergence and spread of antibiotic-resistant bacteria is nonhuman niches in which antibiotics are used. It is now well established that antimicrobial use in food animals is associated with both resistance in bacterial species that contaminate food and infect humans, primarily *Salmonella* and *Campylobacter* species, and the transfer of resistance determinants to human counterparts, such as *Enterococcus* (69). Compelling evidence also exists that high rates of ciprofloxacin resistance in *E. coli* can be associated with the use of fluoroquinolones in poultry (64). Finally, the European outbreak of vancomycin-resistant enterococci with the *van*A determinant was almost certainly fueled by the use of avoparcin (a glycopeptide antibiotic) as a growth promoter in food animals (266). Data are also emerging that the use of antibiotics to promote growth of animals is often expensive and unnecessary, which has prompted many stakeholders in this issue to outline specific instances in which such antimicrobial use will be permitted.

Genetic Bases of Resistance

Acquired antimicrobial resistance results from biochemical processes that are encoded by bacterial genes. A general list of mechanisms of resistance is presented in Table 1. In order to understand the biochemical processes, it is useful to first discuss the genetic underpinnings of resistance and its evolution. Antimicrobial resistance arises by (i) mutation of cellular genes, (ii) acquisition of exogenous resistance genes, or (iii) mutation of acquired genes.

Mutation of Cellular Genes

All antibiotics have targets, which are often (but not always) proteins with important functional responsibilities in cell growth or maintenance. Cellular genes encode these proteins. Interactions between antibiotics and target proteins are often quite specific, and changing a single amino acid, frequently as a result of a single base change in the gene, can sometimes alter these interactions. Perhaps the most familiar example of this mechanism is resistance to rifampin. Rifampin targets the cellular RNA polymerase (encoded by *rpoB*), and a single point mutation in the RNA polymerase gene may confer complete resistance. These mutations occur in most bacterial species at a relatively high frequency (ca. 10^{-8}/CFU). Incubating enough cells with inhibitory concentrations of rifampin will eliminate susceptible cells and allow the resistant mutants to proliferate. The rifampin in the medium is not actually causing resistance but rather selecting mutants that occur naturally but which have no selective advantage for survival in the absence of rifampin in the environment. Other examples of mutational resistance include resistance to streptomycin through ribosomal mutation (63), resistance to fluoroquinolones through mutations of cellular topoisomerases (144), and resistance to linezolid through mutations in the rRNA (197), among others.

Resistance mutations may also be found in genes that regulate cellular processes. Perhaps the most completely studied example of regulatory mutation resulting in resistance is the derepression of the chromosomal β-lactamase of *Enterobacter* spp. (111). Mutations in a cellular amidase gene (designated *ampD*) result in the buildup of a cell wall breakdown product that has the effect of dramatically increasing expression of a chromosomal β-lactamase gene (*ampC)*. Other examples of regulatory changes include the downregulation of expression of the porin OmpD2 in *Pseudomonas aeruginosa* associated with resistance to imipenem (134) and the insertion of an insertion sequence (IS element) upstream of a chromosomal carbapenemase gene conferring imipenem resistance on *Bacteroides fragilis* (188).

Whether mutational resistance is likely to persist will depend in some measure on whether the resistance mutation is tolerable to the cell. For example, although decreased expression of OMPD2 appears to be readily achievable for *P. aeruginosa,* the fact that the resistant strains have not spread widely in the nearly 20 years of carbapenem use probably reflects the fact that this porin has functions that are beneficial to the bacterium, favoring reexpression of the porin once the imipenem threat has been dissipated. Similarly, intermediate levels of susceptibility to vancomycin in *S. aureus* have thus far been attributed to marked changes in the composition of the cell wall (231). These changes are unlikely to be favored in an environment free of vancomycin, since *S. aureus* likely "decided" a long time ago the optimal size and composition of its cell wall. The deleterious effects of acquiring resistance are often referred to as the fitness cost.

Disadvantageous resistance mutations do not always disappear. Although initial point mutations in the *rpoB* gene

TABLE 1 Common associations of resistance mechanisms

Antibiotic class	Resistance type	Resistance mechanism	Common example
Aminoglycosides	Decreased uptake	Changes in outer membrane permeability	*P. aeruginosa*
	Enzymatic modification (AMEs)	Phosphotransferase	Wide range of enteric gram-negative bacteria
		Adenyltransferase	Wide range of enteric gram-negative bacteria
		Acetyltransferase	Wide range of enteric gram-negative bacteria
		Bifunctional enzyme	*aac(6′)-aph(2″)* in *S. aureus, E. faecium,* and *E. faecalis*
ß-Lactams	Altered PBP(s)	PBP2a (additional PBP)	*mecA* in *S. aureus* and coagulase-negative staphylococci
		PBP2x, PBP2b, PBP1a (acquired from other streptococci by transformation)	*S. pneumoniae*
		PBP5 (point mutation)	*E. faecium*
	Enzymatic degradation (β-lactamases)	Ambler class A	TEM-1 in *E. coli, H. influenzae,* and *N. gonorrhoeae* SHV-1 in *K. pneumoniae* K1 (OXY-1) in *Klebsiella oxytoca* ESBLs (TEM-3+, SHV-2+, and CTX-M types) in *K. pneumoniae* and *E. coli* BRO-1 in *Moraxella catarrhalis* PC1 in *S. aureus* PSE-1 in *P. aeruginosa* ß-lactamases of *C. koseri* and *P. vulgaris*
		Ambler class B	L-1 in *Stenotrophomonas maltophilia* CcrA in *Bacteroides fragilis*
		Ambler class C	AmpC in *E. cloacae* and *Citrobacter freundii,* and similar enzymes in *Serratia marcescens, Morganella morganii, Providencia stuartii,* and *P. rettgeri*
		Ambler class D	OXA-1 in *E. coli*
Chloramphenicol	Enzymatic degradation	CATs	CAT in *S. pneumoniae*
	Efflux	Membrane transporters	*cmlA* and *flo*-encoded efflux in *E. coli* and *Salmonella* spp.
Glycopeptides	Altered target	Altered peptidoglycan cross-link target (D-Ala–D-Ala to D-Ala–D-Lac or D-Ala–D-Ser) encoded by complex gene cluster	VanA gene cluster in *E. faecium, E. faecalis,* and *S. aureus;* VanB gene cluster in *E. faecium* and *E. faecalis*
	Target overproduction	Excess peptidoglycan	Glycopeptide-intermediate strains of *S. aureus* and *Staphylococcus haemolyticus*
Oxazolidinones	Altered target	Mutation leading to reduced binding to active site	G2576U mutation in rRNA in *E. faecium* and *S. aureus*
Macrolides-lincosamides-streptogramin B	Altered target	Ribosomal active-site methylation with reduced binding	*erm*-encoded methylases in *S. aureus*, *S. pneumoniae*, and *Streptococcus pyogenes*
Macrolides	Efflux	Mef efflux pump	*mef*-encoded efflux in *S. pneumoniae* and *Streptococcus pyogenes; msrA* in *S. aureus*
Streptogramin A	Enzymatic degradation	Acetyltransferases	*vat*(A)-, *vat*(B)-, and *vat*(C)-encoded enzymes in *S. aureus* *vat*(D)- and *vat*(E)-encoded enzymes in *E. faecium*
Quinolones	Altered target	Mutation leading to reduced binding to active site(s) (quinolone resistance-determining region)	Mutations in *gyrA* in enteric gram-negative bacteria and *S. aureus* Mutations in *gyrA* and *parC* in *S. pneumoniae*

(Continued on next page)

TABLE 1 Common associations of resistance mechanisms *(Continued)*

Antibiotic class	Resistance type	Resistance mechanism	Common example
	Efflux	New membrane transporters	NorA in *S. aureus*
	Protection from DNA binding	Acquired protection protein	*qnr* gene and variants
	Enzymatic modification	Mutated aminoglycoside acetyltransferase	*aac(6′)-Ib* variant in *E. coli*
Rifampin	Altered target	Mutations leading to reduced binding to RNA polymerase	Mutations in *rpoB* in *S. aureus* and *Mycobacterium tuberculosis*
Tetracyclines	Efflux	New membrane transporters	*tet* genes encoding efflux proteins in gram-positive bacteria (mainly group 2) and gram-negative bacteria (mainly group 1)
	Altered target	Production of proteins that bind to the ribosome and alter the conformation of the active site (ribosomal protection proteins)	*tet*(M) in a variety of gram-positive bacteria
Sulfonamides	Altered target	Mutation or recombination of genes encoding DHPS	Found in a wide range of species, e.g., *E. coli, S. aureus,* and *S. pneumoniae*
		Acquisition of new, low-affinity DHPS genes	*sul*I and *sul*II in enteric gram-negative bacteria
Trimethoprim	Altered target	Mutations in gene encoding DHFR	*S. aureus, S. pneumoniae,* and *H. influenzae*
		Acquisition of new, low-affinity DHFR genes	*dhfr*I and *dhfr*II encoded, found in a wide range of species
	Overproduction of target	Promoter mutation leading to overproduction of DHFR	*E. coli*

that confer rifampin resistance on *Salmonella enterica* serovar Enteritidis appear to decrease the fitness of the organism for survival in vivo, persistence in a live host is frequently associated with compensatory mutations that at least partially restore fitness to the strain while retaining the resistance (rather than mutating back to susceptibility) (22). Similarly, transfer of mutated *pbp5* into *E. faecium* strains is often associated with decreases in the expression of ampicillin resistance, but growth on increased concentrations of ampicillin easily yields colonies that grow well at higher concentrations (209). Similar findings have been reported for *S. aureus* strains transformed with the *mec*A gene encoding methicillin resistance (156). In summary, although mutational resistance often confers a fitness cost, subsequent adaptations may make the expression of resistance less costly.

Acquisition of Resistance Genes

If resistance is not achievable through mutation, threatened bacterial species have little choice but to look elsewhere for resistance determinants. They are aided in this effort by the fact that most antimicrobial agents are natural products or derivatives of natural products. Therefore, resistance genes for most antibiotics must exist in the microbial world, either in the species that produce the antibiotic or within species that live in the same ecological niche as the antibiotic producers (54). The challenge for susceptible human pathogens is to find and acquire these resistance determinants. To assist in this acquisition, bacteria have evolved a range of mechanisms that promote gene exchange. Perhaps the simplest of these techniques is natural transformation, referring to the ability of some bacterial species to absorb naked DNA molecules from the environment under the appropriate circumstances (92). Once taken up by the susceptible bacterium, these foreign pieces of DNA enter the bacterial chromosome by recombining across regions of sufficient homology. In some cases, functional genes result from this recombination. If the acquired gene encodes a protein that is less susceptible to inhibition than the native protein, a reduction in susceptibility may result. Perhaps the best-studied example of the formation of these "mosaic" genes to confer resistance is penicillin and cephalosporin resistance in *Streptococcus pneumoniae* (92). A variety of mosaic PBP *(pbp)* genes in resistant strains have been described previously, with the level and degree of resistance determined by the number and nature of gene recombinations. Mosaic topoisomerase genes in fluoroquinolone-resistant transformable bacteria have also been described previously (55).

Most bacteria are incapable of natural transformation and so have developed other mechanisms for acquiring useful genetic determinants. A commonly employed mechanism for genetic exchange is the transfer of conjugative plasmids. These extrachromosomal replicative DNA forms may carry a variety of important genes. Some plasmids are relatively narrow in their host range, and others transfer into and replicate within several different species. Transfer frequencies can be very high, as in the F factor of *E. coli* (virtual complete transfer in 1 h) and the pheromone-responsive plasmids found in *Enterococcus faecalis* (ca. 10^{-1}

transconjugant/recipient CFU in 24 h), or more modest, as observed with the broad-host-range enterococcal plasmids such as pAMß1 one (10^{-7} to 10^{-6} transconjugants/recipient CFU in 24 h) (32). Having entered into a new genus on broad-host-range plasmids, resistance determinants can readily transfer onto more frequently transferable plasmids to increase their movement through the new genus. In the first case of true vancomycin-resistant *S. aureus* described in the literature, it appears that vancomycin resistance transposon Tn*1546* entered into *S. aureus* from *E. faecalis* on a broad-host-range plasmid and then transposed into a conjugative plasmid native to the staphylococcus (79, 268). Plasmids may also integrate into the chromosomes of the recipient strains, potentially increasing the stability of the genetic information they carry.

Bacteria also take advantage of bacterial viruses (bacteriophages) for genetic exchange. These discreet packages deliver to uninfected cells quantities of DNA approximating the sizes of their genomes (in most cases roughly 40 kb). Designed to incorporate their own genomes into the manufactured phage head, they sometimes incorporate bits of chromosomal DNA adjacent to the phage integration site (specialized transduction) and other times incorporate an appropriately sized plasmid or chromosomal DNA segment unrelated to the integrated phage genome (generalized transduction). Since the staphylococcal ß-lactamase gene is frequently identified on nonconjugative plasmids of approximately 35 to 40 kb and since bacteriophages in staphylococci have been well described for decades, it has been speculated that the high prevalence of β-lactamase production in staphylococci has resulted from the bacteriophage-mediated transfer of these plasmids. Bacteriophages have also been implicated in the transfer of virulence determinants (71).

Nonreplicative mobile elements known as transposons have also been implicated in the transfer of resistance genes (204). Transposons encode their own ability to transfer between replicons (autonomously replicating DNA segments). In some cases, the transposons themselves encode conjugation functions, which allow them to transfer from bacterial chromosome to bacterial chromosome. The best characterized of these conjugative transposons is Tn*916,* an 18-kb element originally identified in *E. faecalis* but which has a very broad host range (205). Tn*916* encodes resistance to tetracycline and minocycline through the *tet*(M) resistance gene. Many different Tn*916*-like transposons have now been identified in enterococci and beyond, and some of them, such as Tn*1545* from *S. pneumoniae,* possess additional resistance genes (conferring resistance to erythromycin and kanamycin) (205). Some investigators have suggested that the conjugation events associated with Tn*916*-like transposons are akin to cell fusion events, in which portions of the genome distinct from those adjacent to the inserted transposon can exchange via homologous recombination (249). Transposons with structural similarity to Tn*916* have been implicated in the transfer of vancomycin resistance between *E. faecium* strains (37).

Transposons lacking conjugative functions may also transfer between strains. The most common mechanism through which this transfer is presumed to occur is either transient or more permanent integration into transferable plasmids. Among the more common classes of nonconjugative transposons are the Tn*3* family of elements (including Tn*917* conferring erythromycin resistance, and Tn*1546,* conferring VanA-type vancomycin resistance) (11, 223) and the composite elements formed by mobile IS elements flanking resistance genes (including Tn*4001*, conferring high-level gentamicin resistance in many gram-positive species) (81).

The precise origin of resistance genes is often difficult to discern, but in some cases it is at least possible to determine that acquired resistance determinants originated in other genera. The VanB-type vancomycin resistance gene in enterococci, for example, has a G+C content of nearly 50% (67). The enterococcal genome, in contrast, has an approximately 35 to 38% G+C content. These differences virtually confirm the origin of the *vanB* determinant in a genus other than *Enterococcus.* The likely origin appears to be streptomycetes, probably species that manufacture glycopeptide antibiotics, with entry into enterococci facilitated by the incorporation of these resistance operons into transposons.

It is worth noting at this point that any concept of the bacterial genome as a fixed entity is untenable. Comparisons of *E. coli* genomes reveal striking differences between enteropathogenic and uropathogenic strains, with the different regions constituting "pathogenicity islands" that confer specific virulence traits that give the strains their clinical profiles (95, 270). Data emanating from a comparative study of 36 *S. aureus* genomes indicate that 22% of the genome is dispensable, with many of the variable regions constituting presumed pathogenicity islands and regions of antimicrobial resistance (78). Finally, it is estimated that 25% of the genome of *E. faecalis* strain V583 was acquired from outside the genus (183).

Mutation of Acquired Genes

As bacteria have responded to the challenge of antimicrobial agents, so have we responded to the challenge of antibiotic resistance. Our typical response to the appearance of antimicrobial resistance has been a concerted effort to develop novel antimicrobial agents that will be active against resistant strains. The emergence of β-lactamase-mediated resistance to antibiotics is an instructive example of this interplay. Ampicillin was developed as the first penicillin with clinically significant activity against gram-negative rods, primarily *E. coli.* Within a few years of the clinical introduction of ampicillin, strains of *E. coli* were described that were resistant to this antibiotic by virtue of production of a plasmid-mediated β-lactamase designated TEM (named after the patient from whom the resistant strain was isolated). *S. aureus* expressed a similar β-lactamase, prompting a concerted effort on the part of the pharmaceutical industry to develop β-lactam antibiotics resistant to hydrolysis. Among the more successful compounds that were developed were methicillin, with activity against β-lactamase-producing *S. aureus;* the cephalosporins and carbapenems, with widespread activity against many β-lactamase-producing species; and the β-lactamase inhibitors, which restored the activity of β-lactams susceptible to hydrolysis.

The most successful and widely developed class of β-lactamase-resistant β-lactam antibiotics is the cephalosporins. So many of these agents have been developed for clinical use that they were frequently lumped into "generations" to facilitate remembrance of their spectra of activity. The extended-spectrum (previously referred to as third-generation), cephalosporins cefotaxime, ceftizoxime, ceftriaxone, and ceftazidime are particularly potent antibiotics that are resistant to hydrolysis by the original TEM enzyme. Unfortunately, increasing clinical use of these agents, particularly ceftazidime, has been associated with the emergence of resistant gram-negative rods, particularly *K. pneumoniae* (114). Molecular analysis of these resistant strains revealed that the resistance is mediated by β-lactamases and that

many of these β-lactamases are derived from the native TEM enzyme through one or more point mutations in the bla_{TEM} gene.

Biochemical Mechanisms of Resistance

Modification of the Antibiotic

Many antibiotic-modifying enzymes have been described previously, including the β-lactamases, the AMEs, and chloramphenicol acetyltransferases (CATs). Although these enzymes are in many cases acquired, some are intrinsic to certain genera. For example, chromosomally encoded β-lactamases are intrinsic to almost all gram-negative rods. Expression of these enzymes is often only at very low levels, conferring resistance to only very susceptible β-lactams, as in the case of *K. pneumoniae* resistance to ampicillin through expression of the chromosomally expressed SHV-1 enzyme (208), or to no β-lactams at all, as in the case of wild-type *E. coli* strains. In some bacterial genera (notably *Enterobacter* and *Pseudomonas*), chromosomally expressed β-lactamases are under regulatory control, with derangements in these regulatory mechanisms resulting in high-level, broad-spectrum β-lactam resistance (112). In some instances, AMEs are intrinsic to bacterial species as well, as in the cases of the chromosomally expressed acetyltransferases of *Providencia stuartii* and *Serratia marcescens* (203, 224).

Modifying enzymes in general confer high levels of resistance to the antibiotics against which they have activity. Expression of the TEM-1 β-lactamase by *E. coli,* for example, can increase the MIC of ampicillin from 8 to >10,000 μg/ml. Similarly, expression of the bifunctional aminoglycoside resistance enzyme in *E. faecalis* raises the MIC of gentamicin from 32 to 64 μg/ml to >2,000 μg/ml. As effective as these mechanisms are, however, some antibiotics appear to be immune to inactivating enzymes. Vancomycin has been in clinical use since 1958, yet there are still no examples of vancomycin-modifying enzymes in bacteria.

Modification of the Target Molecule

Since antibiotic interaction with target molecules is generally quite specific, minor alterations of the target molecule can have important effects on antibiotic binding. Numerous examples exist of antibiotic target modification as a mechanism of resistance, including the many erythromycin ribosomal methylases that confer resistance to the macrolide-lincosamide-streptogramin B classes of antibiotics (269). Modifications of PBPs can affect the affinities of these molecules for β-lactam antibiotics, as noted above for *S. pneumoniae,* and especially for ampicillin-resistant *E. faecium* through mutations in PBP5 (92, 209). Modification of PBPs seems to be a favored mechanism of β-lactam resistance in gram-positive bacteria, whereas β-lactamase production is favored in gram-negative rods. Although the reason for this difference is unknown, it is interesting that β-lactamases produced by gram-positive bacteria diffuse into the external medium once produced whereas those produced by gram-negative rods are kept within the periplasmic space by the outer membrane. The ability to concentrate β-lactamases enhances their efficacy and may help explain the preference for this mechanism among gram-negative rods.

Other important examples of target modifications include the altered cell wall precursors that confer resistance to glycopeptide antibiotics; mutated DNA gyrase and topoisomerase IV, conferring resistance to fluoroquinolone antimicrobial agents; ribosomal protection mechanisms conferring resistance to tetracyclines; and RNA polymerase mutations conferring resistance to rifampin. The degree of resistance conferred by target modifications is variable and may be dependent upon the ability of the mutated target to perform its normal function. Mutations in PBPs of *S. pneumoniae,* for example, confer a relatively low level of resistance (although one that is significant in the treatment of meningitis) (92), whereas VanA-type vancomycin resistance mutations confer a very high level of resistance to vancomycin on enterococci (12).

Restricted Access to the Target

It is axiomatic that an antibiotic must reach its target in order to be effective. Therefore, for targets for which barriers must be crossed by the antibiotic, strengthening of these barriers can be a highly effective mechanism of resistance. All gram-negative bacteria have an outer membrane that must be traversed before the cytoplasmic membrane can be reached. Reductions in the quantities of known or presumed porins (channels for movement of materials across the outer membrane) have been documented as important contributors to resistance to imipenem in *P. aeruginosa*, cefepime in *Enterobacter cloacae*, and cefoxitin and ceftazidime in *K. pneumoniae* (129, 134, 145). In most instances, this restricted entry must be in combination with the production of an at least moderately active β-lactamase to confer high-level resistance. Barriers to entry can also exist in the cytoplasmic membrane. Movement of aminoglycosides across the cytoplasmic membrane is an oxygen-dependent process, so these antibiotics are inactive in anaerobic environments (and hence against strictly anaerobic species) (127).

Efflux Pumps

Among the most active areas of research in antimicrobial resistance is the identification and characterization of pumps that efflux one or more antibiotic classes from the bacterial cell. Several classes of pumps in gram-positive and/or gram-negative bacteria have been described previously. The pumps may be quite selective, or they may have broad substrate specificities. The majority of these pumps are located in the cytoplasmic membrane and use proton motive force to drive drug efflux. The major families of efflux transporters are (i) the major facilitator superfamily, which includes QacA and NorA/Bmr of gram-positive bacteria and EmrB of *E. coli;* (ii) the small multidrug-resistance family, including Smr of *S. aureus* and EmrE of *E. coli;* and (iii) the resistance-nodulation-cell division (RND) family, including AcrAB-TolC of *E. coli* and MexAB-OprM of *P. aeruginosa.* The structure of the AcrAB-TolC RND-type efflux pump is shown in Fig. 2. Deciphering the crystal structure of this pump was a major achievement (157). Among other things, it revealed that there is a periplasmic opening in the pump that can allow passage of molecules, explaining the previously confusing observation that RND pumps include β-lactam antibiotics (which do not enter the cytoplasm) among their substrates. In some instances, combinations of different types of pumps can result in higher levels of resistance than are achieved by the activity of a single pump alone (128).

Attribution of resistance to a specific mechanism may be difficult when more than one mechanism is involved. For example, resistance to imipenem in *P. aeruginosa* is contributed to by reduced access (through down-regulation of OmpD2) and production of AmpC β-lactamase (134). Neither mechanism alone is sufficient to yield clinically significant levels of resistance, yet both are required for high levels of resistance to result.

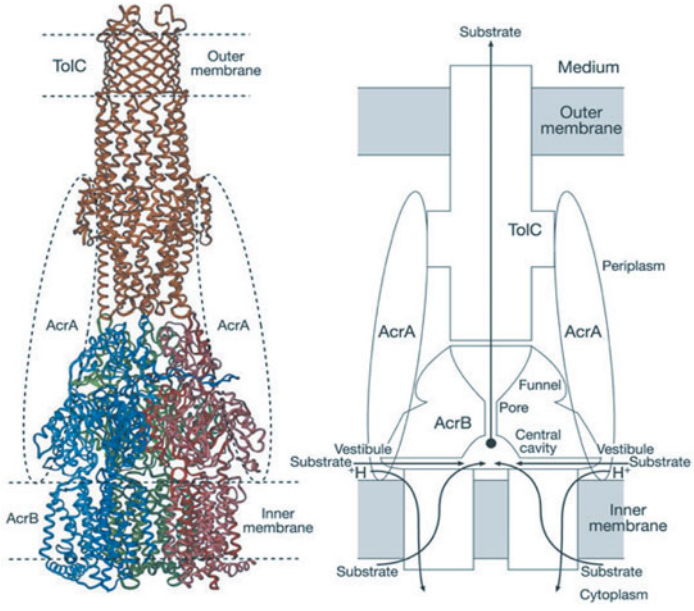

FIGURE 2 Representation of the crystal structure of the AcrAB-TolC three-component resistance nodulation-cell division-multidrug efflux pump. On the left are the three components of the pumps as they link the cytoplasmic (inner) membrane to the outer membrane. The periplasmic linker protein (AcrA) is shown only in outline to allow visualization of the linkage between AcrB and TolC. On the right, an outline of the pump shown at the left is presented, detailing the functional regions of the pump. Reprinted from reference 157 with permission of the publisher.

RESISTANCE MECHANISMS FOR DIFFERENT ANTIMICROBIAL CLASSES

Aminoglycoside Resistance

In explaining resistance to aminoglycosides (amikacin, gentamicin, kanamycin, neomycin, netilmicin, paromomycin, streptomycin, and tobramycin), we will first explain how aminoglycosides reach their targets in bacterial cells and then review their mechanism of action. The clinical indications for aminoglycoside therapy will also be summarized.

The aminoglycosides contain an aminocyclitol ring (streptidine or 2-deoxystrepamine) and two or more amino sugars linked by glycosidic bonds. They are hydrophilic antibiotics whose antimicrobial activity is concentration dependent. They are particularly active against aerobic, gram-negative rods. As a class, these agents have other highly desirable qualities: they are rapidly bactericidal, demonstrate a "postantibiotic" effect, and exhibit predictable pharmacodynamics.

Mechanism of Action of Aminoglycosides

Aminoglycosides have unique effects on protein translation in prokaryotes. These effects may explain why aminoglycosides are bactericidal whereas most other antibiotics that target the ribosome (chloramphenicol, macrolides, and tetracyclines) are bacteriostatic.

First, aminoglycosides penetrate bacteria by three main steps. The positively charged aminoglycosides bind to the negatively charged bacterial cell. Next, in an energy-dependent process driven by the membrane-bound electron transport system present only in aerobic bacteria, a small fraction of the aminoglycosides that are attached to the bacterium are taken into the cell.

Once inside the cell, the principal target of aminoglycoside action is the 30S subunit of the ribosome. The molecular details of aminoglycoside binding to the ribosome are unique. Gentamicin attaches to the highly conserved tRNA acceptor A site of the *E. coli* 16S rRNA (152). This binding prevents the elongation of the growing peptide chain by causing misreading or premature termination of peptide synthesis. By interfering with the translation of mRNA, protein production is altered, aberrant proteins are synthesized and inserted into the cell membrane, cell permeability is increased, more aminoglycosides are taken up into the cell, and cell death ensues.

Mistranslated proteins may also affect the bacterial cell. Paromomycin increases the error rate of protein translation by allowing the incorporation of the wrong tRNAs (the missense substitution rate of amino acids at specified positions in proteins is 1 in 3,000). Spectinomycin, a nonaminoglycoside aminocyclitol, inhibits translocation of the peptidyl-tRNA from the A site to the P site. Streptomycin also makes the ribosome error prone by allowing the binding of different tRNAs (39). Resistance to aminoglycosides can occur through four mechanisms: (i) loss of cell permeability (decreased uptake); (ii) alterations in the ribosome that prevent binding; (iii) expulsion by efflux pumps; and (iv) enzymatic inactivation by AMEs.

Resistance Due to Decreased Uptake and Altered Electrical Potential, Divalent Cations, and Efflux

It is well known that bacterial respiration generates an electrical potential across the membrane. Hence, anaerobes and facultative anaerobes (e.g., enterococci and certain small-colony variants of staphylococci) do not allow movement of aminoglycosides across their cell membranes. This

intrinsic resistance confers low-level cross-resistance to all aminoglycosides.

Studies of *P. aeruginosa* and *E. coli* indicate that movement across the outer membrane may be due to a self-promoted uptake mechanism. The cationic aminoglycosides displace divalent cations (e.g., Mg^{2+}) that bridge adjacent lipopolysaccharide molecules, thereby permeabilizing the outer membrane and allowing the entry of aminoglycosides (118). Consistent with this model, divalent cations have long been known to antagonize the activity of aminoglycosides against gram-negative bacteria (35).

Recent data indicate that *P. aeruginosa* possesses an inducible RND-type pump (MexXY-OprM) that effluxes aminoglycosides (115, 141). In *E. coli*, aminoglycosides are captured from both the periplasm and the cytoplasm by the AcrD multidrug efflux transporter (2). Evaluating a multidrug-resistant strain, *Acinetobacter baumanii* BM4454, that was resistant to aminoglycosides, Magnet et al. found an RND-type efflux pump (139), and Marchand et al. showed that the pump was under stringent control by a two-component regulatory and sensor system, *ade*RS (142).

Modification of the Ribosome

Bacterial cells have multiple copies of the rRNA genes. Mutations that affect aminoglycoside binding to the ribosome include alterations in ribosomal proteins and 16S rRNA and enzymatic methylation of the rRNA. Ribosomal mutations have been demonstrated to confer resistance to spectinomycin and streptomycin (258) and more recently to other aminoglycosides as well (148). The newly identified 16S rRNA methylases (RmtA, RmtB, and ArmA) in gram-negative rods have been noted as emerging problems (280). The first such novel enzyme was found in *K. pneumoniae* BM4536 and designated *armA* ("aminoglycoside resistance methylase A") (82, 83).

Aminoglycoside-Modifying Enzymes

As that of β-lactamases (see below), inactivation of aminoglycosides by AMEs is the most important mechanism in terms of frequency and level of resistance (15). AMEs are believed to originate from *Actinomycetes* that synthesize these antibiotics (*Streptomyces* and *Micromonospora* spp.). It is also possible that AMEs originated from enzymes involved in normal cellular respiration (housekeeping functions) (202). These enzymes are phosphotransferases (APHs), nucleotidyltransferases or adenyltransferases (ANTs), and acetyltransferases (AACs). AMEs covalently modify specific amino or hydroxyl groups, resulting in aminoglycosides that bind poorly (higher K_ms, lower affinities) to the ribosome. AMEs can be passed from one bacterium to another by mobile genetic elements. These resistance determinants are frequently carried on specialized genetic elements called integrons (225, 273).

Sites of AME modification of aminoglycosides are identified by a standard numbering system. The streptidine or 2-deoxystreptamine nucleus forms the center for the numbering scheme (from 2-deoxystreptamine derive all aminoglycosides except streptomycin and spectinomycin). The first sugar moiety at the 4 position has positions numbered with a single prime (1′ to 6′); the second sugar moiety at the 6 position gets positions numbered with a double prime (1″ to 6″). Hence, AAC(6′) acetylates an amino group at the 6′ position (via an acetyltransferase) on the amino sugar attached to the 4 position (Fig. 3). Each AME class consists of numerous enzymes that can modify different OH or NH_2 groups. These classes are divided into subclasses. In each subclass, there are different enzyme types that are designated by a roman numeral, e.g., AAC(3)-I. Isoenzymes are also described and are designated by a lowercase letter "a" or "b," etc. These isoenzymes are functionally identical and confer identical resistance phenotypes.

Currently, there are seven major phosphotransferases [APH(3′), APH(2″), APH(3″), APH(6), APH(9), APH(4), and APH(7″)], four nucleotidyltransferases [ANT(6), ANT(3″), ANT(4′), and ANT(2″)], and four acetyltransferases [AAC(2′), AAC(6), AAC(1), and AAC(3)]. A bifunctional AME also exists that is able to acetylate and phosphorylate AAC(6)-APH(2″). This enzyme is found in *Staphylococcus*, *Streptococcus,* and *Enterococcus* species and is responsible for high-level resistance to aminoglycosides (70). The gene *aac(6′)-aph(2″)* that encodes the synthesis of this enzyme is present on Tn*4001*-like transposons which are inserted both into plasmids and into the chromosomes of aminoglycoside-resistant isolates. Most health care-associated MRSA strains express this enzyme.

Resistance to β-Lactam Antibiotics

Penicillin-Binding Protein-Mediated Resistance

β-Lactam antibiotics act by inhibiting the PBPs, the transpeptidases that manufacture peptidoglycan. The specific functions of different PBPs have been identified for some bacteria, but the precise ways in which they interact with one another and with cell wall precursors remain largely a mystery. Some are clearly essential for cell viability (generally the high-molecular-weight transpeptidases and their partner transglycosylases), whereas others appear to be dispensable, with

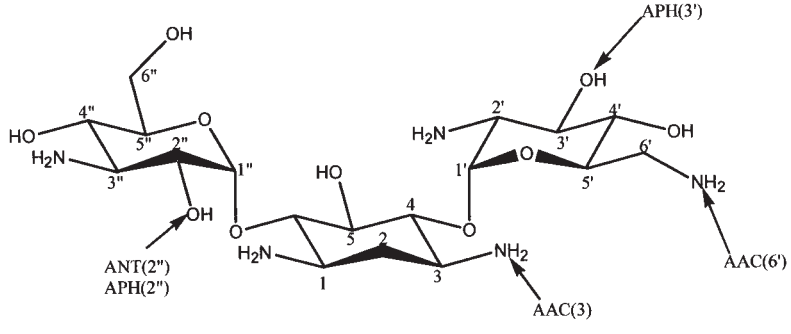

FIGURE 3 Sites of modification on kanamycin B by various AMEs. The arrows point to the sites of modification by the specific enzymes, namely, acetyltransferases, phosphotransferases, and nucleotidyltransferases. Reprinted from reference 125 with permission.

no apparent deleterious effects on cellular structure or function resulting from their absence (most commonly the low-molecular-weight carboxypeptidases). It has long been suspected that some PBPs are redundant and can serve the functions of others. For example, *E. faecium* strains in which all of the PBPs except low-affinity PBP5 are saturated grow normally, implying that PBP5 can perform all of the penicillin-inhibiting functions required for cell wall synthesis (276). On the other hand, *E. faecium* strains in which *pbp5* has been deleted grow normally as well, implying that the other PBPs can provide all of these functions (209).

PBPs are all members of a larger family of serine peptidases that includes most of the β-lactamases. PBPs and β-lactamases interact with β-lactam molecules (which themselves are structural analogues of the peptidyl-D-alanyl-D-alanine termini of peptidoglycan precursors) by catalytically disrupting the β-lactam bond, resulting in a serine-ester-linked acyl-enzyme derivative (Fig. 1). In the case of β-lactamases, a water molecule then hydrolyzes the ester linkage of the acyl-enzyme intermediate, releasing the irreversibly damaged penicilloyl (or cephalosporyl) moiety and regenerating the active enzyme. PBP-β-lactam acyl-enzyme derivatives are in general less accommodating of nucleophilic attack by the water molecule, resulting in persistence of the covalent bond and inactivation of the PBP. The stability of this interaction allows identification of these proteins by binding to radiolabeled penicillin and is the genesis of their designation as "penicillin binding proteins."

Inhibition of PBPs interrupts cell wall synthesis, which by itself should inhibit cell growth rather than kill the cell. However, the interaction of β-lactam molecules with PBPs triggers the activity of cell wall-degrading molecules known as autolysins, which rupture the cell, leading to cell death (248). The extent to which these autolytic enzymes are activated correlates in most cases with the killing activity of a β-lactam against a particular bacterial strain.

Some bacterial species are intrinsically resistant to some β-lactam antibiotics by virtue of decreased PBP affinity. For example, enterococci are resistant to clinically achievable levels of cephalosporin antibiotics because of the presence of low-affinity PBP5. Similar low affinities are demonstrated for the semisynthetic antistaphylococcal penicillins nafcillin and oxacillin, as well as for the antipseudomonal penicillins carbenicillin and ticarcillin. Ampicillin, mezlocillin, and piperacillin bind enterococcal PBP5 with diminished affinity, resulting in MICs that are higher than those for streptococci. These concentrations are within the achievable range in human serum.

PBP-mediated resistance for normally susceptible bacteria takes several forms, including (i) overproduction of a PBP, (ii) acquisition of a foreign PBP with low affinity, (iii) recombination of a susceptible PBP with more resistant varieties, and (iv) generation of point mutations within PBPs that lower affinities for the β-lactam antibiotic.

PBP Overexpression

Increased expression of a PBP as a mechanism of conferring resistance is relatively uncommon. Clear examples of settings in which increased quantities of a PBP are associated with resistance include the increased levels of methicillin resistance found in *S. aureus* strains overexpressing PBP4 (99) and increased levels of penicillin resistance in *E. faecium* strains that overexpress PBP5 (209). The existence of this mechanism serves as a reminder that, like that of β-lactamases, susceptibility or resistance depends on the number of β-lactam molecules relative to the number of targets. Increasing the number of target molecules can, under the correct circumstances, result in resistance. Imipenem's effectiveness against *E. coli* has been partially attributed to the fact that its primary target is PBP2, which is present in roughly 200 copies, in contrast to PBP3, estimated to be present in 2,000 copies.

Acquisition of Foreign PBPs

Acquisition of a foreign PBP as a mechanism of resistance is best exemplified by the expression of methicillin resistance in *S. aureus* strains by virtue of the expression of PBP2a, a low-affinity PBP not native to *S. aureus* (42). Structural analysis of PBP2a suggests that it possesses both transglycosylase and transpeptidase domains. However, it is not clear that the transglycosylase domain is functional. In fact, the transglycosylase domain from PBP2 is required for proper functioning of PBP2a (187). PBP2a confers resistance to all β-lactam antibiotics, although it is bound relatively well by ampicillin (43). The fact that virtually all MRSA strains express β-lactamase limits the utility of ampicillin, but in vitro and animal studies suggest that combinations of ampicillin with β-lactamase inhibitors may be effective (43). To date, there are no clinical data in humans to support using these combinations to treat MRSA infections.

The origin of the *mecA* gene (which encodes PBP2a) is unknown. A *mecA* homologue has been identified in *Staphylococcus sciuri*, a staphylococcal species associated with rodents and primitive mammals (50). The deduced amino acid sequences of the two product enzymes exhibit 88% similarity across the entire proteins and 91% identity within the transpeptidase domain. *Staphylococcus sciuri* strains are not methicillin resistant, however, which may owe to the lack of an effective promoter upstream of the gene (279).

Expression of methicillin resistance in *S. aureus* is commonly under regulatory control, either by the product of the upstream *mecI* gene or *in trans* by the homologous *blaI* gene that regulates the expression of β-lactamase (the promoter regions of *mecA* and the *blaZ* β-lactamase genes are similar) (91). The *mecI* and *blaI* repressors are in turn controlled by the *mecR1* and *blaR1* sensor-transducers, although the precise mechanism of this interaction is incompletely understood. The efficiency of induction varies with the mechanism (*blaR1-blaI*-mediated induction is faster), leading to difficulties in detecting the methicillin resistance phenotype. In fact, only a small minority of a resistant population may express high levels of resistance. Several techniques are used in the laboratory to bring out the resistance (e.g., prolonged incubation or an increase of salt in the media), and more recently techniques have been developed to bypass phenotypic expression in favor of directly identifying the *mecA* gene or directly detecting the PBP2a protein.

Expression of PBP2a-mediated resistance to β-lactams in *S. aureus* is also influenced by the expression of other genetic loci called *fem* ("factors essential for methicillin resistance") or *aux* ("auxiliary") genes (42). *fem* and *aux* genes were first identified by transposon mutagenesis of MRSA to look for insertions that would reduce the expression of resistance. Many *fem* and *aux* factors have now been identified, and all are involved in the formation of the staphylococcal cell wall (42). These data indicate that minor perturbations of the normal processes prevent PBP2a from functioning, suggesting that it has a restricted substrate specificity.

The *mecA* gene is located within a larger (ca. 21 to 67 kb) region of the chromosome known as the staphylococcal cassette chromosome *mec* (SCC*mec*) region (110). It has now been conclusively demonstrated that SCC*mec* is a mobile

element, with mobility conferred by the presence of the *ccrA* and *ccrB* genes. The basic elements of SCC*mec* are the *mecR1-mecI-pbp2a* region and *ccrA* (Fig. 4). In recent community-acquired *S. aureus* isolates, little else is included in the SCC*mec* complex (173). Hence, the SCC*mec* regions in these isolates are relatively small (20 to 30 kb) and the isolates themselves tend to be resistant only to β-lactams. Nosocomial isolates have larger SCC*mec* regions, owing to the accumulation over time of integrated plasmids or transposons that contribute to the multiresistance of these isolates (110). Although the SCC*mec* element has never been shown to be transferable in vitro, compelling data have emerged from the study of clinical isolates indicating that the type IV SCC*mec* element has been recently acquired (72). It is intriguing that these data are being found now that the smaller SCC*mec* elements are more prevalent. Since they fall below the 40 kb typical of the staphylococcal bacteriophage, it is conceivable that SCC*mec* type IV is transferable by transduction. The large sizes of SCC*mec* types I to III preclude this sort of transfer, providing a rationale for the prominence of person-to-person spread of MRSA in the hospital rather than the spread of the resistance determinant from strain to strain. Transfer of the *mec* region between staphylococcal strains has never been conclusively documented. The spread of MRSA within institutions is therefore largely due to the transmission of resistant organisms from patient to patient, probably on the hands of transiently colonized health care workers (228). Single strains have spread through entire hospitals and even cities (211). Recent data indicate that *mecA* stabilities differ among different *S. aureus* clones (119), suggesting one potential explanation for the limited lineages within which the resistance determinant has been found.

Resistance Mutations by Recombination with Foreign DNA

Resistance through recombination between PBPs of native, susceptible species and those of less susceptible species is a phenomenon largely restricted to species that are capable of natural transformation or of taking up of naked DNA from the environment. Prominent among these species are *S. pneumoniae,* viridans group streptococci, *Neisseria gonorrhoeae,* and *Neisseria meningitidis* (92). *S. pneumoniae* contains six PBPs (1a, 1b, 2a, 2b, 2x, and 3), all of which are subject to recombination with foreign PBPs taken up by transformation. In most cases, resistant *pbp*

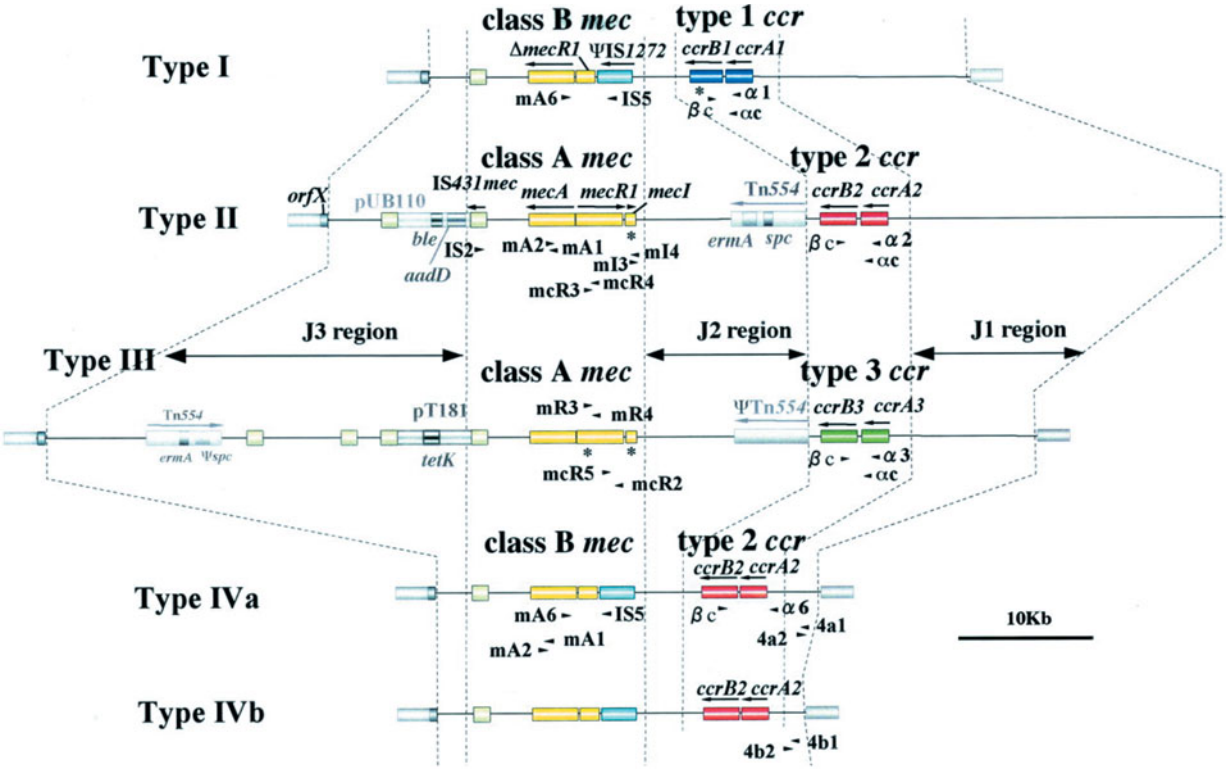

FIGURE 4 Four (of five currently described) SCC*mec* types. Types I, II, and III are found predominantly in health care-associated MRSA, whereas type IV is commonly found in the more susceptible community-associated MRSA around the world. The individual classes of *mec* regions are indicated, as are the variants of the *ccrA* and *ccrB* genes that confer mobility. IS elements and integrated transposons are also indicated. J, or junkyard, regions indicate areas that are not components of the basic SCC*mec*. Antimicrobial resistance genes found within the integrated transposons or plasmids are indicated below the lines, whereas the names of the integrated transposons or plasmids are indicated above the lines. Type V SCC*mec*, recently described, is slightly larger than the type IV elements, reflecting the inclusion of three genes of a putative restriction-modification system. Reprinted from reference 173.

genes demonstrate mosaic patterns (individual segments of foreign *pbp* genes integrated with the native *pbp* gene) with the foreign DNA from the less-penicillin-susceptible viridans group streptococci (92). In fact, genetic exchange appears to be common among these closely related species, with mosaic patterns demonstrable even in PBPs from susceptible *Streptococcus mitis* strains (7). Penicillin resistance in *S. pneumoniae* can be established by alterations in PBP2x, PBP2b, or PBP1a, whereas alterations in PBP2x or PBP1a are required for cephalosporin resistance (17). Penicillin resistance in *S. pneumoniae* has been reported for some time, with cephalosporin resistance emerging more recently, most commonly in strains already resistant to penicillin. However, strains resistant to cephalosporins but susceptible to penicillin have also been reported (234). High-level resistance (≥2 μg/ml) usually implies modification of more than one PBP, sometimes with several mosaic regions in each one (17).

Like that of PBP2a-mediated resistance to methicillin in *S. aureus,* expression of penicillin and cephalosporin resistance in *S. pneumoniae* is dependent on the proper functioning of auxiliary genes. The *fib* locus of *S. pneumoniae (fibA* and *fibB)* is analogous to *femA* and *femB* in *S. aureus*. It is involved in the formation of interpeptide bridges, and inactivation of the *fib* locus is associated with reduction of cross-linked muropeptides and loss of penicillin resistance even in the presence of low-affinity mosaic PBPs (265). The *murM-murN* operon encodes enzymes involved in the biosynthesis of branched, structured cell wall muropeptides commonly found in penicillin-resistant pneumococci (74). Inactivation of *murM-murN* results in the loss of branched-chain muropeptides as well as the loss of penicillin resistance.

Among gram-negative species, *Neisseria* species are well known to be naturally transformable. It is therefore not entirely surprising that strains of both *N. gonorrhoeae* and *N. meningitidis* have been described in which mosaic PBP genes are associated with decreased susceptibility to penicillin (92). Similar to those in *S. pneumoniae*, the resistant portions of the PBP genes have been acquired from closely related commensal *Neisseria* species that are more resistant to penicillin (239). Although penicillin resistance in *N. meningitidis* remains extremely rare, both β-lactamase-mediated resistance and PBP-mediated resistance to β-lactams in *N. gonorrhoeae* are quite common.

Generation of Point Mutations

The final mechanism of PBP-mediated β-lactam resistance is the generation of point mutations within the *pbp* genes that result in lower affinity for the β-lactam in question. This form of mutational resistance is seen most commonly in PBP5 of *E. faecium* strains, raising MICs of penicillin from 4 to 16 μg/ml to as high as >1,000 μg/ml. Strains with high-level penicillin resistance now represent the majority of clinical *E. faecium* isolates in the United States (218). These mutations further reduce the affinities for cephalosporins and other β-lactams with lower affinities for the nonmutated version, leading to an increase in resistance that may have implications for the likelihood that antibiotic use will promote colonization with multiresistant *E. faecium* (57). Most of the mutations occur in the vicinity of one or more of several conserved boxes important for β-lactam binding (216). A systematic study of several common mutations of PBP5 has revealed that resistance increases with an increasing number of mutations, with some loci conferring higher levels of resistance than others (206). Among those in gram-negative species, point mutations of the *ftsI* gene of *Haemophilus influenzae* (encoding the transpeptidase domain[s] of PBP3a and/or PBP3b) have been associated with non-β-lactamase-mediated resistance to ampicillin and cephalosporins (255). Although mutations within PBP4 have also been noted in this species, it is not clear that these have a significant impact on β-lactam susceptibility.

β-Lactamase-Mediated Resistance

Classification of β-Lactamases

Two schemes are currently used to classify β-lactamases: the Ambler classification system and the Bush-Medeiros-Jacoby classification system (6, 33, 34). The Ambler classification separates β-lactamases into four distinct classes based on similarities in amino acid sequences. Classes A, C, and D are serine β-lactamases, whereas class B enzymes are metallo-β-lactamases that require zinc for activity (see above). The Bush-Medeiros-Jacoby scheme classifies β-lactamases according to functional similarities (substrate and inhibitor profiles). There are four categories and multiple subgroups in the Bush-Medeiros-Jacoby system (groups 1, 2, 2a, 2b, 2br, 2d, 2be, 2c, 2f, 3, and 3a, etc.) (34). A comparison of the two classification systems is summarized in Table 2. In the discussions that ensue, we will refer to both classification systems.

TABLE 2 ß-lactamase classification

Bush-Jacoby-Medeiros system	Major subgroups	Ambler system	Main attributes
Group 1 cephalosporinases		C (cephalosporinases)	Usually chromosomal; resistance to all ß-lactams except carbapenems; not inhibited by clavulanate
Group 2 penicillinases (clavulanic acid susceptible)	2a	A (serine ß-lactamases)	Staphylococcal penicillinases
	2b	A	Broad-spectrum: TEM-1, TEM-2, SHV-1
	2be	A	Extended-spectrum: TEM and SHV variants, predominantly
	2br	A	Inhibitor-resistant TEM
	2c	A	Carbenicillin hydrolyzing
	2e	A	Cephalosporinases inhibited by clavulanate
	2f	A	Carbapenemases inhibited by clavulanate
	2d	D (oxacillin hydrolyzing)	Oxacillin-hydrolyzing (OXA)
Group 3 metallo-β-lactamase	3a	B (metalloenzymes)	Zinc-dependent carbapenemases
	3b	B	
	3c	B	
Group 4		Not classified	Miscellaneous enzymes, most not yet sequenced

At the time of this writing, 533 β-lactamases have been reported (Karen Bush, personal communication). These include 64 group 1 chromosomal cephalosporinases and 415 group 2 β-lactamases (these are penicillinases that are usually inhibited by clavulanic acid). The group 2be β-lactamases consist of 213 extended-spectrum β-lactamases (ESBLs). As will be discussed below, ESBLs in gram-negative bacteria confer resistance to ceftazidime and other extended-spectrum cephalosporins and are susceptible to inhibition by clavulanic acid. Twenty-nine inhibitor-resistant β-lactamases (resistant to clavulanic acid inactivation; group 2br) have been found, and 12 carbapenemases have been described previously. There are 45 group 3 enzymes (metallo-β-lactamases), and fewer than a dozen β-lactamases that are still unclassified (group 4).

β-Lactamase Mechanism

β-Lactamases are members of a superfamily of active-site serine proteases (147). The mechanism of hydrolysis of β-lactams by β-lactamases has been best studied with TEM-1. TEM-1 β-lactamase disrupts the amide bond of a β-lactam in a two-step reaction. First, the negatively charged carboxylate group of the β-lactam antibiotic is attracted to the active site by the enzyme's positively charged residues. There, the β-lactam is properly positioned, participating in key hydrogen bonding interactions with the enzyme (122). Next, the β-lactam is acylated (Fig. 1). A conserved serine, Ser70, in the active site of TEM-1 serves as the reactive nucleophile in this acylation reaction. Recent ultrahigh-resolution X-ray crystallography studies of TEM-1 (0.85 Å) indicate that Glu166, acting through the catalytic water, activates Ser70 for nucleophilic attack of the β-lactam ring. Then, a strategically positioned water molecule is activated by a general base (e.g., again Glu166). This water molecule deacylates the β-lactam and regenerates the active β-lactamase. This symmetric mechanism is also supported by the ultrahigh-resolution structure (0.90 Å) of another common class A β-lactamase, SHV-2, found in *K. pneumoniae* (170).

β-Lactamase Processing

Generally speaking, β-lactamases are secreted into the periplasmic space in gram-negative bacteria and into the surrounding medium by gram-positive bacteria. Membrane-associated enzymes (in *Bacillus licheniformis, Bacillus cereus,* and *Bacteroides vulgatus*) have been reported rarely. β-Lactamases are synthesized as precursor proteins. As that in other bacteria, the export of proteins into the periplasmic space is mediated by an amino-terminal signal peptide. After transport, the signal peptide of the β-lactamase is cleaved by a processing enzyme, signal peptidase I.

Genetic Environment of β-Lactamases

β-Lactamases can be chromosome-, plasmid-, or transposon- expressed enzymes that are produced in a constitutive or inducible manner. An increasing number of β-lactamases have been found that are carried on integrons. Integrons are genetic elements of variable lengths that contain a 5′ conserved integrase gene (*int*), mobile antibiotic resistance genes (called cassettes), and an integration site for the gene cassette, *attI* (att, "attachment"). To date, five distinct integron classes have been found to be associated with cassettes that contain antibiotic resistance genes. Three main classes of integrons (classes 1, 2, and 3) have been identified in gram-negative bacteria. Integrons capture antibiotic resistance gene cassettes by using a site-specific recombination mechanism. In the class 1 integrons, the 3′ conserved segment includes two open reading frames of known function: *qacEΔ1,* a deletion derivative of the antiseptic resistance gene *qacE,* and *sul*I, a sulfonamide resistance gene (Fig. 5). As integrons carry multiple resistance determinants and can be readily mobilized, their impact on antibiotic resistance is significant. In the words of Hall and Collis, "integrons thus act both as natural cloning systems and as expression vectors" (93). The capture and spread of antibiotic resistance determinants by integrons underlie the rapid evolution of multiple-antibiotic resistance among diverse gram-negative clinical isolates (213). It should be noted that gene cassettes are mobile and can also exist in free circular form. However, these cassettes do not include all functions required for their mobility. Cassettes are formally part of the integron only when they are integrated at the integron-receptor site. The genes within the cassette do not have promoters.

Integrons are an important source of the spread of *bla* genes. Integrons carrying β-lactamases encompassing Ambler classes A, B, and D have been found in *Acinetobacter baumannii, P. aeruginosa,* and other species of gram-negative bacteria (271). The β-lactamases carried on integrons are VEB-1, VEB-2, GES-1, GES-2, IBI-1, CTX-M-2, CTX-M-9, PSE-1, and numerous OXA β-lactamases (163, 190, 191). OXA and metallo-β-lactamases that confer resistance to carbapenems (IMP-1 to IMP-4 and IMP-8 to IMP-12, VIM-1, VIM-2, and GIM-1) are also included among integron-carried β-lactamases (41, 271).

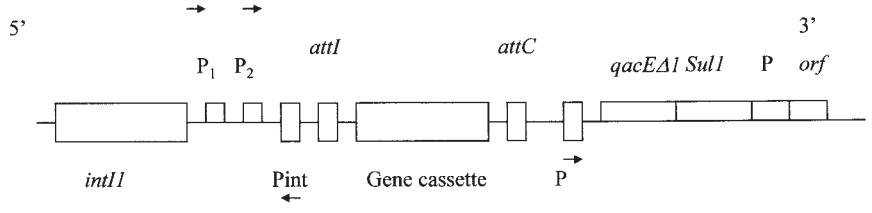

FIGURE 5 Simplified representation of a class 1 integron. P_1, promoter for the gene cassette; P_2, second promoter; Pint, promoter for the integrase; *attI,* integration site; *att*C, sequence in the gene cassette recognized by the integrase; *qacEΔ1,* partially deleted gene that encodes quaternary ammonium compound resistance; *Sul1*, gene for sulfonamide resistance; P, promoter; *orf,* open reading frame. As pictured, integrons contain components of a site-specific recombination system that recognizes and captures mobile gene cassettes. Gene cassettes can be antibiotic resistance genes followed by a repeat sequence called a 59-bp element (59be) or *att*C. Cassette-free integrons exist in which the *int* and *sul* regions are contiguous.

Class A β-Lactamases (Bush Group 2b Penicillinases)

Class A β-lactamases possess four important structural motifs that create a complex hydrogen bonding network to fix the β-lactam in the substrate binding pocket. Residues Ser70-Xaa-Xaa-Lys73, Ser130-Asp131-Asn132 (SDN loop), and Lys/Arg234-Thr/Ser235-Gly236 define the conserved residues critical for β-lactam binding and hydrolysis (122). The Ω loop (amino acids Arg164 to Asn179) is unique in class A β-lactamases. A highly conserved Glu166 residue that functions as a general base (electron donor) in the catalytic process is located in the Ω loop. The salt bridge formed between Arg164 and Asn179 defines the limits, or neck, of the Ω loop.

The two commonly encountered class A β-lactamases found in *Enterobacteriaceae* are designated TEM-1 and SHV-1. TEM-1 and SHV-1 β-lactamases are primarily penicillinases with diminished activity against cephalosporin substrates. These two families of β-lactamases have received considerable attention over the past two decades since they are the progenitors of the ESBLs and the inhibitor-resistant TEM β-lactamases now common in many hospitals.

Bush group 2be. ESBLs are generally class A β-lactamases that have expanded or changed substrate profiles as a result of amino acid substitutions. Normally, extended-spectrum cephalosporins are very poor substrates for hydrolysis by Bush group 2b enzymes (high K_ms and low k_{cat}s). Extended-spectrum cephalosporins are extremely potent β-lactams. Mutations at critical amino acids expand the spectra of these enzymes and allow the hydrolysis of extended-spectrum cephalosporins (185). In most cases, ESBL mutations render the enzymes more susceptible to inhibition by mechanism-based inactivators (clavulanic acid, sulbactam, and tazobactam). It is unclear why this increased susceptibility occurs. The impact of enteric gram-negative rods possessing ESBLs on the choice of empiric and definitive antimicrobial therapy has been substantial (123, 135, 178, 180, 181).

Among the TEM family enzymes, five amino acid residues appear to be most important for conferring the ESBL phenotype: Gly238 and Ala237 (located on the b3 β-pleated sheet), Arg164 and Asp179 (located on the neck of the Ω loop), and Asp104 (located directly across from G238 and A237 at the opening of the active-site cavity (122, 200). Of note, the replacement of Gly to Ser, Ala, or Asp at the Ambler position 238 is a common mutation in both TEM and SHV ESBLs (http://www.lahey.org/studies/webt.html).

Non-TEM, non-SHV ESBLs. Among the non-TEM, non-SHV ESBLs, the CTX-M β-lactamases are the most prevalent. They can be divided into distinct clusters (see http://www.lahey.org/studies/webt.html). Unlike most (but not all) TEM- and SHV-derived ESBLs, CTX-M β-lactamases hydrolyze cefotaxime and cetriaxone better than they do ceftazidime. It appears that CTX-M enzymes are more readily inhibited by tazobactam than they are by clavulanic acid. The first CTX-M type β-lactamase (MEN-1) was described nearly a decade ago. There are now nearly 60 members of this family.

CTX-M β-lactamases are commonly found in *K. pneumoniae, E. coli,* typhoidal and nontyphoidal *Salmonella, Shigella* spp., *Citrobacter freundii, Enterobacter* spp., and *Serratia marcescens* (121, 126, 179). The chromosome-carried β-lactamase of *Kluyvera ascorbata* is a probable progenitor of some plasmid-carried CTX-M enzymes (121). Other CTX-M β-lactamases may derive from *Kluyvera georgiana* (174). A recent comprehensive review delineates the lineage of many CTX-M enzymes resulting from *Kluyvera* spp. (25). Of note, different genetic elements may be involved in the mobilization of bla_{CTX-M} genes.

Many other clinically important non-TEM, non-SHV ESBLs have been described previously (K1, GES-1, PER-1, PER-2, VEB-1, BES-1, IBI-1, IBI-2, and OXA type) (28, 29, 193).

Structural biology of ESBLs. Important insights have emerged from the study of a number of atomic structures of class A ESBL enzymes. The common theme that emerges is that the active site is selectively remodeled and expanded to accommodate the bulky R1 side chain of extended-spectrum cephalosporin. Although the details of this modification are different for many of the ESBLs, the remodeling comes at a price. Many of these ESBLs are not as catalytically efficient as are the wild-type progenitors against certain substrates. With the expanded substrate spectrum, one uniformly observes decreases in MICs of penicillin and in k_{cat}/K_m ratios. In addition, these enzymes are less stable under proteolysis and heat. The structures of Toho-1, TEM-52, TEM-64, the Gly238Ala ESBL in TEM, SHV-2, and K1 β-lactamases all reveal insights into why expanded-spectrum cephalosporins fit into the active site (45, 108, 109, 170, 175, 229, 251, 264).

Serine carbapenemases of Bush group 2f or class A type. In the past, β-lactamases able to hydrolyze carbapenems were rare. It is regrettable that this is no longer the case. Representatives of these carbapenemases are Sme-1, Sme-2, NMC-A, IMI-1, GES-2, and KPC-1, KPC-2, and KPC-3 (191, 281). Class A carbapenemases hydrolyze imipenem but are not resistant to clavulanic acid inhibition. bla_{NMC-A} and bla_{IMI-1} are chromosomally located genes in *E. cloacae* and are induced by cefoxitin and imipenem (168, 201). bla_{NMC-A} is regulated by a LysR-type regulatory protein (160). It is felt that bla_{IMI-1} is regulated in the same manner (201). bla_{Sme-1} is a chromosomally located gene encoding serine carbapenemase of class A in *E. cloacae* and *Serratia marcescens.*

A notable increase in bacteria expressing class A carbapenamases has occurred in the United States. Numerous studies are revealing that KPC ("*Klebsiella pneumonia* carbapenemase") β-lactamases are becoming endemic in East Coast cities. First found in *K. pneumoniae,* these β-lactamases have been detected in *Salmonella enterica* serotype Cubana, *Klebsiella oxytoca,* and *Enterobacter* spp. strain MS 412 (106, 153, 281, 282). bla_{KPC-1} is located on a nonconjugative plasmid (281), and bla_{KPC-2} in *Salmonella* and *Klebsiella oxytoca* was isolated from conjugative plasmids (153, 282). The plasmid carrying bla_{KPC-3} from New York was also transferable by conjugation (278).

Detection of KPC β-lactamases may be a problem for clinical laboratories because of the positive ESBL confirmation tests (clavulanate-potentiated activities of ceftriaxone, ceftazidime, cefepime, and aztreonam). To improve detection of KPC-expressing *K. pneumoniae*, careful inoculum preparation for broth-based susceptibility methods must be carried out to avoid underinoculation. Investigators in this area have found that resistant isolates are readily detected by agar-based methods but not by broth methods (31). Bratu et al. have also advised that using ertapenem or meropenem will improve detection (31).

Among these serine carbapenemases exists a notable curiosity. bla_{GES-2} is a plasmid-carried β-lactamase gene

found in *P. aeruginosa* (194). bla_{GES-2} is a point mutation mutant of the clavulanic acid-inhibited ESBL gene bla_{GES-1} (a non-TEM, non-SHV ESBL gene). It is curious that GES-1 is an ESBL and that a single point mutation (Gly → Asp at position 170 in the Ω loop) can add an imipenemase activity to GES-2. The OXA carbapenemases will be discussed subsequently.

Inhibitor-resistant class A β-lactamases: Bush group 2br. Amino acid mutations within TEM and SHV that confer resistance to inhibition by β-lactamase inhibitors have also been characterized at the following amino acid positions: Met69, Ser130, Arg244, Arg275, and Asn276 (26, 56, 68, 196, 220, 242, 247, 257, 260). Most inhibitor-resistant β-lactamases are variants of the TEM-1 enzyme, with only two descriptions of clinical isolates expressing SHV β-lactamases that are resistant to inhibitors (SHV-10 and SHV-49) known at the time of this writing (59, 196). It is possible that the frequency of inhibitor-resistant β-lactamases in TEM and SHV family enzymes is underestimated, since many laboratories in the United States do not identify the corresponding strains routinely (120). Cephalosporins or high-dose piperacillin-tazobactam may be effective for the treatment of infection with *E. coli* strains expressing some inhibitor-resistant β-lactamases.

Mutants of TEM β-lactamases are being recovered that maintain the ESBL phenotype but also demonstrate inhibitor resistance. These are referred to as complex mutants of TEM (CMTs). There are now four identified CMTs (73, 164, 192, 232). It is still unknown how these enzymes will impact empirical treatment. At this time, clinical microbiology laboratories do not have the resources to detect such complex phenotypes.

Class B β-Lactamases (Bush Group 3 Enzymes)

In contrast to the serine-dependent β-lactamases (those of classes A, C, and D), class B β-lactamases are metalloenzymes. These enzymes contain an αββα motif with a central β sandwich and two α helices on each side. As such, class B β-lactamases require zinc or another heavy metal for catalysis and their activities are inhibited by chelating agents (EDTA). The zinc atom is held in place by three histidines and a water molecule. Some metallo-β-lactamases contain a second Zn binding site. These two sites function separately, with the primary Zn binding site assisted by the secondary site. A coordinated water molecule also serves a critical role in catalysis (263).

With few exceptions (see below), class B β-lactamases confer resistance to a wide range of β-lactam compounds, including cephamycins and carbapenems. The class B β-lactamases are resistant to inactivation by clavulanate, sulbactam, and tazobactam. Aztreonam, a monobactam, may act as an inhibitor, but there are metallo-β-lactamases that hydrolyze aztreonam. Of note, isolates expressing VIM-2 can be susceptible to aztreonam (189).

Class B β-lactamases can be grouped into three different subclasses (B1, B2, and B3). Amino acid positions can be assigned according to a specific numbering system, designated BBL, that is based upon structural alignment (84). Although the genes encoding metallo-β-lactamases show very little primary structure sequence identity (17 to 37%), the three-dimensional structures of the known metallo-β-lactamases appear similar (36, 48, 238, 256).

Because of the metal ion, the catalytic pathway for metallo-β-lactamases does not involve an acyl-enzyme intermediate as it does for class A and C β-lactamases. The catalytic pathway for class B also incorporates a hydrolytic water molecule (the bridging water molecule) that possesses enhanced nucleophilicity due to the proximity to the metal ion. The zinc ions coordinate two water molecules. The addition of the hydroxide to the carbonyl carbon of the β-lactam leads to the formation of a transient, noncovalent reaction intermediate.

The majority of metallo-β-lactamases are chromosomally encoded, and their expression may be constitutive or inducible. The metallo-β-lactamases of *Bacillus cereus, Stenotrophomonas maltophilia, Aeromonas hydrophilia,* and *Aeromonas jandaei* are inducible. In *Aeromonas jandaei,* regulation of the metallo-β-lactamase appears to involve two-component-signal transduction systems (4).

The metallo-β-lactamases of the VIM and IMP types are becoming increasingly important as threats to our antimicrobial armamentarium. These metallo-β-lactamases are broad-spectrum enzymes, are active against most β-lactams, including carbapenems, and have been found in various gram-negative clinical isolates mostly in the Far East and the Mediterranean regions. bla_{VIM} is an integron-borne metallo-β-lactamase gene that is usually found in *P. aeruginosa* isolates. bla_{VIM-2} has now spread to more than 20 countries. The majority of metallo-β-lactamase genes are mobilized on integrons, transposons, and mobile common regions (263). At the time of this writing, there are 13 VIM and 18 IMP types identified. Like VIM metallo-β-lactamase genes, IMP metallo-β-lactamase genes are widespread. IMP metallo-β-lactamase genes have been found as parts of integrons in the following bacteria: *P. aeruginosa, Pseudomonas putida, Serratia marcescens, Pseudomonas stutzeri, Acinetobacter baumannii, Pseudomonas fluorescens, K. pneumoniae, Klebsiella oxytoca, Enterobacter aerogenes, Achromobacter xylosoxidans,* and *E. coli* (263).

As stated above, the atomic structures of a number of class B β-lactamases have been solved (36, 48, 84, 85). The structures are being used to design novel inhibitors of class B β-lactamases.

Class C β-Lactamases

Ambler class C (Bush-Jacoby-Medeiros group 1) chromosomally encoded β-lactamases are produced to a greater or lesser degree by almost all gram-negative bacteria (*Salmonella* and *Klebsiella* being the only known exceptions). Chromosomally encoded (and inducible) enzymes are particularly important in clinical isolates of *Citrobacter freundii, Enterobacter aerogenes, E. cloacae, Morganella morganii, P. aeruginosa,* and *Serratia marcescens.* Although class C β-lactamases hydrolyze cephalosporins (including extended-spectrum cephalosporins) more effectively than they do penicillins, it should be kept in mind that these enzymes have great efficiencies for the hydrolysis of penicillins (the K_ms are very low). Most class C enzymes are resistant to inhibition by clavulanate, sulbactam, and tazobactam.

Class C β-lactamases have larger active-site cavities than class A enzymes, which may allow them to bind the bulky extended-spectrum cephalosporins (oxyimino-β-lactams) (51, 136). It is claimed that this conformational expansion and flexibility facilitate hydrolysis of oxyimino-β-lactams by making the acyl-enzyme intermediate more open to attack by water (51, 136, 151).

The important structural elements described for class A enzymes are also present in class C β-lactamases. The active-site serine (Ser64) is located near the N terminus of a long helix and is followed on the next helix turn by a lysine (Ser64-Xaa-Xaa-Lys67). The second element contains a Tyr-Xaa-Asn (Tyr150) or Ser-Xaa-Asn pattern corresponding to the Ser130-Asp131-Asn132 loop of class A β-lactamases.

The opposite side of the active site is marked by Lys315/Arg/His-Thr/Ser-Gly corresponding to the KTG motif of class A enzymes.

Class C cephalosporinases acylate β-lactams in the same manner that class A enzymes do. First, the catalytic Ser64 attacks the β-lactam carbonyl carbon and the acyl-enzyme forms. The approaches of the activated water molecule are different between AmpC and class A enzymes (for class C, the approach is from the β-face). This difference implies that the deacylation mechanism is distinct. Unlike that of class A enzymes, the ring amine of the acyl-enzyme of class C facilitates deacylation. This substrate-assisted catalysis distinguishes class C from class A. In examination of the catalytic mechanism, a Glu166 equivalent in class C β-lactamases is not readily apparent; this role may be filled by the tyrosine (Tyr150) in the Tyr-Xaa-Asn motif.

The first class C β-lactamase structure determined was that of the AmpC cephalosporinase of *Citrobacter freundii* by Oefner et al. (171). Determination of the structures of the P99 β-lactamase of *E. cloacae,* AmpC β-lactamase from *E. coli,* and *E. cloacae* GC1 and *E. cloacae* 908R β-lactamases has ensued (51, 137; http://www.rcsb.org). The GC1 β-lactamase of *E. cloacae* has improved hydrolytic activity for oxyimino-β-lactam antibiotics because of a tripeptide insertion in the Ω loop (tandem repeat Ala211-Val212-Arg213). In a strict sense this is a class C ESBL. As a result of this addition, the opening of the active-site binding cavity is wider and the substrate spectrum has expanded (51).

In the clinically important class C enzyme-producing gram-negative rods, β-lactamase production is normally repressed. The details of the repression have been mostly elucidated for *Enterobacter* spp. (111). Repression and activation are closely linked to the processes of cell wall synthesis and breakdown. The molecule that serves as both the repressor and the activator of *amp*C transcription is AmpR, a transcriptional regulator of the LysR family. AmpR is present as a repressor by virtue of its interaction with UDP-MurNac-pentapeptide, a peptidoglycan precursor molecule. In this form AmpR is incapable of activating *amp*C and in fact serves as a repressor of *ampR* expression. In the setting of high concentrations of cell wall breakdown product anhydro-MurNAc-tripeptide (or anhydro-MurNac-pentapeptide), however, UDP-MurNAc-pentapeptide is displaced from its site in AmpR, resulting in the conversion of AmpR into an activator of *amp*C transcription.

Increases in *amp*C expression may result from the action of β-lactam antibiotics, certain of which cause the release of significant quantities of anhydro-MurNAc-tripeptide and/or -pentapeptide from the peptidoglycan. This anhydro-UDP-MurNAc-tripeptide enters the cell through a channel (AmpG) and overwhelms the recycling ability of the cytosolic amidase (AmpD) specific for recycling of muropeptides. Under these circumstances (induction), β-lactamase is produced only as long as the antibiotic is present in the medium.

Constitutive high-level production of AmpC β-lactamase most commonly results from a mutation in the *ampD* gene, reducing the quantity of (or eliminating) AmpD from the cytoplasm. Under these circumstances, a constant high level of anhydro-MurNAc-tripeptide is present in the cytoplasm, and AmpR serves as a constitutive activator of *amp*C transcription. Constitutive production can also result from deletion of *ampR,* but in this circumstance β-lactamase production is generally at a low level.

The widespread dissemination of *amp*C-type β-lactamase genes on transferable plasmids is a continuing challenge. These plasmid-carried AmpC cephalosporinases are separated into four general groups. Group 1 plasmid-carried AmpC cephalosporinases consist of those that originated from the chromosomally encoded AmpC of *Citrobacter freundii* (BIL-1, CMY-2, LAT-1, and LAT-2). Members of group 2 are related to the chromosomally encoded cephalosporinase of *E. cloacae* (MIR-1 and ACT-1); group 3 β-lactamases belong to the AmpC group of *P. aeruginosa* (CMY-1, FOX-1, and MOX-1), and group 4 enzymes belong to the CMY-1 β-lactamases (CMY-1 cluster). Plasmid-mediated class C β-lactamases have been identified in many gram-negative bacteria from all parts of the world. Host strains harboring these enzymes include *K. pneumoniae, Enterobacter aerogenes, S. enterica* serotypes Enteritidis and Senftenberg, *E. coli, Proteus mirabilis, Morganella morganii,* and *Klebsiella oxytoca*. The loss of porin proteins in clinical isolates with plasmid-carried AmpC enzymes may result in resistance to carbapenems (30, 240).

Class D β-Lactamases

The OXA-type (oxacillin-hydrolyzing) β-lactamases have been most commonly identified in *Enterobacteriaceae, Acinetobacter* spp., and *P. aeruginosa* (161). OXA enzymes confer resistance to a wide variety of penicillins. They are only weakly inhibited by clavulanic acid but are inhibited by sodium chloride (NaCl). Overall, the amino acid identities between class D and class A or class C β-lactamases are less than 20%. The frequent location of class D genes on mobile genetic elements (plasmids or integrons) facilitates spread (162, 190, 261).

Several OXA β-lactamases (OXA-11 and OXA-14 to OXA-20) are associated with an ESBL phenotype. These OXA types have been found exclusively in *P. aeruginosa*. A comparison of the crystal structure of the OXA-10 β-lactamase with that of the class C enzyme from *E. cloacae* P99 and that of the class A TEM-1 enzyme from *E. coli* shows that the class D and class A enzymes share a common fold pattern (α helices and β-pleated sheets), although the distributions of secondary-structure elements are different. A remarkable feature is the nearly perfect symmetry of all atoms that constitute the catalytic machinery for acylation (Ser67, Lys70, Ser115, and Lys205 in OXA-10 and Ser70, Lys73, Ser130, and Lys234 in TEM-1). There seems to be an extension of the substrate binding site (tripeptide strand) in OXA-10. The role of the peptide extension is not known. The oxyanion hole is provided by the main-chain nitrogen atoms of Ser67 and Phe208. In class D the same residue (Lys70) is involved in acylation and deacylation (149, 176).

OXA enzymes are assuming greater importance due to the ability of members of this class to hydrolyze carbapenems. The first description of a serine carbapenemase in *Acinetebacter baumannii* was that of ARI-1 (OXA-23) in 1985 (182). Although OXA carbapenemases hydrolyze imipenem inefficiently, their presence in an organism with an active efflux pump or a porin mutation may confer clinically significant levels of resistance (101). It is notable that *Acinetobacter baumannii* isolates possess a chromosomally encoded oxacillinase, OXA-69, that confers very low level imipenem resistance. The OXA-69 gene is ubiquitous in *Acinetobacter baumannii* and is referred to as a housekeeping gene (100).

Resistance to Chloramphenicol

Acetyltransferases

Chloramphenicol is a broad-spectrum antimicrobial agent whose use has waned in recent years due to well-characterized hematologic toxicity and a wealth of less toxic therapeutic options. The most common mechanism of resistance to

chloramphenicol is the elaboration of CATs. A large number of CAT genes have been reported, and these determinants generally confer extremely high levels of resistance on the organisms expressing them. Substantial structural similarities exist among the different CAT variants, although their nucleotide sequences may be quite divergent (159). Relationships among the different CATs have been described in detail in a recent review by Schwarz and colleagues (222). Chloramphenicol contains two hydroxyl groups that are acetylated in a reaction catalyzed by CAT in which acetyl coenzyme A serves as the acyl donor. Initial acetylation occurs at the C-3 hydroxyl group to give 3-acetoxy-chloramphenicol (226). Following nonenzymatic rearrangement into 1-acetoxy-chloramphenicol and reacetylation, the 1,3-diacetoxy-chloramphenicol product is formed. Neither the mono- nor the diacetoxy derivatives are able to bind to the 50S ribosomal subunit and inhibit prokaryotic peptidyltransferase (226).

CATs are generally divided into two types: type A (classical) CATs and type B (xenobiotic) CATs (222). Five structurally similar type A CATs (A, B, C, D, and that expressed by the prototypic plasmid pC194) in *S. aureus* have been described previously (77). The *cat* genes encoding these enzymes are commonly located on small, multicopy plasmids, and expression is inducible through a translational attenuation mechanism (222). *E. faecalis* and *S. pneumoniae* also express inducible CAT genes that are similar to the type D gene of *S. aureus*. Two CAT genes encoding constitutive CAT expression in *Clostridium perfringens* have been described previously. *catP* is generally found within transposon Tn*4451*, whereas *catQ* (nearly identical to *catD* of *Clostridium difficile*) is chromosomal (222).

Three types of type A CATs (I, II, and III) have been identified in gram-negative bacteria. The widely prevalent type I enzymes are distinguished by their ability to bind and inhibit (without acetylation) the activity of fusidic acid (19). These enzymes are frequently found associated with transposon Tn9 or related elements. Type II CATs are notable for their sensitivity to inhibition by thiol-reactive agents and for their association with *H. influenzae* (158). Most knowledge of the structural features of the type A CAT enzymes comes from the study of the type III enzyme, for which the tertiary structure is known at high resolution (159). The structural determinants of binding for each substrate are also known for this enzyme.

Type B (xenobiotic) acetyltransferases (159) are structurally unrelated to classic CATs, and those that have been demonstrated to acetylate chloramphenicol confer only low levels of chloramphenicol resistance even when the genes are present in high copy numbers. Their natural substrate is likely something other than chloramphenicol, explaining their limited ability to acetylate this antibiotic. First described in *Agrobacter tumefaciens,* they have now been identified in a wide range of species (222). Included among this class of agents are the virginiamycin acetyltransferases found in *S. aureus* and *E. faecium* (see "Resistance to Macrolides" below). In fact, although they are members of this class, the *vat* gene products do not confer resistance to chloramphenicol nor have they been demonstrated to be able to acetylate chloramphenicol in vitro (159). They are, however, quite adept at acetylating streptogramins. The crystal structures of two trimeric type B CATs have been determined previously (18, 198).

Decreased Accumulation of Chloramphenicol

It is now well recognized that chloramphenicol serves as a substrate for many of the multidrug-resistance efflux pumps that exist in gram-positive and gram-negative bacteria, including those found in *E. coli, P. aeruginosa, Bacillus subtilis,* and *S. aureus* (165). In addition, there are efflux systems that are specific for chloramphenicol. The first chloramphenicol-specific efflux gene to be described was *cmlA* within the In*4* integron of Tn*1696* (21). *cmlA* encodes an efflux mechanism that uses chloramphenicol but not florfenicol (a chloramphenicol derivative licensed for use in animals in 1996 in the United States for the treatment of bovine respiratory pathogens) as a substrate. Gram-negative bacteria also express efflux genes specific for both chloramphenicol and florfenicol (flo_{Pp} and flo_{St}). These resistance genes are being reported with increasing frequency from animal-derived *E. coli* and *Salmonella* isolates (24, 272). In fact, the chloramphenicol resistance expressed by multiresistant *S. enterica* serotype Typhimurium DT104 is most commonly encoded by flo_{St} (24), emphasizing again the potential negative impact of using similar antimicrobial agents in humans and animals.

Resistance to Glycopeptides

Glycopeptide antibiotics (vancomycin and teicoplanin) inhibit cell wall synthesis by binding to the pentapeptide peptidoglycan precursor molecule as it exits the cytoplasmic membrane. This binding prevents the cross-linking (transpeptidation) of peptidoglycan precursors necessary for the formation of normal, stable cell walls. The large size of the glycopeptide molecules also appears to inhibit the other major peptidoglycan linkage reaction (transglycosylation) by steric hindrance. The specific moiety bound by vancomycin is the terminal D-alanyl-D-alanine of the pentapeptide. The vast majority of bacteria that have been studied have peptidoglycan precursors that are pentapeptides terminating in D-Ala-D-Ala and therefore are theoretically susceptible to vancomycin. However, the large size of the vancomycin molecule exceeds the exclusion limits of the porins in gram-negative-bacterium outer membranes, so vancomycin cannot access the target in these species. Hence, vancomycin is active only against bacteria lacking outer membranes, which are predominantly gram positive.

Acquired resistance to vancomycin in gram-positive bacteria comes in three varieties largely defined by the species in association with which they have been described: (i) altered precursor formation in enterococci, (ii) mutational cell wall changes in staphylococci, and (iii) tolerance in pneumococci. The importance of the first type of resistance is characterized more by its prevalence than by the importance of the species as causes of infection, whereas the other two types of resistance are defined more by the importance of the species involved than by their prevalence.

To date, six varieties of enterococcal glycopeptide resistance have been described (corresponding to VanA through VanE and VanG). Of these, the most clinically important are VanA and VanB (12). VanA and VanB are encoded by similar operons in which three genes (*vanH, vanA,* and *vanX* or $vanH_B$, *vanB,* and $vanX_B$) are required for the expression of resistance (12). Two other genes (*vanY* and *vanZ* or $vanY_B$ and *vanW*) serve to amplify resistance but are not required for its expression (8, 9), and two more genes (*vanS* and *vanR* or $vanS_B$ and $vanR_B$) regulate the transcription of the three essential genes (10, 66). The ultimate purpose of these genes is to alter the structure of the pentapeptide precursor from terminating in D-alanyl-D-alanine to terminating in D-alanine-D-lactate and in so doing to reduce the binding affinity of vancomycin for its target (roughly 1,000 fold). Since the terminal amino acid is cleaved off of the pentapeptide in the

transpeptidation reaction, the final composition of the cell wall is indistinguishable from that in strains lacking the resistance determinant.

VanA enterococci are phenotypically resistant to vancomycin and teicoplanin, whereas VanB strains are resistant to vancomycin but appear to be susceptible to teicoplanin. This susceptibility results from the fact that teicoplanin does not induce expression of resistance (66). Once the VanB operon is expressed, however, resistance to teicoplanin results. Consequently, teicoplanin has been disappointing as a therapy for infections caused by VanB enterococci, since mutations in the VanB regulatory apparatus resulting in either inducibility by teicoplanin or constitutive expression occur readily during therapy (13, 96, 117).

Both VanA and VanB operons are carried by transposons. The VanA operon is found exclusively within transposon Tn*1546*, a 10.4-kb Tn*3* family element that is presumed to disseminate among enterococci by integrating into conjugative plasmids (11). The genes of the VanA operon are highly conserved in their sequences among different strains, but the restriction maps of the operons and of Tn*1546* often differ markedly among clinical strains (53). These differences result from insertions of a variety of IS elements with or without subsequent deletions of parts of the mobile element and have been used by some investigators to establish lineages of strains within defined clinical settings. The VanB operon is most commonly carried on transposons designated Tn*5382* or Tn*1549* (37, 86). It is likely that Tn*5382* and Tn*1549* are identical. These transposons exhibit significant homology to prototype enterococcal conjugative transposon Tn*916*. In contrast to the *vanA* gene, *vanB* has three allelic variants (*vanB1*, *vanB2*, and *vanB3*). The *vanB2* gene is associated with Tn*5382*.

The overwhelming majority of clinical vancomycin-resistant strains are *E. faecium*, a predilection that remains unexplained (218). In the United States, the vast majority of *E. faecium* strains that are resistant to vancomycin also express high levels of resistance to ampicillin, thereby negating the two most effective and reliable antienterococcal agents. In some strains, this linkage is actually physical, with insertion of Tn*5382* immediately downstream of the *pbp5* gene resulting in high-level ampicillin resistance (37). These two determinants transfer between enterococcal chromosomes together through mechanisms that are yet to be determined.

The origins of the vancomycin resistance determinants are obscure, but it is clear from sequence comparisons that they did not develop within the enterococci (see above). Their entry into enterococci, markedly delayed considering that vancomycin was introduced into clinical use in 1958, was likely facilitated by the administration of high concentrations of glycopeptides to mammalian gastrointestinal tracts. In Europe, this exposure occurred largely in the gastrointestinal tracts of food animals that were fed the glycopeptide avoparcin as a growth promoter (266). Evidence is now quite convincing that the animal strains transferred to the European human population through the food chain (237). In the United States, where glycopeptides were never used in animal feeds, the exchange event likely occurred in the gastrointestinal tracts of hospital patients who were given vancomycin orally to treat real or presumed *Clostridium difficile*-associated diarrhea. The U.S. *E. faecium* strains were likely highly adapted to the hospital environment through acquisition of antibiotic resistance and virulence determinants. These differences in origin may explain why vancomycin-resistant infections in European hospitals are quite rare, despite sometimes heavy colonization of the community population, whereas vancomycin-resistant infections in the United States now constitute more than 25% of all enterococcal infections acquired in the hospital, despite no compelling evidence of colonization in the community at all. Emerging data indicate that many of the vancomycin-resistant strains isolated from outbreaks of clinical infection belong to a specific clonal group, suggesting that some vancomycin-resistant *E. faecium* strains are particularly likely to disseminate and cause clinical infections (275). Thankfully, the VanA and VanB operons have remained restricted to *E. faecalis* and *E. faecium*, with few exceptions. Despite in vitro transfer of the VanA determinant to *S. aureus* (167), and at least three instances in which VanA-expressing *S. aureus* isolates have been recovered from clinical samples (41a), vancomycin-resistant *S. aureus* remains exceedingly rare. In all cases, resistance has been conferred by the VanA operon and in one well-characterized case transfer appears to have been facilitated by the presence of Tn*1546* on a broad-host-range plasmid in *E. faecalis*, with transposition of Tn*1546* to a staphylococcal plasmid once entry into the staphylococcus occurred (79, 268).

The VanC operon is intrinsic to the cell wall synthesis machinery of minor enterococcal species *Enterococcus casseliflavus* (including the biotype formerly classified as *Enterococcus flavescens*) and *Enterococcus gallinarum* (60, 262). The peptidoglycan precursor in VanC strains terminates in D-alanine-D-serine, reducing vancomycin affinity about sevenfold and resulting in low levels of resistance. Precursors terminate in D-alanine-D-serine in strains of *E. faecalis* with VanE (76), whereas in VanD-expressing *E. faecium* it terminates in D-alanine-D-lactate. The failure to observe dissemination of VanD may be explained in part by the fact that the VanX equivalent enzyme in *E. faecium* BM4339 appears to be ineffective in an enterococcal background. Resistance is expressed in BM4339 because that strain lacks a functional cellular ligase *(ddl)* gene, eliminating the need for VanX activity to express resistance (40).

Mutational resistance to glycopeptides in *S. aureus* is a rare clinical entity that most commonly takes the form of reduced susceptibility rather than frank resistance. For resistant strains, alternately called vancomycin-intermediate *S. aureus* or GISA (glycopeptide-intermediate *S. aureus*), MICs of vancomycin are in the 4- to 8-μg/ml range (133). However, within these cultures are smaller populations of cells that express higher levels of resistance. Animal studies suggest that the level of resistance expressed by GISA strains will reduce the effectiveness of vancomycin therapy (47).

The exact mechanism of glycopeptide resistance in GISA strains remains incompletely understood (27). One consistent finding is a thickened cell wall with increased numbers of unlinked precursors and abnormal septum formation (52). Consistent with this phenotype is the fact that all clinically isolated GISA strains studied have virtually undetectable quantities of PBP4, a low-molecular-weight PBP associated with peptidoglycan cross-linking (75). Restoration of PBP4 on a high-copy-number plasmid restores cross-linking and vancomycin susceptibility to these strains. Preliminary work suggests that a range of genes may be involved in the expression of vancomycin resistance, that the phenotype may be due to different genetic mutations in different strains, and that vancomycin-resistant mutants may evolve from strains that are hypermutators (14). It has been suggested that vancomycin resistance results from the absorption of most of the vancomycin by the unlinked precursors (false vancomycin targets) before it can arrive at its true target, the peptidoglycan precursors attached to lipid II as they emerge from the

cytoplasmic membrane (104). Further work will be required before we understand the details of vancomycin resistance in these rare but troublesome strains.

Glycopeptide resistance in coagulase-negative species of staphylococci has also been reported. In contrast to that in *S. aureus,* resistance in *Staphylococcus haemolyticus* has been associated with changes in the compositions of the cross-links of the peptidoglycan (20). The mechanism by which this would lead to vancomycin resistance is unknown.

Vancomycin is, in general, a less bactericidal antibiotic than are the β-lactams. Evidence for the importance of this observation can be found in several studies. The bacteremia associated with *S. aureus* endocarditis, for example, takes roughly twice as much time to clear with vancomycin treatment as with treatment with β-lactam oxacillin (131). Recent clinical data also suggest that vancomycin treatment is associated with higher rates of failure and relapse than nafcillin treatment of bacteremia due to methicillin-susceptible *S. aureus* (44). Reports of vancomycin tolerance in *S. pneumoniae* first appeared in 1990 (253). *S. pneumoniae* is the most common cause of bacterial meningitis in most patient populations, and bactericidal therapy is optimal for treatment of this condition. At least one case of presumed recrudescence of meningitis after treatment of a case of vancomycin-tolerant pneumococcal meningitis has been reported (98). Tolerance appears to involve mutations within an operon *(vex123)* encoding an ABC transporter, but the mechanism by which this occurs remains undefined (90). Recent work suggests that tolerance may be more common in clinical pneumococcal isolates than was previously believed, that tolerance is associated with antibiotic resistance, and that vancomycin-tolerant strains are more likely to be tolerant to other classes of antimicrobial agents as well (212). Further work will be required before we understand the true importance of pneumoccocal tolerance for the treatment of clinical infections.

Resistance to Linezolid

The oxazolidinone antibiotic linezolid inhibits bacterial protein synthesis by interacting with the *N*-formylmethionyl-tRNA-ribosome-mRNA ternary complex commonly referred to as the initiation complex (230). Linezolid exerts excellent bacteriostatic activity against a wide range of gram-positive pathogens, including methicillin-resistant staphylococci and multiresistant enterococci. Clinical use of this agent has been associated with the emergence of resistant strains, most commonly after prolonged therapy of infections with difficult-to-eradicate bacteria. Resistance in both *E. faecium* and *S. aureus* has now been described, and there are suggestions that the rate of emergence of resistance in *E. faecium* may be significant. Analysis of linezolid-resistant enterococcal laboratory mutants suggests that resistance is associated with a G2576U (*E. coli* numbering scheme) point mutation in the 23S rRNA, although mutations at other positions may also contribute to resistance (197). A G2576U mutation has been described in resistant clinical isolates of *E. faecium* and in the analogous position of the 23S ribosomal subunit of a resistant *S. aureus* isolate (88, 252). Since the 23S subunit genes exist in multiple copies in different bacteria (four in *E. faecalis* and six in *E. faecium*), it has been suggested that more than one copy of the genes must be mutated to confer resistance. This in fact appears to be the case, with strains having a higher percentage of mutated 23S genes expressing greater levels of resistance (143). Multiple mutated gene copies do not arise independently, however. Once the first gene is mutated, subsequent copies can be mutated through recombination with the resistant gene (138). In this fashion, persistent selective pressure exerted by linezolid can lead to rapid development of high-level (MIC, >128 μg/ml) resistance. Despite this potential and the increasing use of linezolid in clinical settings, rates of resistance to this antimicrobial agent remain very low.

Resistance to Macrolides

Erythromycin (the first macrolide) was initially isolated from *Streptomyces erythreus,* a soil organism found in the Philippines. There are currently four macrolides in common use: erythromycin, clarithromycin, azithromycin, and roxithromycin. Macrolides inhibit protein synthesis in susceptible organisms by binding reversibly to the peptidyl-tRNA binding region of the 50S ribosomal subunit, inhibiting translocation of a newly synthesized peptidyl-tRNA molecule from the acceptor site on the ribosome to the peptidyl (or donor site). Erythromycin does not bind to mammalian ribosomes. Most gram-negative organisms are resistant to erythromycin because entry of erythromycin into the cell is restricted.

Resistance to macrolides occurs through several mechanisms. Among the more important of these mechanisms is methylation of the ribosome, preventing erythromycin binding (269). This methylation is most commonly accomplished by different *erm* ("erythromycin ribosomal methylase") genes. Methylated ribosomes confer resistance to macrolides, the related lincosamides (clindamycin and lincomycin), and streptogramin B (MLS_B resistance). Many *erm* genes have been described previously, such as *erm*(A) and the related *erm*(TR) and *erm*(B) and the related *erm*(AM), and resistance is frequently inducible by macrolides but not by clindamycin ($iMLS_B$). In some strains, *erm*-type resistance is expressed constitutively ($cMLS_B$), resulting in resistance to clindamycin as well.

The second major mechanism of resistance to macrolides is through expression of efflux pumps encoded by *mef* genes (Mef in gram-positive bacteria and AcrAB-TolC in *H. influenzae* and *E. coli*) (284). The efflux pumps confer resistance to the macrolides but not to clindamycin, hence the phenotypic description of this resistance type as M type. *mef* genes have been studied most extensively in *S. pneumoniae* [*mef*(E)] and *Streptococcus pyogenes* [*mef*(A)], but similar genes in a variety of gram-positive genera have been described. The prevalence of *mef*-mediated resistance versus that mediated by MLS_B-type mechanisms in *S. pneumoniae* varies in different parts of the world. Minor mechanisms of resistance to macrolides include esterases that hydrolyze the antibiotics and point mutations within the genes for the 50S ribosomal subunit.

Resistance to Ketolides

Ketolides belong to a new class of semisynthetic 14-membered-ring macrolides, which differ from erythromycin by having a 3-keto group instead of the neutral sugar L-cladinose. Ketolides bind to an additional site on the bacterial ribosome, increasing their binding affinities relative to those of other macrolides (58). Telithromycin, a ketolide, is uniformly and highly active against pneumococci (regardless of their susceptibility or resistance to erythromycin and/or penicillin), erythromycin-susceptible *Streptococcus pyogenes,* and erythromycin-resistant *Streptococcus pyogenes* strains of the M phenotype or the $iMLS_B$ or $cMLS_B$ phenotype [in which resistance is mediated by a methylase encoded by the *erm*(TR) gene] (16). Ketolides are less active against erythromycin-resistant *Streptococcus pyogenes* strains with the $cMLS_B$ phenotype or the $iMLS_A$ subtype [in which resistance is mediated by a methylase encoded by the *erm*(AM) gene],

these strains ranging in phenotypes from the upper limits of susceptibility to resistant. Methicillin-resistant staphylococci, which commonly express a $cMLS_B$ phenotype, are not susceptible to telithromycin (16).

Resistance to Quinupristin-Dalfopristin

Quinupristin-dalfopristin is a mixture of semisynthetic streptogramins A and B licensed in Europe and the United States. A related streptogramin A and B combination, virginiamycin, has been used for years as a growth promoter in animal feed. Resistance to these mixtures can result from resistance to streptogramin A alone, was first described in staphylococci, and was conferred by genes encoding streptogramin A acetyltransferases [*vat*(A), *vat*(B), and *vat*(C)] or ATP binding efflux genes [*vga*(A) and *vga*(B)]. Quinupristin-dalfopristin's excellent activities against *E. faecium* and MRSA make it an attractive alternative for the treatment of multiresistant *E. faecium* and health care-associated infections with methicillin-resistant staphylococci, especially since the combination retains in vitro activity against streptogramin B-resistant strains. Two acetyltransferase-encoding resistance genes have now been described that confer resistance to quinupristin-dalfopristin in *E. faecium* strains—*vat*(D) [previously *sat*(A)] and *vat*(E) [previously *sat*(G)]. In most cases, these resistance genes are found along with an *erm* resistance gene (236), suggesting that resistance to both streptogramin A and B may be necessary to confer clinically significant levels of resistance to quinupristin-dalfopristin in *E. faecium*. The presence of these resistance genes on transferable plasmids suggests that the potential for their spread within the genus is significant. Although quinupristin-dalfopristin remains active against the majority of human *E. faecium* strains, the use of virginiamycin in animal feeds has been associated with high percentages of resistance in isolates derived from animals (97). In many cases, the known mechanisms of resistance to quinupristin-dalfopristin are not present in these isolates (97), indicating that there is still much to be learned about resistance to quinupristin-dalfopristin in *E. faecium.*

Metronidazole Resistance

Metronidazole is a member of the nitroimidazole family of bactericidal antimicrobials. The 5-nitroimidazole molecule is a prodrug whose activation depends upon reduction of the nitro group in the absence of oxygen. An exception to this rule occurs in *Helicobacter pylori,* where the RdxA protein reduces metronidazole in a microaerophilic environment (259). The nitro group of metronidazole accepts a single electron from electron transport proteins (ferredoxins) in bacteria, yielding a toxic radical anion. Metronidazole's activity appears to result in DNA damage and cell death (62). Resistance to metronidazole is rare. Decreased uptake and/or a reduced rate of reduction is believed to be responsible for metronidazole resistance in some cases (61). Five *Bacteroides* genes, *nimA* to *nimE,* have been implicated in resistance to 5-metronidazole antibiotics. Analysis of the NimA-susceptible and -resistant *Bacteroides* strains and recent crystal structure analysis suggest that the enzyme utilizes pyruvate for a two-electron reaction resulting in an amine that prevents the formation of the toxic anion radical (38, 130). Expression of *nim* genes varies depending on the positioning of a variety of IS elements that supply active promoters (235).

Resistance to Nitrofurantoin

The antibiotics nitrofurazone and nitrofurantoin are used in the treatment of genitourinary infections and as topical antibacterial agents. Nitrofurazone is used primarily as a topical antiseptic (89). Nitrofurantoin, 1-[(5-nitrofurfurylidene)amino]hydantoin, is a synthetic antibacterial agent used primarily in the treatment of urinary tract infections. The mechanisms of action of nitrofurazone and nitrofurantoin have not been fully elucidated. Investigators have reported that the ability of nitrofurantoin to kill bacteria correlates with the presence of bacterial nitroreductases which convert nitrofurantoin into highly reactive electrophilic intermediates (150). These intermediates are believed to attack bacterial ribosomal proteins nonspecifically, causing complete inhibition of protein synthesis. In *E. coli,* nitroreductases are type I oxygen-insensitive enzymes encoded by the *nfn*A (*nfs*A) and the *nfn*B (*nfs*B) genes. Strains of bacteria that are resistant to nitrofurantoin have been shown to possess diminished nitroreductase activity (199). Resistance to nitrofurantoin from reduced nitroreductase activity seems to be present in other genera as well.

Resistance to Polymyxin B and Polymyxin E (Colistin)

Clinical and scientific interest in the cationic polypeptides colistin (polymyxin E) and polymyxin B is increasing. Although they were first used in the early 1960s, these agents are now viewed as the last-line therapeutic option for multidrug-resistant gram-negative-bacterium infections. As a chemical class, the polymyxins are polycationic peptide antibiotics isolated from *Bacillus polymyxa* (116). These polypeptide antibiotics exert their bactericidal activity by binding to the gram-negative-bacterium cell membrane and disrupting its permeability, resulting in leakage of intracellular components. They also disrupt bacterial biofilm formation. In mechanistic terms, polymyxin binds to phosphorylated head groups of lipid A. Hence, by disrupting cell membranes, these agents become rapidly bactericidal against certain gram-negative bacteria (244, 254).

Not all gram-negative bacteria are susceptible to polymyxins. Organisms that are resistant to polymyxins have cell walls that prevent access of the drug to the cell membrane. In general, polymyxins are bactericidal against *P. aeruginosa, Acinetobacter* spp., some *Proteus mirabilis* strains, and some strains of *Serratia marcescens*. *Proteus* spp., *Providentia* spp., *Neisseria* spp., and gram-positive bacteria are resistant to polymyxins (244, 254).

Polymyxin-resistant mutants and bacteria exhibit a modified lipopolysaccharide. In *E. coli, S. enterica* serotype Typhimurium, and many other pathogenic gram-negative bacteria, modification of the phosphate groups of lipid A confers resistance to polymyxin and cationic antimicrobial peptides. Lipopolysaccharide modifications that include alteration of the fatty acid content of lipid A, phosphoethanolamine addition to the core and lipid A head groups, and 4-amino-4-deoxy-L-arabinose (Ara4N) addition to the core and lipid A regions have been well studied (254). Recent evidence also implicates the presence of the MtrC-MtrD-MtrE efflux pump and lipid A modification as well as the type IV pilin secretion system to modulate levels of polymyxin resistance in *N. meningitidis* (254).

Concerns exist about the reliability and reproducibility of susceptibility testing methods for polymyxins. A recent article addresses the urgent need for quality control ranges for susceptibility determination (116).

Resistance to Quinolones

The fluoroquinolones are among the most widely used antimicrobial agents in both hospital and community settings.

Quinolone antibiotics all act by directly inhibiting DNA synthesis. Their targets include two type II topoisomerases, DNA gyrase and topoisomerase IV. These two enzymes are structurally related in that both exist as tetramers composed of two different subunits (GyrA and GyrB of DNA gyrase; ParC and ParE of topoisomerase IV). DNA gyrase maintains the negative supercoiling of DNA, whereas topoisomerase IV separates interlocked daughter DNA strands formed during replication, facilitating segregation into daughter cells. Fluoroquinolones bind to the topoisomerase-DNA complexes and disrupt various cellular processes involving DNA (such as those involving the replication fork, transcription of RNA, and DNA helicase) (102, 227, 277). The end result is cellular death through unclear mechanisms.

The affinities of fluoroquinolones for the two targets vary, explaining to some degree the differing potencies of the various agents against different bacterial species. The enzyme for which a particular fluoroquinolone exerts the greatest affinity is referred to as the primary target (5, 23, 177). In general, the primary target of fluoroquinolones in gram-negative bacteria is DNA gyrase, whereas in gram-positive bacteria it is topoisomerase IV.

Alterations in Target Enzymes

The most common mechanism of clinically significant levels of fluoroquinolone resistance is through alterations of the topoisomerase enzymes. These alterations are created by spontaneous mutations that occur within the respective genes. In GyrA and ParC, resistance-associated mutations are often localized to a region in the amino termini of the enzymes that contains the active-site tyrosine that is covalently linked to the broken DNA strand. This 130-bp region of *gyrA* has been referred to as the quinolone resistance-determining region. X-ray crystallographic studies of a fragment of the GyrA enzyme suggest that these mutations are clustered in three dimensions, lending support to the hypothesis that the region constitutes a part of the quinolone binding site (155). Particularly frequent sites for resistance-associated mutations are Ser83 and Asp87 of DNA gyrase and Ser79 and Asp83 of ParC (186).

Experimental data suggest that point mutations occur singly in roughly 1 in 10^6 to 10^9 cells. The level of resistance conferred by a single point mutation in the primary target enzyme depends upon the reduction of enzyme affinity created by the mutation, as well as the affinity of the fluoroquinolone for the secondary target. In this scenario, it is expected that fluoroquinolones exhibiting strong affinity for both target enzymes would be less likely to be associated with the emergence of resistant strains, since the retained activity against the secondary target would be enough to inhibit the bacterium even in the presence of a primary target mutation. Fluoroquinolone-species combinations for which single mutations result in significantly higher MICs (such as ciprofloxacin and *S. aureus* or *P. aeruginosa*) would be expected to readily select out resistant mutants in the clinical setting (and have [49]).

Most highly resistant strains exhibit more than one mutation in both the GyrA and ParC enzymes, a phenomenon that can be reproduced in the laboratory by serial passage of strains on progressively higher concentrations of fluoroquinolones. It is noteworthy in this context that fluoroquinolone resistance conferred by enzyme mutations is essentially class resistance. In other words, the activities of all fluoroquinolones are impacted by mutations that result in resistance. Therefore, while single point mutations that confer resistance to one fluoroquinolone may not result in MICs of another that represent clinical resistance, the MICs of the second fluoroquinolone will inevitably be increased. In the setting of such preexisting mutations, the second fluoroquinolone could then select out an additional mutation that would result in clinically significant levels of resistance. This reasoning has led to the recommendation that the most potent and broadly active fluoroquinolone should always be used first, to prevent the emergence of resistance. The wisdom of this recommendation remains to be tested.

Mutations in GyrB and ParE are far less common than those in their companion subunits and tend to cluster in the middle portion of the subunit (105). A clear understanding of the impact these mutations have on enzyme structure or function will await detailed crystallographic studies of enzyme-fluoroquinolone complexes.

Resistance Due to Decreased Intracellular Accumulation

Fluoroquinolones penetrate the outer membranes of gram-negative bacteria through porins, and so the absence of specific porins can impact the level of susceptibility. However, their ability to diffuse through outer and cytoplasmic membranes is sufficient to retain activity against strains lacking solely porins (166). More important in reducing intracellular accumulation of fluoroquinolones is the expression of multidrug-resistance pumps (186). Several such pumps have been identified in human pathogenic bacteria. Resistance results when the expression of pumps is increased due to mutations within the regulatory genes (285). By themselves, pumps generally confer only a low level of resistance to fluoroquinolones. However, their expression may amplify the level of resistance conferred by point mutations within the topoisomerase genes. By so doing, they may increase the risk that a given fluoroquinolone will select out resistant mutants through single point mutations.

In the past few years, plasmid-mediated and transferable resistance to fluoroquinolones has been recognized in a variety of gram-negative-bacterium species. This resistance is conferred by the product of the *qnr* gene and its homologues (113, 169). The mechanism underlying the resistance is protection of the DNA from quinolone binding (250). In general, only low levels of resistance are conferred by this mechanism, but as with other accessory mechanisms, the presence of Qnr can facilitate the clinical emergence of strains resistant by virtue of point mutations in the topoisomerase genes. The prevalence of this mechanism appears to be increasing, which may be explained partly by the frequent presence of *qnr* within complex *sul*I-type integrons (169).

Resistance to Rifampin

Rifampin is particularly active against gram-positive bacteria and mycobacteria. It acts by inhibiting bacterial DNA-dependent RNA polymerase. Point mutations in the chromosomal *rpoB* gene confer resistance to rifampin (267). The frequency with which these point mutations occur precludes using rifampin as a single agent for the treatment of bacterial infections.

Resistance to Tetracyclines

The tetracyclines are a group of bacteriostatic antibiotics that act by inhibiting attachment of aminoacyl-tRNA to the ribosome acceptor site, thereby preventing elongation of the peptide chains of nascent proteins (221). In order to gain access to the bacterial ribosome, tetracyclines need to enter the cell. In *E. coli* and presumably in other gram-negative bacteria, they enter the periplasmic space through outer membrane porins

OmpC and OmpF, probably chelated to magnesium ions (221). Once in the periplasmic space, the weakly lipophilic tetracycline molecule dissociates from the magnesium ion and crosses into the cell by diffusing through the lipid bilayer in an energy-dependent process. Once inside the cell, tetracycline-ion complexes bind to the ribosome at a single, high affinity binding site on the 30S subunit, blocking access of the aminoacyl-tRNA to the ribosome acceptor site. Although high affinity, binding of tetracycline to the ribosome is reversible (46).

Tetracyclines are broad-spectrum and effective antimicrobial agents. Unfortunately, widespread use of tetracyclines to treat clinical infections and to promote growth in livestock has been associated with the emergence and dissemination of a variety of resistance determinants. As a consequence, the number of infections for which tetracyclines are considered recommended first-line therapy has been limited for many years (217). The vast majority of tetracycline resistance determinants fall into one of two classes: (i) efflux or (ii) ribosomal protection. The designations of the different resistance determinants and their classes can be found in detail in an excellent review of tetracyclines by Chopra and Roberts (46). Initial designations of tetracycline resistance determinants used the prefix *tet* or *otr* with letters (A, for example) designating the different determinants. Since the number of resistance determinants now exceeds the number of letters in the alphabet, a system using numbers has been devised (132).

Tetracycline efflux proteins are all membrane associated and members of the major facilitator superfamily of proteins. They expel tetracycline from the cell by exchanging a proton for a tetracycline-cation complex. In general, the efflux proteins confer resistance to tetracyclines but tend to spare minocycline (46). The single exception to this rule is the gram-negative-bacterium Tet(B) protein that confers resistance to both tetracycline and minocycline. The efflux proteins have been divided into six groups based on amino acid identity. Group 1 consists of Tet efflux proteins that are found primarily in gram-negative species [with the exception of Tet(Z)], whereas group 2 [consisting only of Tet(K) and Tet(L)] is found primarily in gram-positive species. Groups 3 through 6 are small groups consisting of one or two efflux proteins each.

Ribosome protection proteins account for the other major mechanism of tetracycline resistance. These proteins exhibit homology to elongation factors EF-Tu and EF-G and exhibit ribosome-dependent GTPase activity (219). They act by binding to the ribosome, thereby changing its conformation and inhibiting binding of tetracycline. Tet(M) and Tet(O) are the best characterized of these proteins. Ribosome protection proteins are widespread in bacteria, in many cases as a result of the incorporation of the corresponding genes into broad-host-range conjugative transposons.

Both efflux proteins and ribosome protection proteins are regulated in ways such that their expression is increased in the presence of tetracyclines. The gram-negative-bacterium efflux proteins are regulated by repressors that are divergently transcribed relative to the efflux proteins (103). Binding of a repressor to tetracycline changes the conformation of the repressor so that it can no longer bind to the operator region, resulting in increased transcription of both the efflux protein and the repressor genes. The gram-positive-bacterium efflux genes are not associated with specific protein repressors, but sequence analysis suggests that these determinants may be regulated by mechanisms similar to translational attenuation. Study of this area has been limited (241). Transcription of ribosome protection genes is augmented by growth in the presence of tetracycline.

Intrinsic mechanisms of tetracycline resistance exist in many if not all gram-negative bacteria. Among the best characterized of these systems is the *mar* ("multiple antibiotic resistance") operon (3). This locus consists of a repressor (MarR) that represses transcription of *mar*A, which encodes a transcriptional activator of a variety of genes. Overexpression of MarA results in decreased expression of OmpF, a porin through which tetracycline enters the periplasmic space, and increased expression of multidrug efflux pump AcrAB, a member of the resistance-nodulation-cell division family of efflux proteins that includes tetracyclines among its substrates. Several similar pump systems have been identified in *P. aeruginosa* and other gram-negative bacteria (195). As our knowledge of the genomes of different bacterial species becomes more complete, we will no doubt discover several other pump systems that impact levels of susceptibility to tetracyclines and other antibiotics.

The remarkable diversity of species within which tetracycline resistance determinants are found owes much to the inclusion of these resistance genes within broad-host-range transferable genetic elements. These include transferable plasmids in gram-negative species, where *tet* genes may be found included within integrons, and conjugative transposons. Among the best studied of the conjugative transposons is the Tn*916* family, originally described in *E. faecalis* (205). The complete sequence of Tn*916* has been determined and is remarkable for its dearth of restriction enzyme digestion sites [except in the region of the *tet*(M) gene, which appears to be a late arrival to the element] (172). This lack of restriction sites likely facilitates the entry of this transposon into a variety of different bacterial species. Transfer of Tn*916*-like elements from enterococci into many other species has been demonstrated in vitro and in animal models, and the remnants of Tn*916*-like sequences in *N. gonorrhoeae* are impressive testimony to the ability of these elements to travel widely (205). Transfer of Tn*916*-like elements, which is increased after exposure to tetracycline, has also been suggested to facilitate transfer of unlinked genes, further amplifying the risks of overexposure to tetracycline in the environment.

Resistance to Tigecycline

The recent licensing of the glycylcycline tigecycline offers a broad-spectrum antimicrobial alternative for treating infections due to resistant pathogens, including MRSA and ESBL-producing *K. pneumoniae.* Tigecycline's broad spectrum of antimicrobial activity is due to its resistance to the common efflux or ribosome protection mechanisms that confer resistance to older tetracyclines. Some bacterial species, notably *P. aeruginosa* and *Proteus* spp., are intrinsically resistant to tigecycline because they express RND-type efflux pumps that effectively extrude the antibiotic (214). Resistance to tigecycline in other gram-negative species has also been reported, generally resulting from activation of normally repressed AcrAB-type RND efflux pumps (215). Determination of the ultimate importance of these pump activations for clinical resistance to tigecycline will await more extensive clinical use.

Resistance to Trimethoprim-Sulfamethoxazole

Biosynthesis of several amino acids and purines depends upon the availability of tetrahydrofolate. With few exceptions, bacteria are unable to absorb preformed folic acid and hence rely upon their ability to synthesize it. Sulfamethoxazole and trimethoprim are inhibitors of two enzymes (dihydropteroic acid synthase [DHPS] and dihydrofolate reductase [DHFR],

respectively) that act sequentially in the manufacture of tetrahydrofolate. It is thought that the two inhibitors act synergistically to inhibit folate synthesis, although the mechanism for possible synergism (since sequential blockage of a fully inhibited pathway should not augment resistance) is not clear.

Intrinsic Resistance

Trimethoprim-sulfamethoxazole is a remarkably broad spectrum antimicrobial agent. Intrinsic resistance is relatively rare and may occur through decreased access to the target enzymes *(P. aeruginosa)* (245), low affinity for DHFR enzymes (*Neisseria* spp., *Clostridium* spp., *Brucella* spp., *Bacteroides* spp., *Moraxella catarrhalis,* and *Nocardia* spp.) (246) or the ability to absorb exogenous folate (*Enterococcus* spp. and *Lactobacillus* spp.) (283) or thymine (*Enterococcus* spp.) (94). The decreased access to the target enzyme in *P. aeruginosa* appears to be the result of both a permeability barrier and active efflux from the cell (124, 146). The percentage contribution of each of these mechanisms to resistance remains unclear.

Acquired Resistance to Trimethoprim

Mutational resistance to trimethoprim has been described for several species and involves promoter mutations leading to overproduction of DHFR (in *E. coli*), point mutations within the *dhfr* gene leading to resistance (in *S. aureus and S. pneumoniae*) or both mechanisms (in *H. influenzae*) (107). More common is the acquisition of low-affinity-associated *dhfr* genes, of which approximately 20 have been described previously (107). Expression of *dhfr*I and variant *dhfr*II genes, which are most commonly found on plasmids in gram-negative bacteria, increases resistance to levels greatly exceeding clinically achievable concentrations of the drug.

Acquired Resistance to Sulfonamides

Point mutations or small insertions of DNA segments within chromosomal *dhps* genes conferring resistance to sulfonamides have been reported for many different species (65, 107). More extensive changes within *dhps* genes resulting in resistance have been reported for *N. meningitidis* and *Streptococcus pyogenes.* In these instances, the extensive changes have suggested acquisition of at least some parts of the *dhps* genes from other species via transformation and recombination (233, 243). Plasmid-mediated, transferable resistance to sulfonamides has been reported for gram-negative bacteria (107). In contrast to the diversity in *dhfr* genes, only two acquired low-affinity *dhps* genes (*sul*I and *sul*II) have been described. Genes conferring resistance to sulfonamides are frequently incorporated into multiresistance integrons, which are themselves frequently integrated into transferable plasmids. The transferability of these resistance plasmids and the frequent association with other resistance genes explain in part the widespread nature and persistence of resistance to sulfonamides. One trimethoprim-sulfamethoxazole-resistant *E. coli* strain was reported to have spread widely in the United States, causing urinary tract infections in young women in at least two states (140), although more recent data suggest that this widespread prevalence may owe more to the parallel emergence of related strains than to the direct spread of an outbreak isolate (80).

Susceptibility Test Methods: General Considerations

JOHN D. TURNIDGE, MARY JANE FERRARO, AND JAMES H. JORGENSEN

72

Determination of the antimicrobial susceptibilities of significant bacterial isolates is one of the principal functions of the clinical microbiology laboratory. From the physician's pragmatic point of view, the results of susceptibility tests are often considered as important as or more important than the identification of the pathogen involved. This is particularly true in an era of increasing antimicrobial resistance in which treatment options are at times limited to newer, more costly antibacterial agents. As a result, the laboratory must give high priority not only to producing technically accurate data but also to reporting those data to physicians in an easily interpretable manner.

The main objective of susceptibility testing is to predict the outcome of treatment with the antimicrobial agents tested. The implication of the result "susceptible" is that there is a high probability that the patient will respond to treatment with the appropriate dosage regimen for that antimicrobial agent. The result "resistant" implies that treatment with the antimicrobial agent is likely to fail. One group has coined the term "90-60 rule," that is, for many infections we can expect treatment success about 90% of the time when the organism tests as "susceptible" to that treatment and success may still occur in around 60% of cases when the organism tests as "resistant" to the agent used (36). The 60% response rate to ineffective antimicrobials is said to reflect the natural response to many bacterial infections in the immunologically normal host (31).

Most test methods also include an "intermediate" category of susceptibility, which can have several meanings. With agents that can be safely administered at higher doses, this category may imply that higher doses may be required to ensure efficacy or that the agent may prove efficacious if it is normally concentrated in an infected body fluid, e.g., urine. Conversely, for body compartments where drug penetration is restricted even in the presence of inflammation (e.g., subarachnoid space containing cerebrospinal fluid), it suggests that extreme caution should be taken in the use of the agent. It may also represent a buffer zone that prevents strains with borderline susceptibilities from being incorrectly categorized as resistant.

A further aim of susceptibility testing is to guide the clinician in the selection of the most appropriate agent for a particular clinical problem. In most clinical settings, susceptibility test results are usually obtained 24 to 48 h or more after the patient has been given empirical treatment. The test results may confirm the susceptibility of the organism to the drug initially prescribed or may indicate resistance, in which case alternative therapy will likely be required. The report describing the susceptibility testing results should provide the clinician with alternative agents to which the organism is susceptible. These alternatives also may be useful if the patient subsequently develops an adverse reaction to the initial antimicrobial agent. There is a growing emphasis from the professional societies and managed care organizations on the use of susceptibility test results to direct therapy toward the most narrow-spectrum, least expensive agent to which the pathogen should respond. This is particularly true for hospitalized patients, in whom the rate of antimicrobial resistance tends to be higher, and it is easier to make therapeutic changes for inpatients than for outpatients. This makes the accuracy of susceptibility testing even more critical for effective patient care.

The clinical microbiology laboratory should perform susceptibility testing only with pathogens for which well-standardized methods are available and pathogens whose resistance is known or suspected to be a clinical problem; susceptibility testing should not be performed on normal flora or colonizing organisms. Currently, routine susceptibility testing methods are best standardized for the common aerobic and facultative bacteria and systemic antibacterial agents. For some uncommon or fastidious bacteria and for topical antibacterial agents, simple routine test methods have not been standardized. Taking into account this limitation, the Clinical and Laboratory Standards Institute (CLSI; formerly the NCCLS) has recently released recommendations on how some of these bacteria may be tested and the results interpreted (10). With some pathogens (e.g., *Mycobacterium tuberculosis* and invasive fungi), routine testing is important for patient management, but testing is best performed by specialized laboratories in which test volumes are sufficient to maintain technical proficiency and where unusual results are likely to be recognized. Susceptibility testing methods for certain other pathogens (e.g., mycoplasmas, chlamydiae, legionellae, spirochetes, viruses, protozoa, and helminths) may not be well established at present and/or are limited to a few specialty laboratories. A number of choices exist in antibacterial susceptibility testing with respect to methodology and selection of agents for routine testing.

SELECTING AN ANTIMICROBIAL SUSCEPTIBILITY TESTING METHOD

Clinical microbiology laboratories can choose from among several conventional or novel methods for performance of routine antibacterial susceptibility testing. These include the broth microdilution, disk diffusion, antimicrobial gradient, and automated instrument methods. In recent years there has been a trend toward the use of commercial broth microdilution and automated instrument methods instead of the disk diffusion procedure. However, there may be renewed interest in the disk diffusion test because of its inherent flexibility in drug selection, ability to respond quickly to changes in interpretive breakpoints, and low cost. The availability of numerous antibacterial agents and the diversity of antimicrobial agent formularies at different institutions have made it difficult for manufacturers of commercial test systems to provide standard test panels that fit everyone's needs. Thus, the inherent flexibility in drug selection that is provided by the disk diffusion test is an undeniable asset of the method. The test is also one of the most established and best proven of all susceptibility tests and continues to be updated and refined through frequent (usually annual) CLSI publications (12, 13). Furthermore, the qualitative interpretive category results of susceptible, intermediate, and resistant provided by the disk test are readily understood by clinicians. Instrumentation is now available for reading and interpreting inhibition zone diameters, as well as storing this information, and may reduce interobserver reading errors (28, 32).

Advantages of the microdilution and agar gradient diffusion methods include the generation of a quantitative result (i.e., an MIC) rather than a category result, the ability to test accurately some anaerobic or fastidious species that may not be tested by the disk diffusion method (6, 8, 11, 22, 25), and the ancillary benefits of computer systems that accompany many of the microdilution and automated systems (22). Indeed, computerized data management systems are very important in laboratories that may have limited or inflexible laboratory information systems. However, an MIC method should not be chosen on the basis that MICs are routinely more useful to physicians. There is no clear evidence that MICs are more relevant than susceptibility category results to the selection of appropriate antibacterial therapy for most infections (17).

A laboratory may choose to perform rapid, automated antibacterial susceptibility testing in order to generate results faster than manual methods can generate them. The provision of susceptibility results 1 day sooner than that provided by conventional methods seems a logical advance in patient care. Two studies have demonstrated both the clinical and economic benefits derived from the use of rapid susceptibility testing and reporting (2, 19), while a further study has not shown such a benefit (4). However, rapid susceptibility testing results may not have substantial impact unless the laboratory uses more aggressive means of communication to make physicians aware of the results (43). This may be because physicians have come to expect antimicrobial susceptibility testing results approximately 48 h after the submission of a specimen or because the results, although generated more rapidly, are still not available soon enough to assist with the initial selection of antimicrobial therapy.

A previously cited shortcoming of rapid susceptibility testing methods was the failure to detect some inducible or subtle resistance mechanisms (21, 28, 41, 42). However, the instruments most notorious for such problems are no longer marketed and the manufacturers of the remaining instruments have made substantial efforts to correct earlier problems (29, 35, 39, 44) or to extend testing to include fastidious organisms (24). It is important to emphasize that accuracy should not be sacrificed in an effort to generate a rapid susceptibility testing result.

SELECTING ANTIBACTERIAL AGENTS FOR ROUTINE TESTING

The laboratory has the responsibility to test and report on the antimicrobial agents that are most appropriate for the organism isolated, the site of infection, and the clinical practice setting in which the laboratory functions. The battery of antimicrobial agents routinely tested and reported on by the laboratory will depend on the characteristics of the patients under care in the institution and the likelihood of encountering highly resistant organisms (23). A laboratory serving a tertiary-care medical center, which specializes in the care of immunosuppressed patients, may need to test routinely agents that are broader in spectrum than those tested by a laboratory that supports a primary-care outpatient practice in which antibiotic-resistant organisms are less commonly encountered.

When a laboratory's routine susceptibility testing batteries are determined, several principles should be followed. First, the antimicrobial agents that are included in the institution's formulary and that physicians prescribe on a daily basis should be tested. Second, the species tested strongly influences the choice of antimicrobial agents for testing. The CLSI publishes tables that list the antimicrobial agents appropriate for testing against various groups of aerobic and fastidious bacteria (13). The guidelines indicate the drugs that are most appropriate for testing against each organism group and for treatment based upon the specimen source (e.g., cerebrospinal fluid, blood, urine, or feces). The lists also include a few agents that may be tested as surrogates for other agents because of the greater ability of a particular agent to detect resistance to closely related drugs (e.g., the use of the cefoxitin disk test to predict overall β-lactam resistance in staphylococci) (13). This initial list of agents must be tailored to an individual institution's specific needs through discussions with infectious disease physicians, pharmacists, and committees concerned with infection control and the institutional formulary (23).

A third important step in defining routine testing batteries is ascertaining the availability of specific antimicrobial agents for testing by the laboratory's routine testing methodology. Certain methods (e.g., the disk diffusion, gradient diffusion, and in-house-prepared broth and agar dilution methods) allow the greatest flexibility in the selection of test batteries. In contrast, some commercial systems may have less flexibility or delays in adding the latest antimicrobial agents approved for clinical use. However, practicality limits the maximum number of drugs that can be tested simultaneously with an isolate by any susceptibility testing method. For example, a maximum of 12 disks can be placed on a 150-mm-diameter Mueller-Hinton agar plate and a similar number can ordinarily be accommodated in a microdilution panel if full concentration ranges of each agent are to be included for routine determination of MICs. Some commercial test panels attempt to resolve this problem by testing a larger array of antimicrobial agents, although in a very limited concentration range (perhaps two to four dilutions for each agent).

ESTABLISHING SUSCEPTIBILITY BREAKPOINTS

There is general agreement that the MIC is the most basic laboratory measurement of the activity of an antimicrobial agent against an organism. It is defined as the lowest concentration that will inhibit the growth of a test organism over a defined interval related to the organism's growth rate, most commonly 18 to 24 h. The MIC is the fundamental measurement that forms the basis of most susceptibility testing methods and against which the levels of drug achieved in human body fluids may be compared to determine breakpoints for defining susceptibility.

The conventional technique for measuring the MIC involves exposing the test organism to a series of twofold dilutions of the antimicrobial agent in a suitable culture system, e.g., broth or agar for bacteria. The twofold dilution scheme was originally used because of the convenience of preparing dilutions from a single starting concentration in broth or agar dilution methods. Subsequently, this system proved to be meaningful because an antibiotic's MICs for a single bacterial species in the absence of resistance mechanisms have a statistically normal distribution when plotted on a logarithmic scale. This provides investigators with the opportunity to examine the distributions of MICs for bacterial populations and distinguish strains for which MICs are abnormally high (potentially resistant strains) from those for which MICs are normal (susceptible strains) (26).

MIC measurements are influenced in vitro by a number of factors, including the composition of the medium, the size of the inoculum, the duration of incubation, and the presence of resistant subpopulations of the organism. The in vitro test conditions also do not encompass other factors that can have an influence on in vivo antimicrobial activity. These include sub-MIC effects, postantibiotic effects, protein binding, effects on organism virulence or toxin production, variations in redox potential at sites of infection, and the pharmacokinetic changes resulting from different drug levels in blood and at the site of infection over time. Nevertheless, if determined under standardized conditions, MIC measurements provide a fixed reference point for the setting of pharmacodynamic breakpoints with the power to predict efficacy in vivo. Pharmacological breakpoints can be applied directly to routine dilution testing methods that generate MICs, such as broth microdilution, agar dilution, gradient methods, and some automated instruments. They also provide reference values for deriving breakpoints for disk diffusion methods. Breakpoints (or interpretative criteria) are the values that determine the categories of susceptible, intermediate, and resistant. The approach to setting breakpoints varies by organization or regulatory body, but with few exceptions it is based on the agent's MICs. Depending on the approach taken, up to four sources of data can be examined in establishing breakpoints.

MIC Distributions

Examination of MIC distributions can indicate the range of MICs for a population of strains that lack any known mechanisms of resistance to the particular drug. These distributions may aid in the recognition of new resistance mechanisms by highlighting strains for which the MICs fall outside the normal distribution. However, the distributions of MICs have limited direct application since they vary between species, and for some strains for which the MICs are outside the normal range, the MICs may be below clinically derived breakpoints. Such strains may or may not respond to treatment. An example of the latter point is the fact that the penicillin MICs for some β-lactamase-producing organisms and the expanded-spectrum cephalosporin MICs for extended-spectrum β-lactamase-producing gram-negative bacilli may be relatively low but do not translate to reliable clinical efficacy. Indeed, knowledge of the presence of specific resistance mechanisms that inactivate compounds of a particular drug class is very useful in deriving microbiological breakpoints.

Pharmacokinetics and Pharmacodynamics

Pharmacokinetics examines the absorption, distribution, accumulation, and elimination (metabolism and excretion) of a drug in the body over time. These parameters are usually determined with healthy volunteers. A drug's MICs can be compared with the concentration of the drug achievable in blood or other body fluids (e.g., cerebrospinal fluid). In the past, breakpoints were chosen generally such that the MICs for susceptible pathogens would be exceeded by the drug level for most or all of the dosing interval. Newer data now considered when establishing breakpoints include pharmacodynamic calculations. Pharmacodynamics is the study of the time course of drug action against the microorganism. For antimicrobial agents, the desired action is pathogen eradication. In vitro pharmacodynamic studies have revealed that agents fall into three classes: those with principally time-dependent antimicrobial action and no or short postantibiotic effects, those with time-dependent action and long postantibiotic effects, and those with prominent concentration-dependent action (17). For drugs with time-dependent action and no or short postantibiotic effects, the critical determinant of bacterial killing in vivo is the percentage of time in a dosing interval that the drug concentration is above the MIC. For the other two classes, the important determinant is the ratio of the area under the concentration-time curve to the MIC and/or the ratio of the peak concentration to the MIC. For β-lactams, short-acting macrolides, and clindamycin, the relevant measure is the percentage of time that the drug concentration is above the MIC, and the ratio of the area under the concentration-time curve or of the peak concentration to the MIC is the relevant parameter for aminoglycosides, long-acting macrolides, tetracyclines, glycopeptides, and fluoroquinolones (18). These values can be used to calculate the maximum MICs or breakpoints that would allow the achievement of optimum efficacy with standard drug dosing schedules.

Clinical and Bacteriological Response Rates

During clinical trials, the clinical and/or bacteriologic eradication response rates of organisms for which the MICs of new antimicrobial agents have been determined give an indication of the relevance of breakpoints selected by using the MIC distributions and the pharmacokinetic-pharmacodynamic properties of the drug. Response rates of at least 80% may be expected for organisms classified as susceptible, although the rates may be lower depending on the site and type of infection. While in some countries breakpoints are determined primarily from clinical and bacteriological response rates, the CLSI evaluates clinical and bacteriological response rates in conjunction with population distributions and pharmacokinetics and pharmacodynamics in establishing the breakpoints in an attempt to provide the best correlation between in vitro test results and clinical outcome (7).

Inhibition Zone Diameter Distributions for Disk Diffusion Methods

Once the MIC breakpoints are selected, disk diffusion breakpoints can be chosen by plotting the inhibition zone diameters against the MICs derived from the testing of a large number of strains of various species. A statistical approach that uses the linear regression formula may be used to calculate the appropriate zone diameter intercepts for the predetermined MIC breakpoints. An alternative, pragmatic approach to deriving disk diffusion breakpoints is the use of the error rate-bounded method, in which the zone diameter criteria are selected on the basis of the minimization of the disk interpretive errors, especially the very major errors (5, 34) (Fig. 1). Newer statistical techniques are being studied to improve correlation with MICs (16). The newest CLSI approach focuses on the rate of interpretive errors near the proposed breakpoint versus those with MICs more than a single $\log_2$ dilution from the MIC breakpoints (7). The concept is that errors that occur with isolates for which MICs are very close to the MIC breakpoints are less of a concern than errors that occur with more highly resistant or susceptible strains.

Breakpoints derived by professional groups or regulatory bodies in various countries are often quite similar. For instance, there are a small number of breakpoint discrepancies between the CLSI and the U.S. Food and Drug Administration, which are under review by both groups. Also, there can be notable differences in the breakpoints used in different countries or regions for the same agents. The reasons for the differences may be that certain countries use different dosages or administration intervals for some drugs. In addition, some countries are more conservative in assessing the susceptibility to antimicrobial agents and place greater emphasis on the detection of emerging resistance, noted primarily by examination of microorganism population distributions. Technical factors such as the inoculum density, atmosphere of incubation, and test medium can also affect MICs and zone diameters, thereby justifying different interpretive criteria in some countries. These technical differences are summarized in chapter 73 of this Manual. Two non-U.S. methods minimize or avoid the use of an intermediate category of susceptibility based on the rationale that such results are of little value to the clinician (3, 31). The lack of a buffer between susceptible and resistant categories can result in higher rates of incorrect categorization. It may be safer for a laboratory to employ a method that uses an intermediate category or, if not, to report intermediate results as resistant.

Information on a range of international susceptibility testing methods and/or breakpoints can be downloaded or purchased from the following websites: the CLSI website at http://www.clsi.org; the European Committee on Antimicrobial Susceptibility Testing website at http://www.eucast.org; the British Society for Antimicrobial Chemotherapy website at http://www.bsac.org.uk; the Société Française de Microbiologie website at http://www.sfm.asso.fr/; the Deutsches Institut für Normung website at http://www.beuth.de/; the Swedish Reference Group for Antibiotics website at http://www.srga.org; a website featuring the Danish commercial disk diffusion method at http://www.rosco.dk; and a website featuring the Australian calibrated dichotomous sensitivity (CDS) disk diffusion method at http://www.med.unsw.edu.au/pathology-cds/.

FUTURE DIRECTIONS AND NEEDS IN ANTIMICROBIAL SUSCEPTIBILITY TESTING

Antimicrobial resistance is becoming widespread among a variety of clinically significant bacterial species (40, 45). Therefore, the microbiology laboratory plays a key role in the patient management process by providing accurate data on which physicians can base therapy decisions. Susceptibility testing results, however, are also used by investigators in surveillance studies and by infection control practitioners to detect and control the spread of antibiotic-resistant organisms (9, 38). Surveillance can be performed at the laboratory, local, regional, national, and international levels through direct interchange of data from laboratory information systems to centralized databases (37). Thus, the

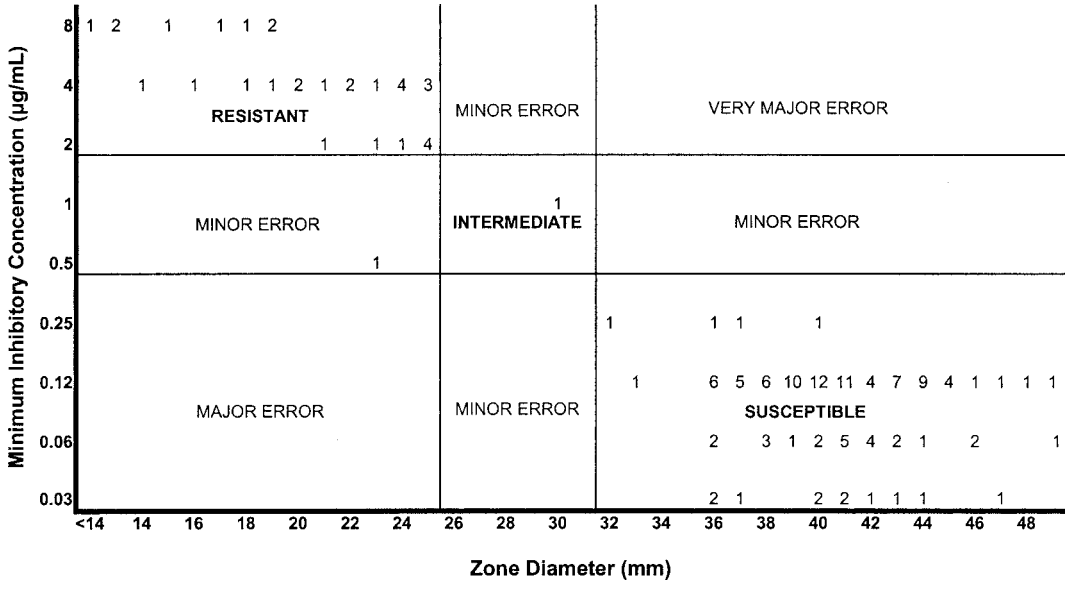

FIGURE 1 Comparison of zone diameters with MICs of a hypothetical antimicrobial agent.

accuracy of stored results becomes almost as important as the accuracy of test performance and interpretation.

To meet these challenges and responsibilities, clinical microbiologists must continuously assess and update their susceptibility testing strategies. The first priority is to use accurate and reliable methods, whether they are conventional or perhaps newer molecular methods. Then, careful monitoring of test performance with well-characterized control strains that challenge the capability of the testing methods becomes essential. Today, laboratories must use a variety of testing methods, each tailored specifically to a particular species or group of organisms. It is not likely that a single method, whether conventional or commercial, will be optimal for all antimicrobial agents, organisms, and resistance mechanisms. This will require increased education and training for clinical microbiologists in the future. Some assistance may be sought from the computer-based "expert" systems that allow a rapid and accurate view of antimicrobial susceptibility profiles and recognition of potentially aberrant results or novel resistance mechanisms (15, 39). Rapid progress is also being made on molecular methods that are starting to have practical application in the routine clinical laboratory (1, 30, 33; chapter 78).

More effective means of conveying critical antimicrobial susceptibility testing information to clinicians in a time frame that allows efficient and effective management of patients and in a format that is unambiguous to clinicians in various practice specialties are still needed. Clinical microbiologists should become more proactive in the reporting of antimicrobial susceptibility results and in cross-linking that information to other databases (e.g., those for pharmacy prescriptions) to ensure that patients receive the most efficacious cost-effective therapy.

Susceptibility Test Methods: Dilution and Disk Diffusion Methods

JAMES H. JORGENSEN AND JOHN D. TURNIDGE

73

A number of methods can be used to perform antimicrobial susceptibility tests in a clinical laboratory setting or for research purposes, such as assessing the activities of new antimicrobial agents. Susceptibility testing can be performed reliably by using broth or agar dilution tests or agar diffusion methods. The choice of methodology to be used in individual laboratories may be based on factors such as relative ease of performance, cost, flexibility in selection of drugs for testing, use of automated or semiautomated devices to facilitate testing, and the perceived accuracy of the methodology (54, 55, 57). A misconception has existed regarding the clinical relevance of determining and routinely reporting MICs versus the interpretive category results (i.e., susceptible, intermediate, or resistant) that are derived using the disk diffusion method. This misconception may have been based on the assumption that the dilution test is the inherently more accurate of the two methods. Since there is a direct relationship between the sizes of the zones of inhibition and the MICs with most drugs and since MICs and zone diameters for reference strains have similar interlaboratory and intralaboratory reproducibilities, there is little objective evidence that one method is more accurate than the other with the majority of common, rapidly growing bacteria (29, 55). While an MIC may be perceived as more accurate than a result from a disk test, the MIC generated using the standard doubling-dilution series may be a concentration somewhere between the concentration inhibiting the organism and the next lower concentration tested (i.e., usually 1 $\log_2$ dilution lower). For example, an organism may grow in the presence of an antimicrobial agent at a concentration of 4 μg/ml but not at 8 μg/ml. The actual MIC could be anywhere between 4 and 8 μg/ml. Despite our statement that MICs are not inherently more accurate, there are some species with resistance mechanisms that may not be reliably detected by standard disk testing (e.g., vancomycin-intermediate *Staphylococcus aureus*) (47, 80), some species for which the standard disk test is not well calibrated (e.g., *Stenotrophomonas maltophilia* and *Burkholderia cepacia*), some species for which no disk test standards exist (e.g., *Corynebacterium* spp. and *Bacillus* spp.) (24), a few drugs that do not appear to diffuse well in agar (e.g., colistin, polymyxin B, and daptomycin) (43, 44), and some species with mechanisms of diminished susceptibility for which MICs are needed to guide selection of therapy and appropriate dosing (e.g., penicillin- and cephalosporin-intermediate *Streptococcus pneumoniae*) (29, 58). However, there are a few instances in which disk testing may provide superior detection of some resistance mechanisms, e.g., use of the cefoxitin disk test to screen for *mecA*-mediated oxacillin resistance in staphylococci (78) and disk approximation testing to detect inducible clindamycin resistance in staphylococci and streptococci (61).

There may also be the misconception that physicians prefer a quantitative (MIC) result rather than a report of a susceptibility category. To the contrary, few physicians other than those who specialize in infectious diseases have the training or experience to reliably interpret MICs. For that reason, the laboratory is obliged to provide a category interpretation (susceptible, intermediate, or resistant) with each MIC result in order to avoid potential misinterpretation of the data (25). There may be only a limited number of specific clinical indications for determining MICs to assist in patient management. These include primarily testing of isolates from patients with endocarditis or osteomyelitis (29). At this time, the pharmacodynamic principles that relate to the importance of the levels of antibiotic in serum or body fluid in relation to the MIC for an organism are useful in determining interpretive breakpoints but are not generally used to optimize therapy of individual patients (30). For research purposes, MICs are useful for evaluating relative degrees of susceptibility of bacteria to various antimicrobial agents and for ranking the activities of drugs against various species. For clinical laboratory purposes, however, the decision as to whether to perform dilution or disk diffusion testing is usually based on logistical reasons, including ease of performance of a method, its cost, and factors such as selection of a system that can provide identification of common bacteria in addition to susceptibility testing (57). Several commercial systems are now available for performing susceptibility testing; however, a major challenge posed by such systems is the relative inflexibility of standard panels of antimicrobial agents that can be tested. The inability to match precisely an institution's antimicrobial agent formulary with drugs readily available in commercial systems has led some laboratories to adopt or retain the highly flexible disk diffusion test for routine use (56).

The selection of antibacterial agents for testing is complicated by the large number of agents available today and the diversity of institutional formularies. Some of these compounds, however, exhibit similar if not identical activities in vitro, so that in some cases, one compound can be

tested as a surrogate to represent one or more closely related compounds. Such extrapolations, which have generally been agreed upon internationally, are listed in Table 1. Use of these drug surrogates can substantially reduce the number of agents required for testing and in some cases provide necessary flexibility in adapting commercial test systems for routine use in a variety of institutions. For instance, the susceptibility of *Staphylococcus* spp. to oxacillin (or cefoxitin) can be extrapolated to apply to all currently available penicillinase-stable penicillins, cephalosporins, and carbapenems. It is thus unnecessary to test any of the agents in these chemical classes, with the exception of the beta-lactamase-labile compounds (e.g., penicillin, ampicillin, amoxicillin, and piperacillin) represented by penicillin itself (25, 26). Other extrapolations are possible, especially if there is demonstrated susceptibility to a less potent member of the chemical class of antimicrobial agent.

It is important that the microbiologist work with the hospital formulary committee to ensure that the antibacterial agents being tested in the laboratory reflect those in the institution's current formulary (56). Failure to do so can contribute to antibiotic misuse (36). Guidelines for the selection of antibacterial agents to be tested routinely are published annually by the Clinical and Laboratory Standards Institute (CLSI; formerly called the NCCLS) (27) and are summarized in Table 2. While this listing is sometimes regarded rigidly as the standard for selecting the agents that must be tested, it is a list of agents that should be considered for routine testing only, and many variables go into the decision as to which agents should be tested in any particular setting (56). The CLSI also cautions that the decision about testing and reporting of some agents selectively should be made by the clinical microbiologist in conjunction with the infectious disease practitioners, the pharmacy, and/or the infection control committees (25, 26, 27).

DILUTION METHODS

Broth or agar dilution susceptibility testing methods are used to determine the minimal concentration, usually in micrograms per milliliter, of an antimicrobial agent required to inhibit or kill a microorganism. Antimicrobial agents are usually tested at $\log_2$ (twofold) serial dilutions, and the lowest concentration that inhibits visible growth of an organism is regarded as the MIC. The concentration range used may vary with the drug, the organism being tested, and the site of infection. Ranges should encompass the concentrations defining the interpretive categories (i.e., susceptible, intermediate, and resistant) and also the ranges that include the expected MICs for quality control reference strains. Other dilution methods include those that test a single concentration or a selected few concentrations of antimicrobial agents (i.e., breakpoint susceptibility tests and single-drug-concentration screens; see below).

Dilution methods offer flexibility in the sense that the standard medium used to test frequently encountered organisms (e.g., staphylococci, enterococci, members of the family *Enterobacteriaceae,* and *Pseudomonas aeruginosa*) may be supplemented or even replaced with another medium to allow accurate testing of certain fastidious bacterial species that may not be reliably tested by disk diffusion. Dilution methods are also readily adaptable to automated test systems.

DILUTION TESTING: AGAR METHOD

Dilution of Antimicrobial Agents

The solvents and diluents needed to prepare stock solutions of most commonly used antimicrobial agents are listed in the CLSI document on dilution testing (25).

TABLE 1 Antibacterial susceptibility results that may be extrapolated from other test results

Test drug (result)	Organism(s)	Drugs for which result can be extrapolated
Penicillin G	*Staphylococcus* spp., *Neisseria gonorrhoeae*	Phenoxymethylpenicillin, phenethicillin, ampicillin, amoxicillin, bacampicillin, cyclacillin, hetacillin, carbenicillin, mezlocillin, azlocillin, ticarcillin, piperacillin
Ampicillin	All	Amoxicillin, bacampicillin, cyclacillin, hetacillin
Ampicillin	*Enterococcus* spp.	Penicillin
Oxacillin	*Staphylococcus* spp.	All penicillins including antistaphylococcal penicillins, all cephalosporins, all beta-lactamase inhibitor combinations, all carbapenems, loracarbef
Cephalothin	*Enterobacteriaceae*	Cephapirin, cephradine, cephalexin, cefaclor, and cefadroxil but not other cephalosporins
Erythromycin	Gram-positive cocci	Azithromycin, clarithromycin, dirithromycin, roxithromyxin
Clindamycin	All	Lincomycin
Tetracycline	All (except *Staphylococcus, Enterococcus,* and *Acinetobacter* spp.)	Doxycycline, minocycline chlortetracycline, demeclocycline, oxytetracycline, methacycline
Sulfisoxazole	All	All sulfonamides
Cephalothin or cefazolin (susceptible)	*Enterobacteriaceae*	Susceptibility to broad-spectrum cephalosporins

TABLE 2 Antimicrobial agents recommended for routine dilution and disk diffusion susceptibility testing[a]

Antimicrobial agent	Group[b] recommended for testing with:						
	Enterobacteriaceae	*Pseudomonas* spp. and other non-*Enterobacteriaceae*[c]	*Acinetobacter* spp.[c]	*Burkholderia cepacia*[c]	*Stenotrophomonas maltophilia*[c]	Staphylococci	Enterococci
Penicillins

Trimethoprim	U					U	
Vancomycin						B	B[e]

[a] Modified from the CLSI informational supplement (27) with permission. Current standards and supplements to them may be obtained from the CLSI, 940 West Valley Rd., Suite 1400, Wayne, PA 19087-1898.

[b] Group A comprises primary drugs to be tested and reported, group B comprises those to be tested as primary drugs but reported selectively, group C comprises supplemental drugs to be reported selectively, and group U comprises drugs to be tested with urinary isolates only.

[c] Some agents should be tested only by using an MIC method and not by using disk diffusion. See the latest CLSI standards for specific examples.

[d] Results of tests with penicillin apply to other penicillins (e.g., ampicillin, amoxicillin, carboxypenicillins, and ureidopenicillins) against beta-lactamase-negative enterococci.

[e] Combination therapy consisting of penicillin, ampicillin, or vancomycin and an aminoglycoside is recommended.

[f] Staphylococci resistant to the penicillinase-resistant penicillins should also be considered resistant to penicillins, beta-lactam-beta-lactamase-inactivating combinations, cephalosporins, and carbapenems.

[g] Ticarcillin-clavulanic acid or piperacillin-tazobactam should not be considered a therapeutic alternative for *P. aeruginosa* isolates resistant to carboxy- or ureidopenicillins.

[h] Cephalothin test results may also be used to represent those for cephapirin, cephradine, cephalexin, cefaclor, cefadroxil, and cefazolin (except against the *Enterobacteriaceae*). Cefuroxime, cefixime, cefpodoxime, cefprozil, ceftibuten, and loracarbef may be tested separately on a supplemental basis because their activities may be greater than those of cephalothin or cefazolin against the *Enterobacteriaceae.*

[i] For use of aminoglycosides to screen enterococci for synergy resistance, see the section "Breakpoint Susceptibility Tests" and "Resistance Screens."

[j] Doxycycline or minocycline may be tested on a supplemental basis because of their greater activities against some nonfermentative gram-negative bacilli and staphylococci.

Preparation, Supplementation, and Storage of Media

Mueller-Hinton agar is the recommended medium for testing most commonly encountered aerobic and facultatively anaerobic bacteria (25). The dehydrated agar base is commercially available and should be prepared as described by the manufacturer. Before sterilization, the molten agar is usually distributed into screw-cap tubes in exact aliquots sufficient to dilute the desired antimicrobial concentrations 10-fold. Tubes of agar, one for each drug concentration to be tested, are sterilized by autoclaving at 121°C for 15 min, and the agar is allowed to equilibrate to 48 to 50°C in a preheated water bath. Once the agar has equilibrated, the appropriate volume of antimicrobial agent is added, the tube contents are mixed by gentle inversion and poured into 100-mm-diameter round or square sterile plastic petri plates set on a level surface, and the agar is allowed to solidify. For growth controls, plates containing drug-free agar are also prepared. All plates should be filled to a depth of 3 to 4 mm (20 to 25 ml of agar per round plate and 30 ml per square plate), and the pH of each batch should be checked to confirm the acceptable pH range of 7.2 to 7.4 (25).

After sterilization and temperature equilibration of the molten agar, any necessary supplements are aseptically added to the Mueller-Hinton agar at the time of addition of the drug solutions. For testing of streptococci, supplementation with 5% defibrinated sheep or horse blood is recommended (25). However, sheep blood supplementation may antagonize the activities of sulfonamide and trimethoprim against some organisms (11). The presence of blood also affects results with novobiocin and nafcillin as well as the in vitro activities of cephalosporins against enterococci (15, 73); therefore, blood supplementation should not be used unless necessary for bacterial growth (see chapter 75 for acceptable methods for testing of fastidious bacterial species). Performance standards for Mueller-Hinton agar have been defined sufficiently such that calcium and magnesium supplementation is unnecessary (22). The agar should be supplemented with 2% NaCl for testing of oxacillin against staphylococci (49).

Once prepared, plates should be sealed in plastic bags and stored at 4 to 8°C. In general, they should be used within 5 days of preparation or as long as the MICs for control strains that are tested routinely are within the acceptable ranges. However, certain agents are sufficiently labile that plates may not be stored prior to use, e.g., carbapenems, cefaclor, and clavulanic acid. Before inoculation, plates that have been stored under refrigeration should be allowed to equilibrate to room temperature and the agar surface should be dry.

Inoculation Procedures

Variations in inoculum size may substantially affect MICs; therefore, careful inoculum standardization is required to obtain accurate results. The recommended final inoculum for agar dilution is 10^4 CFU per spot (25). This may be achieved in either of two ways. Four or five colonies are picked from overnight growth cultures on agar-based medium and inoculated into 4 to 5 ml of suitable broth that will support good growth (usually tryptic soy broth). Broths are incubated at 35°C until visibly turbid, and then the suspension is diluted until it matches the turbidity of a 0.5 McFarland, barium sulfate ($BaSO_4$), or latex particle turbidity standard (ca. 10^8 CFU/ml). The 0.5 McFarland standard may be purchased or the barium sulfate standard may be prepared as described in the CLSI document (25). The accuracy of the standard should be verified by using a spectrophotometer with a 1-cm light path; for the 0.5 McFarland standard, the absorbance at 625 nm should be 0.08 to 0.13 (25). An alternative inoculum standardization method, one that is preferred by many microbiologists, utilizes direct suspension of colonies from overnight growth cultures on a nonselective agar medium in saline or broth to a turbidity that matches the 0.5 McFarland standard. This approach eliminates the time needed for growing the inoculum in broth (25). In either case, normal saline or sterile broth is used to make a 1:10 dilution of the suspension to give an adjusted concentration of 10^7 CFU/ml (25).

Once the adjusted bacterial inoculum suspension is prepared, inoculation of the antimicrobial agent plates should be accomplished within 30 min, since longer delays may lead to changes in inoculum size. By using a pipette, a calibrated loop, or, more commonly, an inoculum-replicating device, 0.001 to 0.002 ml (1 to 2 μl) of the 10^7-CFU/ml suspension is delivered to the agar surface, resulting in the final desired inoculum of approximately 10^4 CFU per spot. For convenience, use of a replicator is preferred, because consistent inoculum volumes for up to 36 different isolates are simultaneously delivered (25, 76). To use this device, an aliquot of the adjusted inoculum for each isolate is pipetted into the appropriate well of an inoculum seed plate and a multiprong inoculator is used to pick up and gently transfer 1 to 2 μl from the wells to the agar surfaces. Replicators are also available that deliver only 0.1 to 0.2 μl per spot and that do not require the 0.5 McFarland standard suspension to be diluted prior to delivery to the agar surface (25). The surfaces of the agar plates must be dry before inoculation, which should begin with the lowest drug concentration. To check for viability of each test isolate and also as an added check for purity, control plates that do not contain drugs are inoculated last. Finally, plates should be clearly marked so that the locations of the different isolates being tested on each plate are known.

Incubation

Inoculated plates are allowed to stand for several minutes until the inoculum drops have been completely absorbed by the medium; then they are inverted and incubated in air at 35°C for 16 to 20 h before results are read. To facilitate detection of vancomycin-resistant enterococci and methicillin-resistant or vancomycin-resistant or -intermediate staphylococci, plates containing vancomycin or oxacillin should be incubated for a full 24 h before results are read (25). Incubation should not be carried out in the presence of an increased CO_2 concentration unless a fastidious organism is being tested (see chapter 75).

Interpretation and Reporting of Results

Before reading and recording the results obtained with clinical isolates, those obtained with applicable quality control strains tested at the same time should be checked to ensure that their values are within the acceptable ranges (see "Quality Control" below) and the drug-free control plates should be examined for isolate viability and purity. Endpoints for each antimicrobial agent are best determined by placing plates on a dark background and examining them for the lowest concentration that inhibits visible growth, which is recorded as the MIC. A single colony or a faint haze left by the initial inoculum should not be regarded as growth. If two or more colonies persist at antimicrobial concentrations beyond an otherwise obvious endpoint or if there is no growth at lower concentrations but there is growth at higher concentrations, the isolate should be subcultured to confirm purity and the test should be repeated. Substances that may antagonize the antibacterial activities of sulfonamides and trimethoprim may be carried over with the inoculum and cause "trailing," or less definite endpoints (11,

15). Therefore, the MICs of these antimicrobial agents should be interpreted as the endpoints at which 80% or more diminution of growth occurs. Although much less pronounced, trailing endpoints may also occur for some organisms with bacteriostatic agents such as chloramphenicol, the tetracyclines, linezolid, and quinupristin-dalfopristin (25).

The MIC of each antimicrobial agent is usually recorded in micrograms per milliliter, although in Europe and in the international standard reference method, the values are expressed as milligrams per liter (39, 40, 50). These quantitative results should be reported with the appropriate corresponding interpretive category (susceptible, intermediate, or resistant), or the interpretive category may be reported alone. The MIC interpretive standards for these susceptibility categories, as currently recommended by the CLSI (25), are provided in Table 3. For detailed instructions concerning the

[a] Adapted from CLSI data (27) with permission. The interpretive data are valid only if the methodologies in documents M2-A8 (26) and M7-A6 (25) are followed. Breakpoints for some agents apply only to certain genera or species. The CLSI frequently updates the interpretive tables through new editions of the standards and supplements to them. Users should refer to the most recent editions. The current standards and supplements to them may be obtained from the CLSI, 940 West Valley Rd., Suite 1400, Wayne, PA 19087-1898.

[b] Penicillin should be used as the class representative for all penicillins (e.g., ampicillin, amoxicillin, mezlocillin, piperacillin, and ticarcillin). Isolates for which MICs are ≤0.03 μg of penicillin per ml generally do not produce beta-lactamase, whereas those for which MICs are ≥0.25 μg/ml do and should be regarded as resistant to penicillins. Isolates for which MICs of penicillin are 0.06 or 0.12 μg/ml should be tested for beta-lactamase.

[c] Therapy for serious enterococcal infections requires high doses of penicillin or ampicillin in combination with an aminoglycoside. Vancomycin may be substituted for the penicillin in instances of penicillin hypersensitivity or of penicillin or ampicillin resistance.

[d] Oxacillin or methicillin may be tested; however, oxacillin is preferred because of its greater stability in vitro. The results from the testing of oxacillin apply also to other penicillinase-resistant penicillins. Oxacillin-resistant staphylococci should be considered resistant to all penicillins, cephalosporins, carbacephems, carbapenems, and beta-lactam–beta-lactamase inhibitor combinations. Disk testing with cefoxitin is the most sensitive and specific method for phenotypic detection of *mec*A-mediated oxacillin resistance in staphylococci (27, 78).

[e] For the treatment of urinary tract infections only.

use of these criteria and categories, the latest CLSI standards for dilution testing methods should be consulted (27). Note that the interpretive standards for most of the penicillin class drugs vary with the organism being tested. In an attempt to minimize confusion regarding different breakpoints that may apply to individual species, the CLSI has divided the interpretive breakpoint tables into a number of different tables for the various organism groups (25).

The three interpretive categories are defined as follows. Susceptible indicates that an infection caused by the tested microorganism may be appropriately treated with the usually recommended dose of antibiotic. Intermediate indicates that the isolate may be inhibited by attainable concentrations of certain drugs (e.g., the beta-lactams) if higher dosages can be used safely or if the infection involves a body site indicating that the drug is physiologically concentrated (e.g., the urinary tract). The intermediate category also serves as a buffer zone that prevents slight technical artifacts from causing major interpretive discrepancies. Resistant isolates are not inhibited by the concentration of antimicrobial agent normally achievable with the recommended dose and/or yield results that fall within a range indicating that specific resistance mechanisms are likely to be present (25).

Advantages and Disadvantages

Dilution testing by the agar method is a well-standardized, reliable susceptibility testing technique that may be used as a reference for evaluating other testing methods. In addition, the simultaneous testing of a large number of isolates with a few drugs is efficient (such as when new agents are evaluated in the pharmaceutical industry), and microbial contamination or population heterogeneity is more readily detected by the agar method than by broth methods. The agar dilution method has been considered the reference test method in many areas of Europe (39), while broth microdilution has been much more widely used for research and clinical purposes in North America (55) and is now considered the international reference method for determining MICs (50). The major disadvantages of the agar method are associated with the time-consuming and labor-intensive tasks of preparing the plates, especially if the number of different antimicrobial agents to be tested for each isolate is high or if only a few isolates are to be tested.

DILUTION TESTING: BROTH METHODS

The general approaches for broth methods include broth macrodilution, in which the broth volume for each antimicrobial concentration is ≥1.0 ml (usually 2 ml) contained in test tubes, and broth microdilution, in which antimicrobial dilutions are most often in 0.1-ml volumes in wells of microdilution trays.

Broth Macrodilution Methods

Dilution of Antimicrobial Agents

Stock solutions are prepared as discussed in the CLSI document on dilution testing (25) and are the same as those used for agar dilution tests. As in the agar method, the actual volumes used for the dilutions would be proportionally increased according to the number of tests being prepared, with a minimum of 1.0 ml needed for each drug concentration. Because addition of the inoculum results in a 1:2 dilution of each concentration, all final drug concentrations must be prepared at twice the actual desired testing concentration (see "Inoculation Procedures" below).

Preparation, Supplementation, and Storage of Media

Cation-adjusted Mueller-Hinton broth (CAMHB) is recommended for routine testing of commonly encountered nonfastidious organisms (25). Adjustment of the cations Ca^{2+} (20 to 25 mg/liter) and Mg^{2+} (10 to 12.5 mg/liter) is required to ensure acceptable results when *P. aeruginosa* isolates are tested with aminoglycosides and when tetracycline is tested with other bacteria (9). However, for convenience and consistency, cation adjustment of Mueller-Hinton broth is now recommended for testing of all species and antimicrobial agents (25). Some manufacturers provide Mueller-Hinton broth that already has appropriate concentrations of divalent cations, so the cation content of commercial dehydrated media must be ascertained and care must be taken to supplement the broth with the appropriate cation levels. If adjustment is necessary, it can be accomplished by the addition of suitable volumes of filter-sterilized, chilled $CaCl_2$ stock (3.68 g of $CaCl_2 \cdot 2H_2O$ dissolved in 100 ml of deionized water for a concentration of 10 mg of Ca^{2+} per ml) and $MgCl_2$ stock (8.36 g of $MgCl_2 \cdot 6H_2O$ in 100 ml of deionized water for a concentration of 10 mg of Mg^{2+} per ml) to the cooled broth (25). Insufficient cation concentrations result in increased aminoglycoside activity (32), and excess cation content results in decreased aminoglycoside activity against *P. aeruginosa* (7, 32). For testing of daptomycin, the calcium level of the test medium must be increased to 50 mg/liter to achieve reliable MICs (25, 43). While the effects of inappropriate calcium and magnesium ion contents are well recognized, other ions, including zinc and manganese, may adversely affect the activities of some drugs, e.g., carbapenems (31). The CLSI has initiated a consensus standard for manufacturers of Mueller-Hinton broth that attempts to specify all known factors that determine performance of the medium (23). Reliable detection of staphylococcal resistance to oxacillin requires that the CAMHB used for testing that agent be supplemented with 2% NaCl (25, 83).

To minimize evaporation and deterioration of antimicrobial agents, tubes should be tightly capped and stored at 4 to 8°C until needed. With most agents, the dilutions should be used within 5 days of preparation or as long as quality control ranges are maintained (see "Quality Control" below). As in agar dilution testing, certain beta-lactam agents are too labile for prolonged storage at final test concentrations.

Inoculation Procedures

The recommended final inoculum is 5×10^5 CFU/ml. Isolates are inoculated into a broth that will support good growth (such as tryptic soy broth) and incubated until turbid. The turbidity is adjusted to match that of a 0.5 McFarland standard (approximately 10^8 CFU/ml). Alternatively, four or five colonies from overnight growth cultures on a nonselective agar plate may be directly suspended in broth to match the turbidity of the McFarland standard (25). This alternative is preferred for testing of oxacillin against staphylococci (25). A portion of the standardized suspension is diluted approximately 1:100 (10^6 CFU/ml) with broth or saline. When 1 ml of this dilution is added to each tube containing 1 ml of the drug diluted in CAMHB, a final inoculum of 5×10^5 CFU/ml is achieved. Broth not containing an antimicrobial agent is inoculated as a control for organism viability (growth control). All tubes should be inoculated within 30 min of inoculum preparation, and an aliquot of the inoculum should be plated to check for purity.

Incubation

Tubes are incubated in air at 35°C for 16 to 20 h before MICs are determined. Incubation should be extended to a full 24 h for the detection of vancomycin-resistant enterococci and oxacillin-resistant or vancomycin-resistant or -intermediate staphylococci (25). An atmosphere with increased CO_2 should not be used.

Interpretation and Reporting of Results

Before MICs for the test strains are read and recorded, the growth controls should be examined for viability, inoculum subcultures should be checked for contamination, and appropriate MICs obtained with the quality control strains should be confirmed (see "Quality Control" below). Growth or lack thereof in the antimicrobial agent-containing tubes is best determined by comparison with the growth control. Generally, growth is indicated by turbidity, a single sedimented button of ≥2 mm in diameter, or several buttons with smaller diameters. As with the agar method, trailing endpoints may be seen when trimethoprim or sulfonamides are tested, and the concentration at which 80% or greater diminution of growth, compared with that of the growth control, occurs should be recorded as the MIC (25). Other interpretation problems include the "skipped tube" phenomenon, in which growth is not observed at one concentration but is observed at lower and higher drug concentrations. Most authorities suggest that when this occurs, the skipped tube should be ignored and the concentration that finally inhibits growth at serially higher concentrations should be recorded as the MIC. If more than one skipped tube occurs or if there is growth at higher antimicrobial concentrations but not at lower ones, the results should not be reported and the test for that drug should be repeated.

The lowest concentration that completely inhibits visible growth of the organism as detected by the unaided eye is recorded as the MIC. The CLSI MIC interpretive standards in effect as of the date of this writing (27) for the susceptibility categories are provided in Table 3. The definitions of and comments concerning these categories that were given for the agar method also pertain to the broth macrodilution method.

Advantages and Disadvantages

The broth macrodilution method is a well-standardized and reliable method that may be useful for research purposes or for testing of one drug with a bacterial isolate. However, because of the laborious nature of the procedure and the availability of more convenient dilution systems (e.g., microdilution), this procedure is generally not useful for routine susceptibility testing in most clinical microbiology laboratories.

Broth Microdilution Method

The convenience afforded by the availability of dilution susceptibility testing in microdilution trays has led to the widespread use of broth microdilution methods. In fact, the broth microdilution method is now considered the international reference susceptibility testing method (50). The disposable plastic trays, containing a panel of several antimicrobial agents to be tested simultaneously, may be prepared in-house or obtained commercially either frozen or freeze-dried. When commercial systems are used, the manufacturers' recommendations concerning storage, inoculation, incubation, and interpretation should be followed. The primary focus of this section will be the in-house preparation and use of broth microdilution panels. However, most of the principles and practices discussed here are pertinent to the broth microdilution method regardless of the source of the antibiotic panels.

Dilution of Antimicrobial Agents

Antimicrobial stock solutions are prepared as outlined in the CLSI document on dilution testing (25). The dilution scheme for preparing broth microdilution panels is the same as that described for agar and broth microdilution methods. Automated dispensing systems for preparation of microdilution panels use tubes that contain from 10 to 200 ml or more of broth containing each antimicrobial concentration. From the master tube dilutions, aliquots of 0.05 or 0.1 ml are simultaneously dispensed into the corresponding wells of each broth microdilution tray by using a mechanized dispenser. If 0.05-ml volumes are dispensed, allowances must be made for the 1:2 dilution of the final drug concentration that will occur when the 0.05 ml of inoculum is added (see "Inoculation Procedures" below). When 0.1-ml aliquots are dispensed, the volume of inoculum normally used is sufficiently small (≤0.005 ml) that adjustments in the antimicrobial dilution scheme are not needed. As a general rule, when the inoculum volume is less than 10% of the broth volume in the well, dilution of the antimicrobial concentration by the inoculum does not have to be taken into account (25).

Preparation, Supplementation, and Storage of Media

CAMHB is the recommended medium for broth microdilution testing of nonfastidious organisms and should be prepared as discussed above for the broth macrodilution method. Also, supplementation of the broth with 2% NaCl is required for detection of oxacillin-resistant staphylococci (25). After the antimicrobial dilutions have been dispensed into the plastic trays, the panels are stacked in groups of 5 to 10, with a tray lid or an empty tray placed on top to minimize contamination and evaporation. Each stack is sealed in a plastic bag and frozen immediately at −20°C or, preferably, at −60°C or colder. At −20°C, preservation is ensured for at least 6 weeks with most drugs, but the shelf life may be extended to months if the trays are stored at −60 to −70°C. Care must be taken in storing highly labile compounds such as cefaclor, clavulanic acid, and carbapenems, which may lose potency during storage. If thawed, panels must be used or discarded but not refrozen, since freeze-thaw cycles cause substantial deterioration of beta-lactam antibiotics. For this reason, −20°C household type freezers with self-defrosting units must not be used.

Inoculation Procedures

As with the macrodilution procedure, the final desired inoculum concentration is 5×10^5 CFU/ml. The isolates may be grown in broth to match the turbidity of a 0.5 McFarland standard (ca. 1×10^8 to 2×10^8 CFU/ml), or a suspension of that density can be made from colonies grown overnight on a nonselective agar medium (8), which is the method preferred for detecting oxacillin-resistant staphylococci (25). For broth microdilution procedures that require 0.001- to 0.005-ml volumes to inoculate wells containing 0.1 ml of broth, a portion of the 0.5 McFarland standard suspension is diluted 1:10 (10^7 CFU/ml) in sterile saline or broth. Multipoint metal or disposable plastic inoculum replicators designed to collect and deliver appropriate volumes are used to transfer the inoculum from the diluted suspension to the wells of the broth microdilution tray, resulting in further dilutions ranging from 1:20 to 1:50. Final inoculum concentrations should be 4×10^5 to 6×10^5 CFU/ml (4×10^4 to 6×10^4 CFU per well). For protocols that use an inoculum volume of 0.05 ml to inoculate 0.05 ml of broth, a 1:100 dilution of a 0.5 McFarland

standard suspension (ca. 10^6 CFU/ml) is used. When the inoculum is added to the wells, the 1:2 dilution of the 10^6-CFU/ml inoculum results in a final inoculum concentration of 5×10^5 CFU/ml (5×10^4 CFU per well) and also halves the antibiotic concentration in each well. Special care should be taken to confirm the inoculum density on a periodic basis to ensure that the appropriate density of inoculum is achieved. Moreover, slight deviations from the initial 1:10 dilution described above may be necessary to provide the target inoculum density with some species or organism groups. Insufficient inoculum can be a significant problem with inducible resistance mechanisms of some organisms and may not be recognized as a problem based on the MICs obtained for the very susceptible quality control strains.

Broth microdilution trays should be inoculated within 30 min of inoculum preparation, and an aliquot should be subcultured to check the purity of the isolates. Finally, one well of each panel not containing an antimicrobial agent should be inoculated and used as a growth control, and a second uninoculated well serves as a sterility control.

Incubation

After inoculation, each tray should be covered with plastic tape, sealed in a plastic bag, or tightly fitted with a lid or an empty tray to prevent evaporation during incubation. Trays are incubated in ambient air at 35°C for 16 to 20 h before results are read and should not be incubated in stacks of more than four trays for uniform temperature distribution. The incubator should be kept sufficiently humid to avoid evaporation but not so humid that condensation results in contamination problems. A full 24 h of incubation is recommended for the detection of vancomycin-resistant enterococci and oxacillin-resistant or vancomycin-resistant or -intermediate staphylococci (25). Incubation in an atmosphere with increased CO_2 should not be used with nonfastidious organisms.

Interpretation and Reporting of Results

Before MICs for the clinical isolates are read and recorded, the growth control wells should be examined for organism viability and the inoculum purity should be checked. The appropriateness of the MICs obtained for the quality control strains should be confirmed if tests of these strains were set up simultaneously with those of clinical isolates (see "Quality Control" below). Various viewing devices are available and should be used to facilitate examination of the broth microdilution wells for growth. The simplest and most reliable method is the use of a parabolic magnifying mirror and tray stand that allow clear visual inspection of the undersides of the microdilution trays. Growth is best determined by comparison with that in the growth control well and generally is indicated by turbidity throughout the well or by buttons, single or multiple, in the well bottom. The occurrence of trailing endpoints with trimethoprim or sulfonamides should be ignored, and the MIC endpoint should be based on ≥80% growth inhibition. Results for drugs with more than one skipped well should not be reported, as with the broth macrodilution test.

The CLSI MIC interpretive criteria (27) for susceptibility categories are given in Table 3. It should be noted that these values are published each year and only the most recent tables should be used for interpretation of results. The definitions of the interpretive categories and the comments concerning the use of these standards for agar and broth macrodilution methods are also applicable to broth microdilution methods.

Advantages and Disadvantages

The broth microdilution method represents a standardized reference method for susceptibility testing. Inoculation and reading procedures allow relatively convenient simultaneous testing of several antimicrobial agents with individual isolates. Because few laboratories have the facilities required for preparation of broth microdilution trays, several sources of commercially prepared antibiotic panels are available today. Such products provide trays with wells containing prepared antimicrobial dilutions either frozen or freeze-dried. Trays with frozen dilutions must be stored frozen in the laboratory, whereas dried panels can be stored at room temperature. Most of these products are accompanied by multipoint inoculating devices, or multichannel pipetters. Results of testing may be determined by visual examination or by use of semiautomated or automated instrumentation.

Breakpoint Susceptibility Tests

Breakpoint susceptibility testing refers to methods by which antimicrobial agents are tested only at the specific concentrations necessary for differentiating between the interpretive categories of susceptible, intermediate, and resistant rather than in a range of five or more doubling-dilution concentrations used to determine MICs. When two drug concentrations are selected adjacent to the breakpoints defining the intermediate and resistant categories, any one of the interpretive categories may be determined. Growth at both concentrations indicates resistance, growth at only the lower concentration signifies an intermediate result, and no growth at either concentration indicates susceptibility.

Like full-range dilution testing, breakpoint methods require the use of appropriately adjusted and supplemented Mueller-Hinton broth or agar. In addition, the standard inoculation, incubation, and interpretation procedures recommended for the full-range dilution methods should be followed.

Considering the limited range of drug concentrations tested, a greater number and variety of antimicrobial agents can be incorporated into a broth microdilution panel for breakpoint testing than into panels designed for full-range dilution testing (37). However, convenient quality control procedures to ensure that appropriate concentrations of each antimicrobial agent are present are lacking for breakpoint panels. One possible approach is to use one organism for which the modal MIC is equal to or no less than one doubling dilution less than the lower or lowest concentration tested and a second organism for which the modal MIC is equal to or no more than one doubling dilution greater than the higher or highest concentration tested (25). One of these two quality control organisms should provide on-scale results (25). Despite the theoretical soundness of this approach, routine quality control of breakpoint panels is difficult and not readily accomplished in the clinical laboratory.

Resistance Screens

In some circumstances, testing a single drug concentration may be a reliable and convenient method for detecting antimicrobial resistance. The most clinically useful resistance screens are those for resistance to oxacillin in *S. aureus,* resistance of *Enterococcus* spp. and *Staphylococcus* spp. to vancomycin, and high-level resistance to gentamicin and streptomycin in enterococci (25). These practical and reliable methods are described in chapter 74 of this Manual.

Gradient Diffusion Method

The E test (AB Biodisk, Solna, Sweden) is a commercial method for quantitative antimicrobial susceptibility testing

that incorporates a preformed antimicrobial gradient applied to one side of a plastic strip to provide drug diffusion into an agar medium. The test is performed in a manner similar to disk diffusion testing, in that a 0.5 McFarland standard suspension of a test isolate is generally swabbed onto the agar surface for inoculation. Following incubation, the MIC is read directly from a scale on the top of the E-test strip at the point where the ellipse of organism growth inhibition intercepts the strip. Several strips, each containing a different antimicrobial agent, can be placed radially on the surface of a large round Mueller-Hinton agar plate, or they can be placed in opposing directions on large rectangular plates. MICs determined by this method generally agree well with MICs generated by standard broth or agar dilution methods (6, 48, 54). The E test combines the simplicity and flexibility of the disk diffusion test with the ability to determine MICs of up to five antimicrobial agents on a single large agar plate. However, E-test strips are much more expensive than the paper disks used for diffusion testing. Strengths of the E-test method include the simplicity of the procedure itself and the ability to determine an MIC of an infrequently tested drug and to test fastidious or anaerobic bacteria by applying the strips onto specialized enriched media (see chapters 75 and 76 of this Manual).

QUALITY CONTROL

Quality control recommendations are designed for evaluation of the precision and accuracy of test procedures, monitoring of reagent performance, and evaluation of the performance of the individuals who are conducting the tests.

Reference Strains

A critical element in accomplishing the goals of quality control is the selection and use of reference bacterial strains that are genetically stable and for which MICs are in the midrange of MICs of each antimicrobial agent tested (25). That is, the dilutions in a series should ideally encompass at least two concentration increments above and below the previously established MIC for the reference strain. If there are four or fewer dilutions in a series or if nonconsecutive dilutions are tested (e.g., in breakpoint susceptibility testing), quality control for the correct interpretive category only rather than actual MIC ranges may be accomplished. *Escherichia coli* ATCC 25922, *P. aeruginosa* ATCC 27853, *Enterococcus faecalis* ATCC 29212, and *S. aureus* ATCC 29213 are the recommended reference strains for both agar and broth dilution methods (25). The beta-lactamase-producing strain *E. coli* ATCC 35218 is recommended only for penicillin–beta-lactamase inhibitor combinations (25). These organisms may be obtained from the American Type Culture Collection or other reliable commercial sources. For proper storage and subculture procedures, the recommendations of either the CLSI (25) or the commercial provider should be followed.

MIC Ranges

The acceptable quality control MIC ranges for the various reference strains are given in the CLSI document on dilution testing (25). Updates of these MIC ranges are published annually (27) and should be readily available in each clinical laboratory. An out-of-control result is defined as an MIC not within the acceptable range of values. Certain out-of-control results can be directly related to the medium used for testing. High MICs of gentamicin for *P. aeruginosa* ATCC 27853 suggest an inappropriately high divalent cation content or excessively low pH of the Mueller-Hinton medium, and low MICs indicate an insufficient divalent cation concentration or elevated pH. Although trimethoprim-sulfamethoxazole is not recommended for therapy of *Enterococcus faecalis* infections, results obtained with the ATCC 29212 strain can be useful for detecting excessive amounts of substances such as thymidine that interfere with the in vitro activity of antifolate drugs. Trimethoprim-sulfamethoxazole MICs of >0.5 to 9.5 μg/ml indicate the presence of such interfering substances (25).

Batch and Lot Quality Control

Representative plates, panels, or trays from each new reagent batch if prepared in-house or from each new lot if obtained from a commercial source should be subjected to quality control and sterility testing. MICs obtained by testing reference quality control strains should be within acceptable CLSI ranges (27). If such accuracy is not achieved, the batch or lot should be rejected or patient results obtained with the antimicrobial agent(s) in question should not be reported (see below). Similarly, if selected uninoculated plates or trays fail the sterility check after incubation, the batch or lot should be rejected. In addition to these formal quality control procedures that use reference strains, careful review of susceptibility results obtained during daily testing of clinical isolates is important to identify aberrant or unusual susceptibility patterns possibly indicative of reagent or technical problems.

Quality Control Frequency

In addition to batch and lot testing, quality control tests should be performed daily, or at least every day that the plates or trays are being used to test clinical isolates. When quality control is performed on each day of testing, performance is considered satisfactory if no more than 3 out of 30 consecutive results for each drug-reference strain combination are outside the acceptable limits. If this frequency is exceeded, the laboratory must perform corrective action to determine the source of the error and to correct it as described below. However, if daily quality control testing does not reveal an excessive rate of errors, daily testing may be replaced by weekly testing as outlined below (25, 27).

To convert to a weekly quality control testing interval, each drug-reference strain combination is tested for 20 or 30 consecutive testing days to obtain a total of 20 to 30 MICs for each combination. If no more than 1 of 20 or 3 of 30 MICs per combination are outside the accuracy range, weekly testing may replace daily testing. During weekly testing, a single MIC outside the acceptable range requires that daily testing be performed for five consecutive days unless there is an obvious source of error (e.g., contamination, use of an incorrect reference strain or an incorrect inoculum density, testing of an incorrect antimicrobial agent, or use of an incorrect atmosphere for incubation). In such a circumstance, the quality control test need be repeated only once. If no obvious source of error is noted, but all five MICs for a problem drug-organism combination are within the accuracy range, weekly testing may be resumed. If one or more of the five MICs for the problem drug-organism combination are outside the accuracy range, daily testing must be initiated and further means to resolve the problem must be pursued. Returning to weekly testing requires again documenting 20 or 30 consecutive days with no more than one or three MICs outside the accuracy range. If more than the acceptable number of MICs for organism-drug combinations are outside the accuracy range, daily quality control testing must be continued while the problem is being resolved (25, 27).

DISK DIFFUSION TESTING

The disk diffusion method of susceptibility testing allows categorization of most bacterial isolates as susceptible, intermediate, or resistant to a variety of antimicrobial agents. To perform the test, commercially prepared filter paper disks impregnated with a specified single concentration of an antimicrobial agent are applied to the surface of an agar medium that has been inoculated with the test organism. The drug in the disk diffuses through the agar. As the distance from the disk increases, the concentration of the antimicrobial agent decreases logarithmically, creating a gradient of drug concentrations in the agar medium surrounding each disk. Concomitant with the diffusion of the drug, the bacteria that were inoculated onto the surface and are not inhibited by the concentration of the antimicrobial agent continue to multiply until a lawn of growth is visible. In areas where the concentration of the drug is inhibitory, no growth occurs, forming a zone of inhibition around each disk.

The disk diffusion procedure has been standardized primarily for testing common, rapidly growing bacteria (10, 26). This method should not be used to evaluate antimicrobial susceptibilities of bacteria that show marked strain-to-strain variability in growth rates, e.g., some fastidious or anaerobic bacteria. The test, however, has been modified to allow reliable testing of certain fastidious bacteria (discussed in chapter 75 of this Manual).

The diameter of the zone of inhibition is influenced by the rate of diffusion of the antimicrobial agent through the agar, which may vary among different drugs depending upon the size of the drug molecule and its hydrophilicity. The zone size, however, is inversely proportional to the logarithm of the MIC, measured as discussed earlier in this chapter. Criteria currently recommended for interpreting zone diameters and MIC results for commonly used antimicrobial agents are listed in Table 3 and published annually by the CLSI (27).

Establishing Zone-of-Inhibition Diameter Interpretive Criteria

The first step in determining interpretive criteria for the disk diffusion test is selection of MIC breakpoints that define susceptibility and resistance categories for each antimicrobial agent. Zone-of-inhibition diameters that correspond to these breakpoints are initially established by testing 300 or more bacterial isolates by both dilution and disk diffusion methods and correlating zone-of-inhibition diameters and MICs determined for each drug tested (21). Isolates tested should include not only those commonly encountered in clinical laboratories but also those with resistance mechanisms pertinent to the class of antimicrobial agent being tested (21). Organisms evaluated should be those most likely to be tested with the antimicrobial agent in question. The data from these studies are analyzed by preparing a scattergram of values (see the example in chapter 72). By convention, each MIC ($\log_2$ scale) is plotted on the *y* axis, and the corresponding zone-of-inhibition diameter (arithmetic scale) is plotted on the *x* axis. Regression analysis can be performed, and a straight regression line showing the best fit is drawn. From this line, an approximation of the MIC can be inferred from any zone-of-inhibition diameter. For antimicrobial agents to which isolates are either susceptible or resistant and only infrequently intermediate, regression analysis is not valid. In such cases, the data are plotted as a scattergram and the interpretive standards are selected so as to allow optimal separation of resistant and susceptible populations (19, 21, 67). This approach, often called the error-rate-bounded method, may also be employed to minimize interpretive errors that can ensue from strictly applying the linear regression formula to a data set (21).

Antimicrobial Agent Disks

The amounts of antimicrobial agents in the disks used for agar diffusion testing are standardized, and in the United States, only a single disk for each drug is recommended (54). The optimal amount of an antimicrobial agent per disk is determined early in the development of a new drug by testing disks with several different drug contents that can be evaluated by using scattergrams and regression lines (21). The most desirable concentration of a drug per disk is that which produces a zone-of-inhibition diameter of at least 10 mm with resistant isolates and a zone diameter of no larger than 30 mm with susceptible isolates.

Commercially prepared antimicrobial disks usually are supplied in separate containers, each with a desiccant. They must not be used beyond the specified expiration date and should be stored under refrigeration (2 to 8°C) or frozen in a non-frost-free freezer at −20°C or colder until needed. Disks containing a beta-lactam agent should always be stored frozen to ensure that they retain their potency, although a small supply may be stored in the refrigerator for up to 1 week. Unopened disk containers should be removed from the refrigerator or freezer 1 to 2 h before use. This allows the disks to equilibrate to room temperature before the container is opened, thus minimizing the amount of condensation that will occur when warm air contacts the cold disks. A commercially available, mechanical disk-dispensing apparatus can be used and should be fitted with a tight cover, supplied with an adequate desiccant, stored in the refrigerator when not in use, and warmed to room temperature before being opened.

Agar Medium

The recommended medium for disk diffusion testing in the United States is Mueller-Hinton agar (26). This unsupplemented medium has been selected by the CLSI for several reasons: (i) it demonstrates good batch-to-batch reproducibility for susceptibility testing; (ii) it is low in sulfonamide, trimethoprim, and tetracycline inhibitors; (iii) it supports the growth of most nonfastidious bacterial pathogens; and (iv) years of data and clinical experience regarding its performance have been accrued. Fastidious bacteria, such as *Haemophilus* species, *Neisseria gonorrhoeae, Neisseria meningitidis,* and streptococci, do not grow satisfactorily on unsupplemented Mueller-Hinton agar but can be tested by the disk method by using supplemented or modified test media as discussed in chapter 75 of this Manual.

Plates of Mueller-Hinton agar may be purchased, or the agar may be prepared from a commercially available dehydrated base according to the manufacturer's directions. If the agar is prepared, only formulations that have been tested according to and have met acceptance limits recommended by the CLSI should be used (22). The prepared medium is autoclaved and immediately placed in a 45 to 50°C water bath. When cool, it is poured into round plastic flat-bottomed petri dishes on a level surface to give a uniform depth of about 4 mm (60 to 70 ml of medium for 150-mm-diameter plates and 25 to 30 ml for 100-mm-diameter plates) and allowed to cool to room temperature. Agar deeper than 4 mm may cause false resistance results (excessively small zones), whereas agar less than 4 mm deep may be associated with excessively large zones and false susceptibility.

Each batch of Mueller-Hinton agar should be checked when the medium is prepared to ensure that the pH is between 7.2 and 7.4 at room temperature, which means that the pH must be measured after the medium has solidified. This can be done by allowing a small amount of agar to solidify around the tip of a pH electrode in a beaker or a cup, by macerating a sufficient amount of agar in neutral distilled water, or by using a properly calibrated surface electrode. A pH outside the range of 7.2 to 7.4 may adversely affect susceptibility test results. If the pH is too low, drugs such as the aminoglycosides, macrolides, and fluoroquinolones will appear to lose potency whereas others (for example, the penicillins and tetracyclines) may appear to have excessive activity. The opposite effects are possible if the pH is too high.

Freshly prepared plates may be used the same day or stored in a refrigerator (2 to 8°C); if refrigerated, they should be wrapped in plastic to minimize evaporation. Just before use, if excess moisture is visible on the surface, plates should be placed in an incubator (35°C) or, with lids ajar, in a laminar-flow hood at room temperature until the moisture evaporates (usually 10 to 30 min). At the time the medium is to be inoculated, no droplets of moisture should be visible on its surface or on the petri dish cover.

Various components of or supplements to Mueller-Hinton medium may affect susceptibility test results; therefore, appropriate quality control procedures (see "Quality Control" below) must be performed and zone diameters must be within acceptable limits. For example, media containing excessive amounts of thymidine or thymine can reverse the inhibitory effects of sulfonamides and trimethoprim, causing zones of growth inhibition to be smaller or less distinct. Organisms may therefore appear to be resistant to these drugs when in fact they are not. Variation in the concentrations of divalent cations, primarily calcium and magnesium, affects results of aminoglycoside and tetracycline tests with *P. aeruginosa* isolates (26). A cation content that is too high reduces zone sizes, whereas a cation content that is too low has the opposite effect. Sheep blood should not be added to Mueller-Hinton medium for testing of nonfastidious organisms, because the blood can significantly alter the zone diameters with several agents and bacterial species (15).

Inoculation Procedure

To ensure reproducibility of disk diffusion susceptibility test results, the inoculum must be standardized (10, 26). The inoculum may be prepared by the growth method or by direct suspension from colonies on the agar plate, as described above for dilution testing.

When trimethoprim-sulfamethoxazole is tested by the direct inoculum suspension method, colonies from blood agar medium may carry over enough trimethoprim or sulfonamide antagonists to produce a haze of growth inside the zones of inhibition with susceptible isolates.

The Mueller-Hinton agar plate should be inoculated within 15 min after the inoculum suspension has been adjusted. A sterile cotton swab is dipped into the suspension, rotated several times, and gently pressed onto the inside wall of the tube above the fluid level to remove excess inoculum from the swab. The swab is then streaked over the entire surface of the agar plate three times, with the plate rotated approximately 60° each time to ensure even distribution of the inoculum. A final sweep of the swab is made around the agar rim. The lid may be left ajar for 3 to 5 min but no longer than 15 min to allow any excess surface moisture to be absorbed before the drug-impregnated disks are applied.

Antimicrobial Disks

Within 15 min after the plates are inoculated, selected antimicrobial agent disks are distributed evenly onto the surface, with at least 24 mm (center to center) between them. Disks are placed individually with sterile forceps or more commonly with a mechanical dispensing apparatus and then gently pressed down onto the agar surface to provide uniform contact. No more than 12 disks should be placed onto one 150-mm-diameter plate and no more than 5 disks should be placed onto a 100-mm-diameter plate to avoid overlapping zones. Some of the antimicrobial agent in the disk diffuses almost immediately; therefore, once a disk contacts the agar surface, the disk should not be moved.

Incubation

No longer than 15 min after disks are applied, the plates are inverted and incubated at 35°C in ambient air. A delay of more than 15 min before incubation permits excess prediffusion of the antimicrobial agents. The interpretive standards for nonfastidious bacteria are based on results of test samples incubated in ambient air, and the zone-of-inhibition diameters for some drugs, such as the aminoglycosides, macrolides, and tetracyclines, are significantly altered by CO_2; therefore, plates should not be incubated in atmospheres with increased CO_2. Testing isolates of some fastidious bacteria, however, requires incubation in 5% CO_2, and zone diameter criteria for those species have been established on that basis (see chapter 75 of this Manual).

Interpretation and Reporting of Results

Each plate is examined after incubation for 16 to 18 h for all nonfastidious bacterial isolates except staphylococci and enterococci, which must be incubated for a full 24 h to allow detection of resistance to oxacillin and vancomycin (26). If plates are inoculated correctly, the diameters of the zones of inhibition are uniformly circular and the lawns of growth are confluent. Growth that consists of individual isolated colonies indicates that the inoculum was too light, and the test must be repeated. The diameters of the zones of complete inhibition, including the diameter of the disk, are measured to the nearest whole millimeter with calipers or a ruler. With unsupplemented Mueller-Hinton agar, the measuring device is held on the back of the inverted petri dish, which is illuminated with reflected light located a few inches above a black, nonreflecting background.

The zone margin is the area where no obvious growth is visible. When isolates of staphylococci or enterococci are tested, any discernible growth (especially a haze of pinpoint colonies) within the zone of inhibition around the oxacillin disk (for staphylococci) or vancomycin disk (for enterococci) is indicative of resistance. For other bacteria, discrete colonies growing within a clear zone of inhibition may indicate testing of a mixed culture that should be subcultured, reidentified, and retested. However, the presence of colonies within a zone of inhibition may also indicate selection of high-frequency mutants indicative of eventual resistance to that agent, e.g., *Enterobacter* spp. with penicillins and cephalosporins. With *Proteus* species, if a thin film of swarming growth is visible in an otherwise obvious zone of inhibition, the margin of heavy growth is measured and the film is disregarded. With trimethoprim, the sulfonamides, and combinations of the two agents, antagonists in the medium may allow some minimal growth; therefore, the zone diameter is measured at the obvious margin, and slight growth (20% or less of the lawn of growth) is disregarded.

The zone diameters measured around each disk are interpreted on the basis of guidelines published by the CLSI, and the organisms are reported as susceptible, intermediate, or resistant to the antimicrobial agents tested (Table 3) (27). The clinical interpretation of the categories of susceptible, intermediate, and resistant has already been provided above under "Dilution Methods." Computer programs are available that accompany some automated zone size reading devices to allow MICs to be derived from the linear regression equation with selected antimicrobial agents and bacterial isolates (14, 63) (see also chapter 17).

Advantages and Disadvantages

The disk diffusion test has several advantages: (i) it is technically simple to perform and very reproducible, (ii) the reagents are relatively inexpensive, (iii) it does not require any special equipment, (iv) it provides susceptibility category results that are easily understood by clinicians, and (v) it is flexible regarding selection of antimicrobial agents for testing. The primary limitation of the disk diffusion test is the spectrum of organisms for which it has been standardized. There have not been adequate studies to develop reliable interpretive standards for disk testing of bacteria not listed in the CLSI disk diffusion document (26) or the recently developed CLSI guideline for infrequently isolated or fastidious bacteria (24). It is also important to note that only certain drugs have been validated for disk diffusion testing of *Stenotrophomonas maltophilia* and *Burkholderia cepacia* (27). The disk test is inadequate for detection of vancomycin-intermediate *S. aureus* (26, 80, 81), does not detect daptomycin resistance in staphylococci and enterococci (45, 72) or colistin resistance in gram-negative bacilli (44), and in the past was reported to have difficulties in the detection of oxacillin-heteroresistant staphylococci (33, 60) and enterococci with low-level (VanB-type) vancomycin resistance (71, 81). A potential disadvantage of disk diffusion susceptibility testing is that it provides only a qualitative result and a quantitative result indicating the degree of susceptibility (MIC) may be needed in some cases, e.g., those involving penicillin and cephalosporin susceptibilities of *S. pneumoniae* and certain viridans group streptococci (see chapter 75 of this Manual).

Quality Control

The goals of a quality control program for disk diffusion are to monitor the precision and accuracy of the procedure, the performance of the reagents (medium and disks), and the performance of persons who do the testing and read, interpret, and report results. To best achieve these goals, reference strains are selected for their genetic stability and their usefulness in the disk diffusion test.

Reference Strains

Reference strains recommended by the CLSI for quality control of the disk diffusion procedure when nonfastidious bacteria are tested are *E. coli* ATCC 25922, *P. aeruginosa* ATCC 27853, *S. aureus* ATCC 25923 (not the same strain used for quality control of MIC tests), *Enterococcus faecalis* ATCC 29212, and *E. coli* ATCC 35218 (27, 28). *E. coli* ATCC 35218 is recommended as a control only for beta-lactamase inhibitor combinations containing clavulanic acid, sulbactam, or tazobactam. *Enterococcus faecalis* ATCC 29212 can be used to ensure that the levels of inhibitors of trimethoprim or sulfonamides in Mueller-Hinton agar do not exceed acceptable limits and can also be used to control disks containing a high concentration of gentamicin or streptomycin (see chapter 74 of this Manual).

The reference strains listed above should be obtained from a reliable source, and stock cultures should be maintained in such a way that viability is ensured and the opportunity for selection of resistant variants is minimal (28). The procedures for maintaining and storing working stock cultures are described in the CLSI standard (26). If an unexplained result indicates that the inherent susceptibility of the strain has been altered, a fresh subculture of that organism should be obtained.

Zone-of-Inhibition Diameter Ranges

The ranges of zone diameters for reference strains used to monitor performance of the disk diffusion test are updated frequently and published annually; therefore, readers should refer to the most recent CLSI document for this information (27). Generally, results of 1 in every 20 tests in a series of tests might be out of the accepted limits. If a second result falls outside the stated limits, corrective action must be taken. The action taken and the results of that action must be documented.

Frequency of Testing

Each new batch or lot of Mueller-Hinton agar must be tested with the reference strains listed above before the medium is released for use with clinical specimens, and quality control must be done before a new lot of antimicrobial disks is introduced. Appropriate reference strains also should be tested each day that the disk diffusion test is performed. The frequency of testing, however, may be reduced if satisfactory performance is documented for 20 or 30 consecutive days of testing: for each combination of drug and reference strain, no more than 1 of 20 or 3 of 30 zone-of-inhibition diameters may be outside the accepted limits published by the CLSI (27). When this criterion is fulfilled, each reference strain need be tested only once per week and any time a reagent component of the test is changed. However, if a zone-of-inhibition diameter falls outside the acceptable control limits, corrective action must be taken. If the problem appears to be caused by an obvious error such as use of the wrong disk or the wrong reference strain, contamination of the reference strain, or incubation in an incorrect atmosphere, repeating the test with the appropriate parameter is acceptable. However, if a cause of the error is not obvious, quality control must be performed daily for a period that will allow discovery of the source of the aberrant result and documentation of how the problem was resolved. This may be accomplished by the same approach described above under "Quality Control" in "Dilution Methods."

Special Disk Tests

Two specialized applications of the disk test are described in detail in chapter 74. In brief, disk testing with cefoxitin is now the preferred method for detection of *mecA*-mediated oxacillin resistance in both *S. aureus* and coagulase-negative staphylococcal species (26, 27, 78). Cefoxitin serves as a surrogate marker for the principal mechanism of oxacillin resistance in staphylococci and provides more reliable results than oxacillin itself. Secondly, inducible clindamycin resistance is not reliably detected by standard dilution or disk diffusion susceptibility testing without induction of the expression of *erm*-mediated macrolide-lincosamide-streptogramin B resistance in staphylococci and hemolytic streptococci (61). Such strains can be accurately detected only by induction of resistance expression by exposure to a macrolide. A disk approximation test in which erythromycin and clindamycin disks are placed in close proximity allows

recognition of inducible resistance by truncating the clindamycin zone and giving rise to a positive "D-zone test" (27, 42). When recognized through disk approximation testing, such strains should be reported as resistant to clindamycin (27, 61). A similar approach may be taken by incorporating a subinhibitory concentration of erythromycin into broth or agar dilution tests with clindamycin, although this approach is not as convenient as the use of the disk approximation method.

ANTIBACTERIAL SUSCEPTIBILITY TESTING METHODS THAT MAY BE USED OUTSIDE OF THE UNITED STATES

The CLSI is best known for developing laboratory testing standards for use in the United States, including those for antimicrobial susceptibility testing (25, 26, 27). The CLSI standards are recognized as U.S. national standards by the American National Standards Institute and by federal regulations, including the Clinical Laboratory Improvement Amendments (46), and as standard reference procedures by the Food and Drug Administration. However, the CLSI procedures are also used by an increasing number of laboratories outside of the United States, including countries in North and South America and in several areas of Europe, Asia, and Australasia. Some countries have national standards or professional committees comprising their own expert microbiologists that establish methods of susceptibility testing for their countries and interpretive criteria for those tests that may or may not be the same as those of the CLSI (17, 41), as described further in chapter 72.

Several variations on dilution and diffusion methods are used for routine susceptibility testing outside the United States (Table 4). Most non-U.S. methods are specific to individual countries, having developed and evolved locally over many years. Many of the non-U.S. methods differ from the CLSI procedures in the choice of media, inoculum preparation procedures, and, for diffusion methods, disk contents. There are also some variations between these methods in breakpoints and the approaches to establishing the breakpoints (41, 69). Variation in test methods can cause considerable confusion in laboratories, especially if both CLSI and non-CLSI methods are used for different organisms. Thus, it is important that any method should be followed in all its detail for valid application of specific breakpoints.

In the past, there have been limited efforts at harmonizing breakpoints internationally (88, 89). The Europeans through the European Society of Clinical Microbiology and Infectious Diseases have formed the European Union Committee on Antimicrobial Susceptibility Testing (EUCAST). EUCAST has defined reference agar and broth microdilution MIC methods (39, 40) for use in Europe. One encouraging prospect for the future is the establishment for the first time of a global standard reference MIC susceptibility method (broth microdilution) developed through the International Organization for Standards (ISO; Geneva, Switzerland) (50) in concert with the European Committee on Standardization (Brussels, Belgium). The global reference method is in essence the CLSI and EUCAST broth microdilution methods with a few differences harmonized in the ISO standard (50). This will hopefully provide a degree of international standardization for reference MIC determinations and allow a benchmark for assessment of the performance of commercial devices for susceptibility testing. In a second document, the ISO has established criteria for acceptable performance of susceptibility testing devices (51).

International Dilution Methods

Both broth and agar dilution methods have been developed in countries outside the United States. In the past, methods using a limited range of concentrations (often one or two), or so-called breakpoint methods, have been advocated (87). They are the standard form of susceptibility testing advocated by the Japanese Society for Chemotherapy (52, 53) and as an alternative to disk diffusion testing by the British Society for Antimicrobial Chemotherapy (BSAC) (1, 16). Reasonably current published methods and standards include those of the BSAC (1; see also http://www.bsac.org.uk), the Société Française de Microbiologie (CA-SFM; http://www.sfm.asso.fr), the Deutsches Institut für Normung (DIN; documents are available through http://www.beuth.de), and the Swedish Reference Group for Antibiotics (SRGA; http://www.srga.org).

Breakpoint methods may be popular in larger laboratories because large numbers of isolates can be tested cost-effectively using replicators and the methods provide susceptibility category (i.e., qualitative) endpoints. Optical readers are available to facilitate reading of agar dilution plates (e.g., Mastascanelite; Mast Laboratories, Bootle, United Kingdom; see http://www.mastascan.com). However, there are considerable difficulties with quality control, including the lack of

TABLE 4 Non-U.S. disk diffusion methods for susceptibility testing

Method (reference)	Country	Society	Agar medium	Comments
BSAC (2)	United Kingdom	BSAC	Iso-Sensitest	
CA-SFM (65)	France	CA-SFM	Mueller-Hinton	Similar to CLSI
DIN (34, 35)	Germany	DIN	Mueller-Hinton	
SRGA (68, 70)	Sweden	SRGA	Iso-Sensitest or Mueller-Hinton	
Neo-sensitabs	Denmark		Mueller-Hinton	Uses antimicrobials incorporated into compressed tablets rather than paper disks. Size of tablets results in substantially larger zones than conventional 6-mm-diam disks.
Calibrated dichotomous sensitivity (12, 13)	Australia		Sensitest	Dichotomous (no intermediate category). Disk strengths chosen to give annular radius of inhibition of ~6 mm where possible.

appropriate control strains for which the MICs are near the breakpoints and the complexity of quantifying drug concentrations prior to use (64). In addition, problems have been reported in the past with the use of Iso-Sensitest agar (3, 84) and with the incorporation of inhibitors to prevent swarming of *Proteus* spp., such as *p*-nitrophenylglycerol (85), or increased agar content for the same purpose (86). In turn, the choice of Mueller-Hinton by the CLSI has been criticized for not providing luxuriant growth of all organisms (88), suggesting that there is no absolutely ideal medium. As the best-studied, most widely used medium for susceptibility testing, Mueller-Hinton broth was chosen for the ISO reference method (50).

International Diffusion Methods

A wide variety of diffusion methods have been developed in different countries over the years. They are quite diverse in their approaches. Almost all have been maintained primarily because of the widespread popularity of disk testing. None appear to offer any major advantage over the modified Kirby-Bauer method (10) advocated by the CLSI (26). As pointed out above, disk methods are inexpensive and flexible and may become more popular through the use of zone readers and interconnected computers for interpretation of zone diameters (4, 63).

The previously recommended BSAC standard diffusion methods and the comparative and Stokes' methods differed from other diffusion methods in that susceptibility categorization was achieved by comparison with a control strain rather than by reference to a defined set of zone diameters (16). This technique attracted criticism because it was not based upon or derived from correlations with MICs (18) and has now been replaced by a correlated diffusion method (2) which is now well developed and kept up-to-date (http://www.bsac.org.uk/susceptibility_testing.cfm). For the new BSAC method, Iso-Sensitest (Oxoid, Basingstoke, United Kingdom) is the recommended agar, supplemented for fastidious bacteria with whole defibrinated horse blood with or without NAD. Mueller-Hinton supplemented with 5% sodium chloride is recommended for the detection of methicillin and oxacillin resistance in staphylococci. The inoculum is prepared to produce semiconfluent growth only, rather than the confluent growth lawn used in the CLSI method. One important change in the newer British method is the elimination of an intermediate category for most organism-antimicrobial agent combinations (62).

Since 1980, the CA-SFM has put considerable effort into standardization of susceptibility testing, including regular updates with breakpoints for new drugs that are published frequently (65; see also http://www.sfm.asso.fr). Like the CLSI, the CA-SFM has selected Mueller-Hinton as the test medium. For diffusion testing, plates can be inoculated by flooding as well as swabbing. In most other aspects, this method resembles that of the CLSI, including the use of control organisms and the choice of disk strength. The CA-SFM provides zone diameter breakpoints for drugs available in France and elsewhere that are not approved for clinical use in the United States, e.g., fusidic acid and pristinamycin (65).

The German standards organization, DIN, published acceptable methods for diffusion susceptibility testing as early as 1979, with irregular updates since then (34, 35). They too use Mueller Hinton agar but will tolerate the use of other media provided that the MIC-zone diameter relationships have been determined for those media. Like the CA-SFM method, the DIN method has much in common with the CLSI method.

The SRGA (68, 77) method uses Iso-Sensitest, although the SRGA also accepts Mueller-Hinton as an alternative. The SRGA system is based on the methodology developed by the original International Collaborative Study (38) that was the first to provide a sound theoretical basis to diffusion susceptibility testing. The breakpoints for susceptibility were restructured in 1981 into the more conventional susceptible, intermediate, and resistant categories (77) and are updated regularly (70).

A method developed by a commercial firm in Denmark differs technically if not in principle from the other methods. This method employs so-called Neo-sensitabs that are compressed tablets 9 mm in diameter into which the antibiotic has been incorporated (Rosco Diagnostica, Taarstrup, Denmark; http://www.rosco.dk). The method and the interpretive zone diameter criteria are updated and published by the manufacturer periodically. Not only are the tablets larger and thicker than conventional 6-mm-diameter paper disks, they usually contain larger amounts of antibiotic, resulting in significantly larger zones of inhibition with most drugs. This has the disadvantage of reducing the number of tablets that can be put on a single plate and still produce readable zones. However, the system does have the advantage that the tablets can be stored at room temperature for up to 4 years, obviating the need for storage under refrigeration or freezing. This is an obvious benefit for laboratories in developing countries where reliable refrigeration and power can be a problem.

A diffusion method developed in Australia in 1975 (12, 13) and still widely used in that country has a number of unique features. The calibrated dichotomous sensitivity method employs Sensitest agar and an unusual method for inoculum preparation and is unique in defining just two categories of susceptibility: susceptible and resistant. In order to simplify test result reading, each new drug is calibrated against the MIC breakpoint to yield wherever possible a zone diameter of 18 mm. This is achieved by adjusting disk strengths, which in most cases are substantially lower than those used with other methods. The lack of an intermediate category, which increases the risk of serious interpretive errors (e.g., susceptible instead of resistant), the absence of some common drugs from the test range, and some unusual use of surrogate drugs for testing have restricted the adoption of this method outside of Australia. The interpretative criteria are updated regularly and can be found on the Web (http://www.med.unsw.edu.au/pathology-cds/).

Non-CLSI Breakpoints

Each international method has, of necessity, had to develop its own breakpoints because of differences in media, inocula, and, in the case of disk diffusion methods, disk strengths. In addition, some non-U.S. organizations have developed specialized methods for setting breakpoints. The BSAC has developed a formula based on maximum blood concentrations, protein binding, and elimination half-life. This is now integrated with other considerations including pharmacodynamics and clinical outcome data (69). The Japanese Society for Chemotherapy uses both a formula and a comparison with favorable outcome in clinical studies where the MICs for the pathogens have been determined (5, 52, 53, 74, 75). The Spanish Society for Chemotherapy has also published breakpoints which tend to be more conservative as they are based primarily on MIC distributions (66). EUCAST has recently set about the task of establishing breakpoints for Europe (see http://www.eucast.org). A feature of the program has been the collation of large amounts of MIC data to establish wild-type strain distributions and cutoff values as a

prelude to formal breakpoint setting (59). EUCAST integrates wild-type strain distributions and pharmacokinetic-pharmacodynamic information in a manner similar to that used recently by the CLSI. As dosages used in Europe can be different from those used in the United States, some breakpoints will differ from those set by the CLSI. Most other groups have set breakpoints without major reference to pharmacokinetics or pharmacodynamics.

COMMON SOURCES OF ERROR IN ANTIBACTERIAL SUSCEPTIBILITY TESTING

Potential sources of error in antibacterial susceptibility testing may be categorized as those that relate to the test system and its components, those associated with the test procedure, those peculiar to certain organism and drug combinations, and those that relate to reporting (34, 60). The most common sources of error encountered in clinical microbiology laboratories are reviewed in the following paragraphs.

Various components of the susceptibility test system may be a source of error. First, the system itself may have limitations regarding the organisms that should be tested. For example, the disk diffusion method should be used only to test rapidly growing bacterial pathogens that have consistent growth rates (those for which interpretive criteria have been developed and published by the CLSI). Second, the medium used may be a source of error if it fails to conform to recommended composition and performance. Factors common to both agar-based and broth-based systems are the pH of the medium, which for Mueller-Hinton agar or broth should be between 7.2 and 7.4, and its cation content. The concentration of magnesium and calcium in the broth medium should be that recommended by the CLSI to ensure reliable results. For detection of oxacillin resistance in staphylococci by testing of oxacillin, it is essential that the proper amount of sodium chloride be included in the agar or broth used for dilution testing. For agar dilution and disk diffusion, the Mueller-Hinton agar should be 3 to 4 mm deep. Third, the components of the system (antimicrobial disks, agar plates, and trays) must be stored properly, and they should not be used beyond the stated expiration dates.

Steps in the susceptibility test procedure that may be a source of error if they are not performed correctly include inoculum preparation, incubation (conditions and duration), endpoint interpretation, and performance of appropriate quality control. The inoculum must be pure, and it must contain an adequate density of bacteria. With rare exceptions, all systems should be incubated in ambient air at 35°C. The incubation time, however, varies. For conventional dilution and disk diffusion systems, incubation for 16 to 20 h and 16 to 18 h, respectively, is recommended except in tests of staphylococci with oxacillin and vancomycin and enterococci with vancomycin, in which systems must be incubated for a full 24 h (25, 26, 82). The endpoints for all susceptibility tests must be measured accurately, following guidelines published by the CLSI (25, 26). If endpoints are interpreted by an instrument, the reliability of that instrument must be monitored. Moreover, with all susceptibility test systems, appropriate reference strains must be tested at regular intervals, any problems that occur must be thoroughly investigated, and corrective action must be well documented.

Testing of certain antimicrobial agents with some bacteria may yield misleading results, because in vitro results do not necessarily correlate with in vivo activity. Examples include narrow- and expanded-spectrum cephalosporins and aminoglycosides tested with *Salmonella* spp. and *Shigella* spp.; all beta-lactam agents except the penicillinase-resistant penicillins (oxacillin, nafcillin, methicillin, or cefoxitin as a surrogate marker) tested with oxacillin-resistant staphylococci; cephalosporins, aminoglycosides (except concentrations used to detect high-level resistance), clindamycin, and trimethoprim-sulfamethoxazole tested with enterococci; and cephalosporins tested with *Listeria* spp. (25, 26, 27). Therefore, for these combinations of organisms and drugs, results should not be reported. Other potential problems associated with reporting are possible transcriptional errors for laboratories that use a manual recording and reporting system and possible errors in transmission of data for laboratories in which an automated susceptibility test system is interfaced with the laboratory and/or hospital information system.

PROBLEM ORGANISMS AND RESISTANCE MECHANISMS

The dilution and diffusion methods described in this chapter have been developed through careful studies and standardized by national professional organizations and diagnostic device manufacturers. Despite this, there are still some organisms for which methods have not yet been standardized (e.g., corynebacteria and some fastidious bacteria in the case of disk testing) or which fail to provide reliable results with some of the standard tests (e.g., *Stenotrophomonas maltophilia* and *Burkholderia cepacia* in the case of disk diffusion testing of some drugs). Certain other organisms may possess resistance mechanisms that are inducible (VanB-type resistance in some enterococci, ampC beta-lactamase in some gram-negative species) or that result in subtle phenotypic expression under standard inoculum and test conditions (e.g., inducible clindamycin resistance in staphylococci and some streptococci; extended-spectrum beta-lactamases in some gram-negative bacilli). Reliable detection of these subtle resistance traits may require the use of different or modified test methods that are outlined in chapter 74 of this Manual. The CLSI adopted revised MIC and disk diffusion breakpoints for testing coagulase-negative staphylococci with oxacillin in an attempt to avoid errors of false susceptibility (25, 26, 27, 79, 90). However, testing of cefoxitin with both *S. aureus* and coagulase-negative species has more recently been recommended by the CLSI as the simplest and most reliable method for detection of *mecA*-mediated oxacillin resistance (27, 78). The screening tests for detection of extended-spectrum beta-lactamases by using cefpodoxime have been expanded by the CLSI to include testing of *Proteus mirabilis* in addition to *E. coli* and *Klebsiella* spp. (27). There has not previously been uniform agreement regarding what level of accuracy is acceptable when selecting a testing method or system for performing antimicrobial susceptibility testing (55). Recently, general guidelines for acceptable performance (e.g., rates of essential agreement and category agreement) have been developed through an international consensus effort (ISO) (51). However, it is important to keep in mind that new resistance mechanisms or decreases in susceptibility to important therapeutic agents can arise at any time to challenge our methods of susceptibility testing, e.g., in the case of vancomycin-resistant or -intermediate *S. aureus* (20, 47, 80, 81). Thus, susceptibility testing methods must continue to evolve and develop over time as new challenges are presented.

Special Phenotypic Methods for Detecting Antibacterial Resistance*

JANA M. SWENSON, JEAN B. PATEL, AND JAMES H. JORGENSEN

74

Special phenotypic tests for detecting antibacterial resistance range from the rapid and simple spot β-lactamase test to the more time-consuming and complex minimal bactericidal concentration (MBC) assays. These tests may either supplement or replace traditional testing methods depending on the organism and the assay. This chapter describes tests for detection of high-level aminoglycoside resistance and acquired vancomycin resistance in enterococci; tests for detection of inducible clindamycin resistance in streptococci; tests for detection of oxacillin, vancomycin, and inducible clindamycin resistance in staphylococci; tests for detection of β-lactamases in multiple organisms; and tests for determination of bactericidal activity.

Quality control information is given for all of the tests in each section; however, guidelines for the frequency of quality control testing are not provided, because they have not been determined and may vary depending on laboratory circumstances. A practical approach would be to perform quality control testing each day clinical isolates are tested or less frequently (e.g., weekly) once a laboratory has thoroughly documented that less frequent quality control testing can validate the reliability of the procedures. However, the College of American Pathologists recommends that quality control testing be done daily on β-lactamase tests. Quality control tests should be performed each time new lots of material are put into use.

TESTS TO DETECT RESISTANCE IN ENTEROCOCCI

Systemic enterococcal infections, such as endocarditis, are commonly treated with a cell wall-active agent (either a β-lactam drug or a glycopeptide such as vancomycin) and an aminoglycoside (usually gentamicin or streptomycin). These agents act synergistically to enhance killing (175). However, when an enterococcal strain is resistant to the cell wall-active agent or has high-level resistance (HLR) to the aminoglycoside, there is no synergism and combination therapy does not provide a bactericidal effect (129). Because of this, it is important to determine the susceptibility to both the aminoglycoside and the cell wall-active agent individually in order to predict the likelihood of synergy. Methods for detection of aminoglycoside and vancomycin resistance are discussed here. A discussion of methods for detection of high-level penicillin and ampicillin resistance was included in the last edition of this Manual.

Detection of High-Level Resistance to Aminoglycosides

Because aminoglycosides have poor activity against enterococci (MICs range from 8 to 256 μg/ml), they cannot be used as single agents for therapy (75, 129). This intrinsic, moderate-level resistance is due to poor uptake of the aminoglycoside by the cell (129). Acquired aminoglycoside resistance in enterococci is due either to mutations resulting in decreased binding of the agent to the ribosome, as occurs with streptomycin (called ribosomal resistance), or, more commonly, to the acquisition of new genes that encode enzymes that modify aminoglycosides (called acquired resistance). Acquired aminoglycoside resistance usually corresponds to MICs that are significantly above the concentrations normally tested in routine susceptibility tests, e.g., ≥2,000 μg/ml for streptomycin and ≥500 μg/ml for gentamicin, and is designated HLR (129) (see also chapters 30 and 71).

Synergy between an aminoglycoside and a cell wall-active agent can be determined directly by performing complex time-kill studies (101) or can be predicted by using less cumbersome screening tests. Gentamicin and streptomycin are the only two agents that should be tested on a routine basis. All enterococcal isolates that are resistant to gentamicin are considered resistant to tobramycin and amikacin as well. Resistance to streptomycin is mediated by a different resistance mechanism, and consequently, streptomycin resistance must be determined separately from gentamicin resistance. Isolates of *Enterococcus faecium* are intrinsically resistant to the synergistic actions of amikacin, kanamycin, tobramycin, and netilmicin with cell wall-active agents, irrespective of in vitro testing results for HLR (125). *E. faecalis* strains that are susceptible to gentamicin may be resistant to kanamycin and amikacin. In vitro tests with amikacin cannot reliably predict HLR to amikacin in *E. faecalis,* but kanamycin may be used to predict HLR to amikacin and kanamycin (161), although optimal methods for testing have not been determined. The genes for two additional

* This chapter contains information presented in chapter 74 by Jana M. Swenson, Janet Fick Hindler, and James H. Jorgensen in the eighth edition of this Manual.

enzymes that mediate gentamicin resistance have been described, *aph2″-(Ic)* and *aph2″-(Id),* (28, 199), neither of which is detected using the screening methods described below since their presence seems to lead to intermediate, not high-level, resistance. Only time-kill or molecular studies can detect the presence of these enzymes. Methods for detection of HLR to aminoglycosides are summarized in Table 1 and discussed below.

Agar Dilution Screening Method

Agar plates are prepared with brain heart infusion (BHI) agar supplemented with 500 μg of gentamicin per ml or 2,000 μg of streptomycin per ml. The plates are inoculated by spotting 10 μl of a suspension that is equivalent to a 0.5 McFarland standard prepared from growth on an 18- to 24-h agar plate, giving a final inoculum of 10^6 CFU per spot. The plates are incubated for a full 24 h in ambient air. The presence of more than one colony or a haze of growth should be read as resistant. For streptomycin, the plates should be reincubated for an additional 24 h if there is no growth at 24 h. Mueller-Hinton agar (MHA), MHA plus 5% sheep blood, or dextrose phosphate agar may be substituted for BHI agar, but because growth is better on BHI agar, this is the preferred medium. Commercially prepared agar screen plates are available and have performed well (61, 157, 158). Kanamycin agar screen tests have not been as extensively evaluated and are not standardized, but it has been reported that for determining HLR to both amikacin and kanamycin in *E. faecalis,* kanamycin at 2,000 μg/ml in BHI agar can be used (161).

Broth Microdilution Screening Method

Broth dilution tests are prepared using a single well or a tube containing BHI broth supplemented with 500 μg of gentamicin per ml or 1,000 μg of streptomycin per ml. The final inoculum concentration is that recommended for routine broth microdilution testing, i.e., 5×10^5 CFU/ml. The plates are incubated for 24 h in ambient air. For streptomycin, the plates should be reincubated for an additional 24 h if there is no growth at 24 h. Any growth is interpreted as denoting resistance.

The recommended streptomycin concentration for use in the broth microdilution screen is one-half that used in the agar dilution screen test. Because this test is often included as part of a routine gram-positive MIC panel, the inoculum is that commonly used in broth microdilution testing (5×10^5 CFU/ml). The total number of cells tested in the agar dilution screening procedure (10^6 CFU/spot) is 20-fold larger than that normally used in the broth microdilution test (5×10^4 CFU/0.1-ml well). In order to provide a test that uses a low inoculum and at the same time maximizes the detection of HLR to streptomycin, it was necessary to lower the concentration recommended for testing streptomycin from 2,000 to 1,000 μg/ml in the broth microdilution test. Because of poorer growth and the lower inoculum, Mueller-Hinton broth is inadequate for use in the broth microdilution screen test (183). The performance of other aminoglycosides in this test has not been evaluated.

Disk Diffusion Screening Method

The standard disk diffusion procedure (37) described in chapter 73 (with unsupplemented MHA) is used, except that special high-content disks (gentamicin at 120 μg and streptomycin at 300 μg) are required (162). Zones are measured after 18 to 24 h of incubation in ambient air at 35°C. Isolates for which the zone diameters are ≥10 mm are categorized as susceptible. The absence of a zone of inhibition corresponds to the presence of HLR. Strains for which the zones of inhibition are 7 to 9 mm usually display HLR, but a few are strains for which the MICs are only moderately elevated (183). Therefore, strains for which the zone diameters are 7 to 9 mm should be tested by either the standard agar or the broth microdilution screen method to determine susceptibility or resistance. High-content gentamicin and streptomycin disks are available commercially.

Quality Control

For both gentamicin and streptomycin, *E. faecalis* ATCC 29212 is used as the susceptible control and *E. faecalis* ATCC 51299 is used as the resistant control strain (182).

TABLE 1 Screening methods for detecting vancomycin and high-level aminoglycoside resistance in enterococci

Parameter	Screening procedure			
	Vancomycin agar dilution	Aminoglycoside agar dilution	Aminoglycoside broth microdilution	Aminoglycoside disk diffusion
Medium	BHI agar	BHI agar	BHI broth	MHA
Inoculum	10^5–10^6 CFU/spot	10^6 CFU/spot	5×10^4 CFU/0.1ml	0.5 McFarland[a]
Incubation (h)	24	24[b]	24[b]	18–24
Drug concn				
Gentamicin	NA	500 μg/ml	500 μg/ml	120 μg/disk
Streptomycin	NA	2,000 μg/ml	1,000 μg/ml	300 μg/disk
Vancomycin	6 μg/ml	NA[c]	NA	NA
Endpoint	>1 colony	>1 colony	Any growth	6 mm = resistant, 7–9 mm = inconclusive,[d] ≥10 mm = susceptible

[a] CLSI disk diffusion method (37).
[b] If streptomycin is negative at 24 h, reincubate for an additional 24 h.
[c] NA, not applicable.
[d] If the zone is 7 to 9 mm, the test is inconclusive, and an agar or broth microdilution test should be performed to confirm susceptibility or resistance.

Only *E. faecalis* ATCC 29212 is used for control of disk diffusion tests. The expected quality control limits are 16 to 23 mm for gentamicin (120-μg) disks and 14 to 20 mm for streptomycin (300-μg) disks (38).

Detection of Vancomycin Resistance in Enterococci

As defined by the Clinical and Laboratory Standards Institute (CLSI, formerly NCCLS), the MIC interpretive criteria for vancomycin are ≤4 μg/ml for susceptible, 8 to 16 μg/ml for intermediate, and ≥32 μg/ml for resistant. The three most common phenotypes of resistance are (i) high-level vancomycin resistance (MICs, ≥64 μg/ml) with accompanying teicoplanin resistance (MICs, ≥16 μg/ml) (VanA phenotype); (ii) moderate- to high-level vancomycin resistance (MICs, 16 to 512 μg/ml), most commonly without teicoplanin resistance (VanB phenotype); and (iii) intrinsic low-level resistance associated with *Enterococcus gallinarum* and *Enterococcus casseliflavus* (MICs, 2 to 32 μg/ml) (VanC phenotype) (107, 108). Both the VanA and VanB phenotypes are most commonly seen in *E. faecalis* and *E. faecium* but have been found in other species (107). Three additional genotypes have been described recently, *vanD* (137, 144), *vanE* (60), and *vanG* (122). The VanD-type resistance, resulting in HLR to vancomycin (MICs, ≥64 μg/ml) and variable resistance to teicoplanin, has been found only in *E. faecium*. The VanE-type resistance, found in *E. faecalis,* exhibits intermediate vancomycin MICs (16 μg/ml), and the organism remains susceptible to teicoplanin. The VanG phenotype is similar to the VanD phenotype.

Many methods commonly used by clinical laboratories, including disk diffusion and the Vitek Legacy and MicroScan systems, have traditionally had problems detecting low-level vancomycin resistance (both VanB and VanC types) (52, 136, 159, 160, 185, 193, 211). However, systems continue to improve (27, 64, 81, 90, 193, 202) and the newer Vitek 2 and Phoenix systems perform very well for the detection of vancomycin resistance in enterococci (1, 50, 54, 177, 202). Disk diffusion testing requires 24 h of incubation and examination of zones under transmitted light.

The vancomycin agar screening test first described by Willey et al. (211) was adopted by the CLSI in 1993 (29, 181) (Table 1). The sensitivity and specificity levels of 96 to 99% and 100%, respectively, were noted at that time. Commercially prepared plates also perform well (52, 61, 204). However, there may still be some confusion among clinical laboratorians about the characterization of susceptibility or resistance for the *van*C-containing enterococci, *E. gallinarum* and *E. casseliflavus,* because their growth is variable on the agar screen plate. Both of these species intrinsically contain a *van*C gene, but the MICs of vancomycin for them range from 2 to 32 μg/ml (107). Whether the presence of this gene is associated with therapeutic failures is not known. Since the vancomycin MICs for these strains are often >4 μg/ml, the strains are likely to grow on the agar screen plates, where a higher inoculum and a richer medium may promote growth (61, 157, 181). Most strains of *van*C-containing enterococci are motile at 30°C; *E. casseliflavus* is typically yellow pigmented. These characteristics have been used to distinguish *van*C-containing enterococci from other species (14, 61, 62). However, some *E. gallinarum* and *E. casseliflavus* strains may be nonmotile. Because of this, a better test to differentiate them from *E. faecalis* and *E. faecium* is fermentation of 1% methyl-α-D-glucopyranoside (MGP). All *van*C-containing enterococci acidify MGP, whereas *E. faecium* and *E. faecalis* do not (149) (see also chapter 30).

Vancomycin Agar Screen Test

Agar plates are prepared with BHI agar supplemented with 6 μg of vancomycin per ml (BHI-V6). Using growth from an 18- to 24-h agar plate, make a suspension equivalent in turbidity to a 0.5 McFarland standard and inoculate the plates by spotting 1 to 10 μl or swabbing an area 10 to 15 mm in diameter. The final inoculum is 10^5 to 10^6 CFU per spot. After inoculation, incubate the plates for a full 24 h in ambient air at 35°C. The presence of more than one colony or a haze of growth indicates resistance.

Quality Control

For quality control, *E. faecalis* ATCC 29212 (no growth, i.e., susceptible) and *E. faecalis* ATCC 51299 (growth, i.e., resistant) should be tested (182). Plates made with BHI agars from certain manufacturers may allow light growth of *E. faecalis* ATCC 29212, especially if the higher inoculum (10 μl) is used or the plates are held longer than 24 h.

Reporting Resistance in Enterococci

For any serious enterococcal infection, results of the screen for HLR to gentamicin and streptomycin should be reported in concert with the results of the testing of the cell wall-active agent (penicillin, ampicillin, or vancomycin), because synergy would not be expected if any one of the agents reported is resistant. Helpful suggestions on reporting the results of enterococcal tests are given by Hindler and Sahm (75).

TESTS TO DETECT RESISTANCE IN STAPHYLOCOCCI

Detection of Oxacillin Resistance in Staphylococci

Strains of *Staphylococcus aureus* resistant to oxacillin are still referred to as MRSA (for methicillin-resistant *S. aureus*). Even though methicillin is no longer available, the acronym "MRSA" has persisted and therefore will also be used here. MIC interpretive criteria recommended by the CLSI for oxacillin and *S. aureus* are ≤2 μg/ml for susceptible and ≥4 μg/ml for resistant (38). At least three different resistance mechanisms contribute to oxacillin resistance in *S. aureus:* (i) production of a supplemental penicillin-binding protein (PBP), PBP 2a, encoded by a chromosomal *mecA* gene; (ii) inactivation of the drug by increased production of β-lactamase; and (iii) production of modified intrinsic PBPs (MOD-SA) with altered affinity for the drug (23, 25, 42, 69, 197). Studies to determine the prevalence of the different resistance mechanisms have not been done; however, it is assumed that the last two occur only rarely. Strains that possess *mecA* (the classic resistance) are either heterogeneous or homogeneous in their expression of resistance. With homogeneous expression, virtually all cells express resistance when tested by standard in vitro test methods. However, testing of a heteroresistant isolate results in some cells that appear to be susceptible and others that appear to be resistant. Often only 1 in 10^4 to 1 in 10^8 *mecA*-positive cells in the test population expresses resistance (71, 156, 198). Heterogeneous expression occasionally

results in MICs that appear to be borderline, i.e., oxacillin MICs of 2 to 8 μg/ml, and consequently, the isolates may be misinterpreted as susceptible (MICs ≤2 μg/ml) (164). Isolates that have classic resistance are usually resistant to other agents such as erythromycin, clindamycin, chloramphenicol, tetracycline, trimethoprim-sulfamethoxazole, older fluoroquinolones, or aminoglycosides. However, some MRSA isolates, such as those described in community-associated infections (referred to as CA-MRSA), are not multiply resistant (18, 138, 216). Resistance mediated by β-lactamase or the presence of modified PBPs (MOD-SA) also results in borderline resistance. β-Lactamase-mediated resistance can usually be distinguished from the classic type (*mecA* positive) of resistance or MOD-SA resistance by the addition of a β-lactamase inhibitor (e.g., clavulanic acid) to the oxacillin MIC test, which lowers the MIC by 2 dilutions or more. Isolates that are resistant by either the β-lactamase or the MOD-SA mechanism usually do not have multiple drug resistance, similar to CA-MRSA.

Reference dilution methods recommended by the CLSI are generally reliable for detection of oxacillin resistance in *S. aureus,* and since lowering of the MIC breakpoints for coagulase-negative staphylococci in 1999 (32), the sensitivity of detection in that group has improved. However, recent studies have found that correlation of these interpretive criteria with the presence or absence of *mecA* is optimal only for *S. epidermidis, S. haemolyticus,* and, possibly, *S. hominis* (66, 80, 115). For other species of coagulase-negative staphylococci (e.g., *S. saprophyticus* and *S. lugdunensis*) the new breakpoints tended to be less specific, i.e., many *mecA*-negative strains were categorized as resistant by disk and MIC methods (59, 80, 115, 121, 150). In 2005, the CLSI revised the staphylococcus tables to group *S. lugdunensis* strains with *S. aureus,* which has helped to resolve some of these problems (35). More recently, it was shown (J. Swenson, unpublished data) that there are still *mecA*-negative *S. lugdunensis* strains categorized as oxacillin resistant by disk diffusion using the 1-μg oxacillin disk (a major interpretive error). Because of this, the CLSI now recommends that testing of *S. lugdunensis* by disk diffusion be done using cefoxitin as a surrogate for oxacillin (see below); oxacillin interpretive criteria for *S. lugdunensis* no longer appear in CLSI M100 tables for staphylococci (38).

Despite continued improvements in reference testing methods with oxacillin, other phenotypic tests have been studied. The use of cefoxitin has recently been highlighted by many investigators as an excellent surrogate for use in detecting *mecA*-mediated resistance in staphylococci. Special phenotypic methods using cefoxitin as well as other methods are discussed below.

Detection Using Cefoxitin as a Surrogate for Oxacillin

Within the past several years, there have been multiple reports of the use of cefoxitin as a surrogate marker for detection of *mecA*-mediated oxacillin resistance. Cefoxitin is a more potent inducer of the *mecA* regulatory system than are other penicillins (123). Following recent studies including a multilaboratory study (187), the CLSI has adopted a cefoxitin disk diffusion method that is equal in sensitivity and specificity to oxacillin disk diffusion for detecting *mecA*-mediated resistance in *S. aureus.* For coagulase-negative staphylococci, the cefoxitin disk diffusion test is equal in sensitivity but greater in specificity when compared to disk diffusion with oxacillin (37). The major drawback of the test is the failure to detect *mecA*-positive strains of *S. simulans* (187).

The cefoxitin disk test is performed using the routine disk diffusion procedure, except that modified interpretive criteria are used: for *S. aureus,* results of ≤19 mm are reported as oxacillin resistant and results of ≥20 mm are considered oxacillin susceptible; for coagulase-negative staphylococci, ≤24 mm is resistant and ≥25 mm is susceptible. The test is easy to read using reflected light and does not require careful examination of the disk diffusion zones for light growth or small colonies. The use of cefoxitin in an agar dilution screen similar to the oxacillin salt-agar screen has also been investigated (58, 187) and warrants further study.

Oxacillin-Salt Agar Screening Test

Although the oxacillin-salt agar screen test has been widely used, recent studies have questioned its sensitivity, especially for heterogeneously resistant strains (17). It is less sensitive than the cefoxitin disk diffusion test (16, 57, 188). The oxacillin-salt agar screen test cannot be used for detecting oxacillin resistance in coagulase-negative staphylococci because it uses 6 μg of oxacillin per ml (190). Consequently, the CLSI eliminated recommendations for using the agar screen to test coagulase-negative staphylococci.

Test Method

MHA supplemented with 4% sodium chloride and 6 μg of oxacillin per ml is used for the agar screen method recommended by the CLSI (36, 37). Plates containing methicillin are not recommended. For the test, inoculum suspensions are prepared by selecting colonies from overnight growth on a nonselective agar plate. The colonies are transferred to broth (e.g., tryptic soy broth) or saline to produce a suspension that matches the turbidity of a 0.5 McFarland standard. This suspension is used to inoculate the oxacillin agar screen plate by either (i) dipping a cotton swab into the test suspension, expressing the excess liquid from the swab, and inoculating an area 10 to 15 mm in diameter (or streaking the swab onto a quadrant of the agar surface) or (ii) spotting an area 10 to 15 mm in diameter with a 1-μl loop that has been dipped in the suspension (186). Test plates are incubated for a full 24 h at 35°C (no higher) in ambient air and examined for growth of more than one colony, which indicates resistance. Once again, the test is currently not recommended for coagulase-negative staphylococci (36, 37).

Quality Control

S. aureus ATCC 29213 (oxacillin susceptible) and *S. aureus* ATCC 43300 (oxacillin resistant) are the recommended quality control strains.

Other Tests for Detection of Oxacillin Resistance in Staphylococci

Several commercial rapid methods that detect oxacillin resistance in staphylococci are available. They include latex agglutination tests that detect the presence of PBP 2a, the MRSA-Screen test (Denka-Seikin Co., Ltd., Tokyo, Japan), the PBP 2′ latex agglutination test (Oxoid Limited, Basingstoke, United Kingdom), the Mastalex test (Mast Diagnostics, Bootle, United Kingdom) (11), and the Slidex MRSA Detection test (bioMérieux, Marcy l'Etoile, France). Only the first two tests have been cleared by the U.S. Food and Drug Administration (FDA). The MRSA-Screen test, cleared for use only with *S. aureus,* has been widely

evaluated and has high sensitivity and specificity for that species (17, 116, 164, 188, 203, 205, 214). Detection of resistance in coagulase-negative staphylococci by the MRSA-Screen test has been less successful, requiring either induction, an increased inoculum, or an increased agglutination time for adequate sensitivity (77, 79, 115, 213). The Oxoid PBP 2′ latex agglutination test was approved by the FDA for testing both *S. aureus* and coagulase-negative staphylococci, the latter requiring induction with oxacillin or cefoxitin. Although not extensively evaluated, its use for same-day reporting of MRSA from blood cultures has been described (119). When confirmation of the presence of the *mecA* gene is required, besides these commercial rapid methods, molecular analysis may also be performed by standard PCR methods (see chapter 16).

Limitations of Methods for Detection of Oxacillin Resistance

Growth of an *S. aureus* isolate on an oxacillin agar screen plate generally means that the isolate is *mecA* positive. When performed properly, the oxacillin agar screen method detects most *mecA*-positive *S. aureus* strains. Occasionally a heteroresistant *mecA*-positive strain is not detected; this may be due in part to a low frequency of resistance expression (17, 153) or to lot-to-lot or manufacturer-to-manufacturer variation in the test medium (74, 76). When the oxacillin agar screen test was compared directly to the use of cefoxitin by disk diffusion, investigators found increased sensitivity in detecting *mecA*-mediated resistance by using cefoxitin disk diffusion, although the statistical significance of this finding was not determined (16, 207).

The oxacillin agar screen test generally does not detect borderline-resistant strains, whether caused by *mecA*-mediated heteroresistance or by the other mechanisms responsible for borderline resistance. Although MOD-SA isolates, particularly those associated with MICs of ≥8 μg/ml, may grow on agar screen plates (186), isolates with borderline resistance due to β-lactamase are usually associated with oxacillin MICs of ≤4 μg/ml and do not usually grow on the screen plates. Cefoxitin disk diffusion testing performs well for detection of borderline resistance caused by *mecA* (57, 187) but does not detect other types of borderline resistance. MOD-SA strains which do not contain *mecA* are categorized as susceptible by cefoxitin disk diffusion despite the oxacillin MIC that they express (187). Since borderline resistance caused by β-lactamase or MOD-SA is infrequently encountered in clinical specimens of *S. aureus,* the possibility of their presence minimally affects the utility of these tests. Testing by a dilution method may also fail to detect extremely heteroresistant, *mecA*-positive *S. aureus* strains (164), which often have borderline resistance. However, if dilution testing is performed so that oxacillin MICs below 2 μg/ml can be detected, MIC testing can be used to discern isolates with borderline resistance, i.e., those with oxacillin MICs of 2 to 8 μg/ml.

Reporting Results

The CLSI recommends that oxacillin-resistant staphylococci be reported as resistant to all β-lactam agents, including penicillins, cephems (i.e., all cephalosporins, including cephamycins), β-lactam/β-lactamase inhibitor combination agents, and carbapenems. These agents are clinically ineffective against oxacillin-resistant staphylococcal infections, even though they may demonstrate in vitro activity (36, 37). Consequently, an isolate that grows on the oxacillin agar screen plate or demonstrates a cefoxitin zone diameter in the resistant range should be considered resistant to these agents as well as to all penicillinase-stable penicillins. Isolates of *S. aureus* that appear oxacillin resistant by an alternative test method but fail to grow on the agar screen plate are probably borderline resistant and lack *mecA* (102, 127, 153). Much less is known about borderline resistance than about *mecA*-positive resistance because there have been few clinical studies (120); however, in animal model studies, isolates with β-lactamase-mediated resistance appear to be effectively treated with β-lactam agents (24, 25, 143, 194). If a phenotypically oxacillin-resistant *S. aureus* strain is isolated from a seriously ill patient and it does not contain *mecA,* this information should be conveyed to the patient's physician. The incidence of phenotypically susceptible *mecA*-positive strains of *S. aureus* is not known. However, should phenotypically susceptible strains be isolated from serious infections in patients with a history of MRSA infection, confirmation by one of the rapid molecular methods such as detection of PBP 2a by latex agglutination should be considered (154, 163, 164).

Detection of Vancomycin Resistance in Staphylococci

Vancomycin resistance in staphylococci is a rapidly evolving subject. Previously, vancomycin-intermediate (MIC of 8 to 16 μg/ml) *S. aureus* (VISA) and *Staphylococcus* species other than *S. aureus* (VISS) were identified and characterized (174). In addition, *S. aureus* strains with reduced susceptibility to vancomycin (MIC, 4 μg/ml) were described and were associated with the same risk factors as VISA (63). More recently, vancomycin-resistant *S. aureus* (VRSA) strains with *vanA*-mediated resistance (MICs, 32 to 1,024 μg/ml) were isolated from four patients in the United States (20–22; T. Madhavan, D. Sievery, J. Rudrik, J. Torresan, and D. Schulman, *Abstr. 43rd IDSA Ann. Meet.,* abstr. 1073, 2005). Until January 2006, the CLSI interpretive criteria for vancomycin and *S. aureus* were as follows: ≤4 μg/ml, susceptible; 8 to 16 μg/ml, intermediate; and ≥32 μg/ml, resistant. As of January 2006, the susceptible category is ≤2 μg/ml, 4 to 8 μg/ml is intermediate, and ≥16 μg/ml is resistant (38). It is important to note that the CLSI interpretive criteria for vancomycin susceptibility in coagulase negative staphylococci (CoNS) were not changed and thus are different from the criteria for *S. aureus.* No *van* gene-mediated vancomycin resistance has been reported for CoNS, but there are reports of isolates with elevated vancomycin MICs (3, 47, 103, 165, 169, 206).

Some routine susceptibility testing methods fail to detect vancomycin-intermediate or vancomycin-resistant staphylococci (191; R. B. Carey, J. B. Patel, S. McAllister, A. Thompson, P. Raney, F. C. Tenover, C. Ginocchio, D. Bopp, N. Dumas, and D. Kohlerschmidt, *Abstr. 44th Intersci. Conf. Antimicrob. Agents Chemother.,* abstr. D-66, 2004; Madhavan et al., Abstr. 43rd IDSA Ann. Meet.). The CLSI reference broth microdilution method and E test are reliable for detection of VISA and VRSA. However, the disk diffusion test cannot detect VISA or VISS because these isolates produce zone sizes within the susceptible range (≥15 mm). In contrast, the disk diffusion test does detect VRSA. An evaluation of automated susceptibility testing systems revealed that not all systems were able to detect one or more VRSA (Carey et al., 44th ICAAC). Some manufacturers of automated susceptibility testing have made adjustments in their testing systems to address this problem.

The BHI-V6 screen agar, used to detect vancomycin-resistant enterococci, was evaluated for detection of

vancomycin-intermediate or -resistant staphylococci in two studies (191; R. B. Carey, D. Lonsway, S. McAllister, J. Patel, P. Raney, and A. Thompson, unpublished data). In both studies, all isolates for which the vancomycin MICs were ≥8 μg/ml grew on the screen agar. Isolates for which the MICs were 4 μg/ml demonstrated variable growth. In both studies, the agar was inoculated with a suspension of organism equal to a 0.5 McFarland standard. In the study by Tenover et al., the plates were inoculated using a 10-μl drop from a calibrated pipette. Carey et al. evaluated the amount and method of inoculum delivery. Delivery of a 10-μl drop from a calibrated pipette was the most sensitive method, demonstrating confluent growth at 24 h for all isolates with MICs ≥8 μg/ml. Inoculation of the agar using a swab immersed in the inoculum and then expressed also resulted in growth of isolates for which the MICs were 8 μg/ml, although for some isolates the growth was a haze or isolated colonies. Other inoculation methods, 10 μl delivered by calibrated loop, 1 μl delivered by calibrated pipette, and 10 μl of a suspension prepared using the Prompt Inoculation System-D (3M Company, St. Paul, Minn.), all demonstrated significantly less sensitivity. In both studies, isolates with a vancomycin MIC ≤2 μg/ml did not grow on commercially prepared media. These studies demonstrate that the BHI-V6 agar is a sensitive method for detection of staphylococci for which the vancomycin MICs are ≥8 μg/ml, using either the 10-μl drop or swab inoculation methods. Additional studies with more isolates are needed to evaluate this agar for detection of *S. aureus* isolates for which the MICs are 4 μg/ml.

Although reduced susceptibility to vancomycin can occur in both *S. aureus* and CoNS, the occurrence in *S. aureus* is more concerning because this species is more frequently a cause of serious infection. It is for this reason that the Centers for Disease Control and Prevention recommended use of the screen agar for detection of *S. aureus* with reduced susceptibility to vancomycin (22). This recommendation is for laboratories that may miss these isolates when using their primary susceptibility testing method. However, some laboratories may consider limiting this testing to methicillin-resistant *S. aureus* strains since these are the isolates most likely to develop reduced susceptibility to vancomycin. Use of the BHI-V6 agar for *S. aureus* is described in the CLSI documents (36, 37).

Test Method

The recommended method for inoculating the agar is a 10-μl drop of a 0.5 McFarland suspension delivered with a micropipette. Alternatively, a swab can be used to spot an area 10 to 15 mm in diameter. The agar plate should be read after 24 h of incubation and carefully examined with transmitted light. Greater than one colony of growth or a light film of growth is considered positive (36, 37).

Quality Control

As mentioned above, the BHI-V6 plate is the same screening agar used to detect vancomycin-resistant enterococci (VRE) and the same quality control strains recommended for the VRE test can also be used for the *S. aureus* test (38). These strains are vancomycin-susceptible *E. faecalis* ATCC 29212 and *vanB*-mediated, vancomycin-resistant *E. faecalis* ATCC 51299. Since the amount of inoculum applied for the VRE test (1 to 10 μl of a 0.5 McFarland suspension) spans the recommended inoculum for the *S. aureus* test, a laboratory that uses this medium for both purposes need perform quality control only once, either daily or weekly.

Reporting Results

Growth of *S. aureus* on the BHI-V6 agar is presumptive for either VISA or VRSA (36, 37) (http://www.cdc.gov/ncidod/dhqp/ar_visavrsa_algo.html). Additional testing is needed to confirm vancomycin resistance. First, the identity and purity of the isolate should be confirmed. Then, the MIC of the isolate should be determined using a validated method. For many laboratories the most available method is the E test. It is recommended that any *S. aureus* isolate for which the vancomycin MIC is ≥4 μg/ml be sent to a reference laboratory for confirmation. In the United States, several states request that VISA and/or VRSA be reported to the public health authority.

Detection of Inducible Clindamycin Resistance by Use of the D-Zone Test

Although erythromycin and clindamycin are in separate antimicrobial agent classes, macrolides and lincosamides, respectively, their mechanisms of action (inhibition of protein synthesis) and mechanisms of resistance are similar. The two main mechanisms of resistance are (i) an efflux pump and (ii) a methylase enzyme that alters the ribosomal binding site of the antimicrobial agents. The first type, which confers resistance to macrolides only (designated M-type, for macrolide), is mediated in staphylococci by *msrA*. The second type, which confers resistance to macrolides, lincosamides, and streptogramin B agents (designated MLS_B type, for macrolide-lincosamide-streptogramin B), is mediated by an *erm* gene. In staphylococci, the MLS_B-type resistance can be either constitutive or inducible; if inducible, the isolate appears to be susceptible to the lincosamide (i.e., clindamycin) when using routine testing methods, unless induced by a macrolide (i.e., erythromycin). It is important to determine if resistance (whether inducible or constitutive) to clindamycin exists when it is being considered for therapy. Detailed explanation of these resistance mechanisms can be found in chapter 71.

Phenotypically, if an isolate has M-type resistance it is resistant to erythromycin but susceptible to clindamycin. If an isolate has MLS_B-type resistance, then it is erythromycin resistant and may be susceptible or resistant to clindamycin because it is either constitutive or inducible to that drug. In strains that are erythromycin resistant but clindamycin susceptible, it is important to determine if inducible clindamycin resistance exists (and an *erm* gene is present) or if the strain remains clindamycin susceptible (and an efflux gene is present).

Test Method

Detection of inducible clindamycin resistance can be easily accomplished using a disk diffusion procedure by placing a 15-μg erythromycin disk adjacent to a 2-μg clindamycin disk and looking for a flattening of the clindamycin zone, which looks like the letter D and is therefore referred to as a D zone. For laboratories that are already performing disk diffusion, this may be done by placing the disks from 15 to 26 mm apart (55) with the other disks tested on an MHA plate. Some disk dispensers may position disks more than 26 mm apart even if the disks are placed in adjacent positions. Therefore, because dispensers may vary and the distance is critical, the distance should be verified before being adopted as a standard procedure. Placing the disks 15 to 20 mm, rather than 26 mm, apart may make the test easier to interpret (179, 215), although to accomplish this the disks must be placed on the plates by hand instead of with a

disk dispenser. For laboratories that routinely perform antimicrobial susceptibility methods other than disk diffusion, Jorgensen et al. have shown that the test can be performed on a standard blood agar plate used for purity checks (94) by streaking one-third of the plate for confluent growth and then streaking for isolation on the rest of the plate. In that study, the investigators showed that dilutions of the 0.5 McFarland inoculum of up to 1:250 can be used. The disks are placed 15 mm apart on the portion of the plate where confluent growth would occur. In a later study, it was determined that the BBL Prompt system (BD, Sparks, Md.) should not be used to inoculate the purity plate for D-zone determination (215). In that study, the investigators suggested that no more than a 1:20 dilution of a 0.5 McFarland suspension should be used to inoculate the purity plate. However, if the Prompt inoculum wand was used directly to inoculate the plate, it may have delivered inadequate inoculum. More recently the Prompt System was successfully used for this purpose (J. F. Hindler and D. A. Bruckner, *Abstr. 105th Gen. Meet. Am. Soc. Microbiol.,* abstr. C-325, 2005) by transferring inoculum from the Prompt reservoir tray, using a 10-μl loop, and streaking one-third of the plate to obtain confluent growth. For either method, organisms that show a blunting or flattening of the clindamycin zone are considered D-zone test positive; those that show no flattening are D-zone test negative.

Quality Control and Quality Assessment

Two strains have been designated for quality assessment purposes (i.e., for training, competency assessment, or test evaluation): *S. aureus* BAA-977, which contains inducible *ermA*-mediated resistance; and *S. aureus* BAA-976, which contains *msrA*-mediated resistance to erythromycin only. *S. aureus* ATCC 25923 should be used as the routine quality control strain for daily or weekly quality control testing of clindamycin and erythromycin disks using MHA. If the test is performed as part of the purity check procedure, the CLSI recommends that the disk content should be verified using *S. aureus* ATCC 25923 on MHA (38). However, this would require that laboratories that do not do disk diffusion routinely would have to have a supply of MHA plates on hand for quality control purposes only. An alternative to this would be to use the two quality assessment strains, BAA-977 and BAA-976, as quality control organisms at daily or weekly intervals based on CLSI recommendations when using the purity plate method.

Reporting Results

The incidence of inducible clindamycin resistance in staphylococci can be highly variable, both by geographic area and by organism group (i.e., hospital-associated MRSA, community-associated MRSA, and coagulase-negative staphylococci). The CLSI now recommends that isolates that are D-zone test positive should be reported as clindamycin resistant (36, 37). However, there is some controversy about this, given that clindamycin has been effective in some situations where inducible resistance was demonstrated (112). As a conservative approach, the CLSI has suggested that inducibly clindamycin-resistant strains could be reported as resistant with a comment stating, "This isolate is presumed to be resistant based on detection of inducible clindamycin resistance. Clindamycin may still be effective in some patients." If the test is not offered routinely, it should be available by request for cases where clindamycin is being considered for therapy (36, 37).

TESTS TO DETECT RESISTANCE IN STREPTOCOCCI

Oxacillin Disk Screen Test for Detection of Penicillin Resistance in Pneumococci

A screening test in which a 1-μg oxacillin disk is used to detect penicillin resistance in pneumococci was first described following an outbreak caused by *Streptococcus pneumoniae* resistant to multiple antimicrobial agents in South Africa in the 1970s (45, 82, 184). Since then, this test has been used extensively and shown to be highly sensitive but not specific for detection of penicillin-nonsusceptible pneumococci (46). Strains identified as nonsusceptible by this method may be penicillin susceptible, intermediate, or resistant. Penicillin MIC tests must be performed with any strain that produces a zone diameter of $\leq$19 mm to determine if it is resistant (46). MIC tests rather than the oxacillin disk screen should be used routinely on strains isolated from cerebrospinal fluid and blood.

Detection of Inducible Clindamycin Resistance by Use of the D-Zone Test

The importance of determining erythromycin and clindamycin resistance phenotypes and the detection of inducible clindamycin resistance follows the same logic as that described for staphylococci (see "Detection of Inducible Clindamycin Resistance by Use of the D-Zone Test" above); however, the gene responsible for the M phenotype (i.e., erythromycin resistance and clindamycin susceptibility) in streptococci is *mef*(A). The MLS_B phenotype exists in isolates of beta-hemolytic streptococci, *S. pneumoniae,* and viridans group streptococci; however, in pneumococci and viridans streptococci it is usually the constitutive type and only rarely inducible (128, 201). Therefore, inducible clindamycin resistance needs to be determined only in isolates of beta-hemolytic streptococci.

Test Method

Detection of inducible clindamycin resistance in beta-hemolytic streptococci can be accomplished using a disk diffusion procedure similar to that for staphylococci by placing a 15-μg erythromycin disk adjacent to a 2-μg clindamycin disk and looking for a flattening of the clindamycin zone, which looks like the letter D and is therefore referred to as a D zone. For laboratories that are already performing disk diffusion, the disks must be placed by hand at a distance of 12 mm from each other (151) on an MHA plate with 5% sheep blood along with other disks being tested. A disk dispenser cannot be used to place the two disks since they must not be farther away than 12 mm (151). For laboratories that routinely perform other antimicrobial susceptibility methods, the purity plate method suggested by Jorgensen et al. can also be performed on a standard blood agar plate used for purity checks (94, 151) by streaking one-third of the plate for confluent growth and then streaking for isolation on the rest of the plate. The disks are then placed 12 mm apart on the portion of the plate where confluent growth would occur. Only the use of a 0.5 McFarland suspension has been evaluated for inoculation of the purity plate (151). For either method, organisms that show a blunting or flattening of the clindamycin zone are considered D-zone test positive; those that show no flattening are D-zone test negative.

Quality Control and Quality Assessment

Two strains have been designated for quality assessment (i.e., for training, competency assessment, or test evaluation)

of the D-zone test: *S. aureus* BAA-977, which contains inducible *ermA*-mediated resistance to clindamycin, and *S. aureus* BAA-976, which contains *msrA*-mediated resistance to erythromycin only. *S. pneumoniae* ATCC 49619 should be used as the routine quality control strain for daily or weekly quality control testing of clindamycin and erythromycin disks, using MHA with 5% sheep blood. If the test is performed as part of the purity check procedure, ideally the disk content should be verified using *S. pneumoniae* ATCC 49619 on MHA with 5% sheep blood. However, this would require that laboratories that do not do disk diffusion routinely would have to have a supply of MHA with 5% sheep blood on hand for quality control purposes only. An alternative to this would be to use the two quality assessment strains, BAA-977 and BAA-976, as quality control organisms at daily or weekly intervals based on CLSI recommendations when using the purity plate method.

Reporting Results

The incidence of inducible clindamycin resistance in beta-hemolytic streptococci can be highly variable, both by geographic area and organism group (44, 106). However, when inducible clindamycin resistance is detected, the CLSI recommends that, as for staphylococci, isolates shown to be D-zone test positive should be reported as clindamycin resistant. As a conservative approach, the CLSI has suggested that inducibly clindamycin-resistant strains could be reported as resistant with a comment stating, "This isolate is presumed to be resistant based on detection of inducible clindamycin resistance. Clindamycin may still be effective in some patients." If the test is not offered routinely, it should be available by request for cases where clindamycin is being considered for therapy.

DETECTION OF ENZYMES MEDIATING RESISTANCE

β-Lactamase Tests

In the clinical laboratory, β-lactamase tests must be used only when they can provide clinically useful information, and the definitions of positive or negative reactions must not be extended beyond their intended meanings. For example, a β-lactamase-positive result for a *Neisseria gonorrhoeae* isolate means that the isolate is resistant to penicillin but does not imply that the isolate is resistant to the extended-spectrum cephalosporin group of β-lactam agents. Similarly, direct β-lactamase tests for members of the family *Enterobacteriaceae* or for *Pseudomonas* spp. (all of which produce a variety of β-lactamases that result in various susceptibilities to β-lactam agents) have little clinical value and should not be used for these species. A list of the organisms for which β-lactamase tests are useful is given in Table 2.

Direct Tests for β-Lactamase Activity

In the direct β-lactamase test, a positive reaction indicates that the isolate is resistant to the β-lactam agents noted in Table 2, but a negative reaction is inconclusive. For example, most ampicillin-resistant *Haemophilus influenzae* isolates produce β-lactamase, which can be detected by direct β-lactamase tests; however, rare strains are ampicillin resistant but β-lactamase negative (8, 46, 56). For the latter, conventional disk diffusion or dilution tests are needed to detect the resistance (see chapter 73). Three direct β-lactamase assays, the acidimetric, iodometric, and chromogenic methods, have been widely used (73, 110). Each method involves testing bacteria grown on nonselective media, and the results are available within 1 to 60 min. The acidimetric and iodometric methods use a colorimetric indicator to detect the presence of penicilloic acid in the reaction vessel following β-lactamase hydrolysis of penicillin. In the acidimetric method, the substrates are citrate-buffered penicillin and a phenol red indicator. A decreasing pH associated with the presence of penicilloic acid results in a color change from red (negative result) to yellow (positive result) (53). The substrates in the iodometric test are phosphate-buffered penicillin plus a starch-iodine complex. Penicilloic acid, if present, reduces the iodine and prevents it from combining with starch, resulting in a colorless reaction (positive); a bluish purple color corresponds to a negative result (15).

The chromogenic cephalosporin nitrocefin can be used in a test tube assay (135) but has been incorporated into

TABLE 2 Bacteria for which β-lactamase tests have been used in the clinical laboratory

Species	Method(s) commonly used	Predicted resistance[a]
Bacteroides spp. and other gram-negative anaerobes, except *B. fragilis* group	Direct β-lactamase tests[b]	Penicillins[c]
Enterococcus spp.	Direct β-lactamase tests	Penicillins[c]
Haemophilus influenzae	Direct β-lactamase tests	Penicillins[c]
Moraxella catarrhalis	Direct β-lactamase tests (nitrocefin only)	Penicillins[c]
Neisseria gonorrhoeae	Direct β-lactamase tests	Penicillins[c]
Staphylococcus spp.	Direct β-lactamase tests with prior induction	Penicillins[c]
Escherichia coli	NCCLS ESBL screening and confirmation tests	Penicillins, cephems, and aztreonam
Klebsiella pneumoniae and *K. oxytoca*	NCCLS ESBL screening and confirmation tests	Penicillins, cephems, and aztreonam

[a] A positive result indicates resistance; however, a negative result is inconclusive, since other resistance mechanisms may occur.

[b] Includes chromogenic cephalosporin, acidimetric, and iodometric tests.

[c] A positive result indicates resistance to all penicillinase-labile penicillins, including amoxicillin, ampicillin, azlocillin, carbenicillin, mezlocillin, piperacillin, and ticarcillin.

several filter paper-type disk or strip products that are commercially available and widely used in clinical laboratories. β-Lactamase hydrolysis of the chromogenic cephalosporin molecule causes an electron shift that results in a colored product (135). Although the acidimetric and iodometric methods have varied in performance, perhaps due in part to lack of experience with these methods, the chromogenic method has been reliable in detecting β-lactamases produced by all of the organisms indicated in Table 2 (92, 134).

The colorimetric β-lactamase tests rely on visualization of a colored product that presumably results from β-lactamase destruction of the substrate β-lactam molecule. However, these tests are not 100% specific, and other substances may yield colored end points. Serum may cause a colored reaction with the nitrocefin test (135), and, if reagents are not stored properly, spontaneous degradation of penicillin may produce false-positive acidimetric or iodometric β-lactamase reactions.

While some bacteria (e.g., *H. influenzae, N. gonorrhoeae,* and enterococci) constitutively produce β-lactamase, others (e.g., staphylococci) may produce detectable amounts of enzyme only after exposure to an inducing agent, which is generally a β-lactam (48). If staphylococci produce a positive β-lactamase result without induction, the results can be reported. However, if no β-lactamase is detected, then the test must be performed with cells that have been exposed to an inducing agent before a negative result is reported. This can be done by testing organisms that have been grown in the presence of subinhibitory concentrations of a β-lactam agent (e.g., 0.25 μg of cefoxitin per ml) in a broth or agar system. Alternatively, growth from around the periphery of the zone surrounding a β-lactam disk (e.g., a 1-μg oxacillin or 30-μg cefoxitin disk) can be tested. A positive result may take longer to develop for staphylococci than for other organisms, and the test should not be considered negative until it has been allowed to react for at least 60 min.

β-Lactamase testing by the chromogenic nitrocefin method with anaerobic gram-negative bacilli other than those from the *Bacteroides fragilis* group may be performed prior to susceptibility testing (33). Members of the *B. fragilis* group characteristically produce β-lactamase, and they should be considered penicillin resistant. As with aerobes, resistance to β-lactam drugs is not always mediated by β-lactamase production (e.g., in some strains of *Bacteroides distasonis* and *B. fragilis*) (2, 33, 83).

The *S. aureus* strains recommended by the CLSI for quality control of routine disk diffusion and dilution tests (36–38) can be used for quality control of β-lactamase tests. *S. aureus* ATCC 25923 is β-lactamase negative, whereas *S. aureus* ATCC 29213 is β-lactamase positive.

Tests for Extended-Spectrum β-Lactamases

The genes generally responsible for β-lactamase-mediated ampicillin resistance in *Escherichia coli, Klebsiella* spp., *Proteus mirabilis,* and some other genera of the family *Enterobacteriaceae* can undergo simple point mutations that result in the production of novel β-lactamases that are capable of hydrolyzing extended-spectrum cephalosporins (e.g., cefotaxime, ceftriaxone, ceftizoxime, and ceftazidime) and aztreonam, as well as older β-lactam drugs. These enzymes are referred to as extended-spectrum β-lactamases (ESBLs) (9, 12, 85, 113, 147, 196) and are discussed in chapter 71. More than 200 different types of ESBLs have been noted to occur in several gram-negative species and are associated with a variety of in vitro antimicrobial susceptibility profiles (12, 196; http://www.lahey.org/Studies/).

The in vitro susceptibility results obtained with an isolate that produces ESBLs often defy typical "hierarchy" rules of β-lactam (particularly cephem) activity. Sometimes the more narrow spectrum cephems (particularly the cephamycins, such as cefoxitin or cefotetan) are more active than broad-spectrum agents (26, 126). Several reports suggest that ESBL-producing isolates should be considered resistant to all extended-spectrum penicillins, cephalosporins, and monobactams even if they appear to be susceptible to these agents in vitro (139, 140, 173). The β-lactamase-stable carbapenems (ertapenem, imipenem, meropenem) are active in vitro (4, 84, 91, 148, 171, 172, 212) and appear to be clinically effective against ESBL producers (88, 124, 139, 142). Some ESBL-producing isolates are susceptible to β-lactam/β-lactamase inhibitor combination agents in vitro, but the effectiveness of these agents in vivo is uncertain, particularly if there is a high concentration of organisms at the infection site (86). The genes that code for production of ESBLs are often linked to other resistance genes, so that ESBL-producing isolates are often multiply resistant (e.g., resistant to aminoglycosides and trimethoprim-sulfamethoxazole) (96).

Routine disk diffusion and MIC tests using traditional breakpoints may not always identify isolates that produce ESBLs (87, 89, 96, 126). Thus, the CLSI has developed MIC and disk diffusion screening breakpoints for aztreonam, cefotaxime, cefpodoxime, ceftazidime, and ceftriaxone for *E. coli, Klebsiella oxytoca,* and *Klebsiella pneumoniae* and, more recently, for cefpodoxime, ceftazidime, and cefotaxime for *Proteus mirabilis* that aid in detecting ESBL-producing isolates (38) of those species. ESBL-producing clinical isolates may demonstrate high-level resistance to one or more of the screening drugs (88, 96, 114, 124, 171, 210). Thus, the sensitivity of the screen test increases when more than one screening drug is used (51, 126, 212). Cefpodoxime is most likely to detect isolates producing ESBLs, but this agent lacks specificity, particularly for *E. coli* (65, 126, 195). However, the CLSI has modified the screening breakpoints for cefpodoxime for *E. coli* and *Klebsiella* spp. in order to increase the specificity with a minimal effect on the sensitivity (34). Only cefpodoxime, cefotaxime, and ceftazidime have been validated for use with *P. mirabilis* (38).

Unlike inducible AmpC β-lactamases, ESBLs are inhibited by clavulanic acid, and this property is used in laboratory tests to identify ESBLs in the clinical laboratory. These tests are based on enhanced activity when a β-lactam (usually ceftazidime or cefotaxime) is tested with clavulanic acid compared to the activity when the β-lactam is tested alone. The CLSI describes standard disk diffusion and broth microdilution MIC tests to be used as phenotypic confirmatory tests for the presence of ESBLs in *E. coli, K. oxytoca, K. pneumoniae,* and *P. mirabilis*. For broth microdilution, cefotaxime and ceftazidime are tested with and without 4 μg of clavulanic acid per ml. A decrease in the MIC of ≥3 dilutions for the agents tested in combination with clavulanic acid compared to the values obtained for the agents tested alone indicates the presence of an ESBL. For disk diffusion, the same agents incorporated into disks with and without 10 μg of clavulanic acid are tested. An increase in the zone diameter of ≥5 mm for either of the disks with clavulanic acid indicates the presence of an ESBL. *K. pneumoniae* ATCC 700603 should be included for quality control purposes; accepted ranges are given in the current CLSI M100 tables (38). Isolates of *E. coli, Klebsiella* spp., and *P. mirabilis* confirmed to be ESBL producers should be reported as resistant to penicillins (not including β-lactam/β-lactamase inhibitor combinations), cephalosporins (which excludes the

cephamycins, cefoxitin and cefotetan), and aztreonam (36–38). For screen-positive strains that do not show a clavulanic acid effect, there are insufficient data to justify modifying reports at present; these isolates should be reported as they test. One of the limitations of the phenotypic confirmatory test is that some ESBL-producing strains may demonstrate a negative confirmatory test result, which may occur as a result of decreased porin production, hyperproduction of a TEM-1 or SHV-1 β-lactamase, production of additional β-lactamases (e.g., AmpC) that are not inhibited by clavulanic acid, or a combination of these (12, 196). Steward et al. (180) showed in a recent study that cefepime with and without clavulanic acid is superior to the current confirmatory test agents (both cefotaxime and ceftazidime with and without clavulanic acid) in detection of ESBLs in some strains that have multiple β-lactam resistance mechanisms. The CLSI has not addressed the utility of the screening or phenotypic confirmatory tests for detecting ESBLs in members of the family *Enterobacteriaceae* other than *E. coli, Klebsiella* spp., and *P. mirabilis.* In theory, however, they should detect ESBLs in other genera that are normally susceptible to extended-spectrum cephalosporins.

Typically, screening for and confirmation of ESBL production is a two-step process; however, there are several FDA-cleared commercial products that incorporate a confirmatory test on a primary susceptibility test panel. The laboratory's ability to detect and report the presence of ESBLs in a timely manner will likely affect the selection of appropriate therapy for patients with infections caused by ESBL-producing strains. Consequently every laboratory should have a procedure to address the detection of ESBLs (105, 140, 148, 173, 192). There is some debate as to the significance of ESBLs in isolates from noninvasive infections, such as uncomplicated urinary tract infections (51, 141). However, regardless of the source, ESBL-producing isolates are important from an infection control perspective.

Tests for Detection of Plasmid-Mediated AmpC-Type β-Lactamases

Inducible AmpC-type β-lactamases occur on the chromosome of several gram-negative bacilli such as *Enterobacter cloacae, Citrobacter freundii, Serratia marcescens,* and *Pseudomonas aeruginosa* (113). These enzymes confer resistance to a wide spectrum of β-lactams, and they are resistant to the commonly used β-lactamase inhibitors (see details in chapter 71). AmpC-type β-lactamases may be located on transmissible plasmids in several bacterial species that lack an inducible chromosomal enzyme, including *E. coli, Klebsiella* spp., *Salmonella* spp., and *P. mirabilis* (146). These plasmids often carry resistant determinants for multiple classes of antimicrobial agents. AmpC-type enzymes in porin-deficient strains can result in carbapenem resistance (10, 176). Therefore, detection of plasmid-mediated AmpC-type enzymes may be important for treatment decisions, infection control, and epidemiological investigations (19, 131, 132).

Isolates with a plasmid-mediated AmpC-type enzyme are usually resistant to cephamycins (e.g., cefoxitin and cefotetan), which is a useful phenotypic marker for the β-lactamase. However, loss of a porin can also result in cephamycin resistance (72), so a more specific test is necessary. Several tests have been proposed for detecting this type of resistance. Two assays, the modified three-dimensional extract test and the cefoxitin-agar medium-based assay, are too labor-intensive for routine use in the clinical laboratory (39, 133). The more promising assay is a disk diffusion assay similar to the CLSI disk diffusion confirmatory test for ESBL detection. This test incorporates 20 μg of β-lactamase inhibitor, 48-1220 or LN-2-128, into a 30-μg cefotetan disk. In one study (7), a 4-mm reduction in zone size around the disk with cefotetan plus 48-1220 when compared to the zone size around the disk with cefotetan only correlated well with the presence of a plasmid-mediated AmpC-type enzyme in isolates of *Klebsiella* spp. and *E. coli*. Although this test holds promise for phenotypic detection of AmpC β-lactamases, these β-lactamase inhibitors are not commercially available so the test cannot yet be used by clinical laboratories.

DETERMINATION OF BACTERICIDAL ACTIVITIES OF ANTIMICROBIAL AGENTS

Most in vitro susceptibility test methods measure the abilities of antimicrobial agents to inhibit the growth of bacteria. It is also possible to assess the ability of a drug to provide a bactericidal effect on an isolate or group of isolates. This may be useful in managing serious infections that require bactericidal action for optimal efficacy such as endocarditis and osteomyelitis (152), for immunosuppressed patients (170), and to study the pharmacodynamic properties of new or established antimicrobial agents or drug combinations (6, 111, 178). The tests most often performed include determination of the MBC, serum bactericidal titers (SBT), and kinetic time-kill assays. Even in the most sophisticated clinical laboratories serving large tertiary-care medical centers, determinations of bactericidal activity probably account for fewer than 1% of all susceptibility tests performed. Thus, these are highly specialized tests performed for very limited indications.

Tests of bactericidal activity are primarily used for selection and monitoring of therapy for patients with infective endocarditis (41, 93, 145, 152, 155, 167, 168, 208), osteomyelitis (93, 130, 145, 152, 209), meningitis (145, 155, 166), or for neutropenic cancer patients (97, 100, 170). These tests may be favored by certain physicians or specialty groups (e.g., infectious disease specialists) for the management of their patients' very complicated infections but do not represent standard care in most medical centers. Data in support of the use of bactericidal activity determinations for patient management are limited, and early studies were often performed using nonstandardized methods (41, 93, 117, 167, 189). Prior reviews have highlighted the technical problems and lack of expert consensus for interpreting the results of bactericidal determinations (117, 118, 152). The perception that the tests are not reproducible may have stifled the development of consensus criteria for when and how these tests can best be applied. The lack of standardization of the specific assays has been addressed by the CLSI through the publication of standard methods for determining bactericidal activity (30, 31). This section discusses bactericidal testing in a clinical laboratory setting and reflects the consensus standards developed by the CLSI.

Clinical Use of Bactericidal Testing

For those who favor the use of bactericidal tests for management of serious infections, a typical sequence is to first determine the MICs and MBCs of a limited number of agents that could be used to treat the patient in order to select the agent with the most favorable (i.e., lowest) MBC relative to the safely achievable levels of the drug. Determination of the MBC provides an opportunity to detect possible tolerance of the patient's isolate to drugs that would normally be considered bactericidal against the species being tested and might

result in clinical failure (43, 70, 78, 130, 200). Once one or more drugs have been selected on the basis of the MIC and MBC results and the patient has been started on standard doses of the agent(s), the second step is to assess the bactericidal activity achieved in the patient by performance of the serum bactericidal test(s). The goal is to ensure that the dosage regimen provides sufficient bactericidal activity in that patient's blood or, possibly, cerebrospinal fluid. The body fluid (usually serum) is serially diluted and inoculated with the patient's infecting organism. The SBT test result is expressed as a titer indicating the dilution of serum or body fluid that is bactericidal; a higher titer indicates better activity. If the SBT is deemed to be too low, it may be possible to alter the dosage regimen or to select an alternative regimen in an effort to avoid a poor therapeutic outcome (152, 208, 209). Performance of the SBT test can also provide an assessment of the effectiveness of drug combinations intended to provide a synergistic effect in order to treat a highly resistant bacterial isolate or an organism not killed by single-agent therapy (e.g., *Enterococcus* spp.) (30).

Performance of bactericidal tests requires considerable technical proficiency on the part of the laboratory and a highly informed and experienced clinician to make use of the data. The interpretation of the SBT must take into account knowledge of the key pharmacodynamic property of the antimicrobial agent (i.e., concentration-dependent versus time-dependent killing activity), the location and severity of the infection, the pathogenic potential of the infecting organism, and the potential toxicity and cost of the treatment regimen. Bactericidal testing should not be performed unless there is close communication between the clinical microbiologist and the requesting clinician. Potential pitfalls include selecting potentially more toxic or expensive drugs on the basis of a low MIC or MBC (unless the physician is very knowledgeable about various classes of antimicrobial agents) and raising antibiotic levels to potentially toxic levels in order to achieve a higher or more favorable SBT. Therefore, laboratories should undertake bactericidal testing only after thorough discussions with their clinician customers.

Determination of the MBC

There are several basic requirements for standardized determination of the MBC. The test may be performed by either the tube broth macrodilution method or the broth microdilution procedure. A detailed description of the methods can be found in the CLSI document that deals specifically with bactericidal tests (31). In brief, the test usually uses standard cation-adjusted Mueller-Hinton broth (with lysed horse blood supplementation if needed for fastidious organisms) dispensed in 1-ml aliquots in glass tubes (13 by 100 mm) or in 0.1-ml volumes in plastic microdilution trays. A significant component in performance of the MBC test is the inoculum preparation and inoculation procedure. An actively growing (log-phase) inoculum is used (31, 189) rather than an inoculum that is allowed to grow to the stationary phase or fresh colonies suspended in broth or saline, as for a standard MIC test (36). Use of a log-phase inoculum is necessary to accurately assess the bactericidal properties of drugs that require actively growing cells to exert a bactericidal effect. In addition, it is important to dispense the standardized inoculum suspension below the meniscus of the broth carefully in each tube or well to prevent splashing that can lead to organisms sticking to the wall of the tube or well above the meniscus rather than being in contact with the drug in the test medium (31). If splashing or aerosolization of the inoculum occurs, viable organisms recovered at the time of the final subculture may represent bacteria that were not sufficiently exposed to the drug during the course of the test and thus would give the erroneous perception that the drug was not bactericidal (31, 98, 189).

After determination of the MIC following incubation at 35°C, quantitative subcultures (usually 0.01 ml) are performed at 24 h (following vortexing or shaking at 20 h) with samples from each tube or well with concentrations at and above the MIC of the drug being tested. The aliquots are streaked across the entire surface of a plate containing a standard growth medium (e.g., sheep blood agar). By transferring a small sample volume and spreading it across the entire plate, possible carryover effects of the antibiotic are minimized. In order to calculate the degree of killing at each antibiotic concentration, it is necessary that colony counts be performed on the positive control tube or well at the time of initial inoculation of the MIC test. As in the standard MIC procedure, the target inoculum density is 5×10^5 CFU/ml (31, 36). After the subculture plates are incubated for 24 to 48 h, any visible colonies are counted on each subculture plate. The standard definition of the MBC is the reduction of the initial inoculum by $\geq$99.9% (3 logs) (31). In practice, it is advisable to correct for pipetting error and to account for the Poisson distribution of bacterial cells in a liquid by using statistically derived rejection value tables (31). The tables define the number of colonies that can be tolerated based on the initial inoculum density of each test. If the number of colonies on a particular plate exceeds the rejection value for that test, the antibiotic did not achieve the strict definition of a bactericidal effect at that given concentration of the drug. It is then hoped that the next higher concentration of the drug will have fewer surviving colonies to fulfill the definition of a bactericidal effect. The MBC of an antibiotic should be reported in micrograms per milliliter in the same manner as the MIC is reported. A given MBC test should be considered invalid if there is evidence of contamination of the inoculum or the subcultured tubes or wells, if there is no growth in the positive control well or tube or there is growth in the sterility well or tube, or if there are several skipped dilutions in the MIC portion of the test (31, 67).

Assessment of Bactericidal Activity by the Time-Kill Method

Measuring the rate of bactericidal activity by time-kill analysis provides the opportunity to assess the speed with which killing may occur at a given antibiotic concentration. It is a more laborious approach than determination of the MBC and thus may be best reserved for research purposes. It is also possible to assess the activities of drugs in combination in order to recognize synergistic, indifferent, or antagonistic effects of two or more drugs tested together (31, 99, 104). This approach appears to correlate better with in vivo studies of combined drug effects than the alternative checkerboard titration method (5, 13, 40). The details of performance of the time-kill test have been defined in the CLSI guideline (31). Many of the same critical factors that affect the outcome of the MBC test apply to the performance of time-kill assays, e.g., preparation of an actively growing inoculum and use of quantitative subcultures from antibiotic-containing tubes. The time-kill method requires that multiple samples be removed at various times (e.g., 0, 4, 8, 12, and 24 h) for colony counts, and thus, the volume of

medium for each antibiotic concentration tested is usually ≥10 ml contained in a glass test tube or flask (31). A given antibiotic is often tested at more than one concentration that relates to the previously determined MIC of that agent (e.g., the MIC, two times the MIC, or four times the MIC). When high concentrations (four or more times the MIC) of a drug are tested by the time-kill method, it is necessary to demonstrate that antibiotic carryover has not falsely diminished the number of colonies on subculture plates (31). The results of a time-kill assay are frequently depicted graphically by plotting the colony counts of each antibiotic and concentration tested over time (Fig. 1). A bactericidal effect is again defined as ≥99.9% killing at a specified time (31). When drugs are tested in combination by the time-kill method, synergy is often defined as a ≥2 log decrease in the number of CFU achieved with a drug combination compared to that achieved with the most active drug tested alone (31).

Performance of the Serum Bactericidal Test

The determinations of the serum inhibitory and bactericidal titers are performed in a manner analogous to the MIC and MBC procedures, except that the patient's serum, rather than preweighed and prediluted concentrations of the drug, is used as the source of antibiotic. A guideline that describes the details of the serum bactericidal test has been published by the CLSI (30). The principal steps in performing the test include (i) obtaining one or more blood samples from the patient at specified intervals; (ii) preparing twofold dilutions of the patient's serum in pooled and pretested human serum in glass tubes or plastic microdilution trays; (iii) inoculating each tube or well with a standardized, actively growing inoculum (as described above for the MBC test) of the patient's own infecting organism in an appropriate growth medium (usually cation-adjusted Mueller-Hinton broth); and (iv) incubating for 20 to 24 h (30). Pooled human serum is recommended as the diluent of the patient's serum in each tube or well in order to make protein binding consistent throughout the range of serum dilutions, especially for drugs that are highly protein bound. The pretesting of the pooled human serum includes screening for human immunodeficiency virus type 1 and hepatitis B and C viruses, for antibiotic activity, and for optical clarity (30). In addition, the pooled serum should be heat inactivated immediately prior to use, and the pH should be adjusted to the correct range of 7.2 to 7.4 (30). An alternative to the laborious serum preparation step just described is the creation of a serum ultrafiltrate that precludes the need for a serum diluent (30, 109).

The blood samples for testing are usually obtained from the patient shortly after the antibiotic is administered, at the time of the presumed peak level in serum (usually 30 to

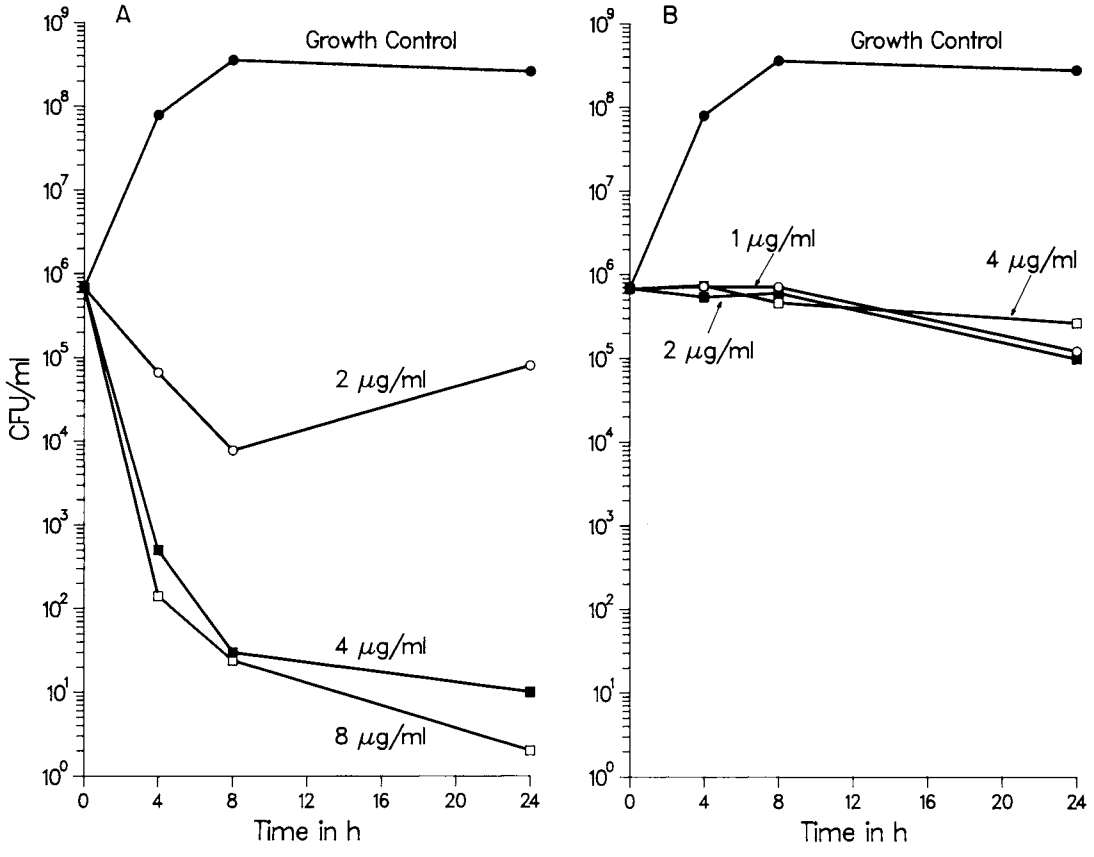

FIGURE 1 Results of time-kill assay of an *Enterococcus faecium* isolate. (A) Daptomycin tested at the MIC (2 μg/ml) and at two and four times the MIC, demonstrating a bactericidal effect at two and four times the MIC. (B) Vancomycin tested at the MIC (1 μg/ml) and at two and four times the MIC, without evidence of a bactericidal effect. Reproduced from reference 95 with permission.

60 min after administration), and often immediately prior to administration of the next drug dose (trough level) (30). The end points of the test are indicated by the highest dilution (titer) of the patient's serum sample that prevents visible growth following the incubation period (serum inhibitory titer). Similar to the MBC determination, quantitative subcultures are performed from each dilution of the patient's serum that has prevented visible growth. The SBT is defined as that dilution (titer) that provides a ≥99.9% reduction of the original inoculum of the test based upon the standard rejection value tables (30). Thus, the results of the test are reported as dilutions (the titer) of the patient's serum rather than as a drug concentration (in micrograms per milliliter) as in the MIC and MBC tests.

Interpreting the Results of Bactericidal Determinations

The interpretation of the results of the bactericidal determinations described above has not received the same degree of critical scrutiny or level of consensus standards that have been achieved for interpretation of MICs. However, a few general statements can be made. A favorable MBC would typically be the same as or perhaps 1 or 2 dilutions greater than the MIC of agents that are normally considered bactericidal (e.g., β-lactams, glycopeptides-lipopeptides, aminoglycosides, and fluoroquinolones). A principal rationale for performing MBC or kinetic time-kill studies would be to detect an isolate that is not effectively killed by a typically bactericidal drug. This failure to exert a bactericidal effect is often described as tolerance and is defined as an MBC ≥32-fold the MIC of a particular agent (31, 70). Failure to achieve at least a 3-$\log_{10}$ reduction of CFU in the kinetic time-kill assay could likewise signify a tolerant strain (31).

Results of the serum bactericidal test that reflect a high titer of antibacterial activity in the serum suggest that the patient has been dosed adequately, has not experienced abnormal elimination of the antibiotic, and does not have a tolerant bacterial isolate. This perception can be quantified by comparing the peak and trough titers obtained with those that have been shown to correlate with rapid organism eradication in collaborative studies (152, 208, 209). For rapid clearance of bacteremia and optimal time to sterilization of cardiac vegetations in endocarditis, a peak SBT of ≥1:64 and a trough SBT of ≥1:32 should be achieved whenever possible (152, 208). However, lower bactericidal titers do not necessarily signify a poor clinical outcome. In patients with chronic osteomyelitis, limited data have suggested that peak SBTs of ≥1:16 and trough SBTs of ≥1:4 predict clinical cure, while titers as low as 1:2 at the trough have been shown to be satisfactory in acute osteomyelitis (152, 209). Titers of ≥1:8 have generally (80% of cases) been associated with satisfactory outcomes for cancer chemotherapy patients (100).

Limitations of Bactericidal Determinations

As stated earlier, clinical microbiologists and infectious disease specialists are not uniformly convinced of the importance of bactericidal determinations as a routine part of even highly complicated bacterial infections. Part of the controversy over the use of these tests may stem from the fact that the procedures themselves have only rather recently been standardized to a significant degree. Indeed, there are still several procedural steps in these tests that can be difficult to control (Table 3), not the least of which are the critical steps of inoculum preparation and dispensing and the final step of accurately counting the surviving bacteria. Despite full attention to the critical details of these test procedures, confusing results may still occur in the form of the skip tube phenomenon (67) or trailing bactericidal end points due to persisters (31). Persisters are thought to represent a fraction of the bacterial population and occasionally exceed 0.1% of the population due to metabolically inactive cells not effectively eradicated during the test (68). A point of occasional concern is the paradoxical or Eagle effect, in which a bactericidal effect can be demonstrated at a relatively low drug concentration, but cells are found not to be killed at very high drug concentrations relative to the MIC (31). This phenomenon has been attributed to secondary effects of some cell wall-active agents on intracellular processes such as protein synthesis, thereby slowing the growth rate and preventing the drug's principal effect on cell wall synthesis of rapidly growing cells (49). A major contribution of the CLSI guidelines is the provision of suggested quality control measures, including established MBC ranges for commonly used control organisms (31, 36). Despite these vigorous efforts to standardize these determinations, it is likely that bactericidal tests will continue to be a subject of discussion and be performed at relatively few institutions for purposes of patient management.

TABLE 3 Technical factors that are critical for reliable determination of MBCs and SBTs and potential pitfalls in those procedure steps

Procedure step	Potential pitfall
Preparation of an actively growing, log-phase inoculum	Use of stationary-phase inoculum will increase the percentage of persisters and potentially result in false tolerance with antibiotics that require rapidly growing cells to exert a bactericidal effect
Delivery of the inoculum aliquot below the meniscus of the broth	Splashing of the inoculum suspension onto the wall of the tube or microdilution well will prevent some cells from contact with the antibiotic and lead to an inaccurate number of colonies upon final subculture
Quantitative subculture of tubes or wells containing drug concentrations at the MIC or higher following incubation	Subculture of too large a volume may cause the problem of antibiotic carryover and persistent inhibition; subculture of an insufficient volume precludes accurate counting of surviving organisms
Determination of ≥99.9% reduction in CFU/ml	Inaccurate pipetting or failure to compensate for pipetting error or Poisson distribution of bacteria will compromise calculation of the bactericidal end point
Failure to account for protein binding in the SBT test	SBT may be falsely elevated with drugs that are highly protein bound (e.g, >90%)

Susceptibility Test Methods: Fastidious Bacteria*

JANET FICK HINDLER AND JEAN B. PATEL

75

Most fastidious bacteria do not grow satisfactorily in standard in vitro susceptibility test systems that use unsupplemented media. For certain fastidious species that are more frequently encountered, such as *Haemophilus influenzae, Neisseria gonorrhoeae, Streptococcus pneumoniae, Neisseria meningitidis,* and other *Streptococcus* spp., slight modifications have been made to standard Clinical and Laboratory Standards Institute (CLSI), formerly NCCLS, disk diffusion and MIC methods to allow reliable testing of these bacteria. The modifications generally involve the use of a test medium with added nutrients and sometimes extended incubation times and/or incubation in an atmosphere with increased levels of CO_2 (Table 1). Specific zone diameter and MIC interpretive criteria have been developed by CLSI for these bacteria, as have acceptable ranges for recommended quality control (QC) strains. CLSI also describes a standard MIC method for testing *Helicobacter pylori* by using an agar dilution procedure. Standard MIC methods for testing potential agents of bioterrorism to include *Bacillus anthracis, Yersinia pestis, Burkholderia mallei, Burkholderia pseudomallei, Francisella tularensis,* and *Brucella* spp. have been developed, and conditions for testing these are listed in Table 2 (41). Most recently, CLSI has published a proposed guideline for testing infrequently isolated or fastidious bacteria including *Abiotrophia* spp., *Granulicatella* spp., *Aeromonas* spp., *Plesiomonas* spp., *Bacillus* spp. (not *B. anthracis*), *Campylobacter jejuni/coli, Corynebacterium* spp., *Erysipelothrix rhusiopathiae,* the *HACEK* group, *Lactobacillus* spp., *Leuconostoc* spp., *Listeria monocytogenes, Moraxella catarrhalis, Pasteurella* spp., *Pediococcus* spp., *Vibrio* spp., (not *V. cholerae*) (38). Interpretive criteria for these organisms were primarily adapted from those for organisms included in CLSI standards (41), taking into consideration information in the literature and the experiences of authors of the guideline. This is in contrast to the extensive microbiological, clinical, and pharmacodynamic databases normally used for development of interpretive criteria that appear in CLSI standards. The classification of M45 as a guideline rather than a standard was based on this fact. A summary of the testing conditions for these organisms appears in Table 3.

There are no specific recommendations for other fastidious bacteria such as *Bordetella* spp. and *Legionella* spp. This is because in part (i) infections caused by these bacteria usually respond to drugs of choice, (ii) isolates are infrequently encountered, and (iii) isolates are often difficult to grow and special media are required.

In addition to conventional MIC test methods (e.g., agar dilution or broth dilution methods), the E-test MIC determination method (AB Biodisk, Solna, Sweden) has been used to test many types of fastidious bacteria. The E-test approach allows placement of strips on special media and the use of various incubation conditions. The limitations of this method include its cost and lack of clearance by the U.S. Food and Drug Administration (FDA) for testing many less commonly encountered fastidious bacteria. Prior to use of the E test for clinical testing in the United States, the FDA clearance status for the particular organism-antimicrobial agent combination should be known. If FDA clearance has not been granted, the results should be interpreted with caution and should be qualified on the patient report.

This chapter summarizes the standard methods recommended by CLSI for antimicrobial susceptibility testing of *Streptococcus* spp. (including *S. pneumoniae*), *H. influenzae, N. gonorrhoeae, N. meningitidis,* and *H. pylori.* The standards for testing potential agents of bioterrorism are also discussed. Methods for testing the infrequently isolated or fastidious bacteria included in the new CLSI M45 guideline are summarized. The incidence of resistance, test methods, and indications for testing and the reporting of results are provided.

S. PNEUMONIAE

Incidence of Resistance

Since it was first reported in 1967, penicillin resistance in pneumococci has been steadily increasing worldwide (15, 62, 63, 114, 216). Interpretive criteria for penicillin and *S. pneumoniae* were originally developed for isolates associated with meningitis and are defined by the CLSI as follows: susceptible, ≤0.06 μg/ml; intermediate, 0.12 to 1 μg/ml; and resistant, ≥2 μg/ml (41). Infections outside the central nervous system, such as pulmonary infections, due to strains for which penicillin MICs are in the intermediate range may be treatable with penicillin (62, 146). It has been suggested

*This chapter contains information presented in chapter 71 by Janet Fick Hindler and Jana M. Swenson in the eighth edition of this Manual.

TABLE 1 Disk diffusion and MIC testing conditions and recommended QC strains for select fastidious bacteria

Organism(s)	Method	Medium[a]	Inoculum source[b]	Incubation atmosphere[c]	Incubation length (h)	Recommended QC strain(s)
S. pneumoniae and *Streptococcus* spp.	Disk diffusion	MHA + 5% sheep blood	18–20-h growth (from SBA)	5–7% CO_2	20–24	*S. pneumoniae* ATCC 49619
	Broth microdilution	CAMHB-LHB	18–20-h growth (from SBA)	Ambient air	20–24	*S. pneumoniae* ATCC 49619
H. influenzae and *Haemophilus parainfluenzae*	Disk diffusion	HTM agar	20–24-h growth (from CHOC)	5–7% CO_2	16–18	*H. influenzae* ATCC 49247, *H. influenzae* ATCC 49766[d]
	Broth microdilution	HTM broth	20–24-h growth (from CHOC)	Ambient air	20–24	*H. influenzae* ATCC 49247, *H. influenzae* ATCC 49766[d]
N. gonorrhoeae	Disk diffusion	GC agar base + supplement	20–24-h growth (from CHOC)	5–7% CO_2	20–24	*N. gonorrhoeae* ATCC 49226
	Agar dilution	GC agar base + supplement	20–24-h growth (from CHOC)	5–7% CO_2	20–24	*N. gonorrhoeae* ATCC 49226
N. meningitidis	Disk diffusion	MHA + 5% sheep blood	20–24-h growth (from CHOC)	5–7% CO_2	20–24	*S. pneumoniae* ATCC 49619
	Broth microdilution	CAMHB-LHB	20–24-h growth (from CHOC)	5–7% CO_2	20–24	*S. pneumoniae* ATCC 49619
	Agar dilution	MHA + 5% sheep blood	20–24-h growth (from CHOC)	5–7% CO_2	20–24	*S. pneumoniae* ATCC 49619
H. pylori	Agar dilution	MHA + 5% aged (≥2-wk-old) sheep blood	72-h growth (from SBA)[e]	Microaerobic; produced by gas-generating system for campylobacters	~72	*H. pylori* ATCC 43504

[a] HTM, GC agar base, and CAMHB-LHB are defined in the text.
[b] Inoculum suspension is in Mueller-Hinton broth or 0.9% NaCl standardized to a 0.5 McFarland standard for disk diffusion. For broth dilution, final organism concentration is 5×10^5 CFU/ml; for agar dilution, final organism concentration is 10^4 CFU/spot; CHOC, chocolate agar; SBA, sheep blood agar.
[c] Incubation temperature, 35°C.
[d] In addition, *H. influenzae* ATCC 10211 can be used to assess growth-supporting capabilities of HTM. *H. influenzae* ATCC 49766 is used for QC of select cephalosporins (e.g., cefaclor, cefamandole, and cefuroxime).
[e] Suspension is in 0.9% NaCl standardized to a 2.0 McFarland standard.

that penicillin MIC interpretive criteria be revised to reflect this (68, 89, 146). The rates for strains not susceptible to penicillin exceed 50% in some parts of the world (15, 99, 104), and in a recent U.S. survey (25), most of the strains not susceptible to penicillin demonstrated high-level resistance (MICs ≥2 μg/ml) rather than intermediate resistance (21.2% versus 14.2%). Some of the highest penicillin resistance rates occur in Asia, where 16.2% of the isolates were reported to be intermediately resistant and 44.1% were highly resistant in 2001–2002 (104). Strains of pneumococci that are susceptible to penicillin generally are susceptible to other β-lactam agents; however, as the penicillin MIC increases, the MICs of other β-lactam agents increase also (25, 99, 114, 160). Pneumococcal strains resistant to cefotaxime or ceftriaxone were not reported until the early 1990s (23, 179), and current rates of resistance to the extended-spectrum cephalosporins vary by location (15, 99, 104, 160). In a recent international survey of over 21,000 isolates, 96.5% of all isolates were susceptible to ceftriaxone (MIC, ≤1.0 μg/ml) whereas among isolates not susceptible to penicillin (MIC, ≥0.12 μg/ml), 89.1% were susceptible to ceftriaxone (160).

Resistance has been described for all classes of antimicrobial agents that are usually considered for treating pneumococcal infections, except for the glycopeptides and linezolid (15, 25, 63, 99, 104, 120, 160). In a recent U.S. survey (24), 31% of isolates were macrolide resistant. Resistance to macrolides in Asian-Pacific countries is much higher, exceeding 75% in some areas (104). Erythromycin MICs for pneumococci with macrolide-lincosamide-streptogramin B (MLS)-type resistance (encoded by the *ermB* gene) are usually ≥64 μg/ml, and clindamycin MICs are ≥8 μg/ml, whereas for isolates of the M phenotype (encoded by the *mef*A gene), erythromycin MICs are in the range of 1 to 32 μg/ml and clindamycin MICs are ≤0.25 μg/ml (54, 99). Susceptibility and resistance to azithromycin, clarithromycin, and dirithromycin among *S. pneumoniae* isolates can be predicted by testing erythromycin (41). Telithromycin, a ketolide, is considerably more active than macrolides against *S. pneumoniae,* with fewer than 1% of isolates showing resistance in recent North American studies (25, 52, 114).

Resistance rates for trimethoprim-sulfamethoxazole (TMP-SMX) range from 35 to 47% in the United States and are similar to those outside the United States (15, 25, 104). Resistance rates for fluoroquinolones remain low (24, 25, 104, 114); however, a higher prevalence of resistance to fluoroquinolones has been shown in other countries (92, 212). Resistance has only been rarely reported for linezolid (6, 25), and resistance rates for quinupristin-dalfopristin are <1% (6, 54) among *S. pneumoniae* strains. Resistance to tigecycline has not been described (69).

Multidrug resistance in *S. pneumoniae* is defined as resistance to three or more antimicrobial classes, commonly penicillins, TMP-SMX, and macrolides (114, 120). As many

TABLE 2 Broth microdilution MIC testing conditions, recommended QC strains, and drugs recommended for testing potential agents of bioterrorism

Organism(s)	Medium[a]	Inoculum source[b]	Incubation atmosphere[c]	Incubation length (h)	Recommended QC strain(s)	Drugs recommended for testing
B. anthracis	CAMHB	16–18-h growth (from SBA)	Ambient air	16–20	*Escherichia coli* ATCC 25922, *S. aureus* ATCC 29213	Ciprofloxacin, doxycycline, penicillin, tetracycline
Brucella spp.	Brucella broth, pH adjusted to 7.1 ± 0.1	48-h growth (from SBA)	Ambient air	48	*E. coli* ATCC 25922, *S. pneumoniae* ATCC 49619	Doxycycline, gentamicin, tetracycline, TMP-SMX, streptomycin
B. mallei, *B. pseudomallei*	CAMHB	16–18-h growth (from SBA)	Ambient air	16–20	*E. coli* ATCC 25922, *E. coli* ATCC 35218, *P. aeruginosa* ATCC 27853	Amoxicillin-clavulanic acid, ceftazidime, doxycycline, imipenem, tetracycline, TMP-SMX (*B. pseudomallei* only)
F. tularensis	CAMHB with 2% defined growth supplement, pH adjusted to 7.3 ± 0.1	24-h growth (from CHOC)	Ambient air	48	*E. coli* ATCC 25922, *S. aureus* ATCC 29213, *P. aeruginosa* ATCC 27853	Chloramphenicol, ciprofloxacin, doxycycline, gentamicin, levofloxacin, streptomycin, tetracycline
Y. pestis	CAMHB	24-h growth (from SBA)	Ambient air	24[d]	*E. coli* ATCC 25922	Chloramphenicol, ciprofloxacin, doxycycline, gentamicin, streptomycin, tetracycline, TMP-SMX

[a] CAMHB, cation-adjusted Mueller-Hinton broth.
[b] Inoculum suspension is in CAMHB standardized to a 0.5 McFarland standard. Final organism concentration is 5×10^5 CFU/ml. CHOC, chocolate agar; SBA, sheep blood agar.
[c] Incubation temperature, 35°C.
[d] If unacceptable growth in the control well, reincubate for an additional 24 h.

as 25% of *S. pneumoniae* isolates in the United States have been reported to be multidrug resistant, and rates are higher in other countries (15, 104, 120).

Reference Test Methods

CLSI describes both a broth microdilution method and a disk diffusion method for the testing of pneumococci (39-41). Details of these procedures are listed in Table 1. The broth microdilution method may be used to test all of the antimicrobial agents recommended by CLSI for pneumococci. With the exception of the oxacillin disk screening test for penicillin susceptibility, the disk diffusion method does not work for testing the β-lactam agents, including the cephalosporins (40, 41, 188). When used to predict penicillin susceptibility, oxacillin disk diffusion zone diameters of ≥20 mm indicate that the isolate is susceptible to penicillin (41). However, strains with zone diameters of ≤19 mm cannot be readily categorized as resistant, since a strain with an oxacillin zone diameter of ≤19 mm may be penicillin susceptible, intermediate, or resistant (53) when the actual penicillin MIC for the strain is determined. Therefore, if the oxacillin screen test is used without follow-up MIC testing for strains with zones of ≤19 mm, the potential for overstating penicillin resistance is high.

Commercial Methods for Testing

Several options are available for determining MICs of various antimicrobial agents for pneumococci. The E-test method has been extensively evaluated, and a recent evaluation was performed by Tenover et al. (191). All drugs recommended by CLSI for testing against pneumococci except clindamycin and telithromycin have been cleared by the FDA for testing by the E test. The accuracy of the E test has been reported to be >90% for most relevant drugs;

TABLE 3 Disk diffusion and MIC testing conditions, recommended QC strains, and agents to consider for primary testing for infrequently isolated or less common fastidious bacteria

Organism(s)	Method	Medium[a]	Inoculum source[b]	Incubation atmosphere[c]	Incubation length (h)	Recommended QC strain(s)	Agents to consider for primary testing
Abiotrophia spp., *Granulicatella* spp.	Broth microdilution	CAMHB-LHB[c] +0.001% pyridoxal HCl	20–24-h growth, from CHOC containing cysteine	Ambient air	20–24	*S. pneumoniae* ATCC 49619	Cefotaxime or ceftriaxone, penicillin, vancomycin
Aeromonas hydrophila complex, *Plesiomonas shigelloides*	Broth microdilution	CAMHB	16–18-h growth (from SBA)	Ambient air	16–20	*E. coli* ATCC 25922, *E. coli* ATCC 35218[d]	Amoxicillin-clavulanic acid, broad-spectrum or extended-spectrum cephalosporins, fluoroquinolones, TMP-SMX
	Disk diffusion	MHA	16–18-h growth (from SBA)	Ambient air	16–18	*E. coli* ATCC 25922, *E. coli* ATCC 35218	
Bacillus spp. (not *B. anthracis*)	Broth microdilution	CAMHB	16–18-h growth (from SBA)	Ambient air	16–20	*S. aureus* ATCC 29213	Clindamycin, gentamicin (for combined therapy, vancomycin)
C. jejuni, *C. coli*	Broth microdilution	CAMHB-LHB	24–48-h growth (from SBA)	10% CO_2, 5% O_2, 85% N_2 (microaerobic)	48 at 36°C or 24 at 42°C	*C. jejuni* ATCC 33560	Ciprofloxacin, erythromycin
Corynebacterium spp.	Broth microdilution	CAMHB-LHB	24–48 h growth, (from SBA or CHOC)	Ambient air	48	*S. pneumoniae* ATCC 49619	Erythromycin, gentamicin, penicillin, vancomycin
E. rhusiopathiae	Broth microdilution	CAMHB-LHB	18–24-h growth (from SBA)	Ambient air	20–24	*S. pneumoniae* ATCC 49619	Penicillin or ampicillin
HACEK group	Broth microdilution	CAMHB-LHB	24–48-h growth, (from CHOC)	Ambient air	24–48	*S. pneumoniae* ATCC 49619, *E. coli* ATCC 35218	Ampicillin, amoxicillin-clavulanic acid, ceftriaxone or cefotaxime, ciprofloxacin or levofloxacin, imipenem, TMP-SMX

Lactobacillus spp.	Broth microdilution	CAMHB-LHB	18–24-h growth (from SBA)	Ambient air	20–24	*S. pneumoniae* ATCC 49619	Penicillin or ampicillin, gentamicin (for combined therapy)
Leuconostoc spp.	Broth microdilution	CAMHB-LHB	18–24-h growth (from SBA)	Ambient air	20–24	*S. pneumoniae* ATCC 49619	Penicillin or ampicillin
L. monocytogenes	Broth microdilution	CAMHB-LHB	18–24-h growth (from SBA)	Ambient air	20–24	*S. pneumoniae* ATCC 49619	Penicillin or ampicillin, TMP-SMX
M. catarrhalis	Broth microdilution	CAMHB	18–24-h growth (from SBA)	Ambient air	20–24	*S. aureus* ATCC 29213, *E. coli* ATCC 35218	Amoxicillin-clavulanic acid, cefaclor or cefuroxime, TMP-SMX
Pasteurella spp.	Broth microdilution	CAMHB-LHB	18–24-h growth (from SBA)	Ambient air	18–24	*S. pneumoniae* ATCC 49619, *E. coli* ATCC 35218	β-Lactam/β-lactamase inhibitor combinations, cephalosporins, fluoroquinolones, macrolides, penicillins, tetracyclines, TMP-SMX
	Disk diffusion	MHA with 5% sheep blood	18–24-h growth (from SBA)	Ambient air	18–24	*S. pneumoniae* ATCC 49619, *E. coli* ATCC 35218, *S. aureus* ATCC 25923 (disk diffusion)	
Pediococcus spp.	Broth microdilution	CAMHB-LHB	18–24-h growth (from SBA)	Ambient air	20–24	*S. pneumoniae* ATCC 49619	Penicillin, gentamicin (for combined therapy)
Vibrio spp. (not *V. cholerae*)[e]	Broth microdilution	CAMHB	16–18-h growth (from SBA)	Ambient air	16–20	*E. coli* ATCC 25922, *E. coli* ATCC 35218	Cefotaxime, ceftazidime
	Disk diffusion	MHA	16–18-h growth (from SBA)	Ambient air	16–18	*E. coli* ATCC 25922, *E. coli* ATCC 35218	Tetracycline, fluoroquinolones

[a] CAMHB-LHB and MHA are defined in the text.
[b] Suspension is in Mueller-Hinton broth or 0.9% NaCl standardized to a 0.5 McFarland standard for disk diffusion. For broth dilution, final organism concentration is 5×10^5 CFU/ml. CHOC, chocolate agar; SBA, sheep blood agar.
[c] Incubation temperature, 35°C (except for *C. jejuni* and *C. coli*).
[d] *E. coli* ATCC 35218 is used for quality control when testing β-lactam/β-lactamase inhibitor combination drugs.
[e] For halophilic species, prepare inoculum in 0.85% NaCl (normal saline).

however, the number of minor errors with penicillin is relatively high. E-test penicillin MICs are slightly lower than those determined by reference broth microdilution (110). Since the E test uses incubation in CO_2, the MICs of the macrolides and ketolides tend to be 1 to 2 dilutions higher than those by the broth tests, in which incubation is done in ambient air (21). This is because these agents are less active at lower pH, which occurs with CO_2 incubation.

Other commercially available FDA-cleared panels or systems specifically designed for testing pneumococci include MicroScan (Dade Behring MicroScan Inc., West Sacramento, Calif.), Phoenix (BD Diagnostic Systems, Sparks, Md.), Sensititre (Trek Diagnostic Systems, Inc, Westlake, Ohio), and Vitek 2 (bioMerieux, Inc., Hazelwood, Mo.). The Pasco, MicroScan MICroSTREP, Sensititre, and Vitek 2 systems have been evaluated and found to produce MICs that are comparable to those obtained with the CLSI broth microdilution reference method (83, 107, 108, 142).

Strategies for Testing and Reporting of Results

CLSI stipulates that *S. pneumoniae* isolates from cerebrospinal fluid (CSF) be routinely tested by a reliable MIC method to determine susceptibilities to penicillin and cefotaxime or ceftriaxone, and meropenem should be added if it is on the institution's formulary. In addition, vancomycin should be tested by either an MIC or a disk diffusion method (41). Along with penicillin, CLSI recommends primary testing and reporting of erythromycin and TMP-SMX for isolates from non-CSF sources. Both drugs can be tested by either an MIC or a disk diffusion method. However, in communities where penicillin resistance is high and resistance to other agents is likely, MIC testing of penicillin, cefotaxime or ceftriaxone, meropenem, vancomycin, and one representative each of the macrolide, fluoroquinolone, and tetracycline classes would be appropriate for testing of strains isolated from non-CSF sources. Other drugs that might warrant testing if being considered for treatment of infections other than meningitis include cefepime, clindamycin, and telithromycin. Infections, such as pneumonia, caused by strains for which the MICs of penicillin are in the intermediate range may be treatable with penicillin or an extended-spectrum cephalosporin if maximal doses are used (68, 89, 146), and it may be appropriate to include a comment to this effect on the patient report. CLSI standards include a second set of nonmeningitis MIC breakpoints for cefotaxime and ceftriaxone that apply to infections other than meningitis (41). For CSF isolates, only interpretations using the original meningitis breakpoints should be reported; for isolates from other sites, both meningitis and nonmeningitis interpretations should be reported (41).

The oxacillin screening procedure should be used only for isolates from patients with non-life-threatening infections. If the zone diameter is ≤19 mm, at a minimum the MICs of penicillin and an extended-spectrum cephalosporin should then be determined (41).

STREPTOCOCCI OTHER THAN PNEUMOCOCCI

Incidence of Resistance

Because there are significant differences in susceptibility of β-lactam agents in viridans group versus beta-hemolytic streptococci, there are separate ampicillin, penicillin, cefotaxime, ceftriaxone, and cefepime interpretive criteria for the two organism groups. As defined by CLSI (41), the members of the viridans group include strains identified as *Streptococcus mitis, S. oralis, S. sanguinis, S. salivarius, S. intermedius, S. constellatus, S. mutans,* and *S. bovis,* as well as the small-colony-forming beta-hemolytic strains with group A, C, F, or G antigens (the *S. anginosus* group, which was previously called *S. milleri*). The beta-hemolytic group includes the large-colony-forming pyogenic strains with group A *(S. pyogenes)*, C, or G antigens and strains with group B *(S. agalactiae)* antigen.

Although beta-hemolytic streptococci have been uniformly susceptible to penicillin, two reports have described penicillin MICs of 0.25 to 0.5 μg/ml for group B streptococci (17) and group C streptococci (194). The clinical significance of these elevated MICs is not known. High-level aminoglycoside resistance has been described for group B streptococci (26). The MLS-type macrolide resistance due to *erm* genes in beta-hemolytic streptococci may be either inducible or constitutive (45). If the resistance is inducible, the strains will be resistant to erythromycin (and the other 14- and 15-membered macrolides) but appear to be susceptible to clindamycin unless resistance is induced. Resistance rates for erythromycin vary for group A streptococci and were recently reported to be as high as 32% in parts of California (213). In a large Canadian study conducted in 2002–2003, the predominant mechanism for erythromycin resistance in group A streptococcus was *mef*A whereas that in group B streptococcus was *erm* (47). Resistance rates among streptococci vary for tetracyclines and are low for fluoroquinolones (6, 25, 69). In several recent large surveillance studies, resistance was not observed for daptomycin (101), linezolid, or quinupristin-dalfopristin (6, 69).

Penicillin resistance in viridans group streptococci has been described, and resistance rates can be >50% (2, 69), particularly for *S. mitis* and *S. sanguinis*. Ahmed et al. noted 67.5% penicillin resistance among 40 blood culture isolates from bacteremic children with cancer (2). Resistance has been described for some viridans group isolates for macrolides, lincosamides, tetracyclines, quinupristin-dalfopristin, and fluoroquinolones (2, 3, 69, 195). Single reports of resistance to vancomycin have been noted for *S. bovis* (161) and for *S. mitis* (124), and resistance to linezolid has been reported on at least one occasion (172). In a recent study, all 92 viridans group streptococci selected to represent more resistant strains were susceptible to daptomycin (101). High-level aminoglycoside resistance has been described for viridans group streptococci (95).

Reference Test Methods

Studies by CLSI to determine interpretive criteria for both MIC and disk diffusion testing have resulted in breakpoints for streptococci that were initially published in 1995. Penicillin and select cephalosporin breakpoints were subsequently modified as mentioned above. Details for MIC and disk diffusion tests are described in Table 1. The disk diffusion test may be used to determine the penicillin susceptibility of beta-hemolytic streptococci; however, it is unreliable and should not be used for viridans group streptococci. Other agents may be tested by either the MIC or the disk method. Aminoglycoside MICs of >1,000 μg/ml for streptococci (207) have been described; however, there are no published methods for screening for high-level aminoglycoside resistance in streptococci.

Susceptibility testing of members of the genera *Abiotrophia* and *Granulicatella* (formerly known as "nutritionally deficient

streptococci") are included in the new CLSI M45 document as described below. Recent CLSI standards describe a disk approximation test for inducible resistance to clindamycin in beta-hemolytic streptococci whereby erythromycin is used to induce resistance to clindamycin. Mueller-Hinton agar (MHA) supplemented with 5% sheep blood is inoculated as for a disk diffusion test, and a 15-μg erythromycin disk and a 2-μg clindamycin disk are placed approximately 12 mm apart on the agar surface. The plate is incubated at 35°C overnight, and flattening of the clindamycin zone indicates inducible clindamycin resistance (41).

Commercial Test Methods

There have been few reports of evaluations of commercial susceptibility test systems for streptococci other than pneumococci, although it might be expected that systems capable of testing pneumococci would also perform adequately for other streptococci. The MicroScan and Phoenix systems are cleared by the FDA for the testing of *Streptococcus* spp. The Vitek 2 system is FDA cleared for testing of group B streptococci. The E test has not been extensively evaluated but does appear to be a possible alternative to the reference methods for testing *Streptococcus* spp. (106, 173).

Strategies for Testing and Reporting of Results

Routine testing of β-hemolytic streptococci is unnecessary since there have been only sporadic reports of decreased susceptibility to penicillin, primarily in group B streptococci (17, 194). However, if erythromycin is being used to treat infections caused by group A streptococci and treatment failure is suspected, testing might be considered. Similarly, if erythromycin is being considered for prophylaxis of pregnant women who are highly allergic to penicillin, in an effort to prevent perinatal group B streptococcal disease, testing should be done. If clindamycin is being considered for β-hemolytic streptococci that test clindamycin susceptible and erythromycin resistant, the determination of inducible clindamycin resistance should be considered. For viridans group streptococci, penicillin MICs should be determined for strains isolated from blood, especially for patients with infective endocarditis. Disk diffusion is not reliable for testing penicillin in viridans group streptococci (10).

H. INFLUENZAE

Incidence of Resistance

Ampicillin resistance in *H. influenzae* is most commonly mediated by a plasmid-borne β-lactamase, TEM-1 being the most common enzyme. The incidence of β-lactamase-producing *H. influenzae* organisms ranges from 5% to nearly 40% in various geographic areas (15, 25, 63, 100, 105, 183, 217). Recently, a decrease in β-lactamase-producing isolates has been documented in North America (90). Ampicillin resistance can result from altered penicillin-binding proteins in β-lactamase-negative, ampicillin-resistant (BLNAR) strains, but this mechanism of resistance appears to be uncommon. In a recent survey, Brown and Rybak noted that 0.4% of 3,296 isolates from throughout the United States were BLNAR (25). Among 395 isolates collected from patients with meningitis during 1999 through 2002 in Japan, 13.9% were shown to be BLNAR (86). However, in a respiratory surveillance study conducted during a similar time in Japan, only one BLNAR strain among 281 isolates was found (98). Compared with β-lactamase-producing or ampicillin-susceptible *H. influenzae,* BLNAR isolates are less susceptible to amoxicillin-clavulanic acid and to various cephalosporins such as cefaclor, cefuroxime, cefixime, and cefotaxime (13). Use of a 2-μg rather than a 10-μg ampicillin disk and a 1/2 μg rather than a 10/30 μg amoxicillin-clavulanic acid disk with the standard CLSI disk diffusion method has been suggested as a method to better identify BLNAR strains (115).

Resistance among *H. influenzae* isolates to broad-spectrum oral cephalosporins (e.g., cefixime and cefpodoxime) and to extended-spectrum cephalosporins (e.g., cefotaxime) is rare (217). Resistance to expanded-spectrum cephalosporins (e.g., cefuroxime) is uncommon, <3% in a recent survey (102). The narrower-spectrum, β-lactamase-labile cephalosporins (e.g., loracarbef and cefprozil) are less active, with resistance rates ranging from 3 to nearly 30% (25, 102, 105, 183, 217).

Resistance to TMP-SMX among *H. influenzae* organisms occurs in approximately 20% of isolates from North America (93, 100, 102, 217), but resistance rates as high as 60% have been noted in other parts of the world including Southeast Asia (64). Resistance to tetracyclines is <3% (25, 102, 217), and resistance to fluoroquinolones is rare (25, 60, 93). Although erythromycin has not been considered a drug of choice for the treatment of infections caused by *H. influenzae,* some of the newer macrolides are more active than erythromycin and may be effective as treatment. Less than 2% of isolates examined in various studies were resistant to azithromycin; however, clarithromycin resistance rates approached 20% (25, 98, 100, 102, 105, 183, 217). Telithromycin is highly active against *H. influenzae* with resistance rates of approximately 1% (25, 98, 217).

Reference Test Methods

β-Lactamase production in *H. influenzae* can easily be detected by the chromogenic cephalosporin, acidometric, or iodometric β-lactamase test methods (see chapter 74).

CLSI has developed broth microdilution MIC and disk diffusion methods for testing *H. influenzae,* and these methods can also be used to test *H. parainfluenzae*. Testing of the more unusual *Haemophilus* spp. including *H. aphrophilus, H. paraphrophilus,* and *H. segnis* are now addressed in the new CLSI M45 document. Specific variables related to each of the methods for testing *H. influenzae* and *H. parainfluenzae* are listed in Table 1. *Haemophilus* test medium (HTM) is recommended and consists of a Mueller-Hinton base, 15 μg of hematin per ml, 15 μg of NAD per ml, and 5 mg of yeast extract per ml. Cation-adjusted Mueller-Hinton broth (CAMHB) is used with the components listed above for the preparation of HTM broth, which also contains 0.2 IU of thymidine phosphorylase per ml. Although HTM agar is transparent, some investigators have reported difficulties in measuring zones and poor growth of some strains (88, 141). Broth microdilution tests with HTM generally give clearer endpoints. The problems most often noted with both the disk diffusion and the broth microdilution methods are equivocal endpoints with BLNAR strains with several β-lactams. Because of this, CLSI recommends that BLNAR strains (which are best detected by tests with ampicillin) be considered resistant to amoxicillin-clavulanic acid, ampicillin-sulbactam, cefaclor, cefamandole, cefetamet, cefonicid, cefprozil, cefuroxime, loracarbef, and piperacillin-tazobactam and that the activities of these agents against BLNAR strains not be tested (41).

Commercial Test Methods

Currently, the only FDA-cleared broth microdilution system for testing *Haemophilus* spp. is Sensititre. The E test has been

cleared by the FDA for testing *H. influenzae* with most drugs that would be used for treating *Haemophilus* infections, and results with E test have been shown to be comparable to those obtained by CLSI reference methods (111).

Strategies for Testing and Reporting of Results

β-Lactamase testing will detect the most common type of clinically significant resistance in *H. influenzae*. β-Lactamase-positive isolates are ampicillin and amoxicillin resistant. To detect BLNAR strains, an ampicillin disk diffusion or MIC test is required. However, since the incidence of BLNAR is low in many geographic areas, such tests may not be routinely needed, and for practical purposes, a negative β-lactamase test result translates into ampicillin susceptibility. Frequently, the β-lactamase test is the only test routinely performed with clinical isolates. Because of increasing resistance to TMP-SMX, testing should be considered and CLSI recommends that this agent be tested and reported routinely (41). Other oral agents that might be considered, such as amoxicillin-clavulanic acid, the oral cephalosporins, newer macrolides, and quinolones, are predictably active against *H. influenzae* and are often prescribed empirically. Consequently, routine testing of these drugs is generally not useful. However, these and other agents may be tested for surveillance or epidemiological purposes (41).

N. GONORRHOEAE

Incidence of Resistance

During the past 2 decades, increasing rates of penicillin and tetracycline resistance among *N. gonorrhoeae* isolates have led to recommending ceftriaxone, cefixime, ciprofloxacin, ofloxacin, or levofloxacin as the primary agents for uncomplicated gonorrhea instead of penicillin or tetracycline (30). Penicillin resistance is due to the production of a plasmid-associated TEM-1 type β-lactamase (penicillinase-producing *N. gonorrhoeae* [PPNG]) or to mutations in chromosomal genes that result in altered penicillin-binding proteins or diminished outer membrane permeability (chromosomally mediated resistant *N. gonorrhoeae* [CMRNG]). The activities of other β-lactams against PPNG are generally unaltered; however, CMRNG may show decreased susceptibility to other β-lactams (49). Tetracycline resistance in *N. gonorrhoeae* can be plasmid- or chromosomally mediated, with plasmid-mediated resistance resulting in a higher level of resistance.

The Gonococcal Isolate Surveillance Program, which tests urethral isolates from male clients visiting sexually transmitted disease clinics throughout the United States, reported that 16.4% of 6,552 isolates were resistant to penicillin or tetracycline or both in 2003. The incidence of PPNG peaked at 11.0% in 1991 and was only 1% in 2003. The incidence of tetracycline resistance has remained fairly stable and was 3.7% in 2003. All 6,552 isolates tested in 2003 were susceptible to ceftriaxone and cefixime; however, there appears to be a subtle shift towards higher MICs for both these agents. Nevertheless, only 4 isolates had elevated ceftriaxone MICs of 0.5 μg/ml and 45 isolates had elevated cefixime MICs of 0.5 to 2.0 μg/ml (29).

Fluoroquinolone resistance has become widespread throughout Asia and is increasing in the United States. In a study of 115 isolates *of N. gonorrhoeae* from female sex workers in the Philippines, 49% of isolates had ciprofloxacin MICs of ⩾4 μg/ml and 63% of isolates had MICs ⩾1 μg/ml (8). In Japan in 2002, 70% of 87 *N. gonorrhoeae* isolates from males with urethritis were ciprofloxacin resistant and only 1 isolate produced β-lactamase (177). The Gonococcal Antimicrobial Susceptibility Program conducted by the World Health Organization noted that ciprofloxacin resistance rates for gonococci from patients in India in 2001 varied from 10.6 to 100% among 10 regions studied (165). In the 2003 Gonococcal Isolate Surveillance Program study, 0.9% of the isolates exhibited intermediate susceptibility and 4.1% were resistant to ciprofloxacin (29). Newman et al. noted that 17% of isolates from 117 patients seen at a public sexually transmitted disease clinic in Hawaii in 2001 were ciprofloxacin resistant (150).

Reference Test Methods

Routine β-lactamase tests readily detect PPNG and can reliably be performed by either the chromogenic cephalosporin, acidimetric, or iodometric method.

CLSI recommends the use of GC agar base for disk diffusion and agar dilution MIC testing. For both tests, a 1% defined growth supplement must be added; however, in agar dilution tests with imipenem and with clavulanate, the growth supplement must be free of cysteine to avoid inhibition of the activities of these two agents (39-41). The agar dilution method is preferred to the broth dilution method for MIC testing because *N. gonorrhoeae* has a tendency to autolyse in liquid media. For other details of testing, see Table 1.

Commercial Test Methods

The only commercial method currently available for susceptibility testing of *N. gonorrhoeae* is E test, which has been shown to produce results comparable to those of conventional reference agar dilution methods (18).

Strategies for Testing and Reporting Results

Generally, there is no need for routine clinical laboratories to perform antimicrobial susceptibility tests with *N. gonorrhoeae* unless there are unusual circumstances. These might include the patient's intolerance to the drugs of choice, treatment failure (assuming that compliance was not an issue), or a disseminated gonococcal infection. Additionally, if fluoroquinolone resistance is noted in a particular geographic area, testing may be warranted if fluoroquinolones are being prescribed. Some laboratories may perform β-lactamase tests for all isolates if β-lactamase results are requested by the local public health departments for epidemiological purposes. However, many public health departments have eliminated this requirement. Surveillance for established and emerging resistance for *N. gonorrhoeae* is generally performed by designated state and local public health agencies.

N. MENINGITIDIS

Incidence of Resistance

Increasing numbers of β-lactamase-negative *N. meningitidis* isolates from the United States and elsewhere have reduced susceptibility to penicillin (MICs, 0.12 to 1.0 μg/ml), although the frequency of these isolates in different regions varies widely (85, 167, 200).

A study of 400 *N. meningitidis* isolates obtained in 1998 and 1999 in Spain showed that 37% of them had penicillin MICs of 0.12 to 1.0 μg/ml (200). In a study of 53 invasive isolates collected in 1998–99 in the United States, 30.2% had penicillin MICs of 0.12 to 0.25 μg/ml (167). There have been two recent reports from Europe of *N. meningitidis* isolates with penicillin MICs of 1.5 μg/ml and 2.0 μg/ml; E test was used for testing the first isolate, and agar dilution was used for the

second (59, 80). The clinical significance of isolates for which penicillin MICs are elevated is uncertain, and penicillin remains the drug of choice for the treatment of meningococcal disease (74, 138). Many infections caused by isolates with reduced susceptibility to penicillin have successfully been treated with high doses of penicillin (186, 208); however, rare reports cited clinical failure (meningitis) when a lower than recommended dose of penicillin was used (198). The broad-spectrum cephalosporins (e.g., ceftriaxone) remain highly active against isolates with elevated penicillin MICs (85, 164, 167, 200). In the 1980s, four isolates of β-lactamase-producing *N. meningitidis* were reported (20, 50, 67), and one isolate was reported in 1996 (201); additional isolates have not been noted.

Regarding agents used for prophylaxis, resistance to sulfonamides occurs frequently, and resistance to rifampin has been documented on several occasions (109, 164, 171, 200). There are two reports of *N. meningitidis* isolated from CSF with decreased susceptibility to ciprofloxacin (MIC, 0.12 and 0.25 μg/ml), one from Australia and another from Spain; however, *N. meningitidis* is typically very susceptible to this agent (MIC, ≤0.03 μg/ml) (4, 178).

Strategies for Testing and Reporting of Results

CLSI recently published standards for susceptibility testing of *N. meningitidis* that utilizes either the broth microdilution method and CAMHB with 2 to 5% lysed horse blood (CAMHB-LHB) or the agar dilution method and MHA with 5% sheep blood, both with incubation in 5% CO_2 (41, 109). Interpretive criteria are listed for agents such as penicillin, cefotaxime, and ceftriaxone, which might be prescribed for treating a meningococcal infection. In addition, interpretive criteria are listed for agents such as ciprofloxacin and rifampin, which might be used for prophylaxis of meningococcal case contacts. CLSI also approved a disk diffusion method for testing *N. meningitidis* which utilizes MHA with 5% sheep blood and CO_2 incubation. As with MIC tests, interpretive criteria are listed for several therapeutic and prophylactic agents. Unfortunately, these do not include breakpoints for ampicillin and penicillin, as results obtained with these agents were unreliable (41). Several investigators have examined modified penicillin disk diffusion methods by using 2- and 10-IU penicillin disks and 1-μg oxacillin disks and also determined that these cannot reliably distinguish *N. meningitidis* isolates that are susceptible from those that have decreased ampicillin and penicillin susceptibility (19, 27, 157). Therefore, disk diffusion testing should not be used for these drugs.

Because of the lack of clinical failures with the drugs of choice for the treatment of meningococcal infections, susceptibility testing is not warranted in most situations (170, 171). Although the E test has not yet been cleared by the FDA for testing *N. meningitidis,* several studies have shown it to be reliable for testing meningococci and to perform best by using MHA with 5% sheep blood incubated in CO_2 (1, 136, 155, 157, 199). However, in a 14-lab study, Vazquez et al. noted some difficulties in obtaining reliable results for rifampin with E test (199).

H. PYLORI

Incidence of Resistance

The rates of resistance for *H. pylori* vary considerably among the agents recommended for therapy (e.g., amoxicillin, clarithromycin, metronidazole, and tetracycline), with resistance to metronidazole being highest. Using the CLSI reference method, Osato et al. reported approximately 35% resistance to metronidazole among 3,193 isolates in the United States (152). In a Korean study that used similar methodologies, 40.6% of 652 isolates were metronidazole resistant (118); however, a study in Japan reported only 12.4% metronidazole resistance among 388 isolates but noted significant differences from various geographic areas (116). Clarithromycin resistance rates were lower, with approximately 11% resistance in the U.S. study and 5.9 and 12.9% resistance observed in the Korean and Japanese studies, respectively. The incidence of resistance to tetracycline and amoxicillin is currently very low (118, 126, 152). Kim et al. recently identified discordant susceptibility results for clarithromycin, metronidazole, and tetracycline when testing multiple isolates from different locations in the stomach of individual patients (117). A similar finding was reported by Osato et al. (151) for metronidazole susceptibility. These results suggest that resistant isolates are not evenly distributed throughout the stomach and susceptibility results for isolates from a single biopsy may not be representative of the entire population.

Reference Test Method

CLSI describes an agar dilution MIC method for testing *H. pylori*. The test medium is MHA supplemented with aged (≥2-week-old) sheep blood. The inoculum is prepared from 72-h-old growth on a blood agar plate to obtain a final concentration of bacteria approximating 10^5 CFU/spot. Incubation is for 3 days at 35°C in a microaerobic atmosphere produced by a gas-generating system typically used for campylobacters. *H. pylori* ATCC 43504 has been designated as a QC strain, and currently there are only interpretive criteria for clarithromycin. Other antimicrobial agents that have been studied and for which there are CLSI QC ranges include amoxicillin, metronidazole, telithromycin, and tetracycline (41).

Commercial Test Methods

Although no commercial methods are FDA cleared for antimicrobial susceptibility testing of *H. pylori,* several investigators have examined the E test. In one study the percent agreement (i.e., results within ±1 doubling dilution) between E test and agar dilution was 84.6% for amoxicillin, 94.1% for clarithromycin, 89.9% for metronidazole, and 89.1% for tetracycline (159). In a multilaboratory study, laboratories correctly identified clarithromycin- and metronidazole-susceptible and -resistant strains 93% of the time using E test (16). However, two studies reported significant discrepancies for metronidazole susceptibility by agar dilution and E test (139, 151). All of these E-test evaluations report differences in methods for agar dilution and E test, such as media, inoculum, and incubation conditions, which may account for the different results.

Strategies for Testing and Reporting of Results

Because of growth requirements and complex antimicrobial susceptibility testing recommendations, testing of *H. pylori* is not practical for the routine clinical laboratory. However, because of the significant resistance noted for metronidazole and clarithromycin, testing may be required in select situations, in which case a reliable reference laboratory should be used. Although there are currently no CLSI interpretive criteria for metronidazole, investigators have used an MIC of >8 μg/ml for resistance (118, 126, 151, 152).

POTENTIAL BACTERIAL AGENTS OF BIOTERRORISM

Several bacterial agents are identified as potential agents of bioterrorism by the Centers for Disease Control and Prevention (http://www.bt.cdc.gov/agent/index.asp). These include *Bacillus anthracis, Yersinia pestis, Francisella tularensis, Burkholderia mallei, Burkholderia pseudomallei,* and *Brucella* spp. Until recently, standardized antimicrobial susceptibility testing methods and interpretive criteria did not exist for any of these bacteria. The antimicrobial susceptibility patterns for most of them are predictable, so susceptibility testing of naturally occurring isolates is often not necessary. However, it is possible for antimicrobial resistance to spontaneously occur among these organisms and, in the case of a bioterrorism event, there is the possibility of engineered resistance. To detect any possible resistance, standardized broth microdilution susceptibility testing methods and interpretive criteria were established and published by CLSI (41).

Acquired resistance to antimicrobial agents commonly used for treatment of infections caused by *B. anthracis, Y. pestis, F. tularensis, B. mallei, B. pseudomallei,* and *Brucella* spp. is rare. Isolates of *B. anthracis* may contain inducible β-lactamases, which can confer resistance to penicillins and cephalosporins (32, 56, 130). Because of this potential resistance, penicillin is recommended for anthrax prophylaxis only when the organism burden would be low and this recommendation is limited to young children and pregnant women who should not receive other prophylaxis therapies such as fluoroquinolones and tetracyclines (28). Laboratory-generated fluoroquinolone resistance in *B. anthracis* was reported, but fluoroquinolone resistance in clinical isolates has not been reported (34, 163). There are reports of two spontaneously occurring drug-resistant *Y. pestis* isolates recovered in Madagascar (71, 81). Both isolates acquired conjugative plasmids. In one isolate, the plasmid carried resistant determinants for ampicillin, chloramphenicol, tetracycline, kanamycin, streptomycin, and sulfonamide. In the other isolate, the plasmid conferred resistance to streptomycin. Susceptibility studies of *B. pseudomallei* and *B. mallei* indicate that most isolates are susceptible to amoxicillin-clavulanic acid, ceftazidime, imipenem, tetracycline, doxycycline, and TMP-SMX, using CLSI interpretive criteria (192). However, some isolates of *B. pseudomallei* have elevated ceftazidime MICs (i.e., MIC ≥8 μg/ml) (97, 192). Clinical isolates of *Brucella* spp. with reduced susceptibility to rifampin and TMP-SMX have been reported (14, 119, 140). In these studies, the susceptibility testing methods used were either not clearly defined or different from the methods currently recommended by CLSI. Also, resistant isolates were not characterized for resistance determinants or mutations. Therefore, the definition of resistance to rifampin or TMP-SMX among *Brucella* spp. is unclear. Isolates of *F. tularensis* demonstrate β-lactamase activity, and they are resistant to β-lactams including cephalosporins and carbapenems (12, 96). Resistance to aminoglycosides, tetracyclines, fluoroquinolones, and chloramphenicol has not been reported.

B. anthracis, B. mallei, B. pseudomallei, and Y. pestis demonstrate sufficient growth with commonly used broth microdilution MIC testing medium and incubation conditions (Table 2). However, the recommended testing medium for *F. tularensis* is CAMHB with 2% of a defined growth supplement. This is the same cysteine-containing defined growth supplement that is added to GC agar base for susceptibility testing of *Neisseria gonorrhoeae*. The supplement is commercially available from two manufacturers: IsoVitalex Enrichment (BD Diagnostics, Franklin Lakes, N.J.) and XV Factor Enrichment (PML Microbiologicals, Wilsonville, Oreg.). Some isolates of *Brucella* spp., particularly isolates of *B. abortus,* require CO_2 incubation. Studies are under way to determine if incubation in CO_2 significantly changes MIC values for antimicrobial agents that should be tested such as aminoglycosides, tetracyclines, or TMP-SMX. For the slower-growing organisms, *F. tularensis, Y. pestis,* and *Brucella* spp., 48 h of incubation may be needed to achieve sufficient growth.

There are few studies comparing alternative susceptibility testing methods to the standard CLSI reference broth microdilution methods. One study compared E test to broth microdilution for testing *B. anthracis* (143). In this study, E-test MICs were within a single doubling dilution of the broth microdilution MICs for ceftriaxone, chloramphenicol, ciprofloxacin, clindamycin, erythromycin, rifampin, tetracycline, and vancomycin, but not for penicillin. Penicillin MIC values for E test tended to be lower than those obtained by broth microdilution. A similar trend for penicillin MICs was noted for *B. anthracis* in a study comparing E test to agar dilution (197). These results suggest that E test is acceptable for susceptibility testing of *B. anthracis* with antimicrobial agents other than penicillin. Similar studies are needed to establish alternative methods for the other potential agents of bioterrorism so that testing is available in more laboratories.

Susceptibility testing of potential agents of bioterrorism raises safety concerns for clinical microbiology laboratories. All of the above-mentioned organisms require at least biosafety level (BSL) 2 practices, containment, and facilities. BSL 3 conditions are recommended for activities with a high potential for aerosol production (166). Since the inoculum preparation for susceptibility testing has the potential for aerosol production, all susceptibility testing procedures must be performed in a BSL 3 facility. Laboratories without BSL 3 facilities should send isolates to an appropriately equipped reference laboratory that has select agent clearance status, such as that at reference laboratories within the Laboratory Response Network and at the Centers for Disease Control and Prevention (http://www.cdc.gov/od/sap/ and http://www.bt.cdc.gov/lrn/biological.asp).

ABIOTROPHIA SPECIES AND *GRANULICATELLA* SPECIES

For *Abiotrophia* spp. and *Granulicatella* spp., resistance has been reported to agents from several different antimicrobial classes including penicillins, cephalosporins, carbapenems, macrolides, lincosamides, fluoroquinolones, and tetracyclines. In a study of 20 blood isolates by Murray et al., resistant rates for specific agents were as follows: penicillin, 5%; cefotaxime, 35%; cefepime, 47%; meropenem, 10%; erythromycin, 30%; clindamycin, 5%; and tetracycline, 10% (145). These results are consistent with those previously reported (73, 196). Murray et al. also noted a levofloxacin-resistant *Abiotrophia elegans* (currently known as *Granulicatella elegans*) which was isolated from a patient who had received 10 days of levofloxacin prophylaxis (145). Little is known about mechanisms of resistance in these bacteria. There is one report of an *Abiotrophia defectiva* isolate with a conjugative, Tn*916*-like, transposon, Tn*3872* (162). The transposon carried *ermB* and *tetM* resistance determinants, which conferred resistance to erythromycin and tetracycline, respectively. This finding demonstrates, that these bacteria are able to

acquire and transfer mobile genetic elements which confer antimicrobial resistance.

Because *Abiotrophia* spp. and *Granulicatella* spp. are fastidious, it is recommended that these be tested in CAMHB-LHB supplemented with 0.001% pyridoxal hydrochloride and incubated in CO_2 (Table 3) (38, 193). In a report by Namdari et al., a procedure for adding pyridoxal to an inoculum prepared with the Prompt system and a MicroScan dried gram-positive panel is described (147). It should be noted that susceptibility testing of aminoglycosides against *Abiotrophia* spp. and *Granulicatella* spp. is not recommended even though aminoglycosides are commonly used in combination therapy with an agent active against the cell wall, such as penicillin or vancomycin, for treating serious infections caused by these organisms. Since the aminoglycoside acts synergistically with the agent, in vitro susceptibility to aminoglycosides does not predict in vivo susceptibility (22).

AEROMONAS HYDROPHILA COMPLEX (*A. CAVIAE, A. HYDROPHILA, A. JANDAEI, A. SCHUBERTII,* AND *A. VERONII*) AND *PLESIOMONAS SHIGELLOIDES*

Aeromonas spp. are typically resistant to ampicillin, show variable results with β-lactam/β-lactamase inhibitor combinations, and are resistant to narrow-spectrum cephalosporins (122, 154, 203, 204). Inducible β-lactamases in *Aeromonas* spp. have been noted, and resistance may emerge during therapy with a β-lactam agent (123). A recent study showed that all 18 isolates from patients with traveler's diarrhea were susceptible to cefotaxime and ciprofloxacin and were variably resistant to chloramphenicol, tetracycline, and TMP-SMX (204). In Taiwan, where *Aeromonas* spp. are frequently encountered, results from 234 isolates in 1996 demonstrated that most isolates were susceptible to expanded-spectrum cephalosporins, fluoroquinolones, and aminoglycosides and approximately one-half of the isolates were susceptible to tetracycline and TMP-SMX. These authors remarked that there appeared to be species differences and *A. sobria* was more susceptible than either *A. hydrophila* or *A. caviae* (122). Similar results were noted by Vila et al. from Spain in 2002 (203).

Plesiomonas spp. are typically resistant to ampicillin and other penicillins including piperacillin and susceptible to β-lactamase inhibitor combinations and several other classes of antimicrobial agents (37, 78, 113, 185). However, Stock and Wiedemann noted ceftazidime resistance for 20 of 52 human isolates when an inoculum of 10^6 CFU/ml was used with a standard CLSI broth microdilution method. In another study, these same authors saw considerable variations in MICs when different media and inoculum concentrations from 10^4 to 10^7 were used to test 30 different β-lactams (184).

Although *Aeromonas* spp. and *Plesiomonas shigelloides* cause diarrheal disease, otherwise healthy individuals with diarrhea due to these bacteria usually recover spontaneously without treatment (78, 203) and routine antimicrobial susceptibility testing of isolates from fecal specimens is not recommended (38). However, both genera can cause a variety of other infections where treatment may be necessary (9, 78, 122, 123, 185, 204). Consequently, for isolates from extraintestinal sources, antimicrobial susceptibility testing may be warranted. These organisms share growth characteristics similar to those of *Enterobacteriaceae,* which led CLSI to recommend broth microdilution MIC testing using a method similar to that used for *Enterobacteriaceae*.

BACILLUS SPECIES

Bacillus spp. other than *B. anthracis* are common contaminants in the clinical laboratory, but these bacteria can cause serious disease. Since the susceptibility profiles of *Bacillus* spp. are quite variable, susceptibility testing should be considered when *Bacillus* spp. are isolated from normally sterile body sites. Isolates of *Bacillus* spp. can have β-lactamases that confer resistance to penicillins and possibly cephalosporins (174). *B. cereus* is the most common species found in clinical specimens, and most of these isolates are resistant to penicillin and extended-spectrum cephalosporins, although penicillin resistance does not always predict cephalosporin resistance (197, 205). Penicillin and cephalosporin resistance also occurs in other species of *Bacillus,* but it is less common. Resistance to several other agents has been reported. These agents include aminoglycosides, erythromycin, clindamycin, chloramphenicol, tetracycline, fluoroquinolones, TMP-SMX, and vancomycin. Resistance to carbapenems has not been reported for *Bacillus* spp. (197, 205; F. Cockerill, unpublished data).

Standard susceptibility testing methods for nonfastidious bacteria can be used for testing *Bacillus* spp. CLSI provides guidelines for broth microdilution testing (Table 3) (38). Agar dilution and E-test methods using MHA were compared in a study by Turnbull et al. (197). In both studies E-test MICs were similar to agar dilution MICs for several agents including cefotaxime, ciprofloxacin, erythromycin, gentamicin, penicillin, tetracycline, and vancomycin. Two commercial β-lactamase tests, Nitrocefin (Oxoid, Basingstoke, England) and Intralactam strips (Mast Diagnostics, Merseyside, United Kingdom) were evaluated in a study by Andrews and Wise (7); both tests failed to detect β-lactamase activity in four of five penicillin-resistant isolates of *B. cereus*. Therefore, β-lactamase testing is not recommended for predicting penicillin susceptibility in *Bacillus* spp.

C. JEJUNI

Resistance to macrolides and fluoroquinolones, the drugs of choice for treating gastrointestinal infections caused by *C. jejuni* and *C. coli,* is being reported with increasing frequency for human and animal isolates. The National Antimicrobial Resistance Monitoring System noted no ciprofloxacin resistance among *C. jejuni* human isolates in 1990, but a resistance rate of 12% occurred in 1997 and this increased to 18% in 2001. Erythromycin resistance was 1% in 1997 and 2% in 2001 (82). Smith et al. examined nearly 5,000 *C. jejuni* isolates from feces of Minnesota residents and noted an increase in the incidence of ciprofloxacin resistance from 1.3% in 1992 to 10.2% in 1998 (180). Of 537 *C. jejuni* isolates from human fecal specimens obtained during 1997 and 1998 in Spain, 75% were resistant to ciprofloxacin and 3.2% were resistant to erythromycin (175). A recent study noted that patients with invasive illness due to resistant isolates were more likely to have adverse effects than those infected with susceptible isolates (91). Resistance among animal isolates, which may subsequently be transmitted to humans, has been associated with the addition of macrolides and fluoroquinolones to animal food as growth-promoting agents (57).

Because of the increasing incidence of resistance, testing of isolates from individual patients with severe illness or

prolonged symptoms may be warranted or isolates might be tested for epidemiologic purposes. Susceptibility testing by broth microdilution in CAMHB-LHB and incubation in a campylobacter environment (Table 3) is suggested. Agar dilution using MHA supplemented with 5% sheep blood has been shown to be satisfactory and is listed as an alternative method by the CLSI (41). Disk diffusion methods have been used successfully by some investigators (72, 175), although CLSI has not yet identified a reliable disk diffusion method. The E test correlated well with agar dilution in a study by Baker when ciprofloxacin, erythromycin, and tetracycline were tested (11), and Hayward et al. had similar success when testing gatifloxacin (87).

CORYNEBACTERIUM SPECIES

The many *Corynebacterium* spp. may exhibit a variety of susceptibility profiles. Most isolates of *C. amycolatum, C. jeikeium,* and *C. urealyticum* are multiresistant to antimicrobial agents that are often considered for therapy of gram-positive infections, including penicillins, cephalosporins, macrolides, aminoglycosides, quinolones, tetracyclines, and clindamycin. These species remain susceptible to teicoplanin and vancomycin. Considerable variation in activities of antimicrobial agents occurs with the various other species of *Corynebacterium,* and many strains may be highly susceptible (70, 127, 158, 169, 182, 206). Virtually all isolates of *C. urealyticum* are resistant to quinolones, which has important implications for empiric therapy for urinary tract infections due to this species (65). Significant antimicrobial resistance remains rare for *C. diphtheriae,* and penicillin resistance has not been reported to date (58). However, among 15 isolates from Vietnamese children with diphtheria, 4 were resistant to erythromycin (121), and 5 of 410 isolates from around the world tested by Engler et al. showed reduced susceptibility to macrolides and ketolides (58).

Growth characteristics among the *Corynebacterium* spp. may vary, and previous studies have used a variety of methods, media, and incubation conditions for antimicrobial susceptibility testing. Prior to the publication of CLSI M45, the absence of interpretive criteria specifically for *Corynebacterium* spp. led to inconsistencies in interpreting results when CLSI interpretive criteria for other gram-positive organisms (e.g., streptococci and staphylococci) were applied (58, 70, 127, 206). CLSI recommends broth microdilution with CAMHB-LHB and incubation in ambient air (Table 3). Some strains grow satisfactorily after 24 h of incubation, but others need 48 h. The 48 h is particularly important for detecting resistance to β-lactams, and it is recommended, if growth is not satisfactory or if an isolate appears susceptible to β-lactams at 24 h, that the test be reincubated and final results be read after 48 h of incubation (38). Currently, disk diffusion testing of *Corynebacterium* spp. is not recommended by CLSI. Several investigators have used E test satisfactorily for testing *Corynebacterium* spp. (215), and Engler et al. used E test to confirm the reduced susceptibility to macrolides and ketolides that was initially identified by agar dilution testing of *C. diphtheriae* (58). Susceptibility testing of *Corynebacterium* spp. is warranted when the organisms are isolated from normally sterile sites.

ERYSIPELOTHRIX RHUSIOPATHIAE

Erysipelothrix rhusiopathiae is an intrinsically vancomycin-resistant gram-positive bacillus. Other agents that have little to no activity against isolates of this species are aminoglycosides and TMP-SMX. Antimicrobial susceptibility studies of isolates from a number of sources have shown all isolates of *E. rhusiopathiae* to be susceptible to penicillins, cephalosporins, carbapenems, and fluoroquinolones (66, 79, 189, 202, 209). Resistance to clindamycin, erythromycin, and tetracycline does occur. In one study of 214 isolates from pigs and swine in Japan the occurrence of resistance was as follows: erythromycin, 2%; clindamycin, 1%; and tetracycline, 53% (209). The tetracycline-resistant isolates were positive for *tet*M (210).

Isolates of *E. rhusiopathiae* are slightly fastidious, so CAMHB-LHB is recommended for broth microdilution MIC testing (38). There are also reports of agar dilution using either MHA supplemented with 5% horse blood or unsupplemented MHA (66, 189, 209).

HACEK GROUP

There are limited antimicrobial susceptibility test data on the HACEK organisms (i.e., *Haemophilus, Actinobacillus, Cardiobacterium, Eikenella,* and *Kingella* spp.) in part because these organisms are infrequently encountered and often difficult to grow. Members of HACEK are susceptible to extended-spectrum cephalosporins and fluoroquinolones and are often susceptible in vitro to ampicillin and penicillin (10, 43, 61, 125). Occasional isolates of *Cardiobacterium hominis, Eikenella corrodens,* and *Kingella* spp. produce β-lactamase (75, 128, 132, 181); however, β-lactamase production in *Actinobacillus actinomycetemcomitans* has not been documented (133, 156). Recent American Heart Association recommendations for treatment of patients with endocarditis caused by HACEK organisms suggest that because of difficulties in performing antimicrobial susceptibility testing and potential failure to identify ampicillin-resistant strains, HACEK organisms should be considered ampicillin resistant and ampicillin should not be used for patients with endocarditis due to HACEK organisms (10).

Broth microdilution with CAMHB-LHB can be used for testing HACEK organisms. Some isolates may require 48 h of incubation to obtain adequate growth as evidenced by substantial turbidity in the positive growth control well. Some isolates may not grow satisfactorily in CAMHB-LHB. Susceptibility testing may be warranted for isolates from normally sterile sites, and β-lactamase testing should be performed on HACEK isolates (38).

LACTOBACILLUS, PEDIOCOCCUS, AND *LEUCONOSTOC* SPECIES

Lactobacillus spp., *Pediococcus* spp., and *Leuconostoc* spp. are intrinsically vancomycin-resistant gram-positive bacteria. It is important to note that some species of *Lactobacillus* are vancomycin susceptible; they include *L. gasseri, L. delbrueckii, L. casei, L. paracasei, and L. acidophilus* (46). Isolates of all three genera are susceptible to penicillin, ampicillin, and amoxicillin (42, 44, 187, 211), but their susceptibility to cephalosporins is variable. For example, in one study the ceftriaxone MIC ranges were as follows: *Leuconostoc,* ≤0.25 to 128 μg/ml ($n = 47$); *Pediococcus,* ≤0.25 to 16 μg/ml ($n = 24$); and *Lactobacillus,* 1 to >128 μg/ml ($n = 13$) (187). Most isolates are susceptible to carbapenems, but isolates with elevated imipenem MICs (>0.5 μg/ml) have been reported for all three genera (42, 76, 187, 211). There is one report of an imipenem

therapeutic failure for a central nervous system infection due to *Leuconostoc* with an imipenem MIC of 4 μg/ml (48). Ciprofloxacin has little activity for all three genera. In a report by Swenson et al. (187) the ciprofloxacin MIC_{90} of *Leuconostoc* and *Lactobacillus* isolates was 4 μg/ml, and for *Pediococcus* the MIC_{90} was 16 μg/ml. Isolates of *Lactobacillus* and *Leuconostoc* are susceptible to clindamycin and erythromycin, but isolates of *Pediococcus* can be resistant to both agents (187, 211). Gentamicin, which may be used in combination therapy, has good activity against isolates of all three genera. In one study, the MIC_{90} was 0.5 μg/ml for *Lactobacillus* and *Leuconostoc* and 2 μg/ml for *Pediococcus* (187).

The medium recommended by CLSI for broth microdilution testing of *Lactobacillus* spp., *Pediococcus* spp., and *Leuconostoc* spp. is CAMHB-LHB (Table 3). There are several reports of susceptibility testing by agar dilution using either unsupplemented MHA or MHA with 5% sheep blood (42, 44, 76). If testing by agar dilution, incubation in air with 5% CO_2 may be necessary to achieve sufficient growth.

L. MONOCYTOGENES

Clinical isolates of *L. monocytogenes* remain susceptible to the drugs of choice including ampicillin (or penicillin) and TMP-SMX. With the exception of occasional resistance to tetracyclines (31), *L. monocytogenes* is typically susceptible in vitro to other agents active against gram-positive bacteria, including chloramphenicol, vancomycin, and macrolides (84, 135, 137, 176); however, these have not proved to be as useful in vivo as the aforementioned agents (94, 103). Although *L. monocytogenes* may appear susceptible to cephalosporins in vitro, these agents are not effective clinically.

Listeria infections are generally treated empirically, and antimicrobial susceptibility testing is usually not necessary. Only criteria for susceptibility (MIC, ≤2.0 μg/ml) are listed for ampicillin and penicillin in CLSI guidelines because clinical isolates of *L. monocytogenes* have not been noted to have results other than those indicating susceptibility (38). *L. monocytogenes* is not truly fastidious, and testing in Mueller-Hinton broth without the blood supplement has been done satisfactorily (137). However, CLSI recommends using CAMHB-LHB. It is important to remember that cephalosporins should not be tested or reported for *L. monocytogenes* as these results might indicate false susceptibility (5). This cautionary note is emphasized in CLSI documents (38) and illustrates why it is inappropriate to indiscriminately report susceptibility results for any agent without knowing if it would be a reasonable therapeutic option. Because cephalosporins are frequently used empirically for the treatment of meningitis, the laboratory should quickly communicate smear or culture findings suspicious for *Listeria* whenever they occur.

M. CATARRHALIS

More than 90% of *M. catarrhalis* isolates produce β-lactamase (15, 63, 93, 100, 102, 183, 217) and are resistant to amoxicillin, ampicillin, and penicillin. These isolates remain susceptible to amoxicillin-clavulanic acid, which is often prescribed for *M. catarrhalis* infections. Most clinical isolates produce one of two types of chromosomally mediated β-lactamases: BRO-1 or BRO-2 (112, 148, 168). BRO-1-producing strains are 10-fold or more prevalent than BRO-2-producing strains, and ampicillin and penicillin MICs for BRO-1 strains appear to be higher (e.g., ≥4.0 μg/ml) than those for BRO-2 strains (e.g., ≤0.5 μg/ml) (51, 112, 168). Because of the low MICs for the latter strains, their clinical significance in response to β-lactamase-labile penicillins is questionable. Resistance rates for TMP-SMX are low in most studies (69, 93, 217); however, Johnson et al. reported over 10% resistance in isolates from Latin America (102). Resistance to the other recommended drugs for treating *M. catarrhalis* infections remains less than 1% (63, 69, 93, 102, 183, 217).

Only the chromogenic cephalosporin method has reliably detected the β-lactamases produced by *M. catarrhalis* (55). Routine β-lactamase testing may not be necessary because of the high incidence of β-lactamase-positive strains. Nevertheless, some advocate reporting of β-lactamase results to highlight the fact that this pathogen is generally unresponsive to some agents (e.g., amoxicillin) commonly prescribed for the treatment of respiratory tract infections. MIC testing without β-lactamase testing can be problematic as there is some overlap in ampicillin and amoxicillin MICs in β-lactamase-positive and -negative strains (168). Since *M. catarrhalis* typically responds to the drugs of choice, testing beyond the β-lactamase test is rarely indicated (38). CLSI document M45-P addresses MIC testing of *M. catarrhalis,* and the recommended test medium is CAMHB (Table 3). Despite the lack of disk diffusion testing recommendations, Doern and Tubert (55) demonstrated that disk diffusion interpretive criteria for nonfastidious bacteria published by NCCLS in 1984 appear to be satisfactory, at least as they pertain to the susceptible category for amoxicillin-clavulanic acid, cephalothin, chloramphenicol, erythromycin, tetracycline, and TMP-SMX (149). However, because of the absence of frank resistance to these agents among the 74 clinical isolates examined, the investigators were unable to make definitive recommendations pertaining to disk diffusion testing.

PASTEURELLA SPECIES

Human isolates of *Pasteurella* spp. are generally susceptible to penicillin with MICs ≤0.5 μg/ml (36, 77, 144); however, β-lactamase production in an isolate from a respiratory tract infection has been documented. β-Lactamase was detected with the nitrocefin-impregnated disk method, and the isolate had an amoxicillin MIC of 8 μg/ml and an amoxicillin-clavulanic acid MIC of 0.25 μg/ml (131). *Pasteurella* spp. are generally very susceptible to many other antimicrobial agents, and no resistance has been documented for parenteral cephalosporins, quinolones, tetracyclines, chloramphenicol, or TMP-SMX (36, 77, 144). Resistance to erythromycin can occur, and there is at least one report of failure of erythromycin to cure a cat bite victim who went on to develop meningitis (129).

Broth microdilution and disk diffusion methods are described by CLSI for testing *Pasteurella* spp. (Table 3). Due to the absence of nonsusceptible strains, there are only susceptible interpretive criteria for agents that might be tested, with the exception of erythromycin. Susceptibility testing may be warranted for isolates from normally sterile sites, and β-lactamase testing should be done on these isolates as well as those from respiratory sources (38). Testing of isolates from bite wounds is not necessary since bite wound infections are generally treated empirically with agents that would cover a variety of organisms likely to be implicated in the infection.

VIBRIO SPECIES (NOT *V. CHOLERAE*)

The non-cholera *Vibrio* spp. are generally susceptible to most antimicrobial agents, including newer cephalosporins,

aminoglycosides, fluoroquinolones, and tetracyclines; however, as with other organisms, resistance to one or more of these can occur (33, 35, 134, 153, 190). One study noted ampicillin resistance for 5 of 6 environmental isolates of *Vibrio vulnificus* (214), but Chuang et al. recently reported that all 42 clinical isolates of *V. vulnificus* were ampicillin susceptible (35). Chuang et al. also demonstrated synergistic killing of *V. vulnificus* with a combination of minocycline and cefotaxime (35), and this finding has contributed to current recommendations for treating *V. vulnificus* infections with doxycycline and ceftazidime (74).

Although the non-cholera *Vibrio* spp. cause diarrheal disease, otherwise healthy individuals with diarrhea due to these bacteria usually recover spontaneously without treatment. When *Vibrio* spp. are isolated from sources associated with serious infections, antimicrobial susceptibility testing of them is warranted (33, 134). CLSI suggests use of broth microdilution or disk diffusion. For testing of these halophilic organisms, some have suggested use of MHA containing 1% NaCl. However, CLSI recommends preparation of the inoculum suspension in 0.85% NaCl solution for both disk diffusion and broth microdilution MIC testing with unsupplemented MHA or CAMHB, respectively (38).

CONCLUSION

Infections caused by many of the fastidious bacteria discussed in this chapter are treated empirically as these bacteria are often susceptible to the drugs of choice. Consequently, susceptibility testing is infrequently needed. In certain circumstances testing may be warranted, such as when there appears to be clinical failure, patient intolerance to the drug(s) of choice, or serious infections for which there are several appropriate drugs that might be prescribed. Additionally, susceptibility testing may aid in species identification (e.g., differentiating *C. jeikeium* from other *Corynebacterium* species). If a physician seems unsure about requesting antimicrobial susceptibility testing on a fastidious organism, he/she should be encouraged to seek assistance from an infectious diseases clinician or pharmacist.

The E test has been examined for testing a variety of fastidious bacteria. For the less common species, many of the data generated have been obtained from comparisons with nonstandardized in vitro test methods with limited examination of the clinical correlation of the results. Consequently, the results for E test should be interpreted with caution in the clinical setting. Requests for susceptibility testing of fastidious bacteria are often for isolates associated with serious infections, and MIC results are likely to be more useful than qualitative results. The disk diffusion test should be used only for bacteria for which there are CLSI interpretive criteria. It is important for laboratory workers to maintain an awareness of the methods available for testing fastidious bacteria and their strengths and limitations. If testing must be performed, it should be done by a laboratory familiar with these limitations.

Susceptibility Test Methods: Anaerobic Bacteria

DIANE M. CITRON AND DAVID W. HECHT

76

The importance of anaerobes as the cause of significant infections, as well as the benefits of specific antimicrobial treatment and prophylaxis against anaerobic bacteria, is well recognized (24, 26). In general, performance of antimicrobial susceptibility testing is viewed as a necessity for effective guidance of antimicrobial therapy. However, when and how susceptibility testing of anaerobes should be performed has been the subject of debate, due in part to several confounding factors and misconceptions (6, 22, 25, 83). For example, specimens obtained from most infections involving anaerobes are polymicrobic, making recovery and identification of individual isolates slow and causing antimicrobial susceptibility results to be unacceptably delayed so that a consistent impact on individual clinical outcomes is difficult to achieve. For the clinician, the combination of surgical management and use of empiric broad-spectrum antimicrobial therapy has limited the correlation of potential antimicrobial resistance with outcome. Such observations have led many laboratories away from the performance of susceptibility testing. However, there is substantial evidence that antimicrobial resistance is significant among many anaerobes worldwide and that inappropriate therapy can result in poor clinical responses and increased mortality (59, 67, 69). Antimicrobial susceptibility data have also revealed significant differences among individual hospitals on a regional and local basis, suggesting that one medical center's patterns are not applicable to organisms from other institutions (45, 72, 73). Thus, the need for susceptibility testing of anaerobes is considerably more important now than in the past.

If possible, individual hospitals should establish patterns of resistance for some anaerobes on a periodic basis, with individual patient isolates being tested as needed to assist in patient care. For surveillance purposes, the testing of 75 to 100 isolates representing anaerobes with known resistance, such as members of the *Bacteroides fragilis* group, *Prevotella* spp., *Fusobacterium* spp., and *Clostridium* spp., should be considered. Preferably, 30 isolates should be from the *B. fragilis* group, and at least 10 of each of the other genera should be tested. Alternatively, cumulative susceptibility results from individual patient isolates should be included in the hospital antibiogram. Antimicrobial agents to be tested should generally be based upon the hospital's formulary, although one agent from each antimicrobial class should be included, even if it is not on the hospital formulary, to detect resistance. These data would be important as part of the cumulative susceptibility report if the formulary were changed and could aid in the choice of empiric therapy. For individual patient management, susceptibility should be performed when (i) selecting an active agent is critical for disease management, (ii) there is consideration for long-term therapy, (iii) anaerobes are isolated from specific body sites (e.g., blood, brain, bone, or joint), or (iv) there is the failure of a usual regimen (Table 1).

This chapter describes currently available methodologies and their interpretation for susceptibility testing of anaerobes. The Clinical Laboratory Standards Institute (CLSI, formerly NCCLS) anaerobe working group has established an agar dilution reference method using brucella blood agar as the testing medium (15–17). This method is not considered simple or economical to perform but will serve as the method to which other more practical methods can be compared (Table 2). At present, alternative testing methods include the limited agar dilution, broth microdilution (for the *B. fragilis* group), and the E test. β-Lactamase testing provides very limited data but can be useful if penicillin therapy is being considered. Broth disk elution and disk diffusion tests are not considered appropriate for anaerobic susceptibility testing because their results do not correlate with those of the agar dilution reference method (14).

CURRENT PATTERNS OF ANTIBIOTIC RESISTANCE

Susceptibility testing of anaerobes has not been routinely performed at most hospitals (39). As a result, most of the published literature reporting susceptibility of anaerobes is generated by reference laboratories testing a limited number of isolates from one or more medical centers (1–3, 31, 37, 44, 45, 72, 73). Over the last decade, significant variations in susceptibility results for anaerobes have been reported from different countries, geographic locations within countries, and even hospitals within the same cities (45, 47, 53, 54, 56, 72, 79). Of particular note, the incidence of clindamycin resistance has increased from <10 to >40% for the *B. fragilis* group at some hospitals (45, 73), while resistance to cephalosporins and cephamycins is also rising (45, 72–74, 79). Some differences in susceptibility results among various reports may be accounted for by the use of different testing methods, lack of uniformity in interpretive breakpoints among countries, and clustering of MICs at the breakpoint for some species with

TABLE 1 Indications for susceptibility testing of anaerobic bacteria

Indication	Examples[a]
Surveillance	
Annual monitoring of isolates at individual medical centers	*B. fragilis* group, *Prevotella* spp., *Fusobacterium* spp., *Clostridium* spp., *B. wadsworthia*
Clinical	
Known resistance of a particular species	*B. fragilis* (clindamycin, cephamycins, piperacillin, fluoroquinolones); *Prevotella* spp. and *Fusobacterium* spp. (penicillin, clindamycin)
Failure of a usual therapeutic regimen	Any anaerobe
Pivotal role of antimicrobial agent in clinical outcome	*B. fragilis* group (osteomyelitis, joint infection)
Need for long-term therapy	*B. fragilis* group, *Prevotella* spp. (osteomyelitis, endocarditis, brain abscess, liver abscess, lung abscess)
Infections of specific body sites	Any anaerobe (brain abscess, endocarditis, prosthetic devices or graft, bacteremia)

[a] Examples only, and not intended as all-inclusive. See the text for specific recommendations.

some antimicrobial agent combinations (4, 42). Regardless, it is clear from recent publications that resistance to many classes of antimicrobial agents among anaerobes is increasing, and clinicians and laboratories can no longer assume susceptibility of anaerobes to these agents without testing. Further, neither national nor even local data from other institutions are sufficient to predict susceptibility of anaerobes to antimicrobial agents at one's own hospital (45, 72, 73). A general outline of current resistance patterns for anaerobic bacteria is provided below (40).

Gram-Negative Bacilli and Cocci

B. fragilis Group

Among the 13 members of the *B. fragilis* group, *B. fragilis* is generally the most susceptible, although greater than 95% of all species are resistant to penicillin and ampicillin. The carboxy- and ureidopenicillins, ticarcillin, and mezlocillin are somewhat more active than penicillin, but <50% of isolates are susceptible (2, 9, 79). Piperacillin is the most active of the ureidopenicillins against the *B. fragilis* group, although susceptibility has fallen from approximately 90 to 70% over the last 8 to 10 years (2, 41, 72, 73). The isoxazolyl penicillins, such as oxacillin and nafcillin, are not active against these organisms. The principal mechanism of resistance to penicillins is β-lactamase production. Thus, β-lactam–β-lactamase inhibitor combinations, such as ampicillin-sulbactam, amoxicillin-clavulanic acid, ticarcillin-clavulanic acid, and piperacillin-tazobactam, are active against nearly all strains of *B. fragilis* group, with <2% resistance reported in most studies (3, 9, 41, 44, 47, 53, 72, 73, 79).

Among the cephalosporins and cephamycins, cefoxitin remains very active against members of the *B. fragilis* group, with 80 to 90% of isolates susceptible. Cefotetan demonstrates activity against *B. fragilis* similar to that of cefoxitin, but it is much less active against the other members of the *B. fragilis* group (2). With the exception of ceftizoxime, broad-spectrum cephalosporins generally have poor activity against most members of the *B. fragilis* group, inhibiting <50% of isolates (73). Susceptibility to ceftizoxime varies widely among published studies (60 to 90%), probably due to differences in testing methods (4). Narrow-spectrum cephalosporins, such as cefazolin, are not active against members of the *B. fragilis* group.

A marked decrease in susceptibility to clindamycin among *Bacteroides* spp. has become widely recognized worldwide, as noted above (1, 3, 9, 44, 45, 47, 53, 72, 73, 79). The clindamycin resistance determinants include several *erm* genes that are frequently located on transferable plasmids and are often linked to transferable tetracycline resistance (65, 82). Among other agents, chloramphenicol, metronidazole, and carbapenems (imipenem, ertapenem, and meropenem) are nearly uniformly active against all members of the *B. fragilis* group in the United States (2, 36, 72), although imipenem-resistant strains have been reported from Japan, the United States, Hungary, Kuwait, and other countries (5, 63, 75). Of note, imipenem resistance is mediated by a zinc metalloenzyme that confers resistance to all current β-lactam and β-lactam–β-lactamase inhibitor combination agents and has

TABLE 2 Methods for susceptibility testing of anaerobic bacteria

Method	Medium	Inoculum	Incubation time (h)	Advantages	Disadvantages
Agar dilution[a]	Brucella blood agar	10^5 cells/spot	48	Reference method, multiple isolates tested/antibiotic	Labor intensive, expensive
Broth microdilution[b]	Supplemented brucella broth	10^6 cells/ml (10^5/well)	48	Economical, commercial panels available, multiple antibiotics/isolate	Limited shelf life of frozen panels, poor growth by some strains
E test	Brucella blood agar	0.5 McFarland, swab plate	24–48	Precise MIC value, convenient for individual patient isolates	Expensive for surveillance use

[a] Media are commercially available.
[b] Frozen panels available from PML Microbiologicals, Inc. (Wilsonville, Oreg.); lyophilized panels are available from Trek Diagnostic Systems.

been reported to be transferable (64, 75). Of more concern, however, strains resistant to metronidazole in France have been reported, associated with a transferable plasmid (64), and in recent years, additional resistant strains carrying *nim* genes have been reported in Washington state, the United Kingdom, and other countries in Europe (27, 55, 70). *nim* genes encode a nitroimidazole reductase which converts nitroimidazoles to aminoimidazole, preventing the formation of the active toxic nitroso residue (11). Among fluoroquinolone agents, trovafloxacin (a trifluoronaphthyridone) had excellent activity against most members of the *B. fragilis* group; however, it is no longer marketed in most countries, including the United States (15, 43, 44, 46, 71, 72). Other fluoroquinolones such as moxifloxacin, recently approved by the FDA for skin structure infections and intra-abdominal infections, and gatifloxacin also exhibit good activity against a broad range of anaerobes (9, 23, 48, 71). Resistance to fluoroquinolones in *Bacteroides* and other anaerobes is increasing with the widespread use of this class of antimicrobial agents (29, 61, 72; D. M. Citron, *Abstr. 45th Intersci. Conf. Antimicrob. Agents Chemother.*, abstr. E-1440, 2005). Tigecycline, a glycylcycline derivative of minocycline, was recently approved by the FDA for intra-abdominal and skin and soft tissue infections. Although breakpoints for anaerobes have not yet been defined by CLSI, several studies describe its activity against anaerobic organisms (10, 49).

Prevotella and *Porphyromonas*

Recent taxonomic changes for this group of anaerobes are provided in reference 51. In general, data on the susceptibility of these organisms (mostly former *Bacteroides* species) are more limited than those of the *B. fragilis* group. Overall, both genera are more susceptible than the *B. fragilis* group. Currently, about 50% of *Prevotella* spp. are resistant to penicillin and ampicillin due to β-lactamase production, with susceptibility to piperacillin, cefoxitin, and cefotetan ranging from 70 to 90% in most published studies (30, 35, 44, 53, 57). Eight percent of *Porphyromonas* strains were reported to produce β-lactamase in a survey from Japan (78), as were 17% of strains recovered from serious pelvic infections (62). Susceptibility of *Porphyromonas* isolates is rarely reported separately in most published literature from the United States, but β-lactamase production is considered rare at present (36). As in the case of the *B. fragilis* group, both genera are nearly uniformly susceptible to carbapenems, metronidazole, and chloramphenicol, although clindamycin resistance has been observed in a small percentage of strains (36).

Other Gram-Negative Bacilli

Penicillin resistance among isolates of the genus *Fusobacterium* has been observed; *Fusobacterium nucleatum* strains from saliva in infants show increasing rates of β-lactamase production related to age, day care attendance, and exposure to antimicrobial agents (60), and a β-lactamase-producing strain was responsible in a case of fatal sepsis in a compromised patient (38). In general, >90% of *Fusobacterium* spp. are susceptible to cephalosporins and cephamycins (36, 50, 53, 81). *Campylobacter rectus* and *Campylobacter curvus* (formerly *Wolinella*) vary in their susceptibility to β-lactams but remain very susceptible to chloramphenicol, metronidazole, and clindamycin (81). *Bilophila wadsworthia* is a gram-negative anaerobe from the gastrointestinal tract that frequently produces β-lactamase and therefore is resistant to penicillin and ampicillin. High MIC_{90} values are also seen when testing piperacillin, with values clustering near the breakpoints. *B. wadsworthia* is susceptible to clindamycin, cefoxitin, β-lactam–β-lactamase inhibitor combinations, carbapenems, and metronidazole (7). *Campylobacter gracilis* (formerly *Bacteroides gracilis*) was previously considered to be resistant to many β-lactam agents. However, data suggest that when properly identified and tested, this organism is susceptible to most agents tested, including β-lactam–β-lactamase inhibitor combinations, cefoxitin, and clindamycin (58). In fact, a newly described but more resistant organism, *Sutterella wadsworthensis,* was often isolated from the same samples and identified as *C. gracilis*. *S. wadsworthensis* may demonstrate resistance to clindamycin, piperacillin, and/or metronidazole (58).

Gram-Positive Bacilli and Cocci

Non-Spore-Forming Gram-Positive Bacilli

The *Eubacterium* group, *Actinomyces, Propionibacterium,* and *Bifidobacterium* are usually susceptible to β-lactam agents, including the penicillins, cephalosporins and cephamycins, carbapenems, and β-lactam–β-lactamase inhibitor combinations. *Lactobacillus* spp. are variably susceptible to cephalosporins and may be inhibited effectively only by penicillin (36). Vancomycin is active against all *Propionibacterium* spp., *Actinomyces* spp., *Eubacterium* spp., peptostreptococci, and some *Lactobacillus* spp., but *Lactobacillus casei* and several other species are usually resistant (36). The newer antimicrobial agents such as linezolid, daptomycin, dalbavancin, telavancin, and ramoplanin with activity against gram-positive aerobic organisms also exhibit excellent in vitro activity against most anaerobic gram-positive species (8, 12, 32–34). Most non-spore-forming gram-positive anaerobes are resistant to metronidazole.

Spore-Forming Gram-Positive Bacilli

Clostridium perfringens is generally very susceptible to most antianaerobic agents and to fluoroquinolones (9, 44, 46). However, non-perfringens *Clostridium* spp. and *Clostridium difficile* have variable susceptibility (19, 35–37, 44, 66, 79). Drugs to which resistance among non-perfringens species is observed include clindamycin, fluoroquinolones, and β-lactams; however, chloramphenicol and metronidazole remain active. *C. difficile* may be resistant to many β-lactams, including cephalosporins, fluoroquinolones, and clindamycin, but retains susceptibility to metronidazole and vancomycin, while *Clostridium innocuum* has vancomycin MICs of 8 to 32 μg/ml (35–37, 66).

Gram-Positive Cocci

At present, only *Peptococcus niger* remains in this genus, and several of the species in the genus *Peptostreptococcus* have been reclassified into other genera (76). In general, these organisms are highly susceptible to all β-lactams, β-lactam–β-lactamase inhibitors, cephalosporins, carbapenems, chloramphenicol, and metronidazole (36, 46, 53, 66, 79, 81). Fluoroquinolone resistance is increasing among the species isolated from skin and soft tissue infections (Citron, 45th ICAAC), and some strains may be resistant to clindamycin. Occasionally, microaerophilic streptococci including *Abiotrophia* and *Granulicatella* species are initially identified as *Peptostreptococcus* spp. and reported to be resistant to metronidazole. The presumptive identification of a metronidazole-resistant *Peptostreptococcus* sp. should prompt further identification of the organism because such isolates are rare. The *nimB* gene coding for metronidazole resistance has been demonstrated in two highly resistant strains of *Finegoldia magna,* although it appears to be prevalent in susceptible strains of other gram-positive cocci as well (80).

DESCRIPTION OF TEST METHODS

Agar Dilution

Media

The recommended medium is supplemented brucella blood agar, which supports the growth of essentially all anaerobes (17). Brucella base agar is supplemented with hemin (5 μg/ml) and vitamin K_1 (1 μg/ml) prior to autoclaving and 5% defibrinated or laked sheep blood after cooling to 48 to 50°C. To prepare hemin stock solution (5 mg/ml), dissolve 0.5 g of hemin in 10 ml of 1 N NaOH and bring to a 100-ml volume with distilled water. Sterilize by autoclaving at 121°C for 15 min. Add 1 ml of agar per liter. The stock solution may be stored at 4 to 8°C for 1 month. Vitamin K_1 stock solution (10 mg/ml) is prepared by mixing 0.2 ml of Vitamin K_1 (3-phytyl menadione) with 20 ml of 95% ethanol, and it is added to the agar base to achieve a final concentration of 1 μg/ml prior to autoclaving. The stock solution can be stored for up to 6 months at 4°C in a dark bottle. Lysed (laked) sheep blood is prepared by a single cycle of alternate freezing and thawing and does not require clarification by centrifugation. Laked blood may be stored at –20°C for up to 6 months.

The agar is dispensed in 17-ml volumes in test tubes prior to autoclaving. After autoclaving, these tubes may be stored at 4 to 8°C for up to 1 month. On the day of the test, the agar is melted by heating and then cooled in a water bath to 48 to 50°C. Laked blood (1 ml) and the antimicrobial dilutions (2 ml) are added, and after mixing by gently inverting the tubes twice, the plates are poured. After they have solidified, the plates are dried in the incubator by inverting them with the lids ajar for 45 min. The CLSI recommends that plates not be stored any longer than 7 days in closed containers at 4 to 8°C. However, for research and precise evaluation purposes, storage for no longer than 72 h is recommended. Due to instability, plates containing imipenem (but not meropenem and ertapenem) or clavulanic acid must be used on the day of preparation.

Inoculum Preparation

The inoculum may be prepared by suspending colonies taken from a 24- to 72-h brucella blood agar plate into brucella broth or other clear broth medium to a density equal to the 0.5 McFarland standard. Alternatively, the initial suspension may be prepared by inoculating five or more colonies into enriched thioglycolate or other broth medium that supports good growth and by incubating for 4 to 24 h to obtain adequate turbidity (dilution may be required) (17). Equivalence to a 0.5 McFarland standard can be measured visually or by using a colorimeter or a simple photometer device (e.g., Vitek, Hazelwood, Mo.; Microscan, West Sacramento, Calif.; Trek Diagnostic Systems, Inc., Cleveland, Ohio). Although it is more accurate than visual inspection, the use of different broth media can affect photometer readings, requiring the user to verify the size of the inoculum by performing colony counts. Species with large cells, such as *C. perfringens,* require fewer cells to achieve this turbidity and will show correspondingly lower colony counts, while the converse is true for organisms with smaller cells, such as *Veillonella* or *Micromonas micros.*

The organism suspensions are dispensed by pipette into the wells of the replicator head (32 to 36 wells) and applied to the plates with a multipronged replicator device that delivers approximately 0.001 ml per spot (10^5 CFU). The drug-free control plates are inoculated first, followed by the antimicrobial plates, starting with the lowest drug concentration. The plates should be marked to ensure proper orientation.

Contamination by aerobic bacteria during the inoculation procedure can be detected by inoculating drug-free plates and incubating them in an aerobic environment. If using thioglycolate or other agar-containing broth media for inoculum preparation, an additional control plate may be inoculated and refrigerated to distinguish the inoculum residue that occurs at the time of setting up the MIC testing plates. Agar dilution plates can be inoculated in an aerobic environment, although the exposure time prior to incubation should be minimized. After stamping the plates, the inoculation spots should absorb for 10 to 15 min into the medium, at which time the plates are stacked upside down (to prevent condensation from falling on spots) and immediately placed into an anaerobic environment for incubation.

Incubation Conditions

An anaerobic chamber or anaerobic jars equipped with disposable hydrogen/carbon dioxide generators and palladium-coated catalyst pellets or ascorbic acid envelopes are recommended for incubating agar dilution plates. The incubation atmosphere should contain approximately 5% CO_2, and an indicator of anaerobiasis should be included. Incubation is at 35 to 37°C for 44 to 48 h (17).

Interpretation of Results

Since 1993, the CLSI has defined the endpoint for agar dilution testing as the concentration at which the change from the growth control is the most marked (14). This change is defined as no growth or lighter growth, a haze, multiple tiny colonies, or one to several normal-sized colonies. The technologist should take care to discern a few colonies that may be present as the result of a "splash" from a resistant neighboring isolate from the few colonies that precede full growth of the strain. Endpoints can be difficult to interpret when testing some gram-negative organisms with β-lactams, particularly ceftizoxime and piperacillin. This is especially problematic with many strains of fusobacteria that produce L forms that appear as transparent hazes in the presence of even very high concentrations of β-lactam agents. The current CLSI document for susceptibility testing of anaerobes now includes a color figure illustrating the endpoints described above and should be utilized as an additional guide when using this test method (17). It is important to compare the drug-containing plates to the drug-free control plate when reading the tests, because spots of different species of anaerobic bacteria can have very different appearances, ranging from mucoid-opaque, as with the *B. fragilis* group, to gray-transparent, as with *Bacteroides ureolyticus*.

The interpretation of MIC results should be done according to criteria recommended by the CLSI (Table 3) (17). In 1993, an intermediate category was established for anaerobic bacteria (14). For many antimicrobial agents used against anaerobes, a significant percentage of strains have susceptibility test endpoints that cluster at or near the suggested breakpoints. In the twofold-dilution method, the degree of acceptable variation of endpoints (usually plus or minus 1 twofold dilution) does not permit adequate distinction of the qualitative categories. If an intermediate value is determined for any anaerobe, the CLSI recommends maximum dosages of the antimicrobial agent for therapy. With such dosages, it is believed that organisms with susceptible or intermediate endpoints are amenable to therapy. This recommendation is predicated upon the presumed surgical intervention that frequently accompanies infections involving these organisms.

TABLE 3 Interpretive categories for MICs for anaerobic bacteria[a]

Antimicrobial agent	MIC (μg/ml)		
	Susceptible	Intermediate	Resistant
Amoxicillin-clavulanic acid	≤4/2	8/4	≥16/8
Ampicillin[b]	≤0.5	1	≥2
Ampicillin-sulbactam	≤8/4	16/8	≥32/16
Cefotetan	≤16	32	≥64
Cefoxitin	≤16	32	≥64
Chloramphenicol	≤8	16	≥32
Clindamycin	≤2	4	≥8
Ertapenem	≤4	8	≥16
Imipenem	≤4	8	≥16
Metronidazole	≤8	16	≥32
Meropenem	≤4	8	≥16
Penicillin[b]	≤0.5	1	≥2
Piperacillin	≤32	64	≥128
Piperacillin-tazobactam	≤32/4	64/4	≥128/4
Tetracycline	≤4	8	≥16
Ticarcillin-clavulanic acid	≤32/2	64/2	≥128/2
Trovafloxacin	≤2	4	≥8

[a] Adapted from reference 17 with permission of the publisher.

[b] Members of the *B. fragilis* group are presumed to be resistant. Other gram-negative anaerobes may be screened for β-lactamase activity by using a chromogenic cephalosporin test if penicillin therapy is contemplated. Higher levels in blood are achievable; infection with non-β-lactamase-producing organisms with higher MICs might be treatable.

Broth Microdilution Test

The broth microdilution procedure has been validated by CLSI for testing only members of the *B. fragilis* group. Other, more-oxygen-sensitive anaerobes did not grow consistently when inoculated on the bench. Testing in an anaerobic chamber using reduced MIC trays may improve growth and make this method suitable for other species of anaerobes. The anaerobe working group of CLSI is evaluating additional antimicrobial agents and other species for correlation of the broth microdilution method to the reference standard.

Media

Brucella broth supplemented with hemin (5 μg/ml), vitamin K_1 (1 μg/ml), and lysed horse blood (5%) is the recommended medium. Microdilution trays may be prepared fresh, frozen after preparation, or purchased commercially as lyophilized or frozen panels. Following the manufacturer's recommendations for storage of commercially prepared panels is recommended, whereas in-house-prepared trays may be kept at −70°C for up to 6 months if stored in sealed plastic bags. Antimicrobial agents should be diluted according to the scheme described by the CLSI (17) and prepared in large volumes, 15 to 100 ml, depending on the device used to simultaneously dispense aliquots of 0.1 ml per well into the standard 96-well panels. If the inoculum is to be added by pipette, the antimicrobial solutions are prepared at twice the desired concentration and the wells are filled with 0.05 ml, after which 0.05 ml of inoculum is added to each well for a final volume of 0.1 ml. Final volumes of less than 0.1 ml are not recommended for testing anaerobes due to loss of liquid by evaporation. Inoculum effects may be exaggerated when smaller volumes are used.

Inoculum Preparation

Inoculum preparation is similar to that of the agar dilution procedure. Organisms may be suspended into a clear broth to equal the turbidity of the 0.5 McFarland standard, or the isolate can be grown in a supplemented thioglycolate or other broth that supports growth of the organism for 4 to 24 h and then diluted to the turbidity of the 0.5 McFarland standard (approximately 1.5×10^8 CFU/ml). The final concentration of the organism is 1×10^6 to 2×10^6 CFU/ml (10^5 CFU/well). Depending on the method of tray inoculation, the dilution technique will differ. If 10 μl is added to each well, then the 0.5 McFarland suspension is diluted 1:10. If 50 μl is added, then the 0.5 McFarland suspension is diluted 1:50. If a lyophilized tray is used, the 0.5 McFarland suspension is diluted 1:100.

Inoculation Procedure

Frozen trays should be brought to room temperature prior to inoculation. The inoculation can be accomplished by using a disposable, hand-held, 96-prong inoculator, a mechanized dispenser, or a multichannel pipettor, depending on the preparation method of the panel, within 15 min after inocula are prepared. While the members of the *B. fragilis* group are relatively oxygen tolerant, reducing the trays in an oxygen-free environment prior to inoculation (2 to 4 h) may enhance the growth of certain fastidious anaerobes and reduce the "edge" effect of outer rows being reduced more rapidly than inner wells (52). Trays should be reduced prior to inoculation if metronidazole is to be tested, since the antimicrobial activity of metronidazole is dependent on the formation of an active intermediate that requires a reduced atmosphere (52). False resistance can occur with nonfastidious, rapidly growing strains that produce significant growth before metronidazole is reduced to its active form. Control wells should include a well with broth but no drug (growth control) and an uninoculated well as a sterility check. This well may also be used as a negative control well for visual comparison with growth in inoculated wells. Alternatively, an uninoculated tray may be incubated as a sterility check, especially if the trays are prepared in-house.

It is advisable to perform a colony count and a purity check of the inoculum. This is accomplished by removing 10 μl from the growth control well, diluting it into 10 ml of saline (1:100), and spreading 0.1 ml onto the surface of a nonselective blood agar plate for anaerobic incubation. The presence of 100 to 200 colonies indicates an inoculum of 1×10^6 to 2×10^6 CFU/ml. A small amount of the growth control well can be inoculated onto a quadrant of a blood agar plate for aerobic incubation to detect aerobic contamination.

Incubation Conditions

Trays are most conveniently incubated in an anaerobic chamber for 40 to 48 h. Alternatively, they can be placed into large anaerobic jars, regular anaerobic jars laid on their side, or anaerobic pouches with the appropriate anaerobic gas generator. No more than four trays should be stacked on top of each other to ensure uniformity of heating and gas exchange. Trays should not be sealed with sealing tape (unless perforated) if set up on the bench, as this will decrease the rate of diffusion of anaerobic gases to the inoculum and may result in poor growth or false resistance to metronidazole.

Interpretation of Results

The plates may be examined with reflective light by using a viewing device, such as a stand with a magnifying mirror. Broth microdilution MIC determinations require criteria similar to those for the agar dilution procedure for reading endpoints: the concentration at which the most significant

reduction in growth is observed is interpreted as the MIC. Similar to that of agar dilution, this decrease in growth may include a tiny, gradually diminishing button of growth, with trailing endpoints also being observed (17). If the growth in the drug-free growth control well is poor, the test should not be read. At this time, breakpoints for broth microdilution are similar to those for agar dilution (17).

E Test

The E test (AB BIODISK, Solna, Sweden) has been used more frequently for testing anaerobic organisms in recent years, primarily because of its convenience. Several studies have demonstrated its utility and indicate that results correlate well with the CLSI reference approved agar dilution method (13, 68). Rosenblatt has noted that some strains of *Prevotella* and *Bacteroides* spp. show very major errors (false susceptibility) with penicillin and ceftriaxone; however, a β-lactamase test would provide the correct result in these instances. In addition, false resistance to metronidazole among anaerobes has been reported when using the E test. This phenomenon can be the result of test conditions and medium quality and is generally eliminated if test plates are reduced in an anaerobic atmosphere overnight prior to their use (18).

Procedure

The E test consists of plastic strips coated with a gradient of antimicrobial on one side and an MIC interpretive scale on the other side. The method consists of streaking to confluence (three directions) a 0.5 to 1 McFarland standard of the test organism on a 150-mm-diameter supplemented brucella blood agar plate. Up to six E-test strips can be applied to the surface of the plate in a radial fashion with the lowest concentration toward the center. If large plates are not available, two strips, one on each half, may be placed on a standard-size plate with the high concentrations of the strips opposite each other. Following 24 to 48 h of anaerobic incubation, an elliptical zone of inhibition is formed. MICs are read at the point of intersection of the ellipse with the interpretive scale of MICs.

Validation for most antimicrobial agents recommended for testing of anaerobes has been confirmed for the E test (68). The complete list of FDA-approved antimicrobial agents for anaerobe testing is found in the E-test package insert. The E test provides a flexible and simple procedure that is well suited for individual isolate testing in smaller laboratories or for those labs that do not perform batch testing of anaerobe susceptibility. Its main drawback is the relatively high cost for each strip. This can be alleviated somewhat by limiting the number of antimicrobial agents being tested to a few relevant drugs from the hospital's formulary.

β-Lactamase Testing

β-Lactamase testing of anaerobes can be performed as described by the CLSI (17). Two easily performed methods include a nitrocefin disk assay (Cefinase; BD Diagnostics Systems, Sparks, Md.) and the S1 chromogenic cephalosporin disk (International BioClinical, Inc., Portland, Oreg.). Both tests should be performed according to the manufacturers' directions. Hydrolysis of the β-lactam ring by β-lactamases causes a color change on the disks from yellow to red. Most reactions occur within 5 to 10 min, but some β-lactamase-positive strains of *Bacteroides* spp. may react more slowly (up to 30 min) (21). When testing *Bilophila wadsworthia,* 1% pyruvate should be added to the testing growth medium for consistent results (77).

β-Lactamase testing has limited utility in detecting resistance to certain β-lactam agents among anaerobes. While a chromogenic cephalosporin test is simple and quick and generally detects β-lactamases produced by species of *Prevotella, Porphyromonas, Bacteroides,* and other anaerobes, resistance to β-lactam drugs is not always mediated by β-lactamase production (e.g., some strains of *Bacteroides distasonis* and *B. fragilis* are resistant because of alterations of penicillin-binding proteins) (20, 28). Therefore, β-lactamase test results are limited in their clinical application. A positive test does, however, provide clinically relevant information quickly in some situations and can predict resistance to penicillin G and ampicillin.

QUALITY CONTROL

A quality control program is designed to monitor the accuracy and precision of a susceptibility test procedure, the performance of reagents and equipment, and the performance of persons who conduct the tests. Quality control must be performed to demonstrate that any new medium used adequately supports the growth of the test organisms and that antimicrobial agents have not deteriorated during shipping or storage. These tests must be a part of any testing program using any of the methods described above. Ideally, the quality control strain(s) that most closely resembles the tested organism(s) should be included. The recommended quality control strains are *B. fragilis* ATCC 25285, *Bacteroides thetaiotaomicron* ATCC 29741, and *Eubacterium lentum* ATCC 43055. The CLSI is currently evaluating a nontoxigenic strain of *C. difficile* (ATCC 700057) for replacement of the *E. lentum* strain. Two quality control strains should be used for each assessment when using the agar dilution procedure. When testing an individual strain using broth microdilution or E test, one quality control strain should be included. Expected values for quality control strains are published by the CLSI (17). For some antimicrobial agent-quality control organism combinations, no quality control ranges are recommended because of the difficulty in reading of endpoints.

CONCLUSIONS

Increasing antimicrobial resistance among anaerobes has become a significant problem in recent years, underscoring the need for more antimicrobial susceptibility testing. Current methodologies allow for accurate surveillance or individual isolate testing by most laboratories. Future studies comparing broth microdilution to the reference agar method and the anticipated development of an improved microdilution system will result in better standardization of the more user-friendly method and possibly more widespread commercial availability.

Susceptibility Test Methods: Mycobacteria, *Nocardia*, and Other Actinomycetes*

GAIL L. WOODS, NANCY G. WARREN, AND CLARK B. INDERLIED

77

In his review article entitled "The White Plague," M. F. Perutz recounted that Cardinal Richelieu (1585 to 1642), Heinrich Heine (1797 to 1856), Frédéric Chopin (1810 to 1849), Anton Chekhov (1860 to 1904), Franz Kafka (1883 to 1924), George Orwell (1903 to 1950), and Eleanor Roosevelt (1884 to 1962) all had a common fate (112). Each of them died of tuberculosis. For many of these famous cases, it is unknown if the disease was only poorly understood or if management of the disease was simply inadequate or even inappropriate. For some, effective antimicrobial agents for the treatment of tuberculosis had not been discovered or were discovered too late. Streptomycin and *p*-aminosalicylic acid were not introduced until the late 1940s, and isoniazid, ethambutol, and rifampin were not used to treat tuberculosis until 1952, 1961, and 1968, respectively. Therefore, it is also possible that the more contemporary of these patients were early victims of antimicrobial resistance. In the same article, Professor Perutz related the response of the Nobel laureate Gerhard Domagk (1895 to 1964) to Otto Warburg's (1883 to 1970) comment that Domagk "deserved monuments in each valley and every mountain." Domagk, who in 1935 discovered Prontosil (a precursor of sulfanilamide), Conteben (thiosemicarbzone), and Neoteben (isonicotinic acid hydrazide), replied to Warburg that "no one is interested any longer in diseases that can be cured." Domagk could not have anticipated the extent to which antibiotic resistance would come to complicate the chemotherapy of all infectious diseases, especially tuberculosis.

ANTIMICROBIAL AGENTS

Although a variety of antimicrobial agents are available for the treatment of mycobacterial diseases, not all agents are suitable for treating all types of infections. Furthermore, in the face of antimicrobial resistance, the choice of alternative therapies can be problematic and clinical experience becomes a prevailing factor. For other uncommon mycobacterial infections, the physician is not infrequently faced with a dilemma in choosing a treatment regimen because of a lack of clinical precedence or unclear efficacy. The situation is confounded further by the need to treat mycobacterial infections with a combination of agents to improve efficacy, to prevent resistance, or to overcome intrinsic resistance (34).

The antimicrobial agents that are used in the treatment of mycobacterial infections are discussed below and, for the most commonly encountered species, the primary agents are summarized in Table 1 (75, 160). For tuberculosis, first-line drugs are those usually used to treat uncomplicated cases. The Clinical and Laboratory Standards Institute (CLSI, formerly National Committee for Clinical Laboratory Standards [NCCLS]) document on drug susceptibility testing of mycobacteria (28) currently recommends that first-line testing include ethambutol (EMB), rifampin (RMP), two levels of isoniazid (INH), and pyrazinamide (PZA). In the United States, streptomycin (SM) has been moved from first-line to second-line testing (28). Second-line drugs are those used when first-line therapy fails or is inappropriate. These agents are often accompanied by more severe side effects.

Drug resistance in *Mycobacterium tuberculosis* occurs randomly and at a low frequency and is usually a result of single-step mutations. There are two types of drug resistance seen in *M. tuberculosis:* primary and acquired. Primary drug resistance occurs when drug-resistant organisms are found in a previously untreated person. Acquired resistance, the most common form of resistance, can emerge against any of the antituberculosis agents during chemotherapy (111).

Antibiotic resistance in bacteria can occur by a number of mechanisms (summarized for *M. tuberculosis* in Table 2). Five of these categories are found in mycobacteria: decreased uptake of drug such as seen in dormant acid-fast bacilli; drug inactivation by production of β-lactamases; increased efflux as seen in fluoroquinolone resistance; alteration of the target as described below with RMP and INH; and reduced prodrug-activating enzymes as exhibited in PZA resistance (157).

Isoniazid

Isoniazid (INH) (isonicotinic acid hydrazide), a synthetic antimicrobial agent introduced in 1952 for the treatment of tuberculosis, is remarkably specific and potently bactericidal for tubercle bacilli. INH has comparatively low toxicity and is active against virtually all wild-type strains of *M. tuberculosis.* The mechanism of action of INH occurs in three steps: (i) activation of the drug, (ii) binding of the "active" form to the target(s) of inhibition, and (iii) exertion of an inhibitory effect. In turn, the mechanism of INH resistance can involve alterations in each of these steps, alone or in combination. While the mechanism of INH activation is not completely resolved, it is likely that the process involves an oxidation

*This chapter contains information presented in chapter 73 by Clark B. Inderlied and Gaby E. Pfyffer in the eighth edition of this Manual.

TABLE 1 Antimicrobial agents recommended for primary treatment of common mycobacterial infections

Mycobacterium species	Site of infection: antimicrobial agents
M. tuberculosis complex[a]	Any site: isoniazid + rifampin + ethambutol + pyrazinamide
M. avium complex	Pulmonary: clarithromycin (or azithromycin) + rifampin + ethambutol; disseminated: clarithromycin (or azithromycin) + ethambutol ± rifabutin
M. kansasii	Pulmonary: isoniazid + rifampin + ethambutol
M. abscessus, M. chelonae, M. fortuitum[b]	Nonpulmonary: clarithromycin (if susceptible) + ≥1 other drug, based on susceptibility test results
M. abscessus[c]	Pulmonary: multidrug regimen, based on susceptibility test results, that includes clarithromycin
M. marinum	Clarithromycin, doxycycline or minocycline, trimethoprim-sulfamethoxazole, or rifampin + ethambutol

[a] Almost all (>95%) *M. bovis* isolates are resistant to pyrazinamide.
[b] Surgical debridement often is important for successful therapy.
[c] Currently there are no drug regimens of proven efficacy. Antimicrobial therapy may provide symptomatic improvement and disease regression. Surgical resection of limited disease (if possible) and multidrug therapy are optimal.

reaction catalyzed by a catalase-peroxidase encoded by the *kat*G gene (182). The oxidized form of INH can then covalently bind to the nicotinamide moiety of NAD(H) to form INH-NAD(H) adducts, which in turn compete with NAD(H) for binding to an enoyl-acyl carrier protein reductase encoded by the *inh*A gene (76).

The primary effect of INH is on mycolic acid synthesis, as evidenced by the increased fragility of the mycobacterial cell, increased intracellular viscosity, decreased cellular hydrophobicity, and loss of acid fastness of INH-resistant isolates (169). The mycolic acids are produced by the fatty acid synthesis (FAS) I and II enzyme systems. It is the FAS II system that synthesizes the long-chain mycolic acids that are species specific. Activated INH targets one of the FASII enzymes, the enoyl-acyl carrier protein (ACP) reductase of InhA. However, InhA is not the only target, because activated INH also targets the fatty acid elongation enzyme ketoacyl-ACP synthase A or KasA. In addition, INH appears to interfere with NAD metabolism, energy metabolism, and macromolecular synthesis (36, 170, 171).

The mechanism of action of INH correlates with the known mechanisms of INH resistance. Banerjee et al. (6) reported that INH and ethionamide resistance in *M. tuberculosis* correlated with a missense mutation in the *inh*A gene. Other studies showed that *kat*G mutations account for 30 to 60% of INH resistance (65, 101) and that *inh*A mutations confer a low level of INH resistance that may not always be clinically significant (89). Mutations in two other genes may confer some INH resistance: the *ahp*C gene, which encodes an alkyl hydroperoxide reductase subunit (38, 80, 142, 168, 181), and the *kas*A gene, which encodes the previously mentioned KasA enzyme (90). The degree to which mutations in *ahp*C and *kas*A contribute to INH resistance is not clear, although the role of *ahp*C appears to be minor. In aggregate, however, mutations in these four genes (*kat*G, *inh*A, *ahp*C, and *kas*A) may account for ~90% of INH resistance (Table 2) (39, 149).

INH is active only against replicating tubercle bacilli in the presence of oxygen; slowly replicating bacilli in the caseous lesions are not readily killed by INH, and dormant bacilli under anaerobic conditions are unlikely to be affected. INH resistance develops rapidly when patients are given monotherapy, and the frequency of INH resistance within a population of tubercle bacilli ranges from 10^{-5} to 10^{-6} (33). Wild-type isolates of *M. tuberculosis* are inhibited by INH at concentrations of <0.2 μg/ml (93). Other slowly growing mycobacteria, such as *M. kansasii* and *M. xenopi,* are inhibited by 1 to 5 μg/ml. Most other nontuberculous mycobacteria, including the *M. avium* complex (MAC), *M. marinum,* and all rapidly growing mycobacteria, are resistant to INH.

TABLE 2 Mechanisms of drug resistance in *Mycobacterium tuberculosis*[a]

Antimicrobial agent	Gene involved	Target	Mechanism of action
RMP	*rpoB*	β Subunit of RNA polymerase	Inhibits transcription
INH	*kat*G	Catalase-peroxidase	Inhibits mycolic acid biosynthesis; other multiple effects on DNA, lipids, carbohydrates, and NAD metabolism
	inhA[b]	EnvM analog 3-ketoacyl-acyl carrier protein reductase analog	
	kasA[b]	B-Keroacyl ACP synthase	
	ahpC[b]	Subunit of alkyl hydroperoxide reductase	
EMB	*embB*	Arabinosyltransferase	Inhibits arbinogalactan synthesis
SM	*rpsL*	Ribosomal protein S12	Inhibits protein synthesis
		16S rRNA	Inhibits protein synthesis
PZA	*pncA*	Pyrazinamidase	Acidifies cytoplasm and de-energizes membrane
Ethionamide	*inhA*		Inhibits mycolic acid biosynthesis
Fluoroquinolones	*gyrA*	DNA gyrase A subunit	Inhibits DNA gyrase
Amikacin, kanamycin	*rrs*	16S rRNA	Inhibits protein synthesis

[a] Adapted from reference 157.
[b] Mechanism of action statement similar to that of *kat*G.

INH is well absorbed when administered orally or intramuscularly; it is distributed throughout the body, and the levels in cerebrospinal fluid (CSF) may equal the levels in plasma in patients with meningeal inflammation or 20% of the levels in plasma in patients without inflammation (160). INH is metabolized in the liver and intestines, primarily by acetylation by an *N*-acetyltransferase, which can vary significantly from person to person. However, the acetylator phenotype of an individual does not appear to influence either the efficacy of INH or the risk of hepatotoxicity. Adverse drug reactions include infrequent, age-related hepatitis and, less frequently, peripheral neuropathy, hypersensitivity reactions such as fever and rash, and arthralgias.

Rifampin

Rifampin (RMP) (rifampicin) was introduced in 1968 as a potent antituberculosis agent. It affects intracellular, slowly replicating bacilli in caseous lesions as well as the actively replicating bacilli in open cavities. RMP is active against a wide variety of non-acid-fast bacteria and several other slowly growing mycobacteria, notably *M. leprae, M. kansasii, M. xenopi,* and *M. marinum,* but has variable activity in vitro against MAC and is inactive against the rapidly growing mycobacteria. It easily diffuses through the mycobacterial cell membrane due to its lipophilic nature and binds to the bacterial RNA polymerase, thus inhibiting RNA synthesis (156). RMP inhibits the prokaryotic DNA-dependent RNA polymerase by binding to the β subunit at the presumed catalytic center of the enzyme. The mammalian RNA polymerase is inhibited by RMP only at significantly higher concentrations than is the prokaryotic enzyme. The RNA polymerase of MAC isolates appears to be susceptible to RMP; therefore, the primary mechanism of intrinsic resistance is most probably impermeability.

Telenti et al. (150) first showed that RMP resistance correlated with changes, primarily amino acid substitutions, within a conserved region of the *rpoB* gene that encodes the β subunit of the *M. tuberculosis* RNA polymerase. Subsequent studies showed that >96% of RMP resistance could be attributed to mutations within an 81-bp region of the *rpoB* gene (103). Rifamycin resistance that is due to mutations outside this "hot spot" are rare, but such mutations appear to cluster at codon 176 at the beginning of the *rpoB* gene (62). In two strains of *M. avium* with high MIC values, missense mutations were detected, but in two other strains, no mutations were detected. This agrees with the observations of Guerrero et al. (54), who showed that mutations in the *rpoB* gene in *M. avium* and *M. intracellulare* are rare and that high RMP MIC values most probably are a reflection of impermeability to the drug.

RMP is well absorbed from the gastrointestinal tract, and peak concentrations of 5 to 10 μg/ml are reached 1 to 2 h after an oral dose of 600 mg; concentrations in CSF reach 50% of the levels in plasma in patients with meningeal inflammation. RMP is available in combination with INH as a single capsule (Rifamate) containing 300 mg of RMP and 150 mg of INH and in combination with INH and pyrazinamide as a single capsule (Rifater). An RMP concentration of 0.5 μg/ml is bactericidal for wild-type isolates of *M. tuberculosis.* Adverse drug reactions include hepatotoxicity, gastrointestinal and hypersensitivity reactions, and a red-orange discoloration of urine, tears, other body fluids, and soft contact lenses. RMP also induces increased hepatic metabolism of several other drugs, including methadone and birth control pills. Of particular concern is the interaction of RMP and, to a somewhat lesser degree, rifabutin with protease inhibitors (saquinavir, ritonavir, and indinavir), which leads to enhanced hepatic metabolism and may result in subtherapeutic levels of the antiviral agents (9).

Rifabutin and Rifapentine

Rifabutin (ansamycin), a spiropiperidyl rifamycin, and rifapentine, a cyclopentyl rifamycin, have potent in vitro activity against *M. tuberculosis*. Rifabutin also is very active against MAC (64, 129). The mode of action and mechanism of resistance of both drugs appear to be identical to those of RMP; however, approximately 30% of RMP-resistant *M. tuberculosis* isolates are susceptible to rifabutin and rifapentine. The latter observation correlates with certain specific mutations in the *rpoB* gene (14). Yang et al. (178) analyzed clinical strains of *M. tuberculosis* for cross-resistance to rifamycins. Alterations at codons 513 and 531 correlate with resistance to RMP, rifabutin, and rifalazil (KRM-1648). Point mutations at codons 516 and 529, deletion at codon 518, and insertion at codon 514 influence susceptibility to RMP but not to rifabutin or KM-1648, while alteration at codons 515, 521, and 533 did not influence susceptibility to RMP, rifabutin, and KR-1648 (178). These findings were confirmed by analyzing recombinant *M. tuberculosis* clones containing plasmids with specific mutations (166). As with RMP, both rifabutin and rifapentine are metabolized to the corresponding biologically active 25-desacetyl metabolite. Rifabutin decreases the incidence of disseminated MAC disease in human immunodeficiency virus (HIV)-infected patients when used as a prophylactic agent, and it is approved for that indication (87, 107). The role of rifabutin as a therapeutic agent for MAC disease is unclear, but there may be a significant dose effect (73). In addition to being more active than RMP on a weight basis, rifabutin has a long elimination half-life in humans and concentrates in tissues, notably lung tissues, where the levels are 10-fold higher than in serum. This may account for the reported effectiveness of rifabutin in the therapy of MAC pulmonary infections.

Rifabutin is absorbed from the gastrointestinal tract and reaches peak levels of 0.5 μg/ml in serum about 4 h after a 300-mg dose. Adverse drug reactions with rifabutin are similar to those observed with RMP, including the above-mentioned important adverse interactions with antiretroviral agents (9). Some unique rifabutin toxicities include leukopenia, thrombocytopenia, arthralgias, and uveitis when coadministered with clarithromycin.

Rifapentine was approved by the U.S. Food and Drug Administration (FDA) for the treatment of tuberculosis in 1998 (5). In a study of 722 patients, 361 received rifapentine plus INH, PZA, and EMB while the remaining patients received RMP in place of rifapentine along with the other drugs (5). In the intensive phase of the study, rifapentine was administered twice a week while RMP was administered daily. In the continuation phase, rifapentine and INH were administered once a week and RMP and INH were administered twice a week. Sputum conversion was somewhat higher in the rifapentine group than in the RMP group: 87 and 81%, respectively. However, relapse was somewhat higher in the rifapentine group than in the RMP group: 10 and 5%, respectively. Rifapentine reaches a peak concentration of 15 μg/ml in serum 5 to 6 h after a 600-mg dose, with a half-life of about 13 h.

Pyrazinamide

Pyrazinamide (PZA) is a synthetic derivative (pyrazine analog) of nicotinamide and, in combination with INH, is rapidly bactericidal for replicating and nonreplicating forms of *M. tuberculosis,* with an average MIC of 20 μg/ml (157). PZA is totally inactive against other *Mycobacterium* species,

including *M. bovis,* MAC, and the rapidly growing mycobacteria. PZA is active only at an acidic pH; therefore, the pH of the growth medium must be adjusted for accurate measurements of the in vitro activity of the drug. It is most likely that PZA is active only in the acidic milieu of the phagolysosome and, depending on the concentration achieved at the site of the infection, may be bacteriostatic or bactericidal. PZA is hydrolyzed in the liver to the active metabolite pyrazinoic acid, and although the mechanism of action of PZA is unknown, its activity depends on this conversion. *M. tuberculosis* produces a pyrazinamidase, and most strains of PZA-resistant *M. tuberculosis* lack this enzyme; however, some PZA-resistant isolates retain enzyme activity, suggesting that there are other mechanisms of resistance such as drug efflux (183, 184).

The lack of pyrazinamidase activity and its correlation with PZA resistance have been associated with mutations in the *pncA* gene that encodes the enzyme (135, 136, 143). Indeed, it now appears that 72 to 97% of PZA resistance can be attributed to mutations in the *pncA* gene (Table 2). Data from one study suggest that this correlation can be used to distinguish between *M. tuberculosis* and *M. bovis* (134); however, PZA-susceptible *M. bovis* isolates, although uncommon, have been described.

PZA is well absorbed from the gastrointestinal tract and widely distributed throughout the body, with maximum levels in serum of approximately 45 μg/ml 1 to 4 h following an oral dose of 1 g (20 to 25 mg/kg of body weight). Hepatotoxicity occurs in a small number of patients; photosensitivity and rash are rare. Gout is an important contraindication because of the hyperuricemia associated with PZA therapy. PZA therapy is usually discontinued after the first 2 months of short-course treatment for tuberculosis, whereas INH and RMP treatment is continued for an additional 4 months.

Ethambutol

Ethambutol (EMB) [dextro-2,2-(ethylenediimino)-di-1-butanol-dihydrochloride] is a synthetic antituberculosis compound that was introduced in 1961. The MIC values of EMB tested against wild-type isolates of *M. tuberculosis* range from 1 to 5 μg/ml, but the activity of the drug against other slowly growing nontuberculous mycobacteria is more variable. The drug is active only against growing bacilli and has no activity against nongrowing mycobacteria. The primary mechanism of action of EMB is bacteriostatic inhibition of cell wall synthesis, while evidence points to a specific effect on arabinogalactan synthesis (147). The frequency of mutation to EMB resistance in *M. tuberculosis* is on the order of 10^{-5}, and there is evidence that EMB resistance in *M. tuberculosis* correlates with a specific mutation (at codon 306) in the *embB* gene, which encodes an arabinosyltransferase (144). Mutations in this codon have been associated with MIC values of 20 to 40 μg/ml for several EMB-resistant isolates of *M. tuberculosis* (1). While mutations in the *embB* gene result in high-level resistance in *M. tuberculosis,* this mutation accounts for only 70% of resistant strains; thus, other gene mutations are likely to play an additional role (157). Although many MAC isolates have high EMB MIC values, combinations of EMB and other agents, notably quinolones and macrolides, are synergistic (66, 78), and it has been shown that the MIC value does not correlate with clinical response (141). It appears that EMB affects the permeability of the MAC cell wall and perhaps increases the intracellular concentration of the other potentially more active drugs (67).

Peak concentrations of EMB in serum are 5 μg/ml 2 to 4 h after a 25-mg/kg dose. The most important adverse effect associated with EMB is decreased visual acuity due to optic neuritis that is related to both the dose and duration of treatment. EMB is not recommended for the treatment of children too young to be monitored for changes in vision unless no other drug is appropriate because of resistance. The effects on vision are generally reversible when the drug is discontinued.

Aminoglycosides

The aminoglycosides that are used for the treatment of tuberculosis and other mycobacterial infections include streptomycin (SM), kanamycin (a glycoside of 2-deoxystreptamine), and amikacin, which is a derivative of kanamycin. In addition, tobramycin is active against *M. chelonae,* and capreomycin and viomycin, basic peptide antibiotics with a mechanism of action similar to that of the aminoglycosides, are active against *M. tuberculosis* and certain other species of mycobacteria. Gentamicin is inactive against mycobacteria at the usual concentrations attained in serum.

The primary mechanism of action of the aminoglycosides is inhibition of the post- to pretranslocation step of protein synthesis by blocking the binding of the aminoacyl-tRNA (e-type binding). Viomycin also blocks aminoacyl-tRNA translocation, and viomycin resistance crosses to capreomycin, suggesting that the mechanism of action is the same. SM MIC values for wild-type isolates of *M. tuberculosis* are usually well below the peak concentration in serum of 25 to 50 μg/ml 1 to 2 h after a 1-g intramuscular dose. Amikacin is the most potent of the aminoglycosides. There is comparatively little clinical experience with amikacin in the treatment of tuberculosis because the drug is expensive and inconvenient to administer, but amikacin often is used in combination with one or more other agents for treatment of serious infections caused by rapidly growing mycobacteria. Amikacin also is active against MAC; the majority of isolates have an MIC of <32 μg/ml, which approaches the maximum concentration in serum. In an early uncontrolled trial of disseminated MAC in HIV-infected patients, amikacin was shown to be the active component of a multiple-drug regimen (26). In that trial, treatment was associated with a positive microbiological and clinical response, but the clinical utility of amikacin for disseminated MAC is uncertain (4). The drug may be useful in an "induction" regimen to clear a bacteremia.

The molecular basis of SM resistance (Table 2) in *M. tuberculosis* results from mutations in the gene that encodes ribosomal protein S12 or from mutations in the 16S rRNA region, which is structurally linked to the S12 protein in the assembled ribosome (47, 81, 104). Finken et al. (47) showed that mutations in the *rpsL* gene coding for the S12 protein were present in 20 of 38 SM-resistant strains and that there was a mutation in the *ssr* gene, encoding 16S rRNA, in 9 strains. Nair et al. (104) determined the nucleotide sequence of the *rpsL* gene and showed that SM resistance, in a small number of isolates, appeared to be a result of point mutations at codon 43 of this gene, a site of SM resistance in *Escherichia coli.* Adverse drug reactions associated with aminoglycosides and peptide antibiotics include hearing loss, tinnitis, loss of balance, and renal failure.

Cycloserine

D-Cycloserine (4-amino-3-isooxazolidinone) is an analog of D-alanine that inhibits the synthesis of D-alanyl-D-alanine, an essential component of the mycobacterial cell wall. Cycloserine is active against all mycobacteria as well as several other types of bacteria. Although it is one of the secondary

drugs for treatment of tuberculosis, in vitro susceptibility testing is not recommended due to technical problems with the test (28, 113). Peak levels in serum of 20 to 40 μg/ml are achieved 4 h following an oral dose of 250 mg. The drug is widely distributed through the body, including the CSF. There are significant adverse drug reactions associated with cycloserine treatment, notably peripheral neuropathy and central nervous system dysfunction including seizures and psychotic disturbances.

Ethionamide

Ethionamide (2-ethyl-pyridine-4-carbonic acid thioamide) is a derivative of isonicotinic acid and, like INH, blocks mycolic acid synthesis. However, isolates of *M. tuberculosis* that are resistant to high concentrations of INH are susceptible to ethionamide, suggesting that the site of action may be different from that of INH. However, mutations in the *inhA* gene have been associated with ethionamide resistance (6). The average MIC for *M. tuberculosis* is 0.6 to 2.5 μg/ml, and levels of 2 to 20 μg/ml in serum are achieved 3 to 4 h following an oral dose of 0.5 to 1 g. Side effects associated with ethionamide include gastrointestinal irritation with nausea, vomiting, and cramps and neurologic symptoms.

Dapsone

Dapsone (diaminodiphenyl sulfone) is a synthetic compound that was shown to be active against *M. leprae* in the early 1940s. Dapsone is an antifolate that, like other inhibitors of folic acid synthesis, exerts primarily a bacteriostatic effect and is only weakly bactericidal. Dapsone is administered orally and is well absorbed and distributed throughout the body. Levels in tissue are approximately 2 μg/ml following a 200-mg dose. The drug has a long half-life in serum, of 10 to 50 h depending on the individual patient. Common adverse drug reactions include nausea, vomiting, anorexia, and methemaglobinemia; hematuria, rash, pruritus, and fever also can occur. Traditionally, dapsone is used in combination with RMP and clofazimine for the treatment of leprosy. Acedapsone is a diacetylated form of dapsone with an extraordinarily long half-life of 46 days; as a result, this drug is administered infrequently (e.g., five injections per year), with peak concentrations in tissue occurring 20 to 35 days after administration. Acedapsone is relatively inactive against *M. leprae,* but in vivo it is deacetylated to the parent compound.

Macrolides and Ketolides

Azithromycin and clarithromycin are the most important agents in the treatment of all forms of MAC disease and are effective and approved prophylactic agents for preventing disseminated MAC disease in HIV-infected persons (58, 117, 180). These drugs also are useful in the treatment of disease caused by *M. marinum, M. haemophilum, M. kansasii, M. simiae,* and rapidly growing mycobacteria other than *M. fortuitum.* Indeed, they are viewed as potential cornerstones in the treatment of nontuberculous mycobacterial infections (4). Azithromycin, an azalide (a subclass of macrolides), and clarithromycin are structurally similar to erythromycin and have modifications that improve their acid stability and increase their potency, half-life, achievable concentrations in tissue, and bioavailability without causing toxicity. These macrolides are bacteriostatic agents and inhibit the growth of microorganisms by binding to the 50S subunit of the prokaryotic ribosome, blocking protein synthesis at the peptidyltransferase step. Meier et al. (92) showed that both clarithromycin- and azithromycin-resistant mutants of *M. intracellulare* have a single-base mutation at adenine-2058 in the 23S rRNA gene, a site of mutation or methylation that has been associated with macrolide resistance in other bacteria (106). The same genetic basis for macrolide resistance was found in *M. chelonae* and *M. abscessus* (158).

The in vitro activity of azithromycin against MAC appears to be quite modest, with MIC values 32- to 64-fold above the maximum concentration in serum (74). The remarkable ability of azithromycin to concentrate in tissues most likely accounts for its therapeutic activity in animal studies and humans (76, 83). Azithromycin is rapidly absorbed from the gastrointestinal tract and widely distributed throughout the body. It has a terminal half-life of 68 h. The peak concentration in serum following a 500-mg dose is 0.4 to 0.6 μg/ml; however, the drug concentrates in tissues to high levels. In a small study with humans, the levels of azithromycin in polymorphonuclear neutrophils were nearly 1,000-fold higher than the levels in serum (3, 133).

Clarithromycin inhibits 90% of MAC isolates with MIC values of 0.25 to 0.5 μg/ml when measured by a radiometric broth macrodilution method at a neutral to slightly alkaline pH (the activities of all macrolides are strongly influenced by pH). Peak levels in serum of 2 to 3 μg/ml are achieved 5 to 6 h following a 500-mg dose; the concentrations in tissue are 4 to 5 times greater than the concentrations in serum, and the concentration in macrophages is 20 to 30 times greater. The elimination half-life is 5 to 7 h following a 500-mg dose twice a day.

The ketolides are semisynthetic derivatives of erythromycin with structural changes that improved antimicrobial activity and pharmacokinetics. Telithromycin, a ketolide licensed in the United States and Europe, is active against mycobacteria in vitro but has not been evaluated in a clinical trial in humans (46, 121).

Quinolones

Ciprofloxacin, ofloxacin, levofloxacin, gatifloxacin, and moxifloxacin are fluorinated carboxyquinolones with good in vitro activity against multidrug-resistant and pansusceptible *M. tuberculosis* (15, 70, 75). MIC values of ciprofloxacin and ofloxacin against susceptible isolates of *M. tuberculosis* range from 0.25 to 3 μg/ml and from 0.5 to 2.5 μg/ml, respectively. Measurements of the early bactericidal activity of ciprofloxacin in patients with pulmonary tuberculosis suggested that the drug is effective at a high dosage (1,000 mg/day) (140). Fluoroquinolones have variable activity against MAC (179). Most *M. fortuitum* group isolates are susceptible to ciprofloxacin (currently the class representative for fluoroquinolones), whereas activity against *M. abscessus* and *M. chelonae* is more variable.

The CLSI recommends that ofloxacin be included as the class representative for fluoroquinolones in the panel of secondary antituberculosis drugs (28). The suggested susceptibility breakpoint is 2 μg/ml for the agar proportion method (28). However, levofloxacin (the L-isomer of ofloxacin) is nearly twice as active against *M. tuberculosis* as ofloxacin in vitro. For this reason, protocols for susceptibility testing of levofloxacin are desirable. Data from a recent study support susceptibility breakpoints of 2 μg/ml for BACTEC TB460 and BACTEC MGIT 960 and 1 μg/ml for agar proportion (132).

The mechanism of action of all fluorinated quinolones is inhibition of DNA synthesis as a result of binding to the DNA gyrase (bacterial topoisomerase II) (123). Although this is the presumed mechanism of action in mycobacteria, fewer studies have been performed with mycobacteria than with other microorganisms. Takiff et al. (148) showed that quinolone resistance in *M. tuberculosis* can be ascribed to mutations in

the *gyrA* and *gyrB* genes, which encode the DNA gyrase subunits (Table 2). In *M. tuberculosis,* fluoroquinolones function by binding to the bacterial enzyme-DNA complex, with suggested mechanisms being strand-breakage, SOS-mediated autolysis, and replication blockage. When combined with various first-line antimycobacterial drugs, fluoroquinolones have shown greater reductions in CFUs within infected macrophages than the individual drugs alone. While there are no reports of cross-resistance between quinolones and other classes of antimycobacterial agents, there is cross-resistance within the quinolone class, such that reduced susceptibility to one quinolone may likely confer reduced efficacy to all quinolones (51).

Recently, moxifloxacin has received attention as being useful in the treatment of tuberculosis, especially multidrug cases. Although slightly delayed in the first few days of response, the antimycobacterial effect of moxifloxacin appears to be similar to that of INH after 5 days of treatment (119). The newer quinolones (sparfloxacin, gatifloxacin, and moxifloxacin) have lower MICs than levofloxicin, ciprofloxacin, and ofloxacin. Treatment studies with mice have shown moxifloxacin has the most bactericidal efficacy against *M. tuberculosis,* followed by sparfloxacin, levofloxicin, and ofloxacin (in that order). Against *M. tuberculosis,* moxifloxacin has a reported MIC of 0.12 to 0.5 μg/ml (51).

Ciprofloxacin is well absorbed from the gastrointestinal tract and is rapidly distributed throughout the body. Maximum concentrations in serum of 2.4 or 4.3 μg/ml are achieved 1 to 2 h after an oral dose of 500 or 750 mg, respectively. The elimination half-life of ciprofloxacin is 4 h in subjects with normal renal function. Maximum ofloxacin concentrations in serum are achieved 1 to 2 h after an oral dose. Following a single 400-mg dose, the concentration of ofloxacin in serum is 2.9 μg/ml; after a steady-state dose, it is 4.6 μg/ml. The maximum concentration of levofloxacin in serum is approximately twice that of ofloxacin at the same dosage. The efficacy of fluoroquinolones in the treatment of pulmonary tuberculosis may relate, in part, to the observation that these quinolones concentrate in lung tissue to levels at least four times greater than the concentration in serum. Adverse effects with ciprofloxacin and other fluoroquinolones may be less severe than with the other secondary agents (12).

p-Aminosalicylic Acid

p-Aminosalicylic acid (PAS) is an antifolate that is active against *M. tuberculosis* but inactive against most other mycobacteria. There is some evidence that PAS also may affect iron transport in *M. tuberculosis* and salicylic acid metabolism. The average MIC for susceptible isolates of *M. tuberculosis* is 1 μg/ml, and peak levels of 7 to 8 μg/ml are achieved in serum 1 to 2 h after a 4-g dose. PAS is incompletely absorbed in the gastrointestinal tract and is associated with significant gastrointestinal side effects; in combination with the need for large dosages (10 to 12 g/day), this leads to frequent problems with treatment adherence.

Clofazimine

Clofazimine [3-(*p*-chloroanilino)-10-(*p*-chlorophenyl)-2, 10-dihydro-2-isopropyliminophenazine] is a substituted iminophenazine, bright red dye. It has weak bactericidal activity against *M. leprae* but is used in combination with RMP and dapsone as a conventional treatment regimen for leprosy. However, it may take up to 50 days of treatment before there is evidence of tissue antimicrobial activity, which may influence the length of time before there is a clinical response in the treatment of leprosy. Clofazimine has good in vitro activity against MAC, but despite this, it appears to offer little in the treatment of disseminated MAC (137). Indeed, treatment regimens that contained clofazimine have been associated with higher mortality than those that did not (24). The drug also has good in vitro activity against *M. tuberculosis,* but there is little or no information on the in vivo activity.

The mechanism of action of clofazimine is unknown; however, it is highly lipophilic and binds preferentially to mycobacterial DNA. The absorption of clofazimine following an oral dose is variable and ranges from 45 to 60%. The average concentrations in serum are 0.7 to 1.0 μg/ml following a dose of 100 to 300 mg. The half-life is extraordinarily long (estimated to be 70 days), and the drug tends to be deposited in fatty tissues and cells of the reticuloendothelial system. Adverse drug reactions are limited primarily to a pink or red discoloration of the skin, conjunctiva, cornea, and body fluids and gastrointestinal intolerance including pain, diarrhea, nausea, and vomiting.

Amithiozone

Amithiozone (Thiacetazone, Tibione, or Panthrone) is a thiosemicarbazole that is active against *M. tuberculosis,* with an average MIC for wild-type strains of 1 μg/ml. Resistance develops quickly when monotherapy is given. Peak levels in serum of 1 to 4 μg/ml are achieved 1 to 2 h following an oral dose of 150 mg. Adverse drug reactions are gastrointestinal irritation and bone marrow suppression, and hepatotoxicity can occur in patients receiving concomitant INH. Additionally, there appears to be an association of Stevens-Johnson syndrome and severe epidermal necrolysis in HIV-infected patients with tuberculosis treated by regimens containing amithiozone (42, 53). Consequently, the World Health Organization recommends that amithiozone not be used to treat patients known or suspected to be infected with HIV (109). Amithiozone is not available in the United States and is not used in Europe because of the adverse effects, but it has been used successfully in combination with INH for the treatment of tuberculosis in some African countries, where adverse effects are believed to be less severe.

M. TUBERCULOSIS COMPLEX

Drug Resistance

In the early 1960s, the World Health Organization organized two meetings that led to the description of reliable criteria and techniques for testing mycobacteria for resistance to antituberculosis drugs (20, 21). The critical proportion for resistance on Löwenstein-Jensen slants varied according to the drug, e.g., 1% for INH and RMP and 10% for SM, EMB, PZA, ethionamide, kanamycin, and cycloserine. However, based on the experience of Russel and Middlebrook with 7H10 agar (128), the Centers for Disease Control and Prevention (CDC) recommended Middlebrook 7H10 agar and 1% as the critical proportion for all drugs (85).

Resistance is fundamentally a phenomenon linked to large initial bacterial populations. In pulmonary tuberculosis, the greatest populations are those prevailing in cavities, which can contain 10^7 to 10^9 organisms, whereas the populations found in hard caseous foci, the most common type of lesion, generally do not exceed 10^2 to 10^4 organisms (19). The greater frequency of resistance during treatment of cavitary tuberculosis was shown as early as 1949 (68, 69). David at CDC (33) demonstrated the probability distribution of drug-resistant mutants and in a fluctuation test showed that *M. tuberculosis* spontaneously mutated to resistance to INH, SM,

EMB, and RMP. The average mutation rates for INH, SM, EMB, and RMP were calculated to be 3×10^{-8}, 3×10^{-8}, 1×10^{-7}, and 2×10^{-10} mutation per bacterium per generation, respectively. Thus, the mutation rate for resistance to two drugs is theoretically less than 10^{-15}. Implicit in all the studies of the genetic basis of antimicrobial resistance in *M. tuberculosis* is that the multiple-drug-resistance (MDR) phenotype (minimally defined as simultaneous resistance to INH and RMP) is the result of accumulative mutations rather than the acquisition of an MDR transfer factor (103).

Special-Population Hypothesis

According to the generally accepted theory, resistance appearing during drug treatment is due to selection and multiplication of the resistant mutants preexisting in the tubercle bacillus population of the host. Inasmuch as the susceptible bacilli are the predominant part of the population, initial killing involves a greater number of microorganisms. The consequence is a sharp fall in the population of bacilli during the initial period of treatment. The rise due to multiplication of the resistant mutants occurs later. This "fall-and-rise" phenomenon, as demonstrated in the patient's sputum, was described in the late 1940s (32, 120). In 1979, Mitchison (97) suggested the "special-populations" hypothesis to explain the action of the major antituberculous drugs against the various subpopulations of tubercle bacilli (Fig. 1). The subpopulations include (i) rapidly growing bacilli in the pulmonary lesions; (ii) bacilli that grow in short metabolic spurts and that might be susceptible to RMP but not INH; (iii) bacilli that reside in the acidic environment of the caseous lesions; and (iv) dormant, nonreplicating bacilli. The hypothesis was developed to explain in part the basis of the early bactericidal activity and the later sterilizing activity of antituberculosis agents. Each drug in the conventional multiple-drug treatment regimen for tuberculosis is more or less effective in eradicating tubercle bacilli within each of these special populations. Thus, the use of multiple drugs in the treatment of tuberculosis is aimed at both preventing drug resistance and achieving a maximum therapeutic effect. Figure 1 depicts the special-populations hypothesis, as presented by Mitchison in 1992 (98) in his Garrod lecture, altered to include a reference to the observation by Wayne and Sramek (165) that dormant *M. tuberculosis* is susceptible to nitroimidazoles. This study was based on the assumption that dormant tubercle bacilli are in an anaerobic metabolic state and therefore would be susceptible to agents such as metronidazole.

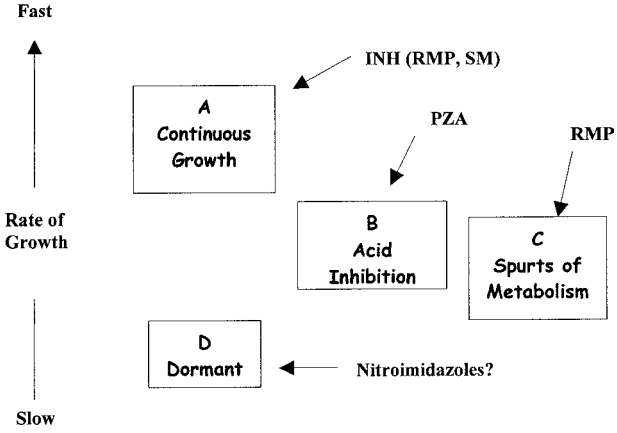

FIGURE 1 Schematic representation of the special-populations hypothesis of Mitchison (98). The model accounts for the action of antimycobacterial agents on different populations of *M. tuberculosis* bacilli in various sites in the infected host. (A) INH, RMP, and SM are active primarily against bacilli in a continuous state of growth, which are the majority population at the start of treatment. (B) PZA is active only against bacilli within the acidic early caseous lesions that develop within the first 2 months of chemotherapy (98). (C) The comparatively rapid bactericidal activity of RMP is important for the eradication of bacilli that grow for short periods (not long enough to be affected by INH). (D) Some tubercle bacilli may be sequestered in lesions in a metabolically inactive and dormant state; however, there is evidence that these dormant bacilli may actually be in an anaerobic state and susceptible to nitroimidazoles such as metronidazole (165). (Reprinted from reference 98 with permission of Oxford University Press.)

Critical Concentrations

The criteria for defining drug-resistant *M. tuberculosis* were established on an empirical basis, i.e., that there is a certain proportion of drug-resistant mutants above which therapeutic success is less likely to be realized. The procedures used to perform drug susceptibility tests and the criteria for interpreting the results take into account two factors: (i) the critical proportion of drug-resistant mutants and (ii) the critical concentration of the drug in the test medium. On the basis of clinical and bacteriologic studies, the significant proportion of bacilli resistant to an antituberculosis drug, above which a clinical response is unlikely, was generally set at 1%. The critical concentration of a drug is the concentration that inhibits the growth of most cells within the population of a wild-type strain of tubercle bacilli without appreciably affecting the growth of the resistant mutant cells that might be present. In other words, if the proportion of tubercle bacilli that are resistant to the critical concentration of a drug exceeds 1%, it is unlikely that the use of that drug will lead to a therapeutic success. It should be noted that this concentration may not have a direct relationship to the peak level of the drug in serum. The critical concentrations of antituberculosis drugs, in different media, are given in Table 3 (28, 82).

Low versus High Critical Concentrations

On occasion, both the agar proportion and BACTEC 460TB methods may indicate that an *M. tuberculosis* isolate is resistant to INH, EMB, or SM at the low critical concentration of the drug (Table 3) but susceptible to the same drug at the high concentration. Indeed, it is unclear if testing the low concentration of EMB has any merit, especially because recent evidence indicates that mutations in the *embB* gene are associated only with resistance at the high concentration (1, 144). Similar studies have not been performed with SM; however, the merit of testing SM at the low concentration must be questioned. If the low concentration of the drug only were tested, the report of "resistant" could potentially mislead a clinician to believe that the drug has no value in the treatment of tuberculosis. On the other hand, low-level resistance to INH may be suggestive of resistance to ethionamide (157). Therefore, it is important to test both concentrations of INH or, if only the low concentration is tested, to reflex test the higher concentration when an isolate is resistant to the lower concentration, recognizing that there is not uniform consensus regarding the clinical relevance of the results of testing at a higher concentration when two concentrations are used (28). The clinician should be alerted that when an isolate is resistant to the low concentration but susceptible to the high concentration, therapeutic effect may be achieved with an

TABLE 3 Critical concentrations of antimycobacterial agents to test against *M. tuberculosis* by radiometric (BACTEC 460TB) or agar proportion methods

Antimicrobial agent	Typical MIC (μg/ml) for susceptible strains	Concn in serum (μg/ml)[e]	Medium and concn (μg/ml)[f]					
			BACTEC 460TB 12B low	BACTEC 460TB 12B high	7H10 low	7H10 high	7H11 low	7H11 high
Primary agents

Ofloxacin[d]	0.5–2.5	3–11	2[h]		2		2	

[a] PZA tested at pH 6 in BACTEC 12B medium.
[b] Kanamycin is the class representative for amikacin.
[c] RMP-susceptible versus RMP-resistant isolates; about 30% of RMP-resistant isolates are rifabutin susceptible.
[d] Ofloxacin is the class representative for fluoroquinolones.
[e] Concentrations in serum 1 to 4 h after administration of the usual dosage.
[f] Unless otherwise stated, the concentrations shown are from references 28, 63, and 106.
[g] Woodley (172) showed that 2.5 μg of EMB per ml and 2.0 μg of SM per ml tested against susceptible and resistant isolates agreed with the 7H10 proportion method 97 to 99 and 100%, respectively.
[h] According to reference 113.
[i] NR, no recommendation.

adjustment in dosage (e.g., INH). The CLSI recommends that the following comment be appended to the results:

> These results indicate low-level resistance to INH. Experts believe that patients infected with strains exhibiting this level of INH resistance may benefit from continuing therapy with INH. A specialist in the treatment of tuberculosis should be consulted concerning the appropriate therapeutic regimen and dosages (28).

Extent of Service

In the United States, mycobacteriology laboratories can be classified by the levels or extents of services provided based on criteria proposed by CDC and the American Thoracic Society (ATS). In general, the criteria emphasize the importance of the number of specimens processed, the expertise of the laboratory staff, and the cost-effectiveness of the procedures and protocols (61, 85). The ATS recognizes three levels of service (levels I, II, and III), ranging from specimen referral, to identification and drug susceptibility testing of *M. tuberculosis,* to identification of other mycobacteria. It is recommended that a laboratory should perform susceptibility testing only if the laboratory is capable of identifying the isolate to species and if it regularly performs susceptibility tests on that type of isolate (e.g., at least 10 tests per week). Because certain drugs are tested infrequently (e.g., cycloserine or amikacin), must be prepared from reference powders (e.g., rifabutin or ciprofloxacin), or are problematic (e.g., cycloserine [113]), second-line drug testing should be referred to a laboratory with specific expertise in testing these agents.

When To Perform Susceptibility Tests

The approved CLSI standard on susceptibility testing of mycobacteria (28) states that the first isolate of *M. tuberculosis* obtained from each patient should be tested. This ensures the most effective treatment for a patient and contributes to the surveillance database for tuberculosis control. Susceptibility testing should be repeated if cultures fail to convert to negative after 3 months of therapy or if there is clinical evidence of failure to respond to therapy. If a laboratory is unable to provide this service, then isolates should be referred to another laboratory for timely testing.

Methods To Test the Susceptibility of *M. tuberculosis*

Methods that are commonly used to test rapidly growing aerobic and facultative anaerobic bacteria are, for a variety of reasons, unsuitable for testing most mycobacterial species. The methods generally accepted for determining the antimicrobial susceptibility of mycobacteria are based on the growth of the microorganisms on solid or in liquid medium containing a specified concentration of a single drug. In the past, four growth-based methods have been described: the proportion method, the radiometric or BACTEC 460TB (Becton Dickinson Microbiology Systems, Sparks, Md.) method (a modified proportion method), the absolute-concentration method, and the resistance ratio method (56, 63, 75, 138). Only the agar proportion, BACTEC 460TB, and the commercial nonradiometric broth systems are discussed further in this chapter; the last two are described elsewhere (63). These nonradiometric methods, either manual or fully automated, have been created mainly to overcome the safety and regulatory principles associated with radiolabeled substrates. They include VersaTREK (formerly called the ESP Culture System II; Trek Diagnostic Systems, Inc., Cleveland, Ohio) (176), the Mycobacteria Growth Indicator Tube (MGIT; Becton Dickinson) (57, 115), automated MGIT 960 (Becton Dickinson), and the MB/BacT ALERT 3D (BioMérieux, Durham, N.C.) (118). Descriptions of luciferase

reporter mycobacteriophages (125) and molecular beacons (86) await further review of broader testing at this time.

Based on the current CLSI guidelines (28), a rapid susceptibility testing method should be used in conjunction with rapid methods of primary culture and identification to allow the earliest possible detection of resistance. The recommended rapid broth methods for susceptibility testing of *M. tuberculosis* are commercial systems that have been cleared by the FDA. At present, three such FDA-approved systems are available, i.e., the BACTEC 460TB, the ESP Culture System II, and, more recently, BACTEC MGIT 960. Most importantly, any such rapid method utilized should have been previously demonstrated to generate results that correlate with those obtained with the standardized agar proportion method. Optimally, susceptibility results for *M. tuberculosis* should be reported within 28 days of receipt of the specimen in the laboratory (13, 152). There are no commercially available broth systems cleared by the FDA for testing nontuberculous mycobacteria.

Source of Inoculum for Susceptibility Testing

The source of the inoculum for a susceptibility test may be either a smear-positive specimen (direct method) or growth from a primary culture or subculture (indirect method). The direct method is used when antimicrobial resistance is known or suspected. However, the indirect method is considered the standard method for inoculum preparation, and results of the direct method are usually confirmed by subsequent testing by the indirect method. With both the direct and the indirect methods, the inoculum must be a pure culture and careful attention must be given to avoid over- or underinoculation.

For the direct method, the inoculum is either a digested, decontaminated clinical specimen or an untreated, normally sterile body fluid, in which acid-fast bacilli are seen in stained smears. To ensure adequate but not excessive growth in the direct susceptibility test on solid medium, specimens are diluted according to the number of organisms observed in the stained smear of the clinical specimen. A typical dilution scheme is shown in Table 4. Theoretically, this type of inoculum is more representative of the population of the tubercle bacilli in a particular lesion in the host. It is prudent to include an undiluted inoculum if the smear-positive specimen is from a patient who is receiving antimicrobial therapy, because a significant proportion of the bacilli seen on the smear may be nonviable. The direct susceptibility test has two major advantages. First, results can be reported within 3 weeks from the time of specimen receipt in the laboratory for a majority of smear-positive specimens. Second, the proportion of resistant bacteria better represents the patient's bacterial population. Use of the direct method may be warranted in situations where there is a high prevalence of drug resistance (49). However, cost can become a critical factor when there is a high incidence of smear-positive specimens containing nontuberculous mycobacteria. Also, it is not possible to accurately calibrate the inoculum, which may result in insufficient or excessive growth on drug-free quadrants. In addition, if contaminants grow, results are not interpretable. The rate of failure for direct susceptibility testing can reach 15% or more, necessitating retesting by the indirect method. The direct method is not recommended for routine use with the BACTEC 460TB or any of the newer, nonradiometric, liquid-medium-based procedures at this time.

TABLE 4 Guidelines for selection of the dilution of a specimen concentrate prior to inoculation of 7H10 medium for susceptibility testing using the direct method

Dilutions to test[a]	No. of acid-fast bacilli observed with:	
	Carbol fuchsin stain	Fluorochrome stain
Undiluted, 10^{-2}	0	<25
10^{-1}, 10^{-2}	1–10	25–250
10^{-2}, 10^{-3}	>10	>250

[a] Dilutions of concentrated specimen are prepared based on the number of bacilli observed in the initial acid-fast smear. Sterile distilled water is used to prepare the dilutions; the carbol fuchsin stain is examined with the oil immersion objective (1,000×), and the fluorochrome stain is examined with the high-dry objective (450×). If the patient is receiving therapy, not all bacilli observed in the smear may be viable; therefore, the undiluted specimen should be tested as well as the appropriate dilution based on the microscopic criteria given in this table.

For the indirect method, the source of the inoculum is a pure subculture, usually from the primary isolation media. Careful attention should be paid to the selection of colony types so that the final inoculum is representative of all types present to ensure that there is a balance of potentially resistant and susceptible bacilli. The source of inoculum for the liquid medium-based susceptibility testing can be growth on a solid medium or in broth. When using turbid growth in a liquid medium (such as Middlebrook 7H9 broth, BACTEC 12B, MGIT, MB/BacT, or VersaTREK), it is important to do a purity check because a mixed culture (tubercle bacilli and nontuberculous organisms) can give rise to apparent resistance.

Media Used for Susceptibility Testing

Although a variety of media have been used for drug susceptibility testing of slowly growing mycobacteria, including Middlebrook 7H10 or 7H11 agar and Löwenstein-Jensen media, there is considerable variability in the results. Egg-based media are unsuitable for susceptibility testing, not only because of uncertainty about the potency of the drugs after inspissation but also because phospholipids, proteins, and certain amino acids present in the medium affect some drugs. In an effort to provide uniformity in the testing of mycobacteria, CDC (85) and CLSI (28) recommend that Middlebrook 7H10 agar supplemented with oleic acid-albumin-dextrose-catalase (OADC) be used as the standard medium for susceptibility testing of slowly growing mycobacteria by the agar proportion method. A majority of *M. tuberculosis* clinical isolates grow on this medium, and under a dissecting microscope, the transparency of 7H10 agar facilitates the recognition of mixed mycobacterial species or the presence of contaminants. Occasionally, there is insufficient growth of drug-resistant strains of *M. tuberculosis* on 7H10 medium for the test to be valid. With these isolates, 7H11 medium may be substituted for 7H10 agar, but it is necessary to use higher concentrations of some drugs, as shown in Table 3 (59, 75). At present there is no standard formulation for Middlebrook 7H10 agar or OADC (such as there is for Mueller-Hinton medium), and it has been demonstrated that quality control of the medium, especially the OADC supplement, is critical (55).

The medium used for studies with mycobacteria in the BACTEC 460TB instrument is an enriched Middlebrook 7H9 broth containing 4 μCi of [^{14}C] palmitic acid per vial, which is referred to as 7H12 or BACTEC 12B medium.

Drugs Used for Susceptibility Testing

Antimicrobial agents for susceptibility testing (reference powders) can be obtained directly from the manufacturer or from commercial sources. In the United States, most antimicrobial agents are also available from U.S. Pharmacopoeial

Convention, Inc., Reference Standards Order Department, 12601 Twinbrook Parkway, Rockville, MD 20852. The reference powder should be accompanied by information about its assay potency (in micrograms per milligram), expiration date, and lot number, as well as the stability and solubility of the agent. Preparations formulated for therapeutic use in humans or animals should not be used. Unopened vials of powders should be stored as specified by the manufacturer, and opened containers should be stored in a desiccator at the recommended temperature. Stock solutions of most agents at 1,000 μg/ml or greater remain stable for at least 6 months at –20°C and for 1 year at –70 to –80°C. Directions provided by the drug manufacturer should be followed in addition to these general recommendations. Paper disks impregnated with standardized amounts of the primary and secondary drugs are available from commercial sources for use in the disk elution modification of the proportion method. Use of these disks obviates errors in weighing and dilution, as well as errors in labeling, because the disks are coded with the drug name and concentration. This technique provides results equivalent to those obtained with solutions prepared from reference powders. Quality control (QC) testing should be performed with each new batch of antimicrobial agent.

Agar Proportion Method

The agar proportion method for susceptibility testing of slowly growing mycobacteria was developed in the early 1960s by G. Canetti (19, 21). The method was modified and standardized in the United States and has been considered the standard method of drug testing for *M. tuberculosis* complex to all drugs except PZA in the United States and many European countries for many years. The preferred medium for the proportion test is Middlebrook 7H10 agar. Drugs can either be prepared from reference powders (agar diffusion) or be added as drug-impregnated disks (disk elution) (56). With regard to testing PZA, the BACTEC 460TB is considered the reference method (28).

Inoculum and Incubation

The inoculum can be prepared by the direct or indirect method. When the direct method is used, cultures should be examined weekly for 3 weeks, and even though mature colonies may appear on control media in less than 3 weeks, a report of "susceptible" should not be submitted until week 3. Resistant strains of *M. tuberculosis* complex may be slow to produce visible growth because of metabolic differences compared with susceptible wild-type isolates. If cultures are incubated beyond 3 weeks, degradation of the antimicrobial compound may permit the appearance of colonies of organisms that were susceptible to the initial concentration of the drug. Because the controls are inoculated with a processed specimen, isolated colonies should also be examined for colony morphology and pigmentation differences, as well as for the presence of mixed species of mycobacteria or contaminants. Small colonies of rapid growers, as well as the rough, dry colonies of some MAC strains, are similar in appearance to *M. tuberculosis* colonies on 7H10 agar. Also, rapidly growing mycobacteria may be slow to develop on primary isolation media and rapidly growing mycobacteria will appear as MDR when tested against primary antituberculosis agents. For a test to be valid, the control must show good growth (at least 50 to 150 colonies). Susceptibility testing results must never be reported without a preliminary identification.

When using the indirect method, a sufficient number of colonies must be selected to make a suspension that is equivalent to a 1.0 McFarland standard or, if there is insufficient growth, a sufficient number should be subcultured into Dubos Tween-albumin broth and incubated at 35 to 37°C until the turbidity matches a 1.0 McFarland standard. The suspension should not contain clumps of organisms. The actual number of CFU per milliliter is likely to vary from suspension to suspension, so that two dilutions (usually 10^{-2} and 10^{-4}) of the suspension must be used to inoculate two sets of media. If the source of the inoculum is old or if there is scant growth, 10^{-1} and 10^{-3} dilutions should be used or the isolate should be subcultured in broth. QC strains should be tested at dilutions of 10^{-2} and 10^{-4}. Quadrant plates are commonly used for the agar proportion method, and 0.1 ml (about 3 drops from a Pasteur pipette) of each dilution of the inoculum is placed into each quadrant, using 1 dilution per set of plates. The plates are allowed to dry thoroughly after inoculation, placed in individual CO_2-permeable polyethylene bags (clear sandwich bags), and incubated at 35 to 37°C in 5 to 10% CO_2 in air. The plates must be protected from light during storage and incubation to prevent the formation of formaldehyde from the medium ingredients. To check strains for purity, blood agar and 7H10 agar plates are inoculated with 1 or 2 drops of the suspension and streaked for isolation.

Reading, Interpreting, and Reporting Results

Purity control plates are examined for contamination after 1 to 2 days; the 7H10 plate should be examined throughout the incubation period, and the blood agar plate should be examined for 1 week. Once the "no-drug" control quadrant of the test isolate or control strain shows at least 50 to 150 colonies, the plates can be read and interpreted. If there are fewer than 50 colonies in the no-drug quadrant by 3 weeks, the test is repeated. Use of the designations 1+ to 4+ to report the amount of growth is discouraged. This grading scheme may be helpful, however, for in-house evaluation of appropriate inoculum size. The reference agar proportion method employs a percentage calculation to detect resistance or susceptibility. The number of colonies observed in each quadrant is reported as a percentage of the number of colonies in the no-drug control quadrant. If the percentage of colonies exceeds 1%, the isolate should be reported as resistant to that drug at the concentration tested. The percentage of resistant colonies can be used as an indicator of therapeutic efficacy and should immediately be reported to the physician, along with the drug concentration and test method.

Microcolonies may be observed when using the agar proportion method, especially when testing against EMB. Several possibilities may account for the presence of microcolonies: growth of susceptible organisms in the presence of degraded drug, true resistance, or partial resistance. One study reported that most strains that had microcolonies in the EMB quadrant had EMB-susceptible results when tested with the BACTEC 460 method (J. Ridderhof, I. George, and W. Gross, *Abstr. Intersci. Conf. Antimicrob. Agents Chemother., 1999*, abstr. 865, 1999). The significance of microcolonies is unknown, and each laboratory should determine how to best report these findings, based on its own in-house experience.

Quality Control

M. tuberculosis H37Rv (ATCC 27294), which is susceptible to all primary and secondary antituberculosis drugs, is recommended for QC. Strains of *M. tuberculosis* that are resistant to INH, RMP, and/or other drugs are available from the American Type Culture Collection; however, these strains are resistant to high concentrations of the respective drugs and are not ideal for QC testing. Ideally, a strain of *M. tuberculosis* that shows resistance at or near the cutoff values of a particular drug

should be used for QC. A number of strains used in the Centers for Disease Control and Prevention's Model Performance Evaluation Program offer these characteristics. Also, for safety considerations, it is not advisable to use a single *M. tuberculosis* strain that is resistant to more than two drugs (28). Aliquots of suspensions of QC strains of *M. tuberculosis,* adjusted to match a 1.0 McFarland standard in 7H9 broth, can be stored at −70°C for up to 6 months. QC testing should be performed with each new batch of medium or antimicrobial agent, and media should be checked for sterility and shown to support adequate growth. Guthertz et al. (55) demonstrated the importance of controlling for all components of 7H10 agar including lots of Middlebrook 7H10 agar, glycerol, and especially OADC. The issue of which QC results should be available before releasing patient test results is discussed below.

BACTEC 460TB Method

Although nonradiometric systems are cleared by the FDA for susceptibility testing of *M. tuberculosis* to primary drugs, the BACTEC 460TB method continues to be important in drug testing. Mycobacteria easily grow in the BACTEC 12B medium containing [^{14}C]palmitic acid. This compound is metabolized, resulting in the production of $^{14}CO_2$; therefore, growth or inhibition of growth in BACTEC 12B medium is measured as changes in the growth-dependent production of CO_2. The instrument quantitatively detects the amount of $^{14}CO_2$ released, expressed in terms of a growth index (GI), and then automatically replaces the headspace with 5 to 10% unlabeled CO_2 in air, thereby maintaining the recommended CO_2 atmosphere. The rate and amount of $^{14}CO_2$ produced are directly proportional to the rate and amount of growth.

The BACTEC 460TB system can be used to test all primary drugs (RMP, INH, PZA, and EMB), as well as the secondary drugs including the newer quinolones and rifamycins (113). The rapid availability of results with the BACTEC 460TB procedure may take precedence over cost considerations. Irrespective of its rapidity, it is prudent to consider the limitations of the BACTEC 460TB method. In some clinical situations, the method might be best considered a screening test, because it does not allow an estimate of the percentage of resistant bacilli and is vulnerable to major errors (false susceptibility or resistance) due to the use of mixed populations of mycobacterial species. Indeed, when an MDR isolate of *M. tuberculosis* is detected for the first time by the BACTEC 460TB method, the identity of the isolate should be confirmed and the presence of a contaminant or mixed culture should be ruled out before secondary agents are tested. While the importance of promptly reporting an MDR isolate of *M. tuberculosis* cannot be overstated, the consequences of a false report of multiple resistance must be recognized as well (108). Clinician concerns about discrepancies between susceptibility test results and clinical response or status must be communicated back to the laboratory as part of an effective quality assurance program.

Three of the primary drugs (INH, RMP, and EMB) and SM are available as lyophilized powders in the BACTEC SIRE kit, designed specifically for use with 12B medium and the BACTEC 460TB instrument. Alternatively, stock solutions of these agents can be prepared from reference powders. Lyophilized vials of PZA are also available for the pH 6.0 modified BACTEC PZA test medium. The secondary drugs must be prepared from reference powders. Critical concentrations for most of these drugs have been established, and the results of the radiometric and proportion methods correlate well (113).

Inoculum and Incubation

The source of inoculum for susceptibility testing should be fresh growth of actively growing bacilli. If growth from a primary BACTEC 12B vial is used for the inoculum, the daily GI reading should be at least 500 or, even better, between 800 and 900. The higher the GI, the shorter the period until the control vial reaches >30 and the earlier the test results can be interpreted. If the primary vial is past the GI peak or if the vial was kept at room temperature for more than 2 days, a fresh 12B vial should be inoculated. Other types of broth culture (Dubos, Middlebrook 7H9, Septichek AFB, VersaTREK Myco, MGIT, or MB/BacT medium) can be used as a source of inoculum; however, it is necessary to ensure that the broth culture is not contaminated or not mixed with other mycobacterial species. A variety of procedures may be used for mycobacterial purity checks (28). After the inoculum is thoroughly mixed to break up clumps, the turbidity should be adjusted to match a 0.5 McFarland standard rather than a 1.0 McFarland standard. This inoculum is then used to inoculate the drug-containing vials. A control vial (without drugs) is inoculated with a 1:100 dilution of the inoculum. All dilutions should be prepared with diluting fluid or distilled water, but not a broth or other substrate-containing medium. Additionally an undiluted control may be used to monitor the growth kinetics of the inoculum and also can serve as a source of inoculum if a test must be repeated.

Also, fresh growth on any solid media may serve as an inoculum source. It is important to harvest several (5 to 10) colonies in order to ensure a representative sample of growth (harvesting from only 2 or 3 single colonies is inadequate), and it is very important to thoroughly homogenize the inoculum in a tube containing 3 to 5 ml of diluting fluid and glass beads. After being vortexed for 1 to 2 min, the tube is left to stand undisturbed for 30 min to allow larger particles to settle, and then the top half of the supernatant is transferred into a new tube. The turbidity is adjusted to match a 0.5 McFarland standard, and this suspension is used to inoculate the drug-containing vials. Blood agar and 7H10 plates are inoculated with a few drops of the inoculum suspension to check for purity.

As safety precautions, disposable tuberculin syringes with a permanently attached needle should be used; rubber gloves, N95 mask, and a gown must be worn; and all steps involving the preparation of inocula and inoculation of vials should be performed in a class II or III biological safety cabinet.

Prior to inoculation, BACTEC 12B vials must be prerun in the BACTEC 460TB instrument to establish a gas phase of 5% CO_2 in air in the headspace of the vial; any vial with an initial GI of 20 must be rejected. Each prerun vial is inoculated with 0.1 ml of the adjusted suspension of the test or QC isolate, and the vials are incubated at 37 ± 1°C (the temperature of incubation is critical) in the dark.

Reading, Interpreting, and Reporting Results

Vials are read on the BACTEC 460TB instrument at intervals of 24 ± 1 h for a minimum of 4 days and until the control vial reaches a GI of 30. For laboratories with limited weekend coverage, an alternative schedule is to inoculate the vials on Friday and first read them on Monday (60). The Monday reading is disregarded, because it reflects 2 days of CO_2 production, and the vials are read daily for at least 3 days (5 days total). Batch testing is discouraged unless the susceptibility test can be started during the same week that the isolate is identified to species, i.e., identified as *M. tuberculosis* complex. In those situations, to avoid any delay, the isolate should be sent to a reference laboratory that works 7 days a week.

When the GI of the control is 30 after a minimum of 4 days, the difference in GI from one day to the next, designated the ΔGI, should be interpreted as follows:

$$\Delta GI \text{ of control} > \Delta GI \text{ of drug} = \text{susceptible}$$

$$\Delta GI \text{ of control} < \Delta GI \text{ of drug} = \text{resistant}$$

If the GI is 500 and >500 on the next reading, the isolate should be considered resistant to that drug regardless of the ΔGI (it is necessary to check that the GI of the control was not >30 in less than 3 days to exclude overinoculation). Continued incubation for a few days may allow one to resolve borderline results, but the incubation should not be extended beyond 3 days after the control vial is positive. Susceptibility test results should never be reported without identification of the isolate as *M. tuberculosis* complex or *M. tuberculosis,* especially when the isolate is resistant to a drug(s). Usually, BACTEC 460TB results are straightforward; however, if the ΔGIs are close (within 10%), a preliminary report should be issued and the test should be repeated. Secondary drugs should be tested if the isolate is resistant to RMP or any two primary drugs (28). Use of the term "borderline," as recommended by the BACTEC manufacturer, is not encouraged, because the definition of this term is unclear and may mislead the clinician into believing that a drug has no use in the treatment of tuberculosis. Susceptibility test results should be reported without delay. The report should include the test method, the name of the drug, the concentration tested, and the result (susceptible or resistant). It is not possible to report the percent resistance by using the BACTEC 460TB method. Drug resistance should be reported by telephone and/or fax to the requesting physician, the infection control program, and the local tuberculosis control program, and a follow-up hard-copy report should be submitted. It is prudent to confirm the receipt of a fax report in lieu of direct communication with the physician or public health official.

Quality Control

Reference strains with known susceptibility patterns should be tested with each new batch of drug and BACTEC 12B medium. In addition, QC tests should be performed at least once a week in laboratories that perform tests daily or weekly or when a patient isolate is tested if tests are performed less frequently. The H37Rv strain of *M. tuberculosis* (ATCC 27294), which is susceptible to all standard antituberculosis agents, is commonly used for QC. Mutants of H37Rv selected for in vitro resistance to single or multiple drugs are also available; however, these strains are resistant to very high concentrations and are not particularly suitable for QC purposes. In addition, reporting the test results for a patient isolate should not be delayed because of the pending test results for a resistant QC strain. Suspensions of QC strains may be prepared in BACTEC diluting solution and frozen at −70°C in 1-ml test samples for up to 6 months (138). A single tube is thawed for QC testing, and the same procedure as that for clinical isolates is used. At present, there is no published consensus on which QC results should be available before the test results on a patient isolate may be released. However, it seems reasonable that the QC test results for medium components be available and acceptable, as well as the results for the "susceptible" QC strain (e.g., ATCC 27294).

Testing PZA

Reliable testing of PZA by the radiometric method is different from testing by the BACTEC 460TB method for the other primary drugs (96), because PZA activity is best measured at pH 5.5 rather than pH 6.8, the usual pH of the growth medium. However, most strains of *M. tuberculosis* grow poorly at pH 5.5 and some fail to grow altogether. As a compromise between testing at the pH for optimum PZA activity and testing at the pH for optimum growth, Salfinger et al. (131) recommended that PZA be tested at pH 5.9 ± 0.1. In addition, to accurately and reliably test PZA, several other adjustments to the standard radiometric method are made. (i) To prepare the inoculum, each isolate must be subcultured in a fresh BACTEC 12B vial supplemented with BACTEC reconstituting fluid, which is an aqueous solution of polyoxyethylene stearate (POES) (139). The isolate is tested daily, and once the GI is 300 to 500, this culture is used for susceptibility testing. Alternatively, a 1:10 dilution of the inoculum (GI = 999 or 0.5 McFarland standard) used for testing the other primary drugs is used and the suspension is vigorously homogenized before use. (ii) Either the lyophilized PZA is reconstituted with POES or PZA reference powder is dissolved in POES to achieve a final concentration of 100 μg/ml, the critical concentration for the BACTEC method, which is equivalent to 25 to 50 μg/ml (used in the proportion method) (138). (iii) A special BACTEC 12B medium at pH 6.0 supplemented with POES is used to test PZA. (iv) The PZA-containing vial and the control vial are inoculated with the same suspension; i.e., the inoculum for the control vial should not be diluted. (v) The vials are tested daily until the control vial reaches a GI of 200; if the GI fails to reach 200 within 14 days, the test is uninterpretable. (vi) The isolate is considered susceptible to PZA if the GI of the PZA vial is <10% of the GI of the control vial. If the GIs of the test and control vials are very close, the result is considered borderline and the test must be repeated. (vii) In addition to the use of H37Rv (PZA susceptible) for QC testing, *M. bovis* BCG (PZA resistant) can be used as a control for PZA resistance. If an isolate tests resistant to PZA, especially if it is resistant to PZA alone, it should be identified to the species level, because *M. bovis* and *M. bovis* BCG are PZA resistant whereas almost all *M. tuberculosis* isolates are PZA susceptible. This is especially important if the laboratory identifies isolates only to the level of the *M. tuberculosis* complex. Some *M. tuberculosis* isolates grow poorly at pH 6.0 (130), and other isolates may be inhibited by the POES supplement (95).

VersaTREK

VersaTREK (fomerly called ESP Culture System II; Trek Diagnostic Systems, Inc.) is a fully automated, continuously monitoring system for growth and detection of mycobacteria (176), which allows testing of the susceptibility of *M. tuberculosis* to major primary drugs (i.e., INH, RMP, EMB, and PZA) as well as the secondary agent SM. The VersaTREK technology is based on detection of pressure changes (gas production or gas consumption due to microbial growth) within the headspace above the broth culture medium in a sealed bottle. The culture medium consists of a Middlebrook 7H9 broth, which has been enriched with glycerol and Casitone, and contains a cellulose sponge. Before the medium is inoculated with a test strain, growth and antibiotic supplements must be added.

Inoculum and Incubation

VersaTREK Myco antibiotics are supplied as lyophilate by the manufacturer. Preparation of the bottles requires the addition of 1.0 ml of antibiotic solution. The final concentrations in the Myco bottles are as follows: INH, 0.1 μg/ml; RMP, 1.0 μg/ml; EMB, 5.0 μg/ml; and SM, 8.0 μg/ml. INH

and EMB can be tested at higher concentrations (0.4 and 8.0 μg/ml, respectively). For the inoculation of organisms into the VersaTREK Myco bottles, 0.5 ml of a 1:10 dilution from a McFarland standard of 1 must be added to the drug-containing bottles. The inoculum can be prepared from either solid (e.g., Löwenstein-Jensen) or liquid (e.g., VersaTREK Myco) medium. Cultures are kept in the instrument at 35°C, and growth is automatically monitored.

Reading, Interpreting, and Reporting Results

At the end of the specified incubation period, as determined by the drug-free control bottle for each isolate that is tested, the isolate is manually determined to be susceptible or resistant to a drug. If the control bottle (without drugs) signals positive, the time to detection is calculated. Drug-containing bottles are monitored for another 3 days after the control bottle has turned positive. Results are interpreted according to the following rules: a strain is considered resistant if the time of detection is the same time as or up to 3 days after that for the control bottle; a strain is considered susceptible if no growth occurs in the drug-containing bottle or if the time of detection is more than 3 days after that for the control bottle. The few studies demonstrate good agreement of the VersaTREK (formerly called ESP Culture System II) with the BACTEC 460TB and the agar proportion method and detection times, which are very comparable to those obtained by the radiometric method (10, 126, 176).

Quality Control

Each new VersaTREK Myco Susceptibility Kit and/or lots of medium and growth supplement should be tested with strains of *M. tuberculosis* appropriate for QC. A pansusceptible strain of *M. tuberculosis* should be included with each testing run (28).

MGIT (Manual and Automated MGIT 960) Systems

In 1995, the MGIT was introduced for the growth and detection of mycobacteria from clinical specimens (57, 115). Each MGIT tube contains modified Middlebrook 7H9 broth, and in the bottom is a fluorescence-quenching-based oxygen sensor (silicon rubber impregnated with a ruthenium pentahydrate). The fluorescent compound is sensitive to the presence of oxygen dissolved in the medium. The fluorescence of the indicator is quenched in the presence of oxygen, but fluorescence increases as soon as actively respiring microorganisms utilize the dissolved oxygen. Fluorescence is detected using a 365-nm UV transilluminator. The MGIT system is available as a manual system or a fully automated, continuously monitoring system called BACTEC MGIT 960. Apart from using nonradiometric medium, it frees the technician from using syringes. In addition to detecting and monitoring growth, the system can be used for testing of susceptibility to INH, RMP, EMB, PZA, and SM. Fluorescence of the drug-containing tubes is compared with that of the drug-free growth control tube. When using the instrument, the ratio of relative growth between the drug-containing tube and the growth control tube is determined by software algorithms. If the relative growth in the drug tube equals or exceeds that in the growth control tube, the organism is considered resistant to the drug; if the relative growth is less than that in the growth control tube, the organism is considered susceptible.

Five drugs (INH, RMP, EMB, PZA, and SM) are designed specifically for use with the BACTEC MGIT 960 instrument. Stock solutions of these drugs also can be prepared from reference powders. Lyophilized vials of PZA are available for testing susceptibility based on an adapted protocol utilizing BACTEC MGIT 960 PZA medium at pH 5.9. Similar to the BACTEC 460TB procedure, the BACTEC MGIT 960 employs a two-tier test, with the first tier comprising the four SIRE drugs being tested at drug concentrations equivalent to the critical concentrations of the agar proportion method (i.e., SM, 1.0 μg/ml; INH, 0.1 μg/ml; RMP, 1.0 μg/ml; and EMB, 5.0 μg/ml). If there is resistance to INH, EMB, and/or SM, a second test that involves a higher concentration of the drug(s) (SM, 4.0 μg/ml; INH, 0.4 μg/ml; and EMB, 7.5 μg/ml) may be used. There appears to be good correlation between the MGIT and the BACTEC 460TB system or the agar proportion method (8, 114, 127). The time to results is comparable to that for the radiometric technique. A multicenter report suggests that an overall correlation between the BACTEC 460 and the agar proportion method could be achieved with amikacin, kanamycin, and ofloxacin; however, inconsistent results in both methods were obtained with cycloserine (113). A recent report validated the use of BACTEC 460 and MGIT 960 for testing the susceptibility of *M. tuberculosis,* including multidrug-resistant strains, to levofloxacin (132).

Inoculum and Incubation

Inoculum (0.5 ml) for drug susceptibility testing may be prepared from either liquid or solid media. To ensure viability of the colonies, accuracy of results, and reproducibility of dilutions, strict adherence to the guidelines of the manufacturer is imperative. Prior to inoculating the AST tubes, 0.8 ml of the BACTEC MGIT 960 drug susceptibility testing supplement (OADC) and 100 μl of the drug solution (INH, RMP, or EMB) are added to the MGIT. With a liquid source of inoculum, the MGIT must nominally be used no sooner than the day following the instrument's positivity (day 1) and no later than 5 days following the day of the instrument's positivity. If it is older, the isolate must first be subcultured again. With solid media, the isolate can be used no longer than 14 days after the first appearance of colonies on the plate or slant.

If growth from a primary MGIT is taken for susceptibility testing, the suspension can immediately be used for testing. Appropriate dilutions (1:5) have been made for day 3 through 5 positive MGIT 960 tubes prior to inoculation of the drug set to avoid overinoculation. When working with a solid medium source, inoculum preparation includes vortexing with glass beads and two specified settling times to ensure homogeneity of the final cell suspension. The suspension has to be adjusted to a McFarland standard of 0.5 equivalent and then diluted 1:5 before inoculation of the MGIT 960 AST set. For the growth control tube, 100 μl of a positive MGIT 960 broth is pipetted into 10 ml of sterile saline to prepare a 1:100 dilution of the growth suspension. From this suspension, 0.5 ml is inoculated into a fresh MGIT without drug. Cultures are kept at 35°C, and growth is automatically monitored.

Reading, Interpreting, and Reporting Results

Drug results are listed automatically on the data report form (S, susceptible; R, resistant; X, invalid result), together with growth units and time to result. As with all drug susceptibility testing, the report should indicate the method used and the concentration of drug tested. Interpretive comments, such as those suggested by the CLSI (28), should be considered.

Quality Control

Reference strains with known susceptibility patterns should be tested with each new batch of drug and MGIT medium and included with each test run (28).

Testing PZA

PZA can reliably be tested by using the novel BACTEC MGIT PZA tube, which contains 7 ml of MGIT broth, modified with a reduced pH (114). Inocula can be prepared either from MGIT medium or from solid medium, such as Löwenstein-Jensen medium. Prior to inoculating the PZA set tubes, 0.8 ml of MGIT PZA supplement and 100 μl of PZA solution (100 μg/ml) are added. MGIT cultures are used no sooner than the day following the instrument's positivity (day 1) and no later than 5 days following the day of positivity. On days 1 and 2 following positivity, the inoculum is used undiluted, while on days 3 to 5, suspensions are diluted 1:5 with sterile saline. Then 0.5 ml is inoculated into the MGIT PZA tubes. The growth control tube is inoculated with 0.5 ml of a 1:10 dilution of the respective suspension. Cultures grown on Löwenstein-Jensen medium are used no later than 14 days after the first colonies appear on the slant. To ensure homogeneity, a suspension adjusted to a McFarland standard of 0.5 equivalent is prepared by using glass beads and then diluted 1:5 prior to inoculation of the MGIT PZA set. All inoculated PZA sets must be loaded into the instrument within 8 h of inoculation. Again, using predefined algorithms, readings are automatically interpreted by the instrument. In contrast to BACTEC 460TB, the PZA "borderline" category no longer exists with this method.

MB/BacT ALERT 3D

The MB/BacT ALERT 3D System (bioMerieux), a fully automated, nonradiometric system, can also be used for mycobacterial culture susceptibility testing of *M. tuberculosis* outside the United States (118). With this technology, carbon dioxide is released into the medium by actively metabolizing microorganisms and is detected by a gas-permeable sensor containing an indicator embedded at the bottom of the culture bottles. Color changes are monitored by a reflectometric detection unit, and data are compiled by an internal database management system.

Inoculum and Incubation

Following the instructions of the manufacturer, the MB/BacT process bottles containing a modified Middlebrook 7H9 medium (with casein, bovine serum albumin, and catalase) are supplemented with the following final drug concentrations: INH, 1 μg/ml; RMP, 1 μg/ml; SM, 1 μg/ml; and EMB, 2 μg/ml. Subsequently, bottles are inoculated with 0.5 ml of a suspension of *M. tuberculosis* adjusted to a McFarland standard of 2. Two bottles without drugs serve as growth controls, one inoculated with 0.5 ml of the cell suspension adjusted to a McFarland standard of 2 (control 1) and one with 0.5 ml of the cell suspension (McFarland standard of 2) diluted 1:100 (control 2).

Reading, Interpreting, and Reporting Results

At the time that the MB/BacT System recognizes growth in the control 2 bottle, testing is terminated and the growth status of the bottles containing the drugs is determined. An isolate is considered resistant if the drug-containing bottle is positive before or on the same day as the corresponding diluted control bottle (control 2). Susceptibility is defined as the drug-containing bottle remaining negative or becoming positive later than the control 2 bottle. On the basis of preliminary studies, there is excellent agreement of the MB/BacT results with susceptibility data generated by the agar proportion method and BACTEC 460TB (18, 40, 118), in particular for INH and RMP. The manufacturer increased the EMB concentration to 2.5 μg/ml in order to improve the correlation with the results of the agar proportion method (138). The time necessary to determine the susceptibility patterns of *M. tuberculosis* is within what has been observed for the BACTEC 460TB System.

Quality Control

Reference strains with known susceptibility patterns should be tested with each new batch of drug and MB/BacT medium, and with each test run (28).

M. AVIUM COMPLEX

Clinical Significance

MAC is commonly isolated from a variety of clinical specimens and in many clinical laboratories is the most frequently encountered *Mycobacterium* species. Isolation of MAC from blood or other sterile sites is almost always clinically significant and is especially important in HIV-infected patients with profound CD4 T-cell lymphocytopenia, i.e., ≤75 CD4 T lymphocytes per μl. Although disseminated MAC infection remains a complication in HIV-infected patients, the incidence has dramatically decreased due to the introduction of effective prophylaxis and immune system restoration associated with the use of highly active antiretroviral therapy. Also, disseminated MAC disease still occurs in patients who fail to respond to antiretroviral treatment because of drug resistance, drug intolerance, or lack of compliance. In many of these patients, MAC infection represents a relapse of MAC disease rather than a new infection. MAC is also a cause of chronic pulmonary lung disease and is the leading cause of lung disease due to nontuberculous mycobacteria in the United States. The incidence of MAC lung disease has been steadily increasing in patients with underlying bronchiectasis, chronic obstructive pulmonary disease, or cystic fibrosis. Nevertheless, the detection of MAC in respiratory or gastrointestinal tract specimens can be difficult to interpret, especially in patients who are not clearly at risk for MAC disease. Clinical, histopathologic, and/or radiologic evidence of MAC disease, repeated isolation of MAC, increasing numbers of bacilli in sequential specimens, or the absence of other identifiable causes of signs and symptoms are important factors to consider in assessing the clinical significance of MAC isolates.

Drug Resistance

Most MAC isolates are intrinsically resistant to INH and PZA, and these antimicrobial agents play no role in the treatment of MAC infection (4). The intrinsic resistance to INH most likely is due to a lack of a complete antimicrobial effect (7, 91). Cell-free in vitro studies have shown that certain drug targets (e.g., ribosomes, ribosomal subunits, and RNA polymerase) bind the corresponding drugs (e.g., macrolides, aminoglycosides, and rifamycins) and that the target functions are inhibited, yet many of these compounds are ineffective against whole cells. MAC isolates have variable MIC values to aminoglycosides (amikacin, kanamycin, and SM) and rifamycins (RMP and rifabutin), and one or both of these agents are often used in combination with other drugs for treatment of MAC disease.

Correlation between in vitro MAC susceptibility test results and clinical response has been demonstrated in a controlled clinical trial only with azithromycin and clarithromycin (23). Although wild-type MAC isolates are uniformly susceptible to macrolides, resistance develops quickly with macrolide monotherapy and may eventually develop with combination therapy. An analysis of macrolide-resistant MAC isolates

showed that over 95% of clinically significant macrolide resistance in MAC is a consequence of mutations in the V-domain of the 23S rRNA gene (92, 106). Therefore, clinically significant macrolide resistance can be defined as a clarithromycin MIC of ≥32 μg/ml or an azithromycin MIC of ≥256 μg/ml (75, 106). Predicting in vivo susceptibility is always less reliable; however, a positive clinical and microbiological response is expected if the MIC values of clarithromycin and azithromycin are ≤4 and ≤32 μg/ml, respectively. Clarithromycin and azithromycin are approved by the FDA for the treatment of MAC disease, but either agent must be combined with at least one and often two additional agents, commonly EMB and RMP (24). Clarithromycin, azithromycin, and rifabutin are approved as prophylactic agents for disseminated MAC infection in HIV-infected patients; however, their mechanism of action as prophylactic agents is unclear.

When To Perform Susceptibility Tests

Universally accepted guidelines regarding indications for susceptibility testing of MAC do not exist. However, testing should be considered for clinically significant isolates from patients on prior macrolide therapy, from patients who become bacteremic while on macrolide preventive therapy, and from patients who relapse while on macrolide therapy. Testing initial isolates from blood or tissue of patients with disseminated disease or respiratory samples from patients with pulmonary disease to establish baseline values also may be valuable. Susceptibility testing should be repeated after 3 months for patients with disseminated disease and after 6 months for patients with chronic pulmonary disease if the patient does not improve clinically and remains culture positive.

Test Methods

Broth microdilution and macrodilution and agar dilution methods that measure, in a quantitative manner, the in vitro activity of antimycobacterial agents against MAC have been described. In Europe, an agar dilution method with Mueller-Hinton agar supplemented with OADC is used; however, in the United States, there is consensus that both radiometric broth macrodilution and broth microdilution methods are accurate and reliable and that agar-based methods should not be used. The current recommendations of the CLSI Subcommittee on Antimycobacterial Susceptibility Testing indicate that susceptibility testing for MAC should be restricted to clarithromycin or azithromycin (28). Clarithromycin results predict those of azithromycin; therefore, testing both agents is not necessary. BACTEC 12B medium can be used for macrodilution testing, and either Middlebrook 7H9 broth with casein or Mueller-Hinton broth supplemented with OADC or OAD is acceptable for microdilution tests. The concentration ranges of clarithromycin and azithromycin to test are shown in Table 5.

The issue of pH remains somewhat controversial. One view is that testing at pH 7.2 to 7.4 is potentially misleading because MAC isolates tend to grow more slowly, and some fail to grow, at this pH. Thus, MIC values measured in this pH range may reflect synergy between a suboptimal pH for growth and inhibitory drug activity (72; S. Beaty, S. Siddiqi, and M. Gnacek, *Abstr. 92nd Gen. Meet. Am. Soc. Microbiol. 1992,* abstr. U-102, 1992). Also, BACTEC 12B medium is unstable at pH 7.2 to 7.4 because of the poor buffering capacity of the medium at pH values above 7.2. In addition, the intracellular environment of MAC-infected macrophages is pH 6.0 to 6.5, which suggests that macrolides should be tested under the mildly acidic, more clinically relevant conditions. Although MAC can block phagolysosome fusion, the intracellular pH remains in the range of pH 6.0 to 6.5 (110, 122, 146). Blocking phagolysosome fusion prevents a drop to pH 5.0 or lower but does not result in an increase in the intracellular pH to 7.2 to 7.4. The CLSI does not make a specific recommendation but states that pH 6.8 and 7.4 are both acceptable, providing that the recommended interpretive criteria are followed (Table 5). Data from a multicenter study (175) showed that testing in broth at either pH is satisfactory, supporting the CLSI view.

Inoculum and Incubation

Currently there are no specific recommendations regarding inoculum preparation. The options include the use of "seed" BACTEC vials (subcultures of fresh growth) for the radiometric method or the preparation of a suspension of mycobacteria taken directly from an agar plate or a broth culture for microdilution. However, if possible, only transparent colony types should be tested because this variant generally is more virulent and more resistant to antimicrobial agents than the opaque variant. The inoculum should be between 10^4 and 10^5 CFU/ml for the radiometric broth macrodilution test and approximately 5×10^5 CFU/ml for the broth microdilution test. Tween 80 or other surfactants should not be used to disperse clumps of bacilli because of the potential synergistic effect of the surfactant activity of Tween 80 and antimicrobial agents.

Incubation is at 37°C. For the radiometric test, incubation should not extend beyond 10 days, and the "no-drug" control should not exceed a GI of 999 in less than 4 days. For broth microdilution, trays are incubated for 7 to14 days. The endpoint for the radiometric test is defined by the GI value for the inoculum diluted 1:100, whereas the endpoint for the broth microdilution assay is visible turbidity.

TABLE 5 Susceptibility testing of clarithromycin and azithromycin against *M. avium* complex[a]

Antimicrobial agent	Concn range (μg/ml) for:		pH	Interpretive criteria			QC (*M. avium* ATCC 700898)	
	BACTEC	Microtiter		Susceptible (μg/ml)	Intermediate (μg/ml)	Resistant (μg/ml)	Concn range (μg/ml)	Expected endpoints (μg/ml)
Clarithromycin	2–64 or 4, 16, and 64	1–64	6.8	≤16	32	≥64	1, 2, and 4	1–4
Clarithromycin	2–64 or 4, 8, and 32	2–64	7.3–7.4	≤4	8–16	≥32	0.5, 1, and 2	0.5–2
Azithromycin	16–512 or 32, 128, and 512	NR[b]	6.8	≤128	256	≥512	8, 16, and 32	8–32

[a] Data from reference 28.
[b] NR, no recommendation.

Reporting Results

When testing clarithromycin or azithromycin, both the MIC value and an interpretation, based on the pH of the medium and the breakpoints listed in Table 5, should be reported (28). Because untreated wild strains of MAC rarely, if ever, are intermediate or resistant to macrolides, the CLSI subcommittee recommends that laboratories confirm such results by repeat testing (28). A confirmed intermediate result may suggest that the patient has a mixed population of MAC organisms and should be monitored for emerging resistance. Testing agents other than the macrolides (e.g., amikacin, ciprofloxacin, or moxifloxacin) should be restricted to situations in which the clinician has extensive experience in the use of these agents in the treatment of MAC disease or for research purposes. Testing EMB or RMP should be discouraged because MIC values do not necessarily correlate with clinical response and, therefore, could be misleading. If drugs other than macrolides are tested, only the MIC values should be reported without an interpretation. However, it is important to recognize that disseminated MAC disease is principally an infection of macrophages in the blood, bone marrow, spleen, and other tissues. Thus, clinical effectiveness is likely to relate to both potent activity and the ability of drugs to accumulate in cells and tissues to levels above the MIC for the infecting microorganism.

OTHER SLOWLY GROWING MYCOBACTERIA

In the mid-1980s, Woods and Washington (177) reviewed the nontuberculous mycobacterioses and concluded that no clear recommendations could be made for treatment of these infections and that the need for susceptibility testing was difficult or impossible to assess. Now, many years later, the situation has not appreciably changed. Nevertheless, for certain species of nontuberculous mycobacteria, there has been an accumulation of information and experience that can be the basis for some recommendations (28). Susceptibility testing is often helpful with these less frequently encountered species because of the paucity of information about treatment options, and in vitro results provide some rational basis for guiding treatment (52). Furthermore, baseline information may be useful if there is a microbiologic relapse. However, the vagaries of testing and interpretation of results mandate that the testing be performed in an experienced laboratory and, to better ensure consistency of results, that follow-up testing be performed by the same laboratory.

M. kansasii

Isolates of *M. kansasii* from patients not previously treated with RMP are predictably susceptible to RMP, and patients have been successfully treated with RMP, INH, and EMB, with or without SM (4). However, resistance to RMP can develop during therapy, and a patient's history of RMP therapy may be unknown or unclear. Therefore, CLSI recommends that all initial isolates of *M. kansasii* be tested for susceptibility to rifampin only, by agar proportion, as described for *M. tuberculosis*, or a broth-based method that yields comparable results (28). Susceptibility testing should be repeated if cultures remain positive after 3 months of appropriate therapy.

Untreated wild strains of *M. kansasii* are susceptible to the critical concentrations of RMP and EMB used to test *M. tuberculosis* (discussed earlier in the chapter) but are resistant to the critical concentration of INH (0.2 μg/ml by agar proportion) and show variable susceptibility to the higher concentration (1.0 μg/ml). Despite these in vitro results, INH appears clinically active. Therefore, because in vitro results do not correlate with clinical outcome, testing susceptibility of *M. kansasii* to INH should not be done. Isolates of *M. kansasii* that are resistant to RMP (MIC ≥1 μg/ml) should be tested against the following secondary drugs: rifabutin, EMB, SM, clarithromycin, amikacin, ciprofloxacin (as the class representative for the older fluoroquinolones), trimethoprim-sulfamethoxazole or sulfamethoxazole, and moxifloxacin. Unfortunately, however, for most of these agents data regarding both concentrations to be tested and optimal testing conditions are limited. Tentative testing and interpretive guidelines for these agents are shown in Table 6 (28).

M. marinum

Routine susceptibility testing of *M. marinum* is not recommended and should be discouraged. Isolates are consistently susceptible to several clinically useful antimicrobial agents, including RMP, EMB, doxycycline (or minocycline), trimethoprim-sulfamethoxazole, and clarithromycin (28). Additionally, the risk of acquired mutational resistance to one or more of these agents is extremely low. Successful treatment may require surgical excision or debridement as well as antimicrobial therapy. However, if a patient fails to respond clinically after several months of appropriate therapy and remains culture positive, susceptibility testing of *M. marinum* should be considered. Agar proportion, agar disk elution, and broth microdilution have been used, but there are insufficient data to recommend any one method. Drugs suggested by CLSI to test are RMP, EMB, clarithromycin (the class agent for newer macrolides), amikacin, and sulfamethoxazole or trimethoprim-sulfamethoxazole (28).

M. haemophilum

M. haemophilum is an opportunistic pathogen in immunocompromised patients, and there is some correlation between susceptibility test results and clinical efficacy, although virtually all treatment regimens examined included combinations of agents (145). Wild-type isolates of *M. haemophilum* appear to be susceptible to quinolones, rifamycins, clarithromycin, and azithromycin and resistant to PZA and EMB; they are likely to be resistant to INH and SM (11, 145).

M. xenopi, M. szulgai, and *M. malmoense*

In vitro susceptibility test results for *M. xenopi, M. szulgai,* and *M. malmoense* may be helpful because of the paucity of

TABLE 6 Tentative breakpoint concentrations for antimicrobial agents that might be tested against *M. kansasii* and selected slowly growing mycobacteria other than *M. tuberculosis*[a]

Antimicrobial agent	Resistance breakpoint (μg/ml)
RMP	1–2
Rifabutin	0.5–2
EMB	5
INH[b]	5
SM	10
Clarithromycin	32
Amikacin	10
Ciprofloxacin	2
Trimethoprim-sulfamethoxazole	2/38

[a] Data from reference 28.
[b] Not recommended for testing *M. kansasii*.

information about the susceptibility patterns of these species. For example, susceptibility testing has been reported to be important to the management of infections caused by *M. xenopi* (153), but an earlier report indicated that the correlation between susceptibility test results and therapeutic response was inconsistent (177). Pulmonary infections by these three species have been successfully treated with INH, EMB, and RMP, and data from at least one report indicated that clarithromycin was effective in the treatment of *M. xenopi* infections (4). Candidate drugs for testing with these species are the same as for *M. kansasii* (Table 6). The test method should be either the BACTEC radiometric, broth microdilution, or agar proportion; however, there may be advantages to defining the in vitro susceptibility in terms of an MIC. Extrapolation of the *M. tuberculosis* "critical concentrations" to these species of mycobacteria may be misleading, because there is some evidence that infections caused by these species can be successfully treated with higher concentrations of INH, SM, and EMB than might be used for *M. tuberculosis* (4).

M. gordonae

Testing *M. gordonae* is inappropriate because isolates almost always represent contaminants; *M. gordonae* rarely causes actual disease (164). Before testing *M. gordonae* isolates, one should ask whether there is convincing evidence that the isolate is playing a role in the disease process. Until these questions are answered in the affirmative, susceptibility testing is inappropriate because the results could be misleading and the patient may be misdiagnosed and inappropriately treated.

The most prudent approach to the testing of slowly growing mycobacteria other than *M. tuberculosis* complex is to restrict it to reference laboratories with extensive experience working with these species. Interpretation of the susceptibility test results requires good communication between the laboratory and the clinician.

RAPIDLY GROWING MYCOBACTERIA

Clinical Significance

Rapidly growing mycobacteria are defined as acid-fast bacilli that form visible colonies from a dilute inoculum on a solid medium within 5 to 7 days. It is important to note that this definition does not necessarily apply to the original culture of a patient's specimen. Although there are over 30 species of rapidly growing mycobacteria, most human disease is caused by *M. abscessus, M. chelonae,* or *M. fortuitum* group (17). These three species/groups are important causes of skin and soft tissue infections, especially following penetrating trauma with possible soil or water contamination. They also cause nosocomial infections (e.g., catheter-related bacteremia and wound infections following augmentation mammaplasty or cardiac bypass surgery), and *M. abscessus* can cause pulmonary disease, especially in patients with cystic fibrosis. Disseminated disease is uncommon and is usually associated with cellular immune deficiency, particularly that due to corticosteroid therapy, although it is rare in HIV-infected patients. Several other rapidly growing mycobacteria are infrequent to rare causes of disease in humans, including *M. mucogenicum, M. immunogenum, M. neoaurum, M. mageritense, M. smegmatis, M. goodii,* and *M. wolinskyi* (17, 161, 162), and at least two species are animal pathogens (51). Clinical isolates of rapidly growing mycobacteria should be identified to species, because the antimicrobial susceptibility patterns differ for the different species. For example, *M. abscessus* and *M. chelonae* are always resistant to trimethoprim-sulfamethoxazole, whereas *M. fortuitum* group virtually always is susceptible.

Susceptibility testing should be performed for any clinically significant, rapidly growing mycobacteria. This includes isolates from blood, sterile body fluids, tissue, and material collected from skin and soft tissue lesions, and multiple isolates from sputum (or other respiratory specimens). The recovery of rapidly growing mycobacteria from sputum or other respiratory specimens is more difficult to interpret, because frequently these isolates are not clinically significant. However, the repeated isolation of a rapidly growing mycobacterium from a respiratory specimen, especially one that is smear positive for acid-fast bacilli, is highly suggestive of true pulmonary disease. In patients with wound infections, debridement and excision of the infected tissue are frequently necessary adjuncts to antimicrobial therapy, although cutaneous infections occasionally resolve spontaneously with neither surgical intervention nor antimicrobial therapy (159).

Methods

Broth microdilution is recommended for susceptibility testing of the *Mycobacterium fortuitum* group, *Mycobacterium chelonae*, and *Mycobacterium abscessus* and, theoretically, also should be appropriate for testing other clinically significant, rapidly growing mycobacteria, although data to support this are not currently available (28). The E test has been evaluated for testing rapidly growing mycobacteria, but the method did not yield results comparable to those of broth microdilution (173) and, therefore, cannot be recommended at this time. As mentioned earlier, for optimal interpretation of MIC results, isolates should be identified to the species level. If cultures (from any site except respiratory) are positive after 6 months of appropriate antimicrobial therapy, susceptibility testing should be repeated, and the species identity should be confirmed.

Broth Microdilution Method

The broth microdilution method for testing rapidly growing mycobacteria is essentially a modification of the CLSI standard method for non-acid-fast organisms that grow aerobically (27); it has been described in detail by Brown et al. (16). Antimicrobial agents (and concentrations in serial twofold dilutions) that should be tested are amikacin (1 to 128 μg/ml), cefoxitin (2 to 256 μg/ml), ciprofloxacin (0.125 to 16 μg/ml), clarithromycin (0.06 to 64 μg/ml), doxycycline (or minocycline) (0.25 to 32 μg/ml), imipenem (1 to 64 μg/ml), and sulfamethoxazole (or trimethoprim-sulfamethoxazole) (1 to 64 μg/ml). Additionally, for isolates of *M. chelonae* only, tobramycin (1 to 32 μg/ml) should be tested. Testing linezolid and one of the newer fluoroquinolones (e.g., moxifloxacin) also should be considered. Commercially manufactured broth microdilution panels are available (Trek Diagnostic Systems). Alternatively, broth microdilution plates can be prepared by the method described by Brown et al. (16); once prepared, the plates can be sealed in plastic bags and stored at −70°C for up to 6 months.

Inoculum

Fresh growth is prepared by inoculating a blood agar plate with the test organism and incubating the plate at 30°C for 72 h. The current recommendation is to prepare the inoculum by collecting growth from the blood agar plate with a sterile cotton swab and making a suspension in sterile distilled water that is equivalent to the density of 0.5 McFarland turbidity standard. The final inoculum should be approximately 5×10^5 CFU/ml or 5×10^4 CFU/100 μl/well of a microtiter plate. The purity of the inoculum should be

checked for each isolate, and periodically the size of the inoculum should be verified by quantitative plate culture.

Incubation and Reading

The microtiter plates are sealed and incubated for 3 to 5 days at 30°C in air. Plates must not be incubated beyond 5 days because of drug instability. If there is not sufficient growth after 5 days of incubation to interpret the results, the test should be repeated. Three days typically is sufficient for *M. fortuitum* complex; *M. chelonae* and *M. abscessus* usually require 4 days (occasionally 5 days). The MIC is defined as the lowest concentration of antimicrobial agent that completely inhibits visible growth. As with other types of bacteria, "trailing" is common when testing sulfonamides, and the MICs of these agents should be read at approximately 80% inhibition of growth. Trailing also is often seen with isolates of *M. fortuitum* group and clarithromycin; when this occurs, the endpoint is read at the end of the trailing.

Reporting Results

MIC values and an interpretation, based on the breakpoints for the rapidly growing mycobacteria listed in Table 7 (28), are reported for each drug, with the following exceptions. Imipenem results should not be reported for *M. chelonae* or *M. abscessus.* This recommendation is based on data from a multicenter evaluation (174), which showed that imipenem MIC values for these two species (which usually are at the resistance breakpoint of 8 to16 μg/ml) were not reproducible, resulting in major category changes of susceptibility. As previously indicated, tobramycin results should be reported only for *M. chelonae*. Because tobramycin is the aminoglycoside of choice for *M. chelonae* infections, amikacin results need be reported only if the isolate of *M. chelonae* is tobramycin resistant.

Quality Control

The QC strain recommended for monitoring test performance and for verifying the concentration of antimicrobial agents is *M. peregrinum* ATCC 700686. *Staphylococcus aureus* ATCC 29213 is an acceptable alternative. QC tests should be performed on each new batch of test plates and once each week or each time testing is performed. Currently, interlaboratory proficiency testing available for testing rapidly growing mycobacteria is limited. Therefore, laboratories are encouraged to submit isolates to reference laboratories with extensive experience in testing these mycobacteria for confirmatory tests in lieu of a formal proficiency test program.

Alternative Susceptibility Testing Methods

In the last decade, drug susceptibility testing of mycobacteria has become a very dynamic field, spawning many new technologies that may prove successful in a clinical laboratory. They all comply with the CDC goal that susceptibility test results be available within a mean of 28 days from the time the specimen arrives in the laboratory (13). Some of these techniques are based on improved methods for measuring inhibition of growth, while others are based on molecular assays for both analytes that correlate with growth or direct detection of mutations associated with resistance (2). Methods that distinguish viable from nonviable tubercle bacilli include tetrazolium dye reduction (29, 48, 102), flow cytometry (99), and a particle-counting immunoassay to quantify mycobacterial antigen (41). Jacobs et al. (77) described a method based on the use of a luciferase reporter mycobacteriophage. The premise was that viable mycobacteria support the infection and multiplication of phages, whereas inhibited or killed mycobacteria do not. Therefore, mycobacteria susceptible to INH or RMP supported the phage infection and expressed luciferase. When exposed to INH or RMP, the cells were killed and no light was produced. This assay was modified to allow easy detection of the emitted light with a Polaroid film box (also known as the "Bronx box") (125). Cooksey et al. (30) introduced the luciferase gene into *M. tuberculosis* H37Ra by electroporation of a plasmid containing the luciferase gene linked to the *hsp60* promoter. The results of a broth microtiter assay with the luciferase-H37Ra strain were comparable to the results of a conventional broth microdilution assay. Cangelosi et al. (22) described an alternative approach based on the measurement of the precursor rRNA. In this assay, *M. tuberculosis* nucleic acid is probed with specific pre-16S rRNA stem sequences in the presence or absence of drugs that have a direct or indirect effect on rRNA synthesis. Responses to RMP and ciprofloxacin were

TABLE 7 Antimicrobial agents to test against rapidly growing mycobacteria by broth microdilution method[a]

Antimicrobial agent	Concn range (μg/ml)	MIC (μg/ml) for:			QC concn range (μg/ml) for:	
		Susceptible strains	Intermediate strains	Resistant strains	*M. peregrinum* ATCC 700686[g]	*S. aureus* ATCC 29213[g]
Amikacin[b]	1–128	≤16	32	≥64	≤1–4	1–4
Cefoxitin	2–256	≤16	32–64	≥128	16–32	1–4
Ciprofloxacin	0.125–16	≤1	2	≥4	≤0.125–0.5	0.125–0.5
Clarithromycin[c]	0.06–64	≤2	4	≥8	≤0.06–0.5	0.125–0.5
Doxycycline[d]	0.25–32	≤1	2–8	≥16	≤0.125–0.5	0.125–0.5
Imipenem[e]	1–64	≤4	8	≥16	2–16	
Sulfamethoxazole	1–64	≤32		≥64	≤1–4	32–128
Tobramycin[f]	1–32	≤4	8	≥16	4–8	0.125–1

[a] Table and footnotes are adapted from reference 28.

[b] An amikacin MIC of ≥64 μg/ml for *M. abscessus* is unusual and must be confirmed.

[c] Class agent for all newer macrolides. *M. chelonae* and *M. abscessus* should be read at 3 days but not more than 4 days. Trailing across a breakpoint should be interpreted as resistance with *M. fortuitum*.

[d] Doxycycline and minocycline are interchangeable.

[e] Do not report for *M. chelonae* or *M. abscessus*. An imipenem MIC of ≥8 μg/ml for *M. fortuitum* is unusual and should be confirmed.

[f] Report results only for *M. chelonae*.

[g] Expected range for QC purposes. Potencies of drug preparations also can be tested with *E. coli* ATCC 25922 and *Pseudomonas aeruginosa* ATCC 27853 and compared with expected ranges as described in CLSI document M7 (27).

detected within 24 and 48 h, respectively. Detectable pre-rRNA was depleted in susceptible cells but remained abundant in resistant cells. The ability of RMP to block the lytic cell cycle of bacteriophage D29 within susceptible *M. tuberculosis* and hence the production of plaques on a lawn has led to another bacteriophage-based assay for susceptibility testing of *M. tuberculosis* to a variety of drugs (43, 44).

Mutations in genes that encode targets of antimycobacterial agents (Table 2) can be detected by a variety of methods. A particular focus of such studies has been RMP resistance because of the pivotal role of RMP in the treatment of tuberculosis and other mycobacterial infections and the conserved nature of the genetic basis for resistance (>96% of RMP resistance correlates with mutations in an 81-bp segment of the *rpoB* gene). The methods used to detect *rpoB* mutations include PCR amplification of the target sequence and detection by DNA sequencing (71, 79, 150; V. Sintchenko, P. J. Jelfs, W. K. Chew, and G. L. Gilbert, Letter, *J. Antimicrob. Chemother.* **44:**294–295, 1999), the line probe assay (31, 37, 88), single-strand conformation polymorphism (45, 151), dideoxy fingerprinting (45), the mismatch RNA-RNA protection assay (105), the heteroduplex generator assay (167), the use of molecular beacons synthesized from modified oligonucleotides (86, 116), and PCR–enzyme-linked immunosorbent assay (50). Similar approaches have been developed for detecting mutations involved in INH (124), EMB and RMP (163), and PZA (35, 100) resistance. Torres et al. (154) have proposed real-time PCR coupled to fluorescence detection for a rapid detection of RMP and INH resistance associated with mutations in *M. tuberculosis*. DNA microarray technology described for mycobacterial identification has also been applied to the efficient detection of mutations associated with resistance to TB drugs (94, 155). Undoubtedly, the application of these assays for routine use in the clinical mycobacteriology laboratory is likely to require technical simplification or automation as well as outcome analysis to justify the anticipated increased costs compared with conventional approaches. Indeed, even if these goals are achieved, it is likely that there are many more mutations to be discovered before antimicrobial resistance in *M. tuberculosis* and other mycobacteria can reliably be detected by molecular assays.

NOCARDIA AND OTHER AEROBIC ACTINOMYCETES

Clinical Significance

Nocardia spp. and other aerobic actinomycetes (*Actinomadura, Rhodococcus, Gordonia, Tsukamurella,* and *Streptomyces* spp.) can cause serious disease in healthy hosts, and infections by these microorganisms in immunocompromised hosts can be systemic and life threatening (84). Combination antimicrobial therapy for several months is often necessary to achieve a positive outcome. In vitro susceptibility testing may be of great value in guiding treatment and monitoring for resistance.

Testing Method

The antimicrobial agents that are recommended for primary and secondary in vitro susceptibility testing are listed in Table 8. The broth microdilution method described for rapidly growing mycobacteria is recommended for testing *Nocardia* and other aerobic actinomycetes (28). The inoculum should

TABLE 8 Antimicrobial agents to test against *Nocardia* and other aerobic actinomycetes[a]

Antimicrobial agent	Concn range (μg/ml)	MIC (μg/ml) for:			QC concn (μg/ml) for[e]:	
		Susceptible strains	Intermediate strains	Resistant strains	*S. aureus* ATCC 29213	*E. coli* ATCC 35218
Primary						
Amikacin[b]	1–16	≤8		≥16	1–4	
Amoxicillin-clavulanic acid	2/1–32/16	≤8/4	16/8	≥32/16	0.12/0.06–0.5/0.25	4/2–16/8
Ceftriaxone	4–64	≤8	16–32	≥64	1–8

Doxycycline	0.5–8	≤1	2–4	≥8	0.12–1	
Gentamicin	1–16	≤4	8	≥16	0.12–1	

[a] Table and footnotes are adapted from reference 28.
[b] The breakpoints for these antimicrobial agents are different from the current CLSI recommendations for organisms that grow aerobically.
[c] Used as a class agent for newer macrolides.
[d] Proposed breakpoint. No *Nocardia* isolates with linezolid MICs of >8 μg/ml have been reported.
[e] At present there are no standard quality control strains of *Nocardia* or other aerobic actinomycetes. These standard *S. aureus* and *E. coli* strains should be used for QC of the concentration of antimicrobial agents.

be prepared as a suspension of microorganisms harvested from a blood agar plate that was incubated for 1 to 3 days at 37°C in air. Some species may require incubation for up to 5 days in order to have sufficient growth. Presently there are no standard strains available for QC, but standard strains of *S. aureus* and *E. coli* can be used for QC of the drug preparations.

Reporting of Results

MIC values and an interpretation, based on the breakpoints for *Nocardia* spp. and other aerobic actinomycetes listed in Table 8 (28), are reported for each drug. The interpretive criteria recommended for the aerobic actinomycetes by the CLSI in document M24-A for amikacin, minocycline, and sulfamethoxazole are different from the criteria for rapidly growing aerobic bacteria recommended by the CLSI in document M7-A5 (27).

Detection and Characterization of Antimicrobial Resistance Genes in Pathogenic Bacteria

J. KAMILE RASHEED, FRANKLIN COCKERILL, AND FRED C. TENOVER

78

For the last several years, innovative new technologies for clinical microbiology laboratories have focused on decreasing the time required to detect pathogenic microorganisms directly in clinical samples. However, the dramatic increase in multidrug resistance among a plethora of bacterial genera has necessitated the development of tests specifically designed to detect resistant strains, particularly to guide infection control efforts in health care facilities. Rapid tests that identify patients colonized or infected with organisms, such as methicillin-resistant *Staphylococcus aureus* (MRSA) and vancomycin-resistant enterococci, can save infection control programs thousands of dollars each year by permitting isolation rooms to be utilized more effectively than would otherwise be the case (208, 247). Yet, multidrug resistance is not an issue just among health care-associated pathogens. Multidrug-resistant *Salmonella* species (258) and pneumococci (123) are among the community-associated pathogens that pose therapeutic challenges.

A wide variety of DNA probes and PCR assays focused on the detection of acquired resistance genes have been described over the last two decades (42, 229). Within the last few years, reports of several novel methods of detecting resistance genotypes have appeared in the literature. These include real-time PCR assays with molecular beacons, peptide-nucleic acid fluorescent in situ hybridization probes, microarrays, and pyrosequencing methods. In addition, sets of PCR primers designated analyte-specific reagents (ASRs) are available commercially. This chapter will focus specifically on genotypic methods for detecting and characterizing antimicrobial-resistant bacterial pathogens. Molecular methods for characterizing viruses and fungi are covered elsewhere in this Manual.

RATIONALE FOR USING GENETIC TESTS TO DETECT RESISTANCE GENES

There are four major reasons to use genetic tests to identify antimicrobial resistance genes or mutations associated with resistance. First, genetic methods can be used to detect resistance genes, or mutations that are associated with resistance, in organisms directly in clinical specimens. These results may be used to guide therapy or to decide whether to place a patient in a hospital isolation room.

Second, genetic methods can arbitrate MIC results that are at or near the breakpoint for resistance for bacterial species. For example, isolates of *S. aureus* for which the oxacillin MICs are between 2 and 8 μg/ml (borderline resistant) may contain the *mecA* (methicillin) resistance gene determinant or may represent a falsely resistant result from an automated susceptibility testing method (76, 222). A test indicating the absence of *mecA* in an isolate of *S. aureus* suggests that a physician could use an antimicrobial agent other than vancomycin to treat the infection.

Third, genetic tests are more accurate than analysis of resistance phenotypes for monitoring the epidemiologic spread of a particular resistance gene in a hospital or community setting. For example, tracking the spread of the *vanA* vancomycin resistance gene in enterococci or *S. aureus* with PCR assays has been helpful in documenting the spread of multiresistant enterococci in Europe (1, 83) and vancomycin-resistant *S. aureus* (VRSA) in the United States (33).

Fourth, genetic tests can be used as the "gold standard" for resistance tests in evaluating the accuracy of new susceptibility testing methods (54, 221).

However, there are several potential pitfalls associated with using genetic tests to detect resistant organisms. These include the lack of expression of resistance genes that are detected (28), the problem of mixed or normal flora that may contain resistance genes (such as *vanB* in *Clostridium* species in fecal samples) (14, 15), mutations in target organisms that alter sequences used for PCR primers and lead to false-negative results, and the emergence of novel resistance genes that are not detected by existing genetic assays. Each of these factors can affect the sensitivity or specificity of molecular assays (42).

GENETIC TESTS FOR RESISTANCE GENES AND DNA SEQUENCING STRATEGIES TO DETECT MUTATIONS ASSOCIATED WITH RESISTANCE

General Guidelines

The ideal genetic test targets nucleic acid sequences within the open reading frame (or coding region) of the resistance gene and avoids sequences outside of the gene that may contain insertion elements or promoter sequences that may be present in susceptible strains or strains with other types of resistance genes. Among the primers that have been described for studying antibacterial resistance are those directed to β-lactamase genes and the genes that encode resistance to aminocyclitols,

aminoglycosides, chloramphenicol, glycopeptides, isoniazid, macrolides, mupirocin, oxazolidinones, quinolones, rifampin, sulfonamides, tetracyclines, and trimethoprim. Examples of PCR primers that target resistance genes or mutations associated with resistance are shown in Table 1. In addition, multiplex PCR assays for the detection of aminoglycoside resistance genes in enterococci, plasmid-carried *amp*C genes in *Enterobacteriaceae,* and glycopeptide resistance genes in enterococci and staphylococci are shown in Table 2. The tables are not meant to be exhaustive but rather give an indication of the types of assays that have been described previously. Appropriate specificity controls (organisms that have a similar resistance pattern but contain resistance genes other than the target gene) should always be included in all reactions using these primers. Examples of DNA probes that can be used to detect resistance genes have been described in previous editions of this Manual (229).

DNA Sequencing

DNA sequence analysis has been particularly helpful for identifying point mutations associated with resistance to fluoroquinolones (54, 86, 104), extended-spectrum β-lactamases (19, 183, 184), oxazolidinones (257), and antimycobacterial drugs (139, 224). There are a number of mutations associated with resistance to isoniazid, rifampin, and streptomycin (10, 69, 266). Unfortunately, additional genetic loci associated with resistance must also be involved since only 60 to 90% of resistance can be explained by these loci, although pyrosequencing assays have improved detection (10, 266). Other novel pyrosequencing assays that target mutations associated with resistance, such as changes in rRNA sequences associated with linezolid resistance, can provide high-throughput results in a few hours (205).

In-House Assays and ASRs

Utilization of home-brew PCR assays for detecting resistance genes or implementing assays reported in the literature in a clinical microbiology laboratory has always been a problem. In-house validation of research protocols can be time-consuming. Yet, many of these assays provide significant advances in turnaround time or cost-effectiveness over those of traditional test methods. A recent advancement is the availability of ASRs. In the United States, reagents for nucleic acid amplification-based technologies may be available from manufacturers in the form of ASRs. ASRs are produced under "good manufacturing practices"; however, unlike Food and Drug Administration (FDA)-cleared diagnostic kits, the clinical utility of the ASRs does not have to be validated in prospective multisite trials before marketing. The process of making materials available through ASRs has its advantages and drawbacks. Because time-consuming clinical trials are obviated, the ASRs can be available to clinical laboratories much sooner than diagnostic kits. From the manufacturers' perspective, the process allows a product to be evaluated by a number of users to ensure optimal performance. Therefore, if optimization of an ASR is indicated, this can be accomplished before time-consuming and costly clinical trials are undertaken for an FDA-approved kit version. A major drawback of ASRs, in contrast to FDA-approved kits, is that FDA guidelines prohibit the provision of testing protocols for the ASRs by the manufacturer. Manufacturers can only refer customers to protocols published in the medical literature or to scientists or practitioners who have established working protocols in their laboratories. Another drawback of ASRs relates to the extent of verification required by certifying agencies before tests can be implemented in clinical practice. For example, the Clinical Laboratory Improvement Amendments of 1988 require a more extensive verification process for ASRs than for FDA-approved kits (44). The FDA requires laboratories to add a disclaimer on reports for tests that use ASRs. The mandatory language for this disclaimer is, "This test was developed and its performance characteristics determined by the (laboratory name). It has not been cleared or approved by the U. S. FDA" (45).

SPECIFIC APPLICATIONS

The following sections review applications of molecular diagnostic methods for specific classes of resistance determinants.

AMINOGLYCOSIDE RESISTANCE GENES

The diversity of known aminoglycoside resistance genes, which are common in both gram-positive and gram-negative organisms (173, 201, 260), continues to expand with the recognition of additional acetyltransferases, adenylyltransferases, and phosphotransferases. Unfortunately, the lack of consensus sequences among the acetyltransferase and adenylyltransferase genes prohibits detection of multiple determinants with a single PCR primer set (201), making it difficult to use amplification-based tests to predict aminoglycoside resistance, especially in gram-negative organisms. However, multiplex assays for high-level gentamicin resistance in enterococci (Table 2) are available to predict the effectiveness of combination therapy (synergy) with aminoglycosides and cell wall-active agents (116, 239). Among the newer aminoglycoside resistance genes reported to be found in gram-negative organisms is the *arm*A resistance determinant (75, 82, 261).

DETECTING GENES ASSOCIATED WITH RESISTANCE TO β-LACTAM DRUGS

Oxacillin Resistance in Staphylococci

Detection of oxacillin resistance in staphylococci, which is mediated primarily by the *mec*A determinant (32), by phenotypic methods continues to be a problem (222), particularly with coagulase-negative staphylococci (228). A *mec*A PCR assay can differentiate those isolates that are borderline resistant to oxacillin due to the modification of penicillin binding proteins (PBPs; the so-called MOD strains) or the production of large quantities of β-lactamase from isolates that are resistant due to the presence of the *mec*A determinant (132). The rare strains of *S. aureus* that are resistant to oxacillin by virtue of containing modified PBPs with reduced affinity for oxacillin may be misclassified as oxacillin susceptible by the *mec*A gene test since these strains are truly oxacillin resistant but do not contain the *mec*A gene (231, 247). A latex agglutination assay to identify the *mec*A gene product, i.e., PBP 2a, can be used for isolated colonies of *S. aureus* (28, 99, 241). These tests provide an alternative to phenotypic tests for the clinical microbiology laboratory, presuming that the caveats of their use are understood.

An increasing body of evidence demonstrates that identification and isolation of hospitalized patients who are nasal carriers of MRSA can reduce the incidence of health care-associated infections caused by these organisms and can reduce costs (161). Therefore, emphasis has been placed on the importance of active microbiology surveillance programs for the detection of nasal carriers of MRSA in the health care

[a] This reference also describes primer sets for the detection of *aac*(6′)*-Ib*, *aac*(6′)*-Id*, *aac*(6′)*-If*, *aac*(6′)*-Ig*, and *aac*(6′)*-Ih*.
[b] This reference also describes primer sets for the detection of *aac*(6′)*-Id*, *aac*(6′)*-Ie*, *aac*(6′)*-Ig*, *aac*(6′)*-Ih*, *aac*(6′)*-Ii*, *aac*(6′)*-Ij*, *aac*(6′)*-Il*, and *aac*(6′)*-IIb*.
[c] This reference also describes primer sets for the detection of *aac*(3)*-IIa*, *aac*(3)*-IIIa*, *aac*(3)*-IVa*, *aad*(4′)*-Ia*, *aac*(6′)*-aph*(2″), and *aph*(3′)*-IIIa*.
[d] This primer set is used in this reference for the synthesis of an intragenic probe and not for direct detection.
[e] This reference also describes primer sets for the detection and sequencing of bla_{SHV} and the detection of bla_{TEM}.
[f] This primer set amplifies genes encoding PSE-1, PSE-4, and CARB-3.
[g] This primer set amplifies both the *nmcA* structural gene and its regulatory gene, *nmcR*.
[h] This primer set is one of six that comprise a multiplex PCR method for the detection of members of six families of plasmid-mediated *amp*C β-lactamase genes.
[i] This reference also describes primer sets for the detection and/or sequencing of bla_{FOX}, bla_{CMY}, and $bla_{ACT\text{-}1}$.
[j] This reference also describes primer sets for the detection of *vanB*, *vanC1*, and *vanC2*.
[k] This reference also describes primer sets for the DNA sequencing of *par*C and *parE* of *E. coli*.
[l] SSCP, single-strand conformational polymorphism.
[m] This reference also describes primer sets for the synthesis of probes for *tet*(C), *tet*(D), *tet*(E), *tet*(G), *tet*(H), and *tet*(M).
[n] This reference also describes primer sets for the synthesis of probes for *tet*(A), *tet*(B), *tet*(C), *tet*(D), and *tet*(G).
[o] RFLP, restriction fragment length polymorphism.
[p] This primer set also amplifies *dfrA5, dfrA15, dfrA15b, dfrA16*, and *dfrA16b*.
[q] I, inosine (International Union of Biochemistry [IUB] codes for DNA bases).
[r] This primer set also amplifies *dfrA1, dfrA5, dfrA6, dfrA15*, and *dfrA16*.
[s] This primer set also amplifies *dfrA17*.
[t] This primer set also amplifies *dfrB2 and dfrB3*.
[u] S, G, or C (International Union of Biochemistry [IUB] codes for DNA bases).
[v] This primer set also amplifies *dfrA13*.

Staphylococcus epidermidis gene fragment	125[b]	

[a] This reference describes primers for the detection of genes within six plasmid-mediated *amp*C-specific gene families in the *Enterobacteriaceae*.
[b] This PCR product is amplified with primers complementary to a chromosomal fragment specific for *S. epidermidis*.

setting. Conventional culture-based methods for detection of MRSA from nasal swabs frequently require ⩾48 h before a final report can be issued. Various studies have evaluated molecular methods that detect nasal carriers of MRSA more rapidly than conventional culture-based methods (96, 161, 247). For example, Warren and colleagues demonstrated the utility of a commercially available real-time PCR method for identifying MRSA directly from nasal swabs (247). This testing method anchors one primer in *orf X,* which is unique to the *S. aureus* chromosome, and the second in the staphylococcal chromosomal cassette carrying the *mec*A gene (SCCmec), which is adjacent to *orf X* (96). These investigators showed that this assay is as sensitive as a direct plating culture method; final results were available within 2 h versus 48 to 72 h for results from culture.

β-Lactam Resistance in Pneumococci

Resistance to penicillin, extended-spectrum cephalosporins, and other antimicrobial agents in pneumococci has become a global problem (123, 133). Resistance to β-lactams develops when pneumococcal PBPs are remodeled through the acquisition of chromosomal DNA from other pneumococci or other streptococcal species (46, 63). Although remodeling is not a random process, it has been difficult to develop PCR primers that accurately differentiate strains with low-level penicillin resistance from those with high-level resistance. Using primers for the *pbp2b* gene, Ubukata et al. (236) attempted to resolve this issue. In their assay, the lack of product in the presence of amplification controls suggests that the *pbp2b* gene had been remodeled and therefore mediates resistance. However, such an assay does not reliably indicate which strains could be treated with penicillin versus an extended-spectrum cephalosporin, as might be desirable for an assay to be used in a clinical laboratory, but may be used as a screening tool for analyzing large groups of strains for resistance. A study by du Plessis et al. (64) also attempted to identify penicillin-resistant pneumococci directly in cerebrospinal fluid by using PCR primers directed to *pbp2b* sequences. This method was modestly successful in identifying isolates with altered PBPs associated with penicillin resistance.

β-Lactamase Genes in Gram-Negative Organisms

A variety of PCR primer sets have been developed to detect the genes encoding the TEM, SHV, OXA, CTX-M, GES, and AmpC (e.g., CMY-2, DHA-1, and MIR-1) β-lactamases and the metallo-β-lactamases (e.g., VIM-1 and SPM-1) present in gram-negative organisms (Tables 1 and 2).

Health care-associated infections caused by *Klebsiella pneumoniae, K. oxytoca* (7, 72, 198, 214), and other *Enterobacteriaceae* that produce extended-spectrum β-lactamases (49, 129) and other enzymes capable of hydrolyzing cefotaxime, ceftriaxone, ceftazidime, cefepime, and aztreonam are increasing in the United States and around the world (7, 18, 23, 78, 103, 122, 160, 253). More important are the emerging KPC-type carbapenemases that mediate resistance to imipenem, meropenem, and ertapenem (24, 27, 95, 140, 256, 262, 263). Resistance mediated by these determinants may be missed by automated methods (26). Other carbapenemases, including NmcA, Sme-1, IMI-1, and GES-2 and IMP-, VIM-, and some class D OXA-type enzymes (142, 145, 175, 185, 200, 203, 246), present in *Enterobacteriaceae, Acinetobacter* species, and *Pseudomonas* species continue to mediate resistance to imipenem and, in most cases, meropenem. Phenotypically, it can be difficult to differentiate resistance caused by a carbapenemase from resistance mediated by an AmpC-type enzyme in a strain with decreased permeability to carbapenems due to down-regulation of one or more porins (25, 102, 169). Thus, PCR assays directed to AmpC β-lactamases (163) and carbapenemase genes (Table 1) can be useful in differentiating the two mechanisms. This differentiation may be facilitated by the findings in a recent report describing a multiplex PCR method for the detection of plasmid-mediated AmpC β-lactamases (Table 2) (163) and specific inhibition of these enzymes by boronic acid compounds (47, 259).

CHLORAMPHENICOL RESISTANCE

Genes encoding chloramphenicol acetyltransferases are present in both gram-negative and gram-positive organisms and mediate resistance to chloramphenicol (199, 202). PCR primers capable of detecting the *cat* genes present in streptococci and enterococci have been described previously (232). Primers to detect the *cat*A1 and *cml*A genes, both of which mediate chloramphenicol resistance in *Salmonella* species (87, 88), have also been reported previously.

RESISTANCE TO VANCOMYCIN AND OTHER GLYCOPEPTIDES

Acquired vancomycin resistance was first noted in enterococci (117, 187, 237) but has subsequently been documented in a variety of other pathogens (14, 15, 159, 176, 177, 215), including *S. aureus* (31, 33, 248). Glycopeptide resistance is mediated by several different determinants, including *van*A, *van*B, *van*C, *van*D, *van*E, and *van*G (11, 50, 57, 68, 134, 155, 164, 196). The *van*A determinant has spread via conjugation from enterococcal donors to five independent isolates of *S. aureus* in the United States (33, 230, 248; Centers for Disease Control and Prevention, unpublished data). Molecular analysis of the transposons involved has shown differences among the first four isolates examined (40; Centers for Disease Control and Prevention, unpublished data). The first VRSA isolate from Michigan and the fourth VRSA isolate (also from Michigan) demonstrate a classic Tn*1546* structure; the others contain insertion sequences but also show deletions at the 5′ end of the transposon (40). PCR assays can differentiate the three unique *vanB* genes, designated *vanB1, vanB2,* and *vanB3* (51, 120), and the three *van*C genes, *vanC1, vanC2,* and *vanC3* (39). Subtypes of *vanD,* including *vanD1, vanD2, vanD3,* and *vanD4,* also exist, but differentiation via PCR is difficult (21, 53). PCR has been used to detect *van*A and *vanB* in enterococci in fecal samples to aid infection control efforts (156, 197). Furthermore, a multiplex PCR method has been developed for the simultaneous detection of the *van* alphabet (*vanA, vanB, vanC, vanD, vanE*, and *van*G) and identification of the most clinically relevant enterococci and staphylococci at the species level (Table 2) (59). Commercial ASRs have become available for the direct and rapid detection of *van*A and *vanB* genes in perirectal swab samples by using real-time PCR. A recent report indicated enhanced sensitivity and a significant reduction in the time to results (3.5 versus ⩾72 h) for one ASR assay compared with those for vancomycin-containing agar plates (208). False-positive results may potentially occur with any assay intended to detect *vanB* genes in enterococci due to the occasional presence of these genes in anaerobic bacteria (14, 15, 62). However, as *van* genes from these organisms could potentially be transferred to enterococci, it may still be important from the infection control perspective to identify them, although this issue remains controversial. Genotypic detection of vancomycin-intermediate *S. aureus* strains has yet to be accomplished via molecular methods.

MACROLIDE, LINCOSAMIDE, AND STREPTOGRAMIN RESISTANCE

Resistance to macrolides, lincosamides (such as clindamycin), and streptogramins can be mediated by a variety of *erm* genes including *ermA* and *ermA* (subclass *ermTR*), *ermB*, and *ermC*. On the other hand, *msrA,* which is primarily in staphylococci, mediates resistance only to macrolides and streptogramins and the macrolide efflux gene *mefA*, found in streptococci and pneumococci, confers resistance to 14- and 15-membered macrolides only (36, 70, 154, 174, 192, 254, 255). Roberts et al. (192) proposed that *mefA* and *mefE,* which show high levels of DNA homology, be considered a single class. However, others suggest that, in spite of the high degree of relatedness of the genes, a distinction between them should be maintained because of significant differences that exist between them (114). A real-time PCR assay which can distinguish *mefA* and *mefE* has been described previously (115). Pneumococci containing both *ermB* and *mefA* are being identified with increasing frequency (67). Many community-associated MRSA isolates are erythromycin resistant and clindamycin susceptible and contain *msrA* (111). PCR assays can differentiate *msrA* from *erm* genes (113, 213). Mutations in 23S rRNA and ribosomal protein L4 mutations in pneumococci have also been shown to mediate macrolide resistance and can be detected through traditional PCR or pyrosequencing assays (58, 89, 223).

Mechanisms active against both the streptogramin A and streptogramin B components of quinupristin-dalfopristin are necessary to result in a resistance phenotype. Several of the loci previously classified as *sat* genes have been reclassified as *vat* genes (93, 192, 250, 251). For example, *vatD* is the former *satA* and *vatE* is the former *satG*. Resistance to the streptogramin B component is mediated by the lactonases *vgb* and *vgbB* or the *ermB* methylase. In staphylococci, in particular, many of these genes are clustered together.

MUPIROCIN RESISTANCE

Mupirocin is an antistaphylococcal agent that is used to reduce nasal carriage of staphylococci among infected patients and hospital personnel. A PCR assay that can detect high-level mupirocin resistance has been described previously (81). However, the practical value of the assay has not been assessed in a clinical laboratory setting.

OXAZOLIDINONE RESISTANCE

Resistance to the oxazolidinone, or linezolid, among staphylococci and enterococci has been described previously (13, 234, 252, 255). Mutations in 23S rRNA, usually at position 2576, are responsible for the resistance phenotype (178). Detection of the G2576T mutations in enterococci can be accomplished by using a simple PCR assay followed by restriction fragment length polymorphism analysis of the products. Alternatively, the mutation can be detected by using pyrosequencing (205, 257).

QUINOLONE RESISTANCE

There are two major mechanisms of quinolone resistance: (i) alteration of the target sites, the organism's gyrase (*gyrA* and *gyrB)*, and topoisomerase (*par*C and *parE)* (66, 100, 224, 225, 233) and (ii) active efflux of the drug out of the cell (56, 66, 100, 162), which limits access of the drug to the target site. Resistance is usually associated with point mutations in the *gyr* or *par* loci. Since DNA probes, in most cases, are not sufficiently sensitive to detect these changes, investigators have used PCR coupled with direct sequencing of the amplification products to identify changes in the nucleotide sequences of the *gyrA, gyrB, par*C, and *parE* genes (86, 104, 109, 244). The primers, however, appear to be species specific (Table 1). Low-level fluoroquinolone resistance mediated by the novel resistance genes of the *qnr* family (100, 106, 146, 172), which are frequently plasmid carried, can be detected via PCR (101, 126, 193).

SULFONAMIDE RESISTANCE

There are three major sulfonamide resistance genes, *sul*I, *sul*II, and *sul*III. All three have been cloned and sequenced, and PCR assays for each gene have been described (85, 98, 181). Interestingly, the *sul* genes are often associated with transposable DNA elements, such as Tn*21* and small, multicopy plasmids (84, 98), that can shuttle multiple resistance genes from organism to organism. Thus, the *sul* genes can serve as indicators of multidrug resistance in gram-negative organisms.

TETRACYCLINE RESISTANCE

Tetracycline resistance is widespread among the bacterial kingdom (35, 121, 190). PCR assays have been developed for the *tet*(A), *tet*(B), *tet*(C), *tet*(D), *tet*(E), *tet*(F), *tet*(H), *tet*(K), *tet*(L), *tet*(M), *tet*(N), *tet*(O), *tet*(Q), *tet*(S), *tet*(U), and *tet*(V) determinants (34, 60, 61, 71, 73, 92, 127, 130, 189, 209, 210, 265). Multiple alleles of several of these determinants exist. For example, there are six *tet*(M) alleles present in *Streptococcus pneumoniae,* designated *tet*(M)1 through *tet*(M)6, that have been differentiated through restriction analysis of PCR fragments (61). Such epidemiologic studies using genotyping of resistance determinants contribute to our understanding of resistance transfer and evolution. Primers for the *tet*(M), *tet*(O), and *tet*(Q) determinants are useful for detecting tetracycline resistance genes directly in periodontal samples (151, 152), where the presence of resistant organisms may indicate those patients who are likely to fail therapy with tetracycline (127). Multiple types of the *tet*(M) gene also have been recognized through sequence analysis (153).

TRIMETHOPRIM RESISTANCE

The number of genes capable of mediating trimethoprim resistance in bacteria continues to expand (9, 97, 98, 119, 206). DNA probes have proven to be powerful tools for detecting and classifying novel trimethoprim resistance genes (called *dhfr*) (9, 105, 179). However, because consensus sequences common to all the *dhfr* genes have not been identified, PCR primers that could simplify the detection of this family of genes have not been developed, although PCR primers for some individual genes have been developed (52, 88, 119, 218).

GUIDELINES FOR USING GENETIC TESTS

PCR assays in which the products are visualized on agarose gels are rapidly being replaced by real-time PCR assays using fluorescent resonance energy transfer probes or molecular beacons for detection of amplification products. These closed systems are more efficient and less prone to overall contamination than traditional PCR assays. The critical issue with PCR assays of any sort, however, is the reliability of results. The need for quality control measures, including controls for the presence of inhibitory substances, cannot be stressed enough, especially for detection of genes directly in clinical specimens. The temperatures used in PCR assays optimized for use with purified DNA or DNA from bacterial isolates obtained in pure culture may not be stringent enough to avoid false-positive results when used with clinical samples, such as blood and cerebrospinal fluid, where considerably more nonspecific priming can occur (227). Using control reactions containing no template DNA to identify nonspecific products due to contamination of *Taq* polymerase with DNA, such as provided by cloning vector DNA, is critical (227, 235).

One should never assume that PCR primers reported in the literature have undergone rigorous testing. Rather, primer sets should be thoroughly tested for specificity, self-complementarity, and dimer formation before use. According to the Clinical Laboratory Improvement Amendments of 1988, validation of DNA probe and PCR tests by the clinical laboratory in which they are to be used is mandatory before they can be used for analysis of clinical specimens. Methods for validation are published by the Clinical and Laboratory Standards Institute (41).

Studies to determine the reservoirs of resistance genes and routes of resistance gene transfer in hospitals and community settings are still needed. Such studies would also help to determine the frequency with which organisms carry resistance genes that are not expressed. Although still considered experimental, many of the PCR methods for detecting resistance genes described herein are already having a positive effect on guiding therapy early in the course of infection and making the treatment of infectious diseases less empiric.

Editorial Board / xiii
Contributors / xv
Preface / xxv

VOLUME 1

SECTION I
GENERAL ISSUES IN CLINICAL MICROBIOLOGY / 1
VOLUME EDITOR: JAMES H. JORGENSEN
SECTION EDITOR: MELVIN P. WEINSTEIN

1 Introduction to the Ninth Edition of the *Manual of Clinical Microbiology* / 3
PATRICK R. MURRAY

2 Laboratory Management / 4
W. MICHAEL DUNNE, JR., AND MARK T. LAROCCO

3 Laboratory Design / 20
MICHAEL L. WILSON AND L. BARTH RELLER

4 Laboratory Consultation, Communication, and Information Systems / 30
JOSEPH M. CAMPOS

5 General Principles of Specimen Collection and Handling / 43
J. MICHAEL MILLER, KAREN KRISHER, AND HARVEY T. HOLMES

6 Procedures for the Storage of Microorganisms / 55
CATHY A. PETTI, KAREN C. CARROLL, AND LARRY G. REIMER

SECTION II
THE CLINICAL MICROBIOLOGY LABORATORY IN INFECTION DETECTION, PREVENTION, AND CONTROL / 63
VOLUME EDITOR: MICHAEL A. PFALLER
SECTION EDITOR: LOREEN A. HERWALDT

7 Decontamination, Disinfection, and Sterilization / 65
ANDREAS F. WIDMER AND RENO FREI

8 Prevention and Control of Laboratory-Acquired Infections / 97
MICHAEL A. NOBLE

9 Laboratory Detection of Potential Agents of Bioterrorism / 107
ROSEMARY HUMES AND JAMES W. SNYDER

10 Infection Control Epidemiology and Clinical Microbiology / 118
DANIEL J. DIEKEMA AND MICHAEL A. PFALLER

11 Laboratory Procedures for the Epidemiological Analysis of Microorganisms / 129
DAVID R. SOLL, CLAUDE PUJOL, AND SHAWN R. LOCKHART

12 Investigation of Foodborne and Waterborne Disease Outbreaks / 152
TIMOTHY F. JONES

SECTION III

DIAGNOSTIC TECHNOLOGIES IN CLINICAL MICROBIOLOGY / 171
VOLUME EDITOR: JAMES H. JORGENSEN
SECTION EDITOR: MELVIN P. WEINSTEIN

13 Microscopy / 173
DANNY L. WIEDBRAUK

14 Principles of Stains and Media / 182
KIMBERLE C. CHAPIN

15 Manual and Automated Systems for Detection and Identification of Microorganisms / 192
KAREN C. CARROLL AND MELVIN P. WEINSTEIN

16 Molecular Detection and Identification of Microorganisms / 218
FREDERICK S. NOLTE AND ANGELA M. CALIENDO

17 Susceptibility Testing Instrumentation and Computerized Expert Systems for Data Analysis and Interpretation / 245
SANDRA S. RICHTER AND MARY JANE FERRARO

18 Immunoassays for the Diagnosis of Infectious Diseases / 257
A. BETTS CARPENTER

SECTION IV

BACTERIOLOGY / 272
VOLUME EDITOR: ELLEN JO BARON
SECTION EDITORS: J. STEPHEN DUMLER, GUIDO FUNKE, J. MICHAEL JANDA, IRVING NACHAMKIN, AND JAMES VERSALOVIC

GENERAL

19 Taxonomy and Classification of Bacteria / 275
PETER A. R. VANDAMME

20 Specimen Collection, Transport, and Processing: Bacteriology / 291
RICHARD B. THOMSON, JR.

21 Reagents, Stains, and Media: Bacteriology / 334
KIMBERLE C. CHAPIN AND TSAI-LING LAUDERDALE

22 Algorithm for Identification of Aerobic Gram-Positive Cocci / 365
KATHRYN L. RUOFF

23 Algorithm for Identification of Aerobic Gram-Positive Rods / 368
GUIDO FUNKE

24 Algorithms for Identification of Aerobic Gram-Negative Bacteria / 371
PAUL C. SCHRECKENBERGER AND DAVID LINDQUIST

25 Algorithm for Identification of Anaerobic Bacteria / 377
DIANE M. CITRON

26 Algorithms for Identification of Curved and Spiral-Shaped Gram-Negative Rods / 379
IRVING NACHAMKIN

27 Algorithms for Identification of *Mycoplasma, Ureaplasma*, and Obligate Intracellular Bacteria / 384
J. STEPHEN DUMLER

GRAM-POSITIVE COCCI

28 *Staphylococcus, Micrococcus*, and Other Catalase-Positive Cocci / 390
TAMMY L. BANNERMAN AND SHARON J. PEACOCK

29 *Streptococcus* / 412
BARBARA SPELLERBERG AND CLAUDIA BRANDT

30 *Enterococcus* / 430
LÚCIA MARTINS TEIXEIRA, MARIA DA GLÓRIA SIQUEIRA CARVALHO, AND RICHARD R. FACKLAM

31 *Aerococcus, Abiotrophia*, and Other Aerobic Catalase-Negative, Gram-Positive Cocci / 443
KATHRYN L. RUOFF

GRAM-POSITIVE RODS

32 *Bacillus* and Other Aerobic Endospore-Forming Bacteria / 455
NIALL A. LOGAN, TANJA POPOVIC, AND ALEX HOFFMASTER

33 *Listeria* and *Erysipelothrix* / 474
JACQUES BILLE

34 Coryneform Gram-Positive Rods / 485
GUIDO FUNKE AND KATHRYN A. BERNARD

35 *Nocardia, Rhodococcus, Gordonia, Actinomadura, Streptomyces*, and Other Aerobic Actinomycetes / 515
PATRICIA S. CONVILLE AND FRANK G. WITEBSKY

36 *Mycobacterium:* General Characteristics, Laboratory Detection, and Staining Procedures / 543
GABY E. PFYFFER

37 *Mycobacterium:* Laboratory Characteristics of Slowly Growing Mycobacteria / 573
VÉRONIQUE VINCENT AND M. CRISTINA GUTIÉRREZ

38 *Mycobacterium:* Clinical and Laboratory Characteristics of Rapidly Growing Mycobacteria / 589
BARBARA A. BROWN-ELLIOTT AND RICHARD J. WALLACE, JR.

GRAM-NEGATIVE BACTERIA

39 *Neisseria* / 601
WILLIAM M. JANDA AND CHARLOTTE A. GAYDOS

40 *Actinobacillus, Capnocytophaga, Eikenella, Kingella, Pasteurella*, and Other Fastidious or Rarely Encountered Gram-Negative Rods / 621
ALEXANDER VON GRAEVENITZ, REINHARD ZBINDEN, AND REINIER MUTTERS

41 *Haemophilus* / 636
MOGENS KILIAN

42 *Enterobacteriaceae:* Introduction and Identification / 649
J. J. FARMER III, K. D. BOATWRIGHT, AND J. MICHAEL JANDA

43 *Escherichia, Shigella*, and *Salmonella* / 670
JAMES P. NATARO, CHERYL A. BOPP, PATRICIA I. FIELDS, JAMES B. KAPER, AND NANCY A. STROCKBINE

44 *Yersinia* / 688
AUDREY WANGER

45 *Klebsiella, Enterobacter, Citrobacter, Serratia, Plesiomonas,* and Other *Enterobacteriaceae* / 698
SHARON L. ABBOTT

46 *Aeromonas* / 716
AMY J. HORNEMAN, AFSAR ALI, AND SHARON L. ABBOTT

47 *Vibrio* and Related Organisms / 723
SHARON L. ABBOTT, J. MICHAEL JANDA, JUDITH A. JOHNSON, AND J. J. FARMER III

48 *Pseudomonas* / 734
EDITH BLONDEL-HILL, DEBORAH A. HENRY, AND DAVID P. SPEERT

49 *Burkholderia, Stenotrophomonas, Ralstonia, Cupriavidus, Pandoraea, Brevundimonas, Comamonas, Delftia,* and *Acidovorax* / 749
JOHN J. LiPUMA, BART J. CURRIE, GARY D. LUM, AND PETER A. R. VANDAMME

50 *Acinetobacter, Achromobacter, Chryseobacterium, Moraxella,* and Other Nonfermentative Gram-Negative Rods / 770
PAUL C. SCHRECKENBERGER, MARYAM I. DANESHVAR, AND DANNIE G. HOLLIS

51 *Bordetella* / 803
MICHAEL J. LOEFFELHOLZ AND GARY N. SANDEN

52 *Francisella* and *Brucella* / 815
DAVID LINDQUIST, MAY C. CHU, AND WILL S. PROBERT

53 *Legionella* / 835
PAUL H. EDELSTEIN

54 *Bartonella* / 850
BRUNO B. CHOMEL AND JEAN MARC ROLAIN

ANAEROBIC BACTERIA

55 *Peptostreptococcus, Finegoldia, Anaerococcus, Peptoniphilus, Veillonella,* and Other Anaerobic Cocci / 862
YULI SONG AND SYDNEY M. FINEGOLD

56 *Propionibacterium, Lactobacillus, Actinomyces,* and Other Non-Spore-Forming Anaerobic Gram-Positive Rods / 872
EIJA KÖNÖNEN AND WILLIAM G. WADE

57 *Clostridium* / 889
ERIC A. JOHNSON, PAULA SUMMANEN, AND SYDNEY M. FINEGOLD

58 *Bacteroides, Porphyromonas, Prevotella, Fusobacterium,* and Other Anaerobic Gram-Negative Rods / 911
DIANE M. CITRON, IAN R. POXTON, AND ELLEN JO BARON

CURVED AND SPIRAL-SHAPED GRAM-NEGATIVE RODS

59 *Campylobacter* and *Arcobacter* / 933
COLLETTE FITZGERALD AND IRVING NACHAMKIN

60 *Helicobacter* / 947
JAMES G. FOX AND FRANCIS MEGRAUD

61 *Leptospira* / 963
PAUL N. LEVETT

62 *Borrelia* / 971
BETTINA WILSKE, BARBARA J. B. JOHNSON, AND MARTIN E. SCHRIEFER

63 *Treponema* and Other Human Host-Associated Spirochetes / 987
VICTORIA POPE, STEVEN J. NORRIS, AND ROBERT E. JOHNSON

MYCOPLASMAS AND OBLIGATE INTRACELLULAR BACTERIA

64 *Mycoplasma* and *Ureaplasma* / 1004
KEN B. WAITES AND DAVID TAYLOR-ROBINSON

65 *Chlamydia* and *Chlamydophila* / 1021
ANDREAS ESSIG

66 *Rickettsia* and *Orientia* / 1036
DAVID H. WALKER AND DONALD H. BOUYER

67 *Ehrlichia, Anaplasma,* and Related Intracellular Bacteria / 1046
JUAN P. OLANO AND MARIA E. AGUERO-ROSENFELD

68 *Coxiella* / 1062
PHILIPPE BROUQUI, THOMAS MARRIE, AND DIDIER RAOULT

69 *Tropheryma* / 1070
DIDIER RAOULT, FLORENCE FENOLLAR, AND DAVID RELMAN

SECTION V
ANTIBACTERIAL AGENTS AND SUSCEPTIBILITY TEST METHODS / 1075
VOLUME EDITOR: JAMES H. JORGENSEN
SECTION EDITORS: MARY JANE FERRARO AND JOHN D. TURNIDGE

70 Antibacterial Agents / 1077
JOSEPH D. C. YAO AND ROBERT C. MOELLERING, JR.

71 Mechanisms of Resistance to Antibacterial Agents / 1114
LOUIS B. RICE AND ROBERT A. BONOMO

72 Susceptibility Test Methods: General Considerations / 1146
JOHN D. TURNIDGE, MARY JANE FERRARO, AND JAMES H. JORGENSEN

73 Susceptibility Test Methods: Dilution and Disk Diffusion Methods / 1152
JAMES H. JORGENSEN AND JOHN D. TURNIDGE

74 Special Phenotypic Methods for Detecting Antibacterial Resistance / 1173
JANA M. SWENSON, JEAN B. PATEL, AND JAMES H. JORGENSEN

75 Susceptibility Test Methods: Fastidious Bacteria / 1193
JANET FICK HINDLER AND JEAN B. PATEL

76 Susceptibility Test Methods: Anaerobic Bacteria / 1214
DIANE M. CITRON AND DAVID W. HECHT

77 Susceptibility Test Methods: Mycobacteria, *Nocardia,* and Other Actinomycetes / 1223
GAIL L. WOODS, NANCY G. WARREN, AND CLARK B. INDERLIED

78 Detection and Characterization of Antimicrobial Resistance Genes in Pathogenic Bacteria / 1248
J. KAMILE RASHEED, FRANKLIN COCKERILL, AND FRED C. TENOVER

VOLUME 2

SECTION VI
VIROLOGY / 1270
VOLUME EDITOR: MARIE LOUISE LANDRY
SECTION EDITORS: ANGELA M. CALIENDO, YI-WEI TANG, AND ALEXANDRA VALSAMAKIS

GENERAL

79 Taxonomy and Classification of Viruses / 1273
CORNELIA BÜCHEN-OSMOND

80 Specimen Collection, Transport, and Processing: Virology / 1284
MICHAEL S. FORMAN AND ALEXANDRA VALSAMAKIS

81 Reagents, Stains, Media, and Cell Lines: Virology / 1297
KIMBERLE C. CHAPIN

82 Algorithms for Detection and Identification of Viruses / 1304
MARIE LOUISE LANDRY, ANGELA M. CALIENDO, YI-WEI TANG, AND ALEXANDRA VALSAMAKIS

RNA VIRUSES

83 Human Immunodeficiency Viruses / 1308
BRIGITTE P. GRIFFITH, SHELDON CAMPBELL, AND DONALD R. MAYO

84 Human T-Cell Lymphotropic Virus Types 1 and 2 / 1330
ANTOINE GESSAIN, CHARLENE S. DEZZUTTI, ELLIOT P. COWAN, AND RENU B. LAL

85 Influenza Viruses / 1340
ROBERT L. ATMAR

86 Parainfluenza and Mumps Viruses / 1352
DIANE S. LELAND

87 Respiratory Syncytial Virus and Human Metapneumovirus / 1361
YI-WEI TANG AND JAMES E. CROWE, JR.

88 Measles and Rubella Viruses / 1378
WILLIAM J. BELLINI AND JOSEPH P. ICENOGLE

89 Enteroviruses and Parechoviruses / 1392
JOSÉ R. ROMERO

90 Rhinoviruses / 1405
MARIE LOUISE LANDRY

91 Coronaviruses / 1414
JAMES B. MAHONY

92 Hepatitis A and E Viruses / 1424
DAVID A. ANDERSON

93 Hepatitis C and G Viruses / 1437
JOHN D. SCOTT AND DAVID R. GRETCH

94 Rotaviruses, Caliciviruses, Astroviruses, Enteric Adenoviruses, and Other Diarrheic Viruses / 1453
TIBOR FARKAS AND XI JIANG

95 Rabies Virus / 1470
LILLIAN A. ORCIARI AND CHARLES E. RUPPRECHT

96 Hendra and Nipah Viruses / 1478
PIERRE E. ROLLIN, PAUL ROTA, SHERIF ZAKI, AND THOMAS G. KSIAZEK

97 Arboviruses / 1486
ROBERT S. LANCIOTTI AND THEODORE F. TSAI

98 Hantaviruses / 1501
CHARLES F. FULHORST AND MICHAEL D. BOWEN

99 Arenaviruses and Filoviruses / 1510
PIERRE E. ROLLIN, STUART T. NICHOL, SHERIF ZAKI, AND THOMAS G. KSIAZEK

DNA VIRUSES

100 Herpes Simplex Viruses and Herpes B Virus / 1523
KEITH R. JEROME AND RHODA ASHLEY MORROW

101 Varicella-Zoster Virus / 1537
ANNE A. GERSHON, JINGXIAN CHEN, PHILIP LaRUSSA, AND SHARON P. STEINBERG

102 Human Cytomegalovirus / 1549
RICHARD L. HODINKA

103 Epstein-Barr Virus / 1564
ANNIKA LINDE AND KERSTIN I. FALK

104 Human Herpesviruses 6, 7, and 8 / 1574
PHILIP E. PELLETT AND GRAHAM TIPPLES

105 Adenoviruses / 1589
CHRISTINE ROBINSON AND MARCELA ECHAVARRIA

106 Human Papillomaviruses / 1601
BRUCE K. PATTERSON

107 Human Polyomaviruses / 1612
EUGENE O. MAJOR, CAROLINE RYSCHKEWITSCH, ALEXANDRA VALSAMAKIS, AND JEAN HOU

108 Human Parvoviruses / 1622
JEANNE A. JORDAN

109 Poxviruses / 1631
INGER K. DAMON

110 Hepatitis B and D Viruses / 1641
REBECCA T. HORVAT AND GARY E. TEGTMEIER

SUBVIRAL AGENTS

111 Transmissible Spongiform Encephalopathies / 1660
ADRIANO AGUZZI AND MARKUS GLATZEL

SECTION VII
ANTIVIRAL AGENTS AND SUSCEPTIBILITY TEST METHODS / 1667
VOLUME EDITOR: JAMES H. JORGENSEN
SECTION EDITOR: JOHN D. TURNIDGE

112 Antiviral Agents / 1669
NELL S. LURAIN AND KENNETH D. THOMPSON

113 Mechanisms of Resistance to Antiviral Agents / 1689
ROBERT W. SHAFER, SHIRIT EINAV, AND SUNWEN CHOU

114 Susceptibility Test Methods: Viruses / 1705
MAX Q. ARENS AND ELLA M. SWIERKOSZ

SECTION VIII
MYCOLOGY / 1719
VOLUME EDITOR: MICHAEL A. PFALLER
SECTION EDITOR: DAVID W. WARNOCK

GENERAL

115 Taxonomy and Classification of Fungi / 1721
DAVID W. WARNOCK

116 Specimen Collection, Transport, and Processing: Mycology / 1728
DEANNA A. SUTTON

117 Reagents, Stains, and Media: Mycology / 1737
MARK T. LAROCCO

118 Algorithms for Detection and Identification of Fungi / 1745
YVONNE R. SHEA

FUNGI

119 *Candida*, *Cryptococcus*, and Other Yeasts of Medical Importance / 1762
KEVIN C. HAZEN AND SUSAN A. HOWELL

120 *Pneumocystis* / 1789
MELANIE T. CUSHION

121 *Aspergillus*, *Fusarium*, and Other Opportunistic Moniliaceous Fungi / 1802
PAUL E. VERWEIJ AND MARY E. BRANDT

122 *Rhizopus*, *Rhizomucor*, *Absidia*, and Other Agents of Systemic and Subcutaneous Zygomycoses / 1839
MALCOLM D. RICHARDSON AND PIRKKO KOUKILA-KÄHKÖLÄ

123 *Histoplasma*, *Blastomyces*, *Coccidioides*, and Other Dimorphic Fungi Causing Systemic Mycoses / 1857
MARY E. BRANDT AND DAVID W. WARNOCK

124 *Trichophyton*, *Microsporum*, *Epidermophyton*, and Agents of Superficial Mycoses / 1874
RICHARD C. SUMMERBELL, IRENE WEITZMAN, AND ARVIND A. PADHYE

125 *Bipolaris*, *Exophiala*, *Scedosporium*, *Sporothrix*, and Other Dematiaceous Fungi / 1898
G. SYBREN DE HOOG AND ROXANA G. VITALE

126 Fungi Causing Eumycotic Mycetoma / 1918
G. SYBREN DE HOOG, ABDALLA O. A. AHMED, MICHAEL R. MCGINNIS, AND ARVIND A. PADHYE

127 Mycotoxins / 1928
WILLIAM J. HALSALL, NANCY C. ISHAM, AND MAHMOUD A. GHANNOUM

128 *Lacazia, Pythium*, and *Rhinosporidium* / 1936
LEONEL MENDOZA

SECTION IX
ANTIFUNGAL AGENTS AND SUSCEPTIBILITY TEST METHODS / 1947
VOLUME EDITOR: JAMES H. JORGENSEN
SECTION EDITOR: JOHN D. TURNIDGE

129 Antifungal Agents / 1949
SEVTAP ARIKAN AND JOHN H. REX

130 Mechanisms of Resistance to Antifungal Agents / 1961
THEODORE C. WHITE

131 Susceptibility Test Methods: Yeasts and Filamentous Fungi / 1972
ANA V. ESPINEL-INGROFF AND MICHAEL A. PFALLER

SECTION X
PARASITOLOGY / 1987
VOLUME EDITOR: MICHAEL A. PFALLER
SECTION EDITOR: LYNNE S. GARCIA

GENERAL

132 Taxonomy and Classification of Human Parasites / 1989
FRANCIS E. G. COX

133 Specimen Collection, Transport, and Processing: Parasitology / 1995
PETER DEPLAZES, LYNNE S. GARCIA, AND ROBYN Y. SHIMIZU

134 Reagents, Stains, and Media: Parasitology / 2013
SUSAN E. SHARP

135 Algorithms for Detection and Identification of Parasites / 2020
LYNNE S. GARCIA, ROBYN Y. SHIMIZU, AND GRAEME P. PALTRIDGE

PARASITES

136 *Plasmodium* and *Babesia* / 2040
WILLIAM O. ROGERS

137 *Leishmania* and *Trypanosoma* / 2057
DAVID A. BRUCKNER AND JAIME A. LABARCA

138 *Toxoplasma* / 2070
MARIANNA WILSON, JEFFERY L. JONES, AND JAMES B. McAULEY

139 Pathogenic and Opportunistic Free-Living Amebae / 2082
GOVINDA S. VISVESVARA

140 Intestinal and Urogenital Amebae, Flagellates, and Ciliates / 2092
AMY L. LEBER AND SUSAN NOVAK-WEEKLEY

141 *Isospora, Cyclospora,* and *Sarcocystis* / 2113
DAVID S. LINDSAY, STEVE J. UPTON, AND LOUIS M. WEISS

142 *Cryptosporidium* / 2122
LIHUA XIAO AND VITALIANO CAMA

143 Microsporidia / 2133
RAINER WEBER, ALEXANDER MATHIS, AND PETER DEPLAZES

144 Nematodes / 2144
HARSHA SHEOREY, BEVERLEY-ANN BIGGS, AND PETER TRAYNOR

145 Filarial Nematodes / 2156
TESS McPHERSON AND THOMAS B. NUTMAN

146 Cestodes / 2166
HECTOR H. GARCIA, JUAN A. JIMENEZ, AND HERMES ESCALANTE

147 Trematodes / 2175
MALCOLM K. JONES AND DONALD P. McMANUS

148 Less Common Helminths / 2188
GARY W. PROCOP AND RONALD C. NEAFIE

149 Arthropods of Medical Importance / 2199

Editorial Board

ANGELA M. CALIENDO SECTION VI

Department of Pathology and Laboratory Medicine, Emory University School of Medicine, 1364 Clifton Road, N.E., Atlanta, GA 30322

KIMBERLE C. CHAPIN REAGENTS, STAINS, MEDIA

Department of Pathology and Laboratory Medicine, Rhode Island Hospital, APC Building, 593 Eddy Street, Providence, RI 02903

J. STEPHEN DUMLER SECTION IV

Division of Medical Microbiology, Department of Pathology, The Johns Hopkins University School of Medicine, 720 Rutland Avenue, Ross 624, Baltimore, MD 21205

MARY JANE FERRARO SECTIONS V AND XI

Clinical Microbiology Laboratory, Massachusetts General Hospital, and Harvard Medical School, Boston, MA 02114

GUIDO FUNKE SECTION IV

Department of Medical Microbiology and Hygiene, Gärtner & Colleagues Laboratories, Elisabethenstrasse 11, D-88212 Ravensburg, Germany

LYNNE S. GARCIA SECTION X

LSG & Associates, 512-12th Street, Santa Monica, CA 90402-2908

LOREEN HERWALDT SECTION II

Department of Internal Medicine, C41S GH, University of Iowa College of Medicine, Iowa City, IA 52242

J. MICHAEL JANDA SECTION IV

Microbial Diseases Laboratory Branch, Division of Communicable Disease Control, California Department of Health Services, 850 Marina Bay Parkway, Room E164, Richmond, CA 94804

IRVING NACHAMKIN SECTION IV

Department of Pathology and Laboratory Medicine, University of Pennsylvania School of Medicine, 4th Floor, Gates Building, 3400 Spruce Street, Philadelphia, PA 19104-4283

YI-WEI TANG SECTION VI

Departments of Medicine and Pathology, Vanderbilt University Medical Center, 4605 TVC, 1161 21st Avenue, South, Nashville, TN 37232-5310

JOHN D. TURNIDGE SECTIONS V, VII, AND IX

Microbiology and Infectious Diseases, Women's and Children's Hospital, 72 King William Road, North Adelaide 5006, SA, Australia

ALEXANDRA VALSAMAKIS SECTION VI

Department of Pathology, Johns Hopkins Medicine, 600 North Wolfe Street, Meyer B1-193, Baltimore, MD 21287

JAMES VERSALOVIC SECTION IV

Department of Pathology, Texas Children's Hospital, 6621 Fannin Street, MC 1-2261, Houston, TX 77030

DAVID W. WARNOCK SECTION VIII

Division of Bacterial and Mycotic Diseases, National Center for Infectious Diseases, Centers for Disease Control and Prevention, 1600 Clifton Road, N.E., Mailstop C-09, Atlanta, GA 30333

MELVIN P. WEINSTEIN SECTIONS I AND III

Departments of Medicine and Pathology, Robert Wood Johnson Medical School, 1 Robert Wood Johnson Place, MEB 364, New Brunswick, NJ 08903-0019

Department of Medicine, Stanford University, Stanford, CA 94305

HERMES ESCALANTE
Department of Microbiology, School of Biological Sciences, Universidad Nacional de Trujillo, Av. Juan Pablo II S/N, Ciudad Universitaria, Trujillo, Peru

ANA V. ESPINEL-INGROFF
Medical Mycology Research Laboratory, Division of Infectious Diseases, VCU Medical Center, 1101 East Marshall Street, Sanger Hall Room 7-049, Richmond, VA 23298-0049

ANDREAS ESSIG
Department of Medical Microbiology and Hygiene, University Hospital Ulm, D-89081 Ulm, Germany

RICHARD R. FACKLAM
Streptococcus Laboratory, Respiratory Diseases Branch, Division of Bacterial Diseases, Centers for Disease Control and Prevention, Mail Stop C0-2, Atlanta, GA 30333

KERSTIN I. FALK
Centre for Microbiological Preparedness, Swedish Institute for Infectious Disease Control, SE-171 82 Solna, Sweden

TIBOR FARKAS
Division of Infectious Diseases, Department of Pediatrics, Cincinnati Children's Hospital Medical Center, University of Cincinnati College of Medicine, 3333 Burnet Avenue, Cincinnati, OH 45229-3039

J. J. FARMER III
United States Public Health Service (retired), 1781 Silver Hill Road, Stone Mountain, GA 30087-2212

FLORENCE FENOLLAR
Unité des Rickettsies, IFR 48, CNRS UMR 6020, Faculté de Médecine, 27 Boulevard Jean Moulin, 13385 Marseille Cedex 5, France

MARY JANE FERRARO
Clinical Microbiology Laboratory, Massachusetts General Hospital, and Harvard Medical School, Boston, MA 02114

PATRICIA I. FIELDS
Foodborne and Diarrheal Diseases Laboratory Section, Foodborne and Diarrheal Diseases Branch, Division of Bacterial and Mycotic Diseases, National Center for Infectious Diseases, Centers for Disease Control and Prevention, Atlanta, GA 30333

SYDNEY M. FINEGOLD
Infectious Diseases Section, VA Medical Center West Los Angeles, Los Angeles, CA 90073, and Department of Medicine and Department of Microbiology, Immunology, and Molecular Genetics, University of California at Los Angeles School of Medicine, Los Angeles, CA 90025

COLLETTE FITZGERALD
National *Campylobacter* and *Helicobacter* Reference Laboratory, Foodborne and Diarrheal Diseases Branch, Centers for Disease Control and Prevention, Atlanta, GA 30333

MICHAEL S. FORMAN
Department of Pathology, Johns Hopkins Medicine, 600 North Wolfe Street, Meyer B1-193, Baltimore, MD 21287

JAMES G. FOX
Division of Comparative Medicine, Massachusetts Institute of Technology, 77 Massachusetts Avenue, Building 16, Room 825C, Cambridge, MA 02139

RENO FREI
Microbiology Laboratory, University Hospital Basel, Petersgraben 4, 4031 Basel, Switzerland

CHARLES F. FULHORST
Department of Pathology, University of Texas Medical Branch, 301 University Boulevard, Route 0609, Galveston, TX 77555-0609

GUIDO FUNKE
Department of Medical Microbiology and Hygiene, Gärtner & Colleagues Laboratories, D-88212 Ravensburg, Germany

HECTOR H. GARCIA
Department of Microbiology, School of Sciences, Universidad Peruana Cayetano Heredia, Av. Honorio Delgado 430, SMP, Lima 31, Peru, and Cysticercosis Unit, Instituto de Ciencias Neurologicas, Lima, Peru

LYNNE S. GARCIA
LSG & Associates, 512-12th Street, Santa Monica, CA 90402-2908

CHARLOTTE A. GAYDOS
Division of Infectious Diseases and Medicine, Johns Hopkins University, 1159 Ross Building, 720 Rutland Avenue, Baltimore, MD 21205

ANNE A. GERSHON
Department of Pediatrics, Columbia University College of Physicians & Surgeons, 650 W. 168th Street, New York, NY 10032

ANTOINE GESSAIN
EPVO Unit, EEMI Department, Institut Pasteur, Paris 75015, France

MAHMOUD A. GHANNOUM
Center for Medical Mycology, Department of Dermatology, University Hospitals/Case Western Reserve University, 11100 Euclid Avenue, Cleveland, OH 44106

MARKUS GLATZEL
University Hospital Zürich, Institute of Neuropathology, Schmelzbergstrasse 12, CH-8091 Zürich, Switzerland

DAVID R. GRETCH
Viral Hepatitis Laboratory, University of Washington Harborview Medical Center, 325 Ninth Avenue, Box 359690, Seattle, WA 98104

BRIGITTE P. GRIFFITH
Virology Reference Laboratory, VA Connecticut Healthcare System, 950 Campbell Avenue, West Haven, CT 06516, and Department of Laboratory Medicine, Yale University School of Medicine, New Haven, CT 06520

M. CRISTINA GUTIÉRREZ
Reference Laboratory for Mycobacteria, Institut Pasteur, 25 rue du Docteur Roux, 75015 Paris, France

WILLIAM J. HALSALL
Center for Medical Mycology, Department of Dermatology, University Hospitals/Case Western Reserve University, 11100 Euclid Avenue, Cleveland, OH 44106

KEVIN C. HAZEN
Division of Clinical Microbiology, Department of Pathology, University of Virginia Health System, P.O. Box 800255, Charlottesville, VA 22908-0255

DAVID W. HECHT
Department of Medicine, Division of Infectious Diseases, Loyola University Medical Center, 2160 S. First Avenue, Building 54-149, Maywood, IL 60153, and Hines Veterans Administration Hospital, Hines, IL 60141

DEBORAH A. HENRY
Child and Family Research Institute, 950 West 28th Avenue, Room 370, Vancouver, British Columbia, Canada V5Z 4H4

JANET FICK HINDLER
Department of Pathology and Laboratory Medicine, UCLA Medical Center, Los Angeles, CA 90095-1713

RICHARD L. HODINKA
Departments of Pediatrics and Anatomic Pathology and Clinical Laboratories, Clinical Virology Laboratory, Children's Hospital of Philadelphia and University of Pennsylvania School of Medicine, Philadelphia, PA 19104

ALEX HOFFMASTER
Meningitis and Special Pathogens Branch, Division of Bacterial and Mycotic Diseases, National Center for Infectious Diseases, Centers for Disease Control and Prevention, 1600 Clifton Road, MS G34, Atlanta, GA 30333

DANNIE G. HOLLIS
Centers for Disease Control and Prevention, Atlanta, GA 30333

HARVEY T. HOLMES
Laboratory Response Branch, National Center for Infectious Diseases, Centers for Disease Control and Prevention, Atlanta, GA 30333

AMY J. HORNEMAN (formerly Martin-Carnahan)
Department of Epidemiology and Preventive Medicine, University of Maryland School of Medicine, 10 South Pine Street, MSTF 900D, Baltimore, MD 21201

REBECCA T. HORVAT
Department of Pathology and Laboratory Medicine, University of Kansas School of Medicine, 3901 Rainbow Boulevard, Mail Stop 4045, Kansas City, KS 66160

JEAN HOU
Laboratory of Molecular Medicine and Neuroscience, National Institute of Neurological Disorders and Stroke, 10 Center Drive, MSC 1296, Building 10, Room 3B14A, Bethesda, MD 20892-1296

SUSAN A. HOWELL
King's College London, Mycology, St. Johns Institute of Dermatology, Guy's and St. Thomas' NHS Foundation Trust, London SE1 7EH, Great Britain

ROSEMARY HUMES
Association of Public Health Laboratories, 8515 Georgia Avenue, Silver Spring, MD 20910

JOSEPH P. ICENOGLE
Measles, Mumps, Rubella, and Herpesviruses Branch, Division of Viral Diseases, National Center for Immunizations and Respiratory Diseases, Centers for Disease Control and Prevention, Mail Stop C-22, 1600 Clifton Road, NE, Atlanta, GA 30333

CLARK B. INDERLIED
Department of Pathology, Keck School of Medicine, University of Southern California, Los Angeles, CA 90033, and Department of Pathology & Laboratory Medicine, Childrens Hospital Los Angeles, 4650 Sunset Boulevard, Mail Stop #32, Los Angeles, CA 90027

NANCY C. ISHAM
Center for Medical Mycology, Department of Dermatology, University Hospitals/Case Western Reserve University, 11100 Euclid Avenue, Cleveland, OH 44106

J. MICHAEL JANDA
Microbial Diseases Laboratory, California State Department of Health Services, 850 Marina Bay Parkway, Room E164, Richmond, CA 94804

WILLIAM M. JANDA
Clinical Microbiology Laboratory, Department of Pathology, M/C 750, University of Illinois Medical Center, 840 S. Wood Street, Chicago, IL 60612

KEITH R. JEROME
Department of Laboratory Medicine, University of Washington, and Program in Infectious Diseases, Fred Hutchinson Cancer Research Center, 1100 Fairview Avenue N., D3-100, Seattle, WA 98109

XI JIANG
Division of Infectious Diseases, Department of Pediatrics, Cincinnati Children's Hospital Medical Center, University of Cincinnati College of Medicine, 3333 Burnet Avenue, Cincinnati, OH 45229-3039

JUAN A. JIMENEZ
Cysticercosis Unit, Instituto de Ciencias Neurologicas, Jr Ancash 1271, Lima 1, Peru

BARBARA J. B. JOHNSON
Division of Vector-Borne Infectious Diseases, Centers for Disease Control and Prevention, Rampart Road, Foothills Campus, Fort Collins, CO 80522

ERIC A. JOHNSON
Department of Food Microbiology and Toxicology, University of Wisconsin, 1925 Willow Drive, Madison, WI 53706-1187

JUDITH A. JOHNSON
VA Medical Center, 10 North Greene Street, Room 4D-150, Baltimore, MD 21201

ROBERT E. JOHNSON
National Center for HIV, STD, and TB Prevention, E-02, Centers for Disease Control and Prevention, 1600 Clifton Road, NE, Atlanta, GA 30333

JEFFERY L. JONES
Parasitic Diseases Branch, Division of Parasitic Diseases, National Center for Infectious Diseases, Centers for Disease Control and Prevention, MS F-22, 4770 Buford Highway, Atlanta, GA 30341

MALCOLM K. JONES
Molecular Parasitology Laboratory, Queensland Institute of Medical Research, 300 Herston Road, Herston, Queensland 4006, Australia

TIMOTHY F. JONES
Communicable and Environmental Disease Services, Tennessee Department of Health, 4th Floor, Cordell Hull Building, 425 5th Avenue N., Nashville, TN 37247

JEANNE A. JORDAN
Department of Pathology, University of Pittsburgh, Magee-Women's Hospital, 204 Craft Avenue, Pittsburgh, PA 15213

JAMES H. JORGENSEN
Department of Pathology, The University of Texas Health Science Center, 7703 Floyd Curl Drive, San Antonio, TX 78229-3700

JAMES B. KAPER
Center for Vaccine Development and Department of Microbiology & Immunology, University of Maryland School of Medicine, 685 West Baltimore Street, Baltimore, MD 21201

MOGENS KILIAN
Department of Medical Microbiology and Immunology, Bartholin Building, University of Aarhus, DK-8000 Aarhus C, Denmark

EIJA KÖNÖNEN
Anaerobe Reference Laboratory, Department of Bacterial and Inflammatory Diseases, National Public Health Insititute (KTL), FIN-00300 Helsinki, Finland

PIRKKO KOUKILA-KÄHKÖLÄ
HUS Diagnostics, Mycology Laboratory, Helsinki University Central Hospital, Helsinki, Finland

KAREN KRISHER
Detroit Medical Center University Laboratories, 4201 St. Antoine, Detroit, MI 48201

THOMAS G. KSIAZEK
Special Pathogens Branch, MS G-14, Centers for Disease Control and Prevention, 1600 Clifton Road, Atlanta, GA 30333

JAIME A. LABARCA
Department of Medicine, Facultad de Medicine, Pontificia Universidad Catolica de Chile, Lira 44, Santiago, Chile

RENU B. LAL
Epidemiology Branch, Division of HIV/AIDS Prevention, National Center for HIV, STD and TB Prevention, Centers for Disease Control and Prevention, Atlanta, GA 30333

ROBERT S. LANCIOTTI
Diagnostic and Reference Laboratory, Arbovirus Diseases Branch, Centers for Disease Control and Prevention, Fort Collins, CO 80521

MARIE LOUISE LANDRY
Department of Laboratory Medicine, Yale University School of Medicine, P.O. Box 208035, New Haven, CT 06520-8035

MARK T. LaROCCO
Department of Pathology, St. Luke's Episcopal Health System, Houston, TX 77030

PHILIP LaRUSSA
Department of Pediatrics, Columbia University College of Physicians & Surgeons, 650 W. 168th Street, New York, NY 10032

TSAI-LING LAUDERDALE
Division of Clinical Research, National Health Research Institutes, Taipei 11529, Taiwan, Republic of China

AMY L. LEBER
Quest Diagnostics, Nichols Institute, 33608 Ortega Highway, San Juan Capistrano, CA 92690

KARIN LEDER
Infectious Disease Epidemiology Unit, Department of Epidemiology and Preventive Medicine, Monash Medical School, Alfred Hospital, Commercial Road, Prahran, Victoria 3181, Australia

DIANE S. LELAND
Indiana University School of Medicine, 350 W. 11th Street, Indianapolis, IN 46202

PAUL N. LEVETT
Provincial Laboratory, Saskatchewan Health, 3211 Albert Street, Regina, Saskatchewan, S4S 5W6 Canada

ANNIKA LINDE
Department of Epidemiology, Swedish Institute for Infectious Disease Control, SE-171 82 Solna, Sweden

DAVID LINDQUIST
Microbial Diseases Laboratory, California Department of Health Services, 850 Marina Bay Parkway, Richmond, CA 94804

DAVID S. LINDSAY
Center for Molecular Medicine and Infectious Diseases, Department of Biomedical Sciences and Pathobiology, Virginia-Maryland Regional College of Veterinary Medicine, Virginia Tech, 1410 Prices Fork Road, Blacksburg, VA 24061-0342

JOHN J. LiPUMA
Department of Pediatrics and Communicable Diseases, University of Michigan Medical School, 1150 W. Medical Center Drive, 8323 MSRB III, 0646, Ann Arbor, MI 48109

SHAWN R. LOCKHART
Department of Biological Sciences, University of Iowa, Iowa City, IA 52242

MICHAEL J. LOEFFELHOLZ
Viromed Laboratories, 6101 Blue Circle Drive, Minnetonka, MN 55343

NIALL A. LOGAN
Department of Biological and Biomedical Sciences, School of Life Sciences, Glasgow Caledonian University, Cowcaddens Road, Glasgow G4 0BA, United Kingdom

GARY D. LUM
Pathology Administration, Northern Territory Government Pathology Service, PO Box 41326, Casuarina NT 0811, Australia

NELL S. LURAIN
Department of Immunology/Microbiology, Rush University Medical Center, 1653 West Congress Parkway, Chicago, IL 60612

JAMES B. MAHONY
Department of Pathology and Molecular Medicine, McMaster University, and Regional Virology and Chlamydiology Laboratory, St. Joseph's Healthcare, 50 Charlton Avenue East, Hamilton, Ontario L8N 4A6, Canada

EUGENE O. MAJOR
Laboratory of Molecular Medicine and Neuroscience, National Institute of Neurological Disorders and Stroke, 10 Center Drive, MSC 1296, Building 10, Room 3B14A, Bethesda, MD 20892-1296

THOMAS MARRIE
Faculty of Medicine and Dentistry, 2J2.01 Walter C. Mackenzie Health Sciences Center, 8440 112th Street, Edmonton, Alberta, Canada T6G 2R7

ALEXANDER MATHIS
Institute of Parasitology, University of Zurich, Winterthurerstrasse 266a, CH-8057 Zurich, Switzerland

DONALD R. MAYO
Virology Reference Laboratory, VA Connecticut Healthcare System, 950 Campbell Avenue, West Haven, CT 06516, and Department of Laboratory Medicine, Yale University School of Medicine, New Haven, CT 06520

JAMES B. McAULEY
Rush University, 1725 W. Harrison Street, Chicago, IL 60612

MICHAEL R. McGINNIS
Medical Mycology Research Center, Center for Tropic Diseases, University of Texas Medical Branch, 301 University Boulevard, Galveston, TX 77555-0609

DONALD P. McMANUS
Molecular Parasitology Laboratory, Queensland Institute of Medical Research, 300 Herston Road, Herston, Queensland 4006, Australia

TESS McPHERSON
Laboratory of Parasitic Diseases, National Institute of Allergy and Infectious Diseases, National Institutes of Health, 4 Center Drive, Bethesda, MD 20892

FRANCIS MEGRAUD
INSERM ERI 10, Laboratoire de Bactériologie, Université Victor Segalen Bordeaux 2, 33076 Bordeaux Cedex, France

LEONEL MENDOZA
Medical Technology Program, Department of Microbiology and Molecular Genetics, Michigan State University, 322 North Kedzie Hall, East Lansing, MI 48824-1031

J. MICHAEL MILLER
Laboratory Response Branch, National Center for Infectious Diseases, Centers for Disease Control and Prevention, Atlanta, GA 30333

ROBERT C. MOELLERING, JR.
Department of Medicine, Beth Israel Deaconess Medical Center, and Harvard Medical School, Boston, MA 02215

RHODA ASHLEY MORROW
Department of Laboratory Medicine, University of Washington, and Program in Infectious Diseases, Fred Hutchinson Cancer Research Center, 1100 Fairview Avenue N., LE-500, Seattle, WA 98109

PATRICK R. MURRAY
Clinical Center, National Institutes of Health, Bethesda, MD 20892-1508

REINIER MUTTERS
Institute of Medical Microbiology and Hospital Hygiene, Philipps University, D-35037 Marburg, Germany

IRVING NACHAMKIN

Acknowledgment of Previous Contributors

The *Manual of Clinical Microbiology* is by its nature a continuously revised work which refines and extends the contributions of previous editions. Since its first edition in 1970, many eminent scientists have contributed to this important reference work. The American Society for Microbiology and its Publications Board gratefully acknowledge the contributions of all of these generous authors over the life of this Manual.

Preface

It seems that much of my professional career has revolved around the *Manual of Clinical Microbiology*, first as an author, then as a section editor, and finally for the last four editions as the editor in chief. I have learned a great deal from this experience, although I must confess that I have forgotten far more science than I have retained. My most valuable lesson has been to rely on my fellow editors. I have been privileged to have worked on all four editions with Ellen Jo Baron and Mike Pfaller, with Jim Jorgensen for the last two editions, and with Marie Landry, who ably filled Bob Yolken's shoes, for this edition. I have also relied on the help of 29 section editors, including 7 new editors for this edition, and hundreds of authors. Almost 40% of the authors of the ninth edition of the *Manual of Clinical Microbiology* (MCM9) are new. For each edition I have purposely selected new editors and authors with the conviction that they will bring a new perspective to their assignment. I have systematically added non-U.S. authors, representing almost 30% of the authors of this edition, so that this Manual will be truly international in scope. These changes have not come without difficulties. My fellow editors and I have frequently had to curtail our authors' "creativity" for the sake of consistency, taught them that eloquence can equate to brevity, and reminded them that deadlines are not the fantasies of publishers. Many unpopular decisions are made in the creation of any work as comprehensive as MCM9, so I must thank the editors and authors for their understanding. If I have offended anyone in the process, it was unintentional.

I am very proud of what we have accomplished with MCM9, and I hope that this feeling is shared by the entire editorial board and all the authors. Although the field of clinical microbiology is undergoing dramatic changes with the confluence of traditional techniques and exciting advances in genomics and proteomics, I believe that the *Manual of Clinical Microbiology* should form the road map for our understanding of this evolving scientific discipline. I hope that the readers share the opinion of the authors and editors that MCM9 successfully meets this goal. An additional feature for the ninth edition is a CD-ROM with close to 500 illustrations from the book. It is available for purchase through ASM Press.

I would be remiss if I did not acknowledge the wisdom and guidance provided by Susan Birch, the ASM Press Production Manager whose name should more appropriately be listed on the cover of MCM9, and Jeff Holtmeier, the director of ASM Press who makes everyone's job a little easier and more pleasant. The entire staff at ASM Press was very supportive and helpful during the process of preparing this edition of the Manual.

GENERAL

Taxonomy and Classification of Viruses

CORNELIA BÜCHEN-OSMOND

79

In 2007, taxonomists will celebrate the 300th anniversary of the birth of Carl von Linné, the founder of the universally accepted system of biological classification. Compared to other areas of biology, virus taxonomy is a relatively modern discipline that is still changing rapidly. Although the need for a taxonomy of viruses has been recognized for about 100 years, application of a strictly hierarchical system of classical Linnaean taxonomy, in which domains are divided into divisions, classes, orders, families, genera, and species, is difficult to apply in virology (14). Simply put, a virus is such a rapidly evolving biological entity that classification needs to be much more responsive to new information, ranging from molecular to clinical research data. Huge amounts of new DNA and RNA sequence data are reported daily on viruses associated with emerging diseases and perceived threats, reflecting viral evolution that is accelerated by horizontal gene transfer, homologous recombination, and other processes. Although viruses are a mere twig on the evolutionary tree, they seem certain to remain "the master explorers of evolutionary space" (13). Indeed, viruses have the most diverse and unusual sequence compositions of all living organisms and their genomes may represent an evolutionary shadow of ancient, long lost kingdoms of the tree of life. Moreover, the number of viruses that are pathogens or silent passengers of other organisms, from bacteria to dominant mammals, is very large. The list of viruses expands as we explore new niches for life and as detection techniques improve in sensitivity and specificity.

Today, the International Committee on Taxonomy of Viruses (ICTV) recognizes about 2,000 virus species, 650 of which infect humans and animals (10), but virologists in different fields of biology are tracking some 40,000 virus strains and isolates. The ICTV is the "international court" of experts that rules on names and relationships of all viruses but only to the level of species. Decision making in the specialist study groups of the ICTV provides the current consensus on higher-level relationships between viruses, and decisions are informed by all sorts of data derived from studies of isolates and lower-level taxa. The overarching framework of virus taxonomy that is continually updated by the ICTV thus sets an agreed-upon context for all aspects of higher-level virus nomenclature and phylogeny and plays an important role in clear communication in this sector of microbiology. An ICTV-approved virus species comprises a population of isolates and strains of closely related viruses. Individual isolates in this population may have identical or different genomic sequences, leading some researchers to subdivide such populations into "quasispecies," but this term has no taxonomic validity.

Although the taxonomy of viruses is a relatively modern discipline that is still changing rapidly under the persuasive influence of molecular biology and sequence data, the classical principles of independent differential diagnosis, based on all sorts of information, remain as important in virus taxonomy as in clinical practice. Recognizing this, the ICTV took early initiatives in electronic data management (1) to support the development of a universal virus database, ICTVdB. The database has been available on the Web since 1993 and was copyrighted in 2002. Originally designed as a tool for taxonomic research (5), ICTVdB has now evolved to serve two primary functions: (i) providing rapid access to contemporary decisions from ICTV study groups on nomenclature of higher-level virus taxa and (ii) serving as a repository for primary data at the level of isolates to facilitate decision making by ICTV study groups. These data are also made available, with linkages to sequence information, etc., as a continually updated reference source for clinical and other uses.

These functions, and the structural elements of the database, are summarized in Table 1 (http://phene.cpmc.columbia.edu/ICTVdB%20History/SFO2005.pdf). This chapter briefly outlines recent developments in virus taxonomy, describes the decimal code of classification that is the core of ICTVdB and that provides an unequivocal identifier of a virus at all taxonomic levels, and summarizes the taxonomy of viruses causing human diseases.

RECENT DEVELOPMENTS IN VIRUS TAXONOMY

The universal system of virus taxonomy devised by the ICTV now accepts Linnean-like classification at the levels of order, family, subfamily, genus, and species. The suffix *-virales* identifies an order. Families are identified by the suffix *-viridae,* subfamilies are identified by the suffix *-virinae,* and genera are identified by the suffix *-virus*. Over the last decade, the subgeneric classification of some viruses infecting humans has been drastically reorganized (9, 22). Few genera have escaped the attention of lumpers and splitters, primarily because sequence information has helped to refine earlier classifications. Recognizing the importance of distinguishing strains and isolates, the ICTV produced the hard-copy publication of its

TABLE 1 Functions and structural elements of ICTVdB[a]

Functions(s) or element(s)	Description
ICTVdB in DELTA format	Assigns unique decimal code identities to all virus taxa, clearly indicating taxonomic status and relationships (e.g., type species of 00.046.0.01, *Influenzavirus A*; 00.046.0.01.001, *Influenza A virus*); uses list of virus properties to generate descriptions of all taxa; includes 40,000-item code book to define 2,700 virus characteristics in natural-language descriptions
ICTVdB Web outputs	
Index of viruses	Catalogues ICTV approved virus taxonomy and nomenclature to species level plus additional data on isolates; linked to ICTVdB descriptions and Genbank
Virus descriptions	Describes all virus taxa down to type species, including about 1,100 plant viruses and some 2,000 isolates of human and animal viruses
Picture gallery	Presents classic EM images of virus species, reconstructions, and diagrams; linked to copyright owners and ICTVdB descriptions, including those of hosts and symptoms
Interactive data retrieval	Provides access to and interrogation of most recent ICTVdB data for virus identification via downloadable reader; linked to ICTVdB descriptions and images
To and from sequence databases	Offer linkages to NCBI, EMBL, and UniProt from ICTVdB via genome, sequence accession, and TaxID numbers (e.g., sequence V00603 and TaxID 11320); offer linkages from NCBI UniProt to ICTVdB via decimal codes (e.g., 00.046.0.01.001, *Influenza A virus*)
PC tools in DELTA	
DELTA database	World standard for data exchange in taxonomy; handles fully annotated biological information of all sorts, with data entry and handling facilitated by a network of dependencies
Natural-language translations	Provide automated translation of annotated data in ICTVdB available in rich text format (camera ready) and HTML (Web output)
Phylogenetic programs	Offer readily available tools for generating phylogenetic relationships from the DELTA data matrix of ICTVdB
Keys for virus identification	Intkey tool is an intelligent search engine that produces similarity, dissimilarity, or summary matrices on the fly for identifying and exploring relationships among virus taxa
To and from reference databases	Offer linkages to PubMed and NLM from ICTVdB; hard-copy references based on ICTVdB

[a] Abbreviations: EM, electron micrograph; NCBI, National Center for Biotechnology Information; PC, personal computer; NLM, National Library of Medicine.

Eighth Report (10) with lists of names of sequenced isolates included below the species name by using designations given by investigating scientists. These names follow laboratory conventions and do not require formal ICTV approval. Although these lower levels are not formally classified by the ICTV, they are readily accommodated in the decimal code of ICTVdB.

Criteria for Virus Classification

Historically, as electron microscopy became a more widely accessible tool in the last half of the 20th century, the morphology of the virus particle (Fig. 1) became a prime characteristic for virus classification. Although most viruses have been seen under an electron microscope, the virions (infectious particles) now tend to be better known by their chemical and genomic makeups, the complex disease symptoms in their hosts, and their vectors and geographic distributions. Virion stability (determined by varying of pHs and temperatures and exposure to lipid solvents and detergents, etc.) and virion antigenicity (determined by various serological methods) have also emerged as essential criteria for classification of viruses. Sequencing of the viral genome is now often done very early in identification protocols, even in developing countries. Although in most cases, sequencing places a virus in a specific taxonomic slot, virion morphology and serological test results remain important criteria for identifying an unknown virus (2, 6). In some recent cases (e.g., early in the identification of the virus causing severe acute respiratory syndrome), it has proven to be difficult to achieve unequivocal clinical disease diagnosis by using sequence data alone and serological tests were needed.

Characteristics Used To Describe Viruses

Today, the primary criteria used to differentiate virus orders, families, and genera are as follows:

- the type and organization of the viral genome
- the strategy of viral replication
- the structure of the virion

The species concept in viral taxonomy is predicated on the fact that viruses are "biological entities and not simply chemicals" (21), but the concept has been particularly fuzzy. Since 1991, the ICTV has accepted the definition that "a virus species is a polythetic class of viruses that constitute a replicating lineage and occupy a particular ecological niche." van Regenmortel (21) lists the following characters for discriminating among virus species:

- relatedness of genome sequence
- natural host range
- cell and tissue tropism
- pathogenicity and cytopathology
- mode of transmission
- physicochemical properties of virions
- antigenic properties of viral proteins

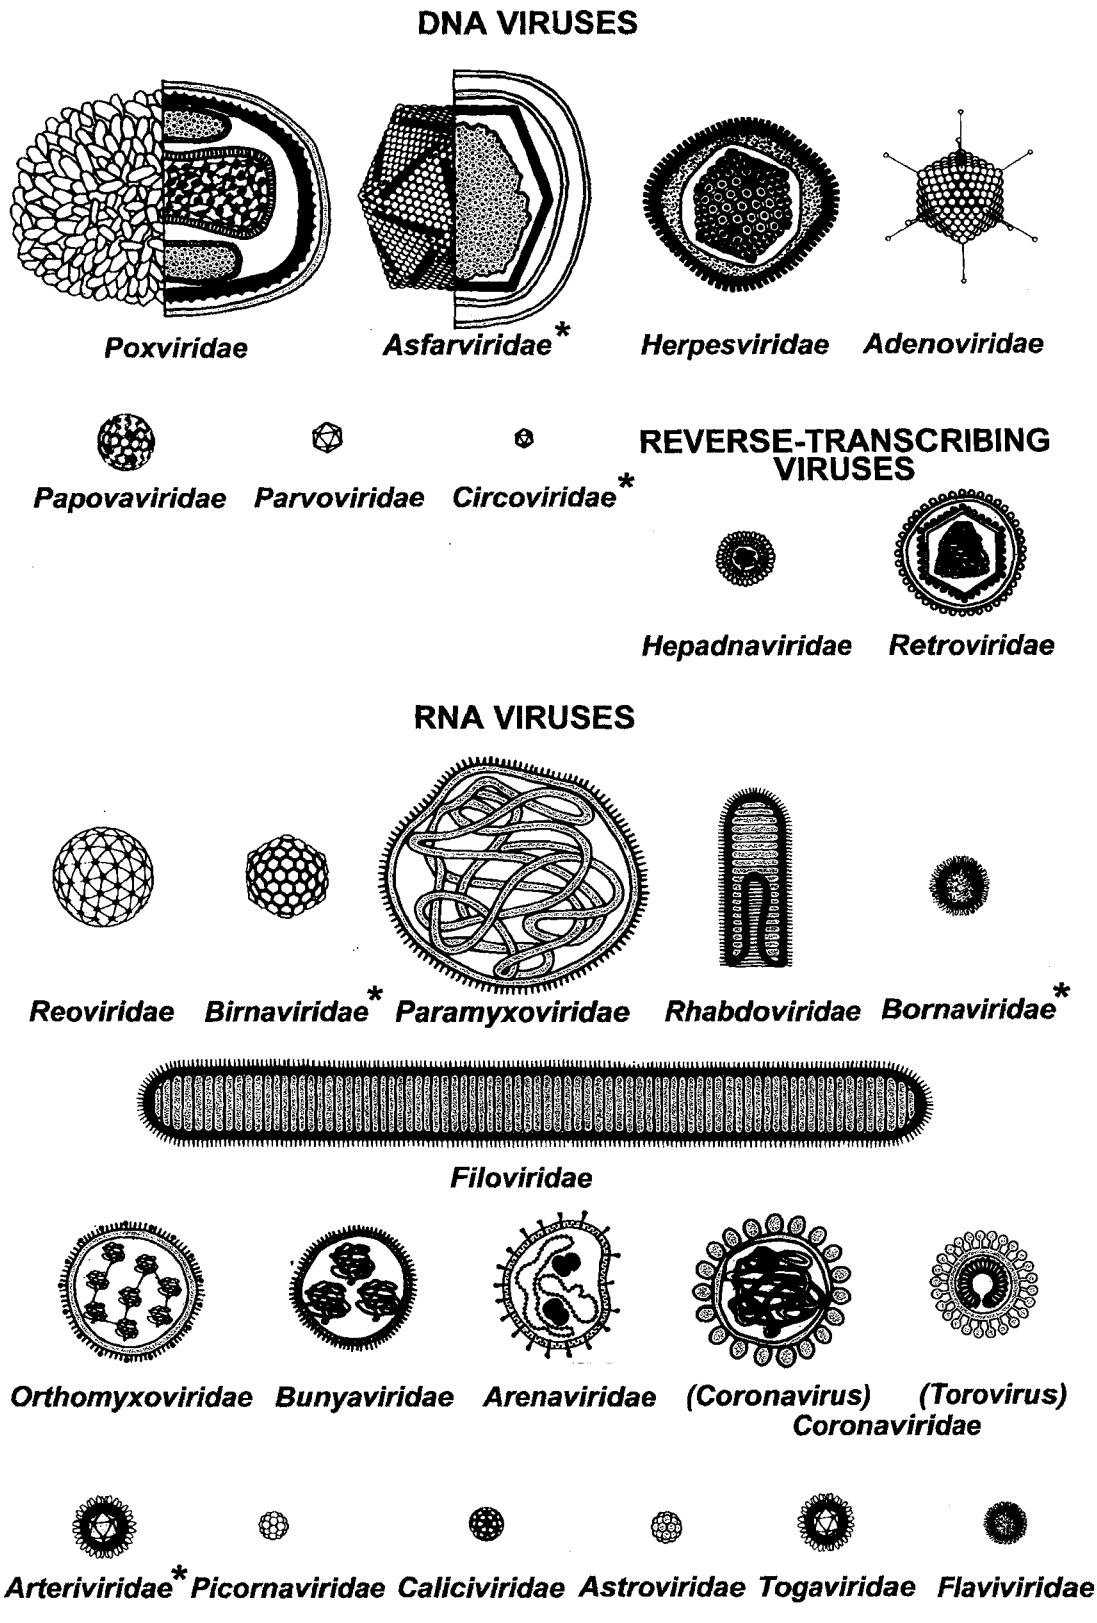

FIGURE 1 Shapes and sizes of viruses of families that include animal, zoonotic, and human pathogens. Names marked by an asterisk indicate viruses only known to infect animals.The virions are drawn to scale, but artistic license has been used in representing their structure. In some, the cross-sectional structures of capsid and envelope are shown, along with a representation of the genome; with the very small virions, only their size and symmetry are depicted.Viruses in families marked with an asterisk are not known to infect humans. BANKING DIVERSE DATA IN ICTVdB

Developed at the Australian National University, and now based at Columbia University, ICTVdB owes much to the support of the U.S. National Science Foundation and sponsorship by the American Type Culture Collection. It was originally constructed to facilitate objective analysis of systematic and evolutionary relationships, but it can be used to generate character or distance matrices and to explore relationships by using all identified virus properties. ICTVdB has thus grown in concept and capability to become a major reference resource and research tool. Examples of this expanded functionality include the fact that the database is now up to date with the higher taxonomy in the ICTV *Eighth Report* (10) and also contains descriptions for 152 severe acute respiratory syndrome virus isolates.

Most databases deal with a relatively limited range of data attributes, such as nucleic acid or amino acid sequences, but the value of more complex (from a database perspective) text annotation is increasingly recognized. A huge range of diverse biological information has to be accommodated in ICTVdB, and all identified virus properties are covered in its character list, which uses a code to define virus characters (http://phene.cpmc.columbia.edu/chars.htm). Although only partly populated, ICTVdB already lists more than 4,000 virus descriptions (items; http://phene.cpmc.columbia.edu/ICTVdB/) constructed from about 3,000 characteristics, some of which (such as host range) have up to 2,000 options for selection (Table 2). By the time available data on virus isolates and strains are entered, the number of descriptions will be close to a million. A few of the data management issues resolved in ICTVdB are outlined here to assist user interaction with the database.

Structural Concepts in ICTVdB

The database uses the Description Language for Taxonomy (DELTA) system (8), developed at the Division of Entomology, Commonwealth Scientific and Industrial Research Organisation, Canberra, Australia, by Michael Dallwitz (7), which has now been adopted as a world standard for data exchange in taxonomy. A distinctive feature of DELTA is its capacity to store an extraordinary diversity of data and to translate these data into natural language for traditional reports and Web publication. On the input side, the capacity of DELTA to handle very large data sets one item at a time is ideally suited to a long list of virus properties (character list), often accompanied by extensive text comments and images.

Another advantage of ICTVdB is a user friendly, online data entry capability enabling peer review of new information, ranging from molecular properties of a virus to its geographic distribution and host range. Such diverse information, with intrinsic dependencies among genomic data and data on protein composition, particle structure, and infectivity, places particular demands on the flat-file system of DELTA. These have been met by building a dependency network in data specification files and by blending data from diverse sources (see below). For example, ICTVdB does not contain sequence data itself but has links to genomic and protein data banks. Conversion of ICTVdB data from DELTA into NEXUS format (an extensible file format for systematic information and construction of phylogenetic trees, commonly used by sequence databases; sequence data can be downloaded from all major sequence data banks in this format for tree analyses) was deemed essential for the comprehensive phylogenetic analyses that are widely used to monitor the evolution of viruses in relation to emerging diseases. If a database is to accept the latest data from all branches of virology and place these diverse data into contemporary taxonomic context, it will most commonly deal with information at the level of strains and isolates. Ideally, ICTVdB will serve virus taxonomy from the bottom up with primary data from researchers who describe their viruses by using rich and diverse semantics, reflecting geographic and linguistic factors. At the same time, the database must accept revisions and consolidations from the top down as the consensus in virus taxonomy reflects this new information.

Most new information in virology is generated at the molecular level and is deposited in sequence databases; however, significant events in virology tend to be associated with "host jumping," epidemics, and environmental disturbances. All of this information can be accommodated in and retrieved from ICTVdB. From the outset, DELTA was designed not only to generate identification keys but also to translate data into natural language for publication in hard copy, into hypertext markup language (HTML) format for publication on the Web, and into many other languages.

The Decimal Code in ICTVdB

The core infrastructure of ICTVdB is its distinctive table of contents, the *ICTV Index to Virus Classification,* a list of ICTV-approved and -unapproved virus names (http://www.ncbi.nlm.nih.gov/ICTVdb/Ictv/). Constructed as a taxonomic database from classifications that do not employ normal Linnean binomial nomenclature, ICTVdB has several distinctive features that are not usually used in systematics but were introduced of necessity (5). Chief among these is its decimal code (3, 4). Because virus names are changed frequently (11, 23), contain diverse linguistic and geographic elements, and are usually coupled to a disease or its symptoms, virus nomenclature (20) presents challenging semantic problems for a database.

The decimal code was introduced because the peculiar nomenclature used in virology defies direct and systematic interrogation in a database, and a decimal code (analogous to the code of enzyme nomenclature) seemed to offer a simple resolution to many problems. For example, the decimal code affords unequivocal identification of a virus to the level of strain or isolate and at the same time indicates its taxonomic context. Although the code was initially alphanumeric, new genera are now simply added numerically. The easy adaptability of the code is exemplified by its application

TABLE 2 Character list for ICTVdB[a]

Section heading	Corresponding nos.[b]
Isolate definition and isolation details	1–77
Classification	78–108
Virion properties	109–1158
Genome organization	1159–1620
Antigenicity	1621–1695
Biological properties	1696–2649
Taxonomic structure	2650–2662
Comments, references, and contributors	2663–2697

[a] Available at http://www.ncbi.nlm.nih.gov/ICTVdb/chars.htm.

[b] Characteristics are numbered in consecutive order of their logical appearance in the list. The character numbers are not unique identifiers but change when new characteristics are added to the list or the characteristics are reordered. In the example in the table, the designation of a virus isolate takes up 77 separate characters. The data defined in the characters 1 to 77 range from the isolation date (one character each for day, month, and year) to the location of the isolation to the isolation host and the person(s) and institution involved in the isolation.

TABLE 3 Decimal code applied to taxonomic revisions of *Poliovirus* (23, 24) and constructed to anticipate the explosion of lower-level data (serotypes, strains, and isolates)

Level	Extended decimal code
Order	00. = (not assigned to an order)
Family	00.05. = *Picornaviridae*
Subfamily	00.052.0. = (not assigned)
Genus	00.052.0.01. = *Enterovirus*
Serogroup	Superseded by new species concept
Species (type species)	00.052.0.01.001. = *Poliovirus*
Species	00.052.0.01.007. = *Poliovirus*
Subspecies	00.052.0.01.007.00. = (not assigned)
Serotype	00.052.0.01.007.00.001. = poliovirus 1
	00.052.0.01.007.00.002. = poliovirus 2
	00.052.0.01.007.00.003. = poliovirus 3
Strain, isolate	00.052.0.01.007.00.001.001. = PV-1[a] Mahoney
	00.052.0.01.007.00.002.001. = PV-2 Lansing
	00.052.0.01.007.00.003.001. = PV-3 Leon/37

[a] PV, poliovirus.

to the recently revised taxonomy of *Poliovirus,* in which the terms poliovirus 1, 2, and 3 now designate serotypes rather than species (Table 3) (17, 18).

Most importantly, the decimal code serves as a file name for database outputs as well as an accession number for external linkage to ICTVdB. It is used as a file name for transposing ICTVdB to the Web and also serves as a surrogate accession number used by sequence databases such as NCBI, EMBL, and UniProt to link to ICTVdB. The increasing focus on such lower-level taxonomic information and more frequent taxonomic revision requires a decimal code expanded to 19 digits that should cope with even the most ambitious splitters in the taxonomic community. Many virologists are finding the decimal code useful. The code has been adopted by *The Springer Index of Viruses* (19) and has been approved by the ICTV, but this invention is by no means universally accepted among virus taxonomists. Eventually, it is envisioned that the decimal code will be used in much the same way as sequence accession numbers and will need to be assigned and cited before publication of information leading to proposals for new taxa.

Operational Aspects of ICTVdB

One of the important operational considerations in ICTVdB is that binary statements at critical points in the character list, such as virus particle with or without envelope, are used to establish dependencies. Only the subsequently valid characters then need to be considered. These dependencies provide the internal linkage hierarchy in the data and direct the search path during interrogation; among other things, they reveal errors during data entry. The dependencies are very important for the decision-making process during identification and data comparison; some multistate characters in key positions (e.g., plant or animal virus) can control the applicability of up to 2,000 characters down the line.

Other important operational considerations in ICTVdB include the strategies developed to facilitate communication across semantic boundaries when one is dealing with data from diverse disciplines (bacteriology, agriculture, and veterinary and medical sciences), each of which has evolved a distinctive vocabulary. Although terms have been standardized within ICTVdB, these standards cannot be imposed on virologists in all disciplines and they cannot be imposed retrospectively on the literature. Therefore, semantic equivalents are given where needed and subsumed within dependencies. For example, the left-hand column of Table 4 lists character 120, which handles the semantic equivalence of tegument, inner lipid protein membrane and capsid, and head of a tailed phage. The right-hand columns of Table 4 show relevant dependencies so that character 120 option 4 or 5, for example, accesses only characters 681 to 725, handling the semantic equivalence of head and capsid. The dependencies build the internal hierarchy of the database.

Images of virus particles are used in several ways in ICTVdB. For example, text descriptions of key morphological characters become much more precise when they are linked in the character list to representative vignettes from electron micrographs. Thin-section electron micrographs of infected tissues are also used to illustrate virus infection cycles and host pathology. Descriptions of all viruses generated from ICTVdB will be enhanced by electron micrographs of the type species, irrespective of the presentation format selected. Not surprisingly, images of virus particles are among the most frequently accessed files in ICTVdB on the Web. A large image file is more instructive to users, but in the database it is functionally equivalent to numerous characters, like "virus 75–80 nm in diameter" in the case of *Rotavirus*. File size considerations and access paths dictate that image files be stored outside the main data set, in either local files or files accessed on the Internet.

The personal computer-based ICTVdB is presented as a natural-language translation on the Web by using HTML conversion for the DELTA-formatted data. This Web environment is essential for universal access, interactive data entry, interrogation, and interoperability with other databases. Currently, a plethora of accessories are available, many of which are standard components of DELTA (e.g., Web Intkey, an interactive identification program). Others, like the data entry forms, Java applets, and scripts used to display directory trees, have been developed specifically for use in ICTVdB. In the future, interoperability will be vastly improved by XML tagging. Just as it is certain that the flow of new information about viruses will not slow, it is also certain that new technology available to ICTVdB to handle these data will emerge.

TABLE 4 Semantic equivalence and dependencies among the major morphological properties of virus particles[a]

Virion or phage components	Dependent character blocks for protein annotations	
	Section heading	Available character nos.
1. An envelope <inner and outer envelope>/	Envelope	598–639
2. A surface membrane	Surface membrane	640–680
3. A tegument <inner lipid protein membrane>/	Tegument	897–918
4. A head <of phage treated as isometric capsid>/	Head	681–725
5. A capsid <including outer and inner capsid>/	Capsid (coat protein)	681–725
6. Spikes <on capsid structure>/	Spikes	726–736
7. A tail <of phage treated as elongated capsid>/	Tail	799–808
8. Fibers <at the tail>/	Fibers	820–830
9. A nucleocapsid/	Nucleocapsid	758–798
10. A core/	Core	831–875
11. A nucleoid <term for nucleocapsid in *Retroviridae*>/	Nucleoid	758–798
12. Lateral bodies/	Lateral bodies	881–904
13. A matrix/	Matrix	876–896

[a] Many viruses consist of a capsid only, whereas others are complex and are constructed from several components.

Incorporating the International Disease Code

The wisdom of retaining important "old-fashioned" taxonomic parameters, such as clinical and pathogenic properties, ecological properties, and transmission characteristics, in ICTVdB became evident during the incorporation of the International Code of Diseases, revision 10 (ICD-10), that is also based on these properties (16, 25). The importance of retaining such parameters is well illustrated by the example of viruses causing hepatitis (Table 5). If the virus infection is enteric and the primary tissue tropism of the infection targets the liver, leading to hepatitis, the disease is ranked according to severity. In ICD-10, the letters A and B are reserved for certain infectious and parasitic diseases. All viral hepatitis diseases in which the primary infection is restricted to the liver tissue are found in the section B15 to B19. For example, acute hepatitis A has been assigned the code B15, whereas B16 is reserved for acute forms of hepatitis B. B18 is used only for chronic forms of hepatitis. The digit after the decimal point is used to classify the form and severity of the disease. B15.0 and B16.0 are used to describe severe forms of hepatitis that have developed into a coma hepaticum; B15.9 and B16.9, on the other hand, refer to less severe forms of hepatitis, which are not accompanied by a coma hepaticum. If the virus infection is not enteric and the primary target tissue is not the liver, the disease is coded according to other criteria even though the infection may eventually result in a liver disease.

At the same time, the rapid growth in sequence information has to be woven into the above-described fabric. This becomes evident in comparisons of *Dengue fever virus* and *West Nile virus*, two clinically important species in the genus *Flavivirus*. The long-recognized *Dengue fever virus* has a single mosquito vector, infects only humans, has shown significant change in its geographical distribution, and shows only small sequence divergence in the isolate population that comprises the four serotypes of this species. However, these small differences in sequences among serotypes are critical determinants of the disease outcome (24). In evolutionary terms, the dengue virus may represent a "mature" virus species. On the other hand, the recent rapid reemergence and rapid extension of the range of *West Nile virus* in North America present a more complex situation. *West Nile virus* has several mosquito vector species and infects a large variety of avian and mammalian hosts. The sequences of isolates of this virus species show broad variability among and within vectors, but less sequence variability exists among isolates collected from birds or mammals. Thus far, it seems that the extensive sequence variability in this virus species is not clearly correlated with differential disease outcomes in vertebrate hosts (12). The challenges in virus taxonomy presented by this comparison are substantial and cannot be resolved by sequence comparisons alone. However, it is believed that the split functions of ICTVdB are adequate to accommodate information flow and decision-making processes in the future taxonomy of *West Nile virus*.

CURRENT TAXONOMY OF VIRUSES INFECTING HUMANS

The most recent taxonomic decisions (10, 11) have been incorporated into the *ICTVdB Index to Virus Classification* (http://www.ncbi.nlm.nih.gov/ICTVdb/Ictv/) and the nomenclature of the 23 families of viruses that infect humans is shown in Table 6. The table summarizes the important characteristics for differentiation of these viruses, listed according to the accepted taxonomic order based on the nature of the genome. As the designation of diseases, signs, and symptoms becomes more standardized throughout the world through the use of ICD-10, it will be a relatively simple matter to expand ICTVdB to include these data. Table 7 illustrates a comprehensive current reconciliation of data from ICTVdB and ICD-10 (16; ICD-10 Diagnosenthesaurus, version 3.0) for one virus family. The full list for other families is available within ICTVdB on the Web (http://www.ncbi.nlm.nih.gov/ICTVdb/Ictv/ICD-10.htm).

The construction, maintenance, and population of ICTVdB continues to owe much to support from members of the Executive Committee and Data Sub-Committee of the ICTV, currently and especially Andy Ball, Lois Blaine, John Mackenzie, and Tony Della-Porta. Eric Zurcher and Mithun Harkara have provided technical support for the infrastructure of ICTVdB. Aljoscha Brandt helped with the design of Table 1 and with comments on the manuscript.

I am grateful to Ian Lipkin for institutional support since 2003.

TABLE 5 Continuing importance of clinical properties, symptoms, and disease designations (as coded in ICD-10) in the taxonomy of viruses causing hepatitis

Virus name	Signs and symptoms	ICD-10 code	ICD disease description
Hepadnaviridae			
Orthohepadnavirus			
Hepatitis B virus (HBV)	Acute hepatitis which may progress to chronic hepatitis, liver cirrhosis, and primary hepatocellular carcinoma	B16.2	Acute hepatitis B without *Deltavirus* with hepatic coma
		B16.9	Acute hepatitis B without *Deltavirus* without hepatic coma
		B18.1	Chronic hepatitis B without *Deltavirus*
Hepatitis B virus and *Hepatitis delta virus*	Acute hepatitis which may progress to chronic hepatitis with superinfection with *Deltavirus*	B16.1	Acute hepatitis B with *Deltavirus* without hepatic coma
		B16.0	Acute hepatitis B with *Deltavirus* with hepatic coma
		B18.0	Chronic hepatitis B with *Deltavirus*
Picornaviridae	Acute hepatitis	B15.0	Hepatitis A with hepatic coma
Hepatovirus		B15.9	Hepatitis A without hepatic coma
Hepatitis A virus (HAV)			
Not assigned to a family	Acute hepatitis	B17.1	Acute hepatitis E
Hepevirus			
Hepatitis E virus (HEV)			
Flaviviridae	Acute hepatitis	B17.1	Acute hepatitis C
Hepacivirus		B18.2	Chronic viral hepatitis C
Hepatitis C virus			
GB virus B (unassigned hepacivirus)	Acute and chronic hepatitis	B17.8	Other acute viral hepatitis
		BB.8	Other chronic viral hepatitis
Unassigned flaviviruses	Acute and chronic hepatitis	B17.8	Other acute viral hepatitis
GB virus A (GB virus A-like agents)		B18.8	Other chronic viral hepatitis
GB virus C (Hepatitis G virus 1)	Acute and chronic hepatitis	B17.8	Other acute viral hepatitis
		B18.8	Other chronic viral hepatitis
Subviral agents unassigned to a virus family	Acute and chronic hepatitis	B16.0	Acute hepatitis B with *Deltavirus* (coinfection) with hepatic coma
Deltavirus			
Hepatitis delta virus		B16.1	Acute hepatitis B with *Deltavirus* (coinfection) without hepatic coma
		B17.0	Acute *Deltavirus* (super) infection of hepatitis B carrier
		B18.0	Chronic viral hepatitis B with *Deltavirus*
Herpesviridae	Cytomegalovirus mononucleosis, infectious mononucleosis	B25.0 (K77.0)	Pneumonitis
Betaherpesvirinae		B25.1 (J17.1)	Hepatitis
Human herpesvirus 5 (HHV-5)		B25.2 (K87.1)	Pancreatitis
		B25.8	Other cytomegalovirus diseases
		B25.9	Disease, unspecified
		B27.0	Gammaherpesvirus mononucleosis
		B27.1	Mononucleosis
Flaviviridae	Hepatitis, fever	A95.0	Sylvatic yellow fever
Flavivirus		A95.1	Urban yellow fever
Yellow fever virus (YFV)		A95.9	Yellow fever, unspecified

TABLE 6 Summary of important characteristics used to differentiate families (and some genera) of viruses infecting humans

Classification		Virion properties						
		Virion					Genome	
Code and group	Virus (disease[s])	Envelope	Shape	Size (nm)	Nucleocapsid symmetry	Nature[a]	Structure	Size (kb or kbp)
00.058. *Poxviridae*	Smallpox virus, monkeypox virus, molluscum contagiosum virus	±	Brick shaped or oval	250 × 200 × 200	Complex	dsDNA, linear	Monopartite, inverted terminal repeats, both ends covalently closed	130–375
00.031. *Herpesviridae*	Herpes simplex virus (chickenpox, shingles, zoster), cytomegalovirus (mononucleosis) Epstein-Barr virus(kissing disease), Kaposi's sarcoma-associated herpesvirus	+	Spherical	150	Icosahedral	dsDNA, linear	Monopartite, terminal and internal reiterated repeats, forming two covalently linked components, making two or four isomeric forms	125–235
00.001. *Adenoviridae*	Human adenovirus A to F (enteric infections, diarrhea, respiratory infections)	−	Isometric	70–90	Icosahedral	dsDNA, linear	Monopartite, inverted terminal repeats, ends covalently linked protein	28–45
00.099. *Papillomaviridae*	More than 100 human papillomaviruses (warts and tumors)	−	Isometric	55	Icosahedral	dsDNA, circular	Monopartite, strands circular supercoiled	6.8–8.4
00.047. *Polyomaviridae*		−	Isometric	40	Icosahedral	dsDNA, circular	Monopartite, strands circular supercoiled	4.7–5.3
00.050. *Parvoviridae*	B19 virus (exanthema in children) Human bocavirus (respiratory infections)	−	Isometric	25	Icosahedral	ssDNA, (−), linear	Monopartite, population mainly (−), same (+); sequence with palindromic ends that allow circularization during replication	5
00.030. *Hepadnaviridae*	Hepatitis B virus (hepatitis)	+	Spherical	30–34	Icosahedral	dsDNA, circular	Monopartite, circular dsDNA with regions of single-stranded DNA	3.2
00.061. *Retroviridae*	Human immunodeficiency virus 1 and 2 (AIDS)	+	Spherical	80–100	Icosahedral	ssRNA, (+), linear	Monopartite, diploid, each 5′ end H bonded, 5′ end capped, 3′ end poly(A)	7–11
00.060. *Reoviridae*	Reovirus (respiratory and enteric infections), rotavirus A and B (diarrhea, enteric infections)	−	Isometric	60–80	Icosahedral	dsRNA, linear	10–12 segments, depending on genus	16–27
01.025. *Filoviridae*	Ebola virus, Marburg virus (hemorrhagic fever)	+	Filamentous, pleomorphic	790–970 × 80	Helical	ssRNA, (−), linear	Monopartite	19.1
01.048. *Paramyxoviridae*	Parainfluenza virus, mumps virus, measles virus, human respiratory syncytial virus, hendravirus, human metapneumovirus	+	Pleomorphic	150–300	Helical	ssRNA, (−), linear	Monopartite	18–20
01.062. *Rhabdoviridae*	Rabies virus	+	Bullet shaped	180 × 75	Helical linear	ssRNA, (−),	Monopartite	13–16

00.046. *Orthomyxoviridae*	Influenza virus types A to C	+	Pleomorphic		Helical	ssRNA, (−), linear	6–8 segments, depending on genus	10–13.6
00.011. *Bunyaviridae*	California encephalitis virus, La Crosse virus, Hantaan virus, Sin Nombre virus, Crimean-Congo hemorrhagic fever virus	+	Spherical, pleomorphic	80–120	Helical	ssRNA, (−), linear	3 segments, negative- or ambisense with sticky ends that allow circularization during replication	11–12
00.003. *Arenaviridae*	Lassa virus, lymphocytic choriomeningitis virus, Guanarito virus, Junin virus, Machupo virus, Sabia virus	+	Spherical	110–130	Helical	ssRNA, (−), circular	2 segments, negative- or ambisense with sticky ends that allow circularization during replication	10–14
03.019. *Coronaviridae*	Human coronavirus (respiratory and gastrointestinal infections), severe acute respiratory syndrome coronavirus	+	Spherical, pleomorphic	80–220	Helical	ssRNA, (+), linear	Monopartite, nested set of transcription, 3′ end poly(A), 5′ end capped	20–30
00.052. *Picornaviridae*	Human enterovirus types A to D, poliovirus, rhinovirus types A to B, hepatitis A virus, parechovirus (human echovirus)	−	Isometric	28–30	Icosahedral	ssRNA, (+), linear	Monopartite, 3′ end poly(A), 5′ end covalently linked protein (VPg)	7.2–8.4
00.012. *Caliciviridae*	Norwalk virus, Sapporo virus	−	Isometric	35–39	Icosahedral	ssRNA, (+), linear	Monopartite, 3′ end poly(A), 5′ end covalently linked protein (VPg)	7.4–7.7
00.084.0.01. *Hepevirus*	Hepatitis E virus (gastroenteritis and hepatitus)	−	Isometric	27–34	Icosahedral	ssRNA, (+), linear	Monopartite, 3′ end poly(A), 5′ end covalently linked protein (VPg)	7.2
00.005. *Astroviridae*	Human astrovirus (gastroenteric and enteric infections)	−	Isometric	27–30	Icosahedral	ssRNA, (+), linear	Monopartite, 3′ end poly(A), 5′ end not known	7–8
00.073. *Togaviridae*	Ross River virus, Chikungunya virus, O'nyong-nyong virus, rubella virus	+	Spherical	70	Icosahedral	ssRNA, (+), linear	Monopartite, 3′ end poly(A), 5′ end capped	9.7–11.8
00.026. *Flaviviridae*	Tick-borne encephalitis virus, dengue virus, Japanese encephalitis virus, Murray Valley virus, St. Louis encephalitis virus, West Nile virus, hepatitis C virus, hepatitis G virus, hepatitis GB virus	+	Spherical	45–60	Icosahedral	ssRNA, (+), linear	Monopartite, *Flavivirus* 5′ end capped, *Pestivirus* and *Hepacivirus* 5′ ends unknown	9.5–12.5

Specimen Collection, Transport, and Processing: Virology

MICHAEL S. FORMAN AND ALEXANDRA VALSAMAKIS

80

In recent years, there have been many advances in diagnostic virology including improvements in cell culture and the development of viral antigen (AG) and nucleic acid (NA) detection assays. The increased sensitivity and decreased turnaround time of these macromolecule detection tests have greatly enhanced the clinical utility of viral diagnostics. Successful laboratory diagnosis of viral infections requires appropriate selection, collection, transport, and processing of a specimen, regardless of the method chosen. Maintenance of specimen quality throughout testing is essential for diagnosing viral infections and ensuring appropriate patient management. Specific laboratory policies must therefore be formulated and enforced. Here we briefly review methods currently employed to diagnose viral infections (synopsized in Table 1) and describe methods for procuring, transporting, and processing specimens to be tested in the clinical laboratory.

SPECIMEN SELECTION, COLLECTION, AND PROCESSING

General Guidelines

Detection of viral pathogens is highly dependent on three variables: (i) obtaining the appropriate specimens, (ii) the timing of specimen collection, and (iii) effective and timely processing. Diagnosis of a viral etiology of an active disease process usually requires collection of a specimen from the affected organ, since this is usually where the highest levels of virus replication occur. Clinical symptoms often identify the target organ(s) involved and help to determine the appropriate specimen(s) to collect. An understanding of viral pathogenesis is helpful in determining the specimen(s) most appropriate for testing. Table 2 lists clinical specimens from which viruses may be detected.

Specimen Collection

The timing of collection in relation to onset of symptoms is of utmost importance in detecting viral pathogens. Since viral titers decrease after the acute phase of illness, selecting specimens with as many viral particles, viral antigens, or viral nucleic acid molecules as possible will improve the laboratory's ability to make a diagnosis. For many virus infections, viral shedding begins before the onset of symptoms and disappears when symptoms resolve. However, the duration of viral shedding depends on the type of virus and the organ or system involved (21). In addition, the immunocompetence of the patient has a significant effect on the time and duration of virus shedding (22, 36). For optimal recovery of most viruses, specimens should be collected within 1 to 3 days of symptom onset. Specimen collection is guided by the test method that will be used to obtain a diagnosis (14). Methods of collection can have a profound effect on recovery rates. Variables such as swab composition and anticoagulants can affect virus recovery and NA detection (2, 23, 61). Specimens should therefore be collected only with validated devices and containers. The use of viral transport medium (VTM) during specimen collection is highly dependent on specimen source. A list of specimens that do and do not require VTM is shown in Table 3. Clinical and epidemiologic data on each patient should be provided when specimens are submitted to the laboratory. Information such as patient history, immune status, time of year, travel, age, and viruses suspected may help the laboratory choose the most suitable diagnostic assay(s) and may therefore improve virus detection (34).

Acceptance Criteria for Specimens

The virology laboratory is responsible for establishing criteria for acceptable specimens and guidelines for rejecting specimens that do not meet these criteria. Upon arrival in the laboratory, the specimen and requisition should be examined to ensure that all criteria for acceptance have been fulfilled. Many institutions use electronic order-entry systems at the site of specimen collection rather than requisitions. In these cases, data in the laboratory information system must be cross-checked for compliance with established guidelines when the specimen reaches the laboratory. Specimens should be rejected if (i) they are unlabeled or mislabeled, (ii) improper specimen collection devices or containers are utilized, (iii) specimen containers are broken and/or leaking, (iv) transport time has exceeded maximum limits, or (v) duplicate specimens have been collected within a short time period. Important information that should be provided with each specimen includes patient data (name, hospital number, sex, birth date, and location), ordering physician, the specific site(s) from which the specimen(s) were collected, specific viruses suspected, time and date of specimen collection, and specific diagnostic tests requested. The physician of record must be contacted immediately regarding rejected specimens or incomplete patient information. Although failure to detect

	Molluscum contagiosum	Molluscum contagiosum virus	Histology
	Cervicitis	Adenoviruses	Culture
		HSV	Culture, NA

[a] Refer to specific chapters for details on individual viruses; only major viral pathogens, not including rare causes of disease, are listed. LCMV, lymphocytic choriomeningitis virus; HAV, hepatitis A virus; HDV, hepatitis D virus; HEV, hepatitis E virus.

[b] Most common detection methods used. NA assays include hybrid capture, nucleic acid sequence-based assay, and PCR; IA, immunoassay (includes immunofluorescent antibody, enzyme-linked immunosorbent assay, and immunochromatographic tests); EA, enzyme (neuraminidase) assay; EM, electron microscopy.

[c] Hemorrhagic fever and smallpox viruses processing requires BSL 4 facilities.

[d] Includes posttransplant lymphomas, immunoblastic B-cell lymphomas, and adult T-cell leukemia/lymphoma.

TABLE 2 Specimens for virus detection

[a] Includes direct virus detection tests such as culture, antigen detection, and nucleic acid detection. Serology is considered separately (see Table 4).
[b] Includes throat and nasal swabs, nasal wash, nasopharyngeal aspirate, and bronchoalveolar lavage specimens.
[c] Includes conjunctiva, cornea, and aqueous and vitreous fluids.
[d] Similar specimen types for distantly related GBV-C (also referred to as "hepatitis G virus").
[e] Neonatal infections.

a virus may occur as a consequence of inappropriate specimen handling, there are instances when a given specimen must be processed even though quality has been compromised (if specimens were collected by surgical procedures, the patient is no longer accessible, or the sample is unique and cannot be re-collected).

Safety Issues during Processing

Specimens should be processed in a biological safety cabinet to protect laboratory personnel from laboratory-acquired infection, to protect the specimen from environmental contamination, and to prevent cross-contamination between samples. Most viruses encountered in the diagnostic virology laboratory are classified as biosafety level 2 (BSL 2) agents. This chapter does not discuss BSL 3 and BSL 4 viruses such as arboviruses, arenaviruses, filoviruses, smallpox, and rabies, which are associated with specific clinical histories and presentations and are diagnosed by laboratories specifically designed to work with these agents. However, at times laboratory workers may unknowingly work with specimens that contain BSL 3 and BSL 4 viruses. All specimens should be handled with Standard Precautions (previously termed Universal Precautions), and specific procedures should be in place when the laboratory is requested to handle BSL 3 and 4 level agents. Of note, NA extraction reagents TRIzol and AVL Buffer have been shown to render alphaviruses,

TABLE 3 VTM use for viral specimens

Specimens that should be collected in VTM	Specimens that should be collected in containers without VTM

Tissue	Bone marrow
	Bronchoalveolar lavage fluid
	CSF
	Ocular fluid (vitreous and aqueous)
	Pericardial fluid
	Pleural fluid
	Urine

flaviviruses, filoviruses, and a bunyavirus noninfectious (4). Poxviruses are inactivated by methods commonly used in the manufacture of plasma-derived products such as pasteurization at 60°C and solvent/detergent treatments (48). Many nucleic acid extraction methods employ both heat and detergents during lysis; however, studies to determine their effect on poxvirus infectivity have not been described.

Samples from patients with transmissible spongiform encephalopathies with the highest infectivity include brain, spinal cord, and eye. Cerebrospinal fluid (CSF) and other tissue may also be infectious. Standard precautions should be followed when working with these samples. Specific decontamination procedures for residual sample and waste must be followed (65).

General Processing Procedures

Upon receipt in the laboratory, the specimen should be vortexed to break up aggregates. Glass beads in the VTM help with this process (26). For virus isolation, grossly contaminated or potentially toxic specimens, such as minced or ground tissue, can be centrifuged, and the virus-containing supernatant can be used as inoculum. If the specimen volume is insufficient for all tests ordered, the ordering physician should be contacted to set priorities. The specimen should be diluted with VTM only if absolutely necessary. For specific test requests, additional specimens may be retrieved from other laboratories with the caveat that contamination from inappropriate handling can affect both culture and NA testing. Excess specimen should be saved at −70° in case additional tests are needed or repeat testing is required.

Collection and Processing of Selected Specimens

Blood

Viremia is often associated with the acute phase of a viral disease and may precede the appearance of symptoms. For example, parvovirus B19 is found in extremely high concentrations in the blood during acute infection and detection of cytomegalovirus (CMV) in blood is predictive of CMV disease in bone marrow and solid organ transplant recipients (43). Early detection of CMV in blood allows for preemptive treatment to prevent CMV disease (17). Detection of BK virus in plasma is predictive of nephropathy in renal transplant patients (41). Detection of adenovirus in blood serves as a marker of dissemination with multiorgan involvement (12). Viremia may also occur in chronic stages of diseases such as with human immunodeficiency virus (HIV), hepatitis B virus (HBV), and hepatitis C virus (HCV).

Blood samples are collected in a 3- to 5-ml vacuum tube collection system (BD Vacutainer tubes; BD, Franklin Lakes, N.J.). Anticoagulant tubes are required when detection of viruses in plasma or leukocyte fractions is required. The most commonly used anticoagulants are EDTA (purple-top), heparin (green-top), and acid-citrate-dextrose (ACD, yellow-top). Collection of blood specimens in EDTA may be preferable over heparin since the latter anticoagulant inhibits the PCR and the infectivity of HIV-1 (2, 23).

For serologic diagnosis, an acute-phase serum specimen should be obtained within the first few days of illness, and a convalescent-phase specimen should be obtained 2 to 4 weeks later. If a virus-specific immunoglobulin M (IgM) assay is available, an acute-phase specimen may be sufficient. The timing of serum collection and the type of antibody detected vary for specific viruses (Table 4).

Blood is a suitable specimen for many different assays in the virology laboratory. It should therefore be processed following the specific instructions dictated by the chosen assay method. A variety of commercial NA assays that detect and quantify viruses in blood are available. Whole blood used for NA amplification must be processed to remove inhibitors of DNA polymerases such as heme and metabolic precursors of heme. Many different extraction protocols are used in both commercial and laboratory-developed amplification tests to

TABLE 4 Serology as a primary diagnostic tool: relevant viruses and timing of serum collection[a]

Antibody testing at presentation	Antibody testing 4–10 days after presentation	Convalescent-phase antibody (2–4 weeks after presentation)[b]
EBV (IgM)	HEV (IgM)	Arboviruses (IgG)
Hantavirus (IgM, IgG)	Arboviruses (IgM)[c]	Human coronaviruses (SARS CoV)

[b] Includes IgG and total antibody (IgG and IgM).
[c] CSF IgM also useful.

remove inhibitors. Whole blood is used in the NA sequence-based Nuclisens assay (bioMerieux, Hazelwood, Mass.) for detection of CMV pp67 mRNA and in the CMV Hybrid Capture assay (Digene, Silver Spring, Md.). In these commercial assays, nucleic acids are isolated using proprietary lysis buffers and, in the case of the Nuclisens assay, are extracted by the Boom extraction method (6).

Plasma is used for qualitative and quantitative detection of viral NAs. Plasma is obtained by centrifuging blood collected in tubes containing anticoagulant (EDTA) at 1,500 × *g* for 20 min at 25°C. Generally, the plasma supernatant is decanted into a plastic tube or vial. A newer tube system (plasma partitioning tubes [PPT]; BD) has a gel barrier that results in physical separation of plasma and cellular constituents and obviates the need for decanting plasma. These tubes decrease the incidence of errors that occur when multiple specimens are being processed simultaneously (e.g., plasma is decanted into a tube labeled with another patient's name). PPTs have been shown to maintain stability of HIV during transport at 4°C (24). Freezing PPTs is not recommended since it leads to increased levels of RNA (20, 52). Therefore, routine testing of plasma from frozen PPTs should not be undertaken unless test performance has been verified with this processing method. Special care should be taken to adhere to blood collection and processing requirements specified by the manufacturer, since deviation may affect assay performance. Plasma for Versant (bDNA) HCV and HIV RNA assays and the Versant (TMA) HCV RNA qualitative assay (Bayer Diagnostics, Berkeley, Calif.) should be separated within 4 h of collection. Plasma to be tested with the Roche Amplicor CMV, HBV, HCV, and HIV Monitor tests, HBV and HCV Taqman tests, and the HCV qualitative test (Roche Molecular Systems, Inc., Pleasanton, Calif.) must be separated within 6 h and refrigerated (4°C) for up to 72 h or frozen (−70°C) for longer periods to prevent viral genome degradation. Repeated freeze-thaw cycles should be avoided for all assays.

Serum is used for serologic testing, for culture (enteroviruses and some arboviruses), and for NA assays to detect parvovirus B19, enteroviruses, HCV, HBV, and BKV. Serum specimens are separated from clotted blood by centrifugation at 1,000 × *g* for 10 min and refrigerated (4°C) for short-term storage (24 to 48 h) or frozen (<−20°C) for longer periods. Barrier tubes similar to PPTs are also available to separate serum from other blood constituents (SST; BD Diagnostic Systems).

Leukocytes can be fractionated from whole blood, and they are particularly useful in the diagnosis of CMV infection. Isolated leukocytes can be cocultured with human diploid fibroblast cells (conventional or shell vial culture [55]), directly stained with fluorescent-labeled antibody to detect the viral protein pp65 in leukocyte nuclei (the so-called antigenemia assay [59]), or extracted to detect CMV and Epstein-Barr virus (EBV) genomes by molecular techniques. Quantifying leukocyte input is essential for optimizing assay sensitivity (35). Leukocytes for antigenemia staining are separated from 3 to 5 ml of blood anticoagulated with EDTA or heparin by using direct red blood cell lysis with ammonium chloride. Leukocytes from a similar volume of blood for CMV culture are separated by gradient sedimentation. Several density gradient methods have been used for separation. Ficoll-Paque plus (Amersham Biosciences Corp., Piscataway, N.J.) and Lymphosep lymphocyte separation medium (MP Biomedicals, LLC., Irvine, Calif.) are used to separate lymphocytes. Mono-Poly resolving medium (MP Biomedicals, LLC., Irvine, Calif.) and Polymorphprep (Technoclone, Vienna, Austria) enable the resolution of both mononuclear and polymorphonuclear leucocytes into two distinct bands. HISTOPAQUE-1077 (Sigma Diagnostics, St. Louis, Mo.) is used for isolation of mononuclear cells, and ZEPTOGEL (ZeptoMetrix, Buffalo, N.Y.) is used for isolation of the total leukocyte fraction. Blood for CMV isolation should be fractionated and inoculated as soon as possible after collection. Processing delays may result in decreased CMV detection by culture. For the antigenemia assay, if processing is delayed, unfractionated blood should be stored at room temperature, with rocking. However, the number of CMV-positive cells quantified by the antigenemia assay is decreased for specimens held overnight (34).

Bone Marrow

CMV and parvovirus B19 are the most common viruses detected in bone marrow. PCR of bone marrow can be used to diagnose parvovirus B19-induced aplastic anemia, congenital anemia, and chronic red cell aplasia (66). Bone marrow can also be used to diagnose disseminated varicella-zoster virus (VZV) and human herpesvirus 6 (HHV-6) infections. Aspirated bone marrow is placed in tubes containing EDTA. The same processing considerations with respect to timing, anticoagulants, and removal of inhibitors that apply to blood also apply to bone marrow.

CSF

Rates of virus recovery from CSF are generally low. Enteroviruses are the most common viruses grown from CSF (with the exception of coxsackie A viruses, which are difficult to isolate in tissue culture). Herpes simplex viruses (HSV) and arboviruses are important causes of sporadic encephalitis in immunocompetent individuals. HSV can be isolated from CSF in neonatal herpes and in some cases of meningitis. Arboviruses are difficult to isolate from CSF, and IgM tests are now standardly used for diagnosis. CMV, VZV, EBV, and JC virus (JCV) are important central nervous system (CNS) pathogens in immunocompromised patients. CMV and VZV are also rarely cultured (8). Methods for EBV and JCV culture are not available in clinical laboratories. The application of molecular techniques has revolutionized the diagnosis of CNS disease caused by neurotropic viruses (47). In particular, NA amplification techniques are now the standard of care when a diagnosis of HSV encephalitis or meningitis is suspected (37). Reverse transcriptase PCR (RT-PCR) for the detection of enteroviruses increases sensitivity and decreases time to diagnosis. Enteroviruses, if cultivatable, typically take 3 to 14 days to isolate. With NA techniques, enteroviral RNAs are detectable within hours (18).

CSF is collected and placed into a sterile leak-proof tube. Dilution of CSF (or other sterile body fluids such as pericardial or pleural fluids) is contraindicated. Therefore, CSF specimens should not be collected in VTM. Susceptible cell lines can be inoculated directly without additional processing prior to culture. However, nucleic acids should be extracted from CSF prior to testing with molecular assays (particularly PCR) because CSF contains globulin and protein from high cell counts as well as uncharacterized substances that inhibit the activity of thermostable polymerases used in PCR (19, 46). Although it is theoretically optimal to quantify the nucleic acid content of a specimen prior to its use in molecular assays, the amount of recovered NA (from CSF or any other relatively acellular specimen) is likely to be below the limit of detection of standard quantitative techniques (e.g., spectrophotometry at an absorbance of 260 nm).

Therefore, in practice, NA is not quantified prior to performance of molecular assays.

Amniotic Fluid

Although rare, viruses can infect the fetus. The most common viruses that cause infections in utero are CMV, parvovirus B19, and HIV. HSV and VZV are less frequently observed. Congenital infections with rubella virus are rarely seen in the postvaccine era. Amniotic fluid is a useful specimen source for the diagnosis of congenital infections. CMV and rubella virus can be detected by culture. Nucleic acid tests can be used to diagnose parvovirus B19 (67), CMV (5), HSV (25, 30), VZV (38), and rubella virus (49). Amniotic fluid is collected by amniocentesis and sent to the laboratory in a sterile container without VTM.

Respiratory Specimens (Throat, Nasopharyngeal Swab, Nasopharyngeal Aspirate, Nasal Wash, and BAL Specimens)

Viruses that cause respiratory tract disease such as influenza viruses, parainfluenza viruses, respiratory syncytial virus (RSV), adenoviruses, and rhinoviruses are most frequently identified in samples of respiratory secretions. Many of these viruses infect the ciliated epithelium lining the posterior nasopharynx. They are often detected by direct AG detection methods such as enzyme immunoassay, immunochromatographic assays, and immunofluorescent-labeled antibody staining. Results of studies comparing nasopharyngeal swabs and aspirates are highly variable; however, nasopharyngeal swabs are generally collected from older children and adults; nasopharyngeal aspirates are the specimen of choice for infants and younger children (1, 32). The convenience of using a swab for specimen collection by medical personnel and the willingness of the older patient to allow collection with a swab (compared to an aspiration or wash) are important factors that explain their frequent use. Nasal wash specimens do not contain a large number of virus-infected cells; however, they are often collected from adults, particularly thrombocytopenic patients for whom nasopharyngeal aspiration is contraindicated. Bronchoalveolar lavage (BAL) and bronchial specimens are useful in the diagnosis of lower respiratory tract infections and offer a less invasive alternative to open lung biopsy.

Nasopharyngeal swab samples are collected by inserting a flexible, fine-shafted swab deep into the nares, past the point of resistance, and gently rubbing the posterior pharynx and the nasal turbinates. The swab is removed and placed in VTM. Aspirates are collected by passage of an appropriately sized tube or catheter into the nasopharynx and aspirating material with a syringe or a mechanical suction device. Aspirates are usually placed in VTM. Nasal wash specimens are obtained by instilling several milliliters of sterile saline into each nostril while the patient's head is tilted back slightly; the head is then brought forward, and the saline is allowed to flow into a small container held beneath the nose (7). BAL specimens are collected by inserting a fiber-optic bronchoscope into the involved segment of the lung, instilling saline, and applying suction to remove the lavage specimen.

All respiratory specimens are acceptable for culture (conventional or shell vial [1, 29, 39, 57, 58]). Respiratory specimens are often contaminated with upper respiratory tract microbial flora. These organisms have little effect on viral culture if they are susceptible to antibiotics in the transport and culture media. However, resistant organisms can overgrow cultures and prevent virus detection. Removal of most microbial contaminants by centrifugation ($3{,}000 \times g$ for 20 min) or filtration of the specimen (0.2-μm pore size) is advantageous; however, these procedures also remove virus-infected cells, resulting in reduced viral titers. AG and NA detection should be performed on the specimen prior to these manipulations since loss of host cells during processing may compromise the sensitivity of these assays. Mucus in respiratory specimens can significantly affect AG detection. In fluorescent-antibody tests, mucus can inhibit fixation of cells to slides and can cause nonspecific fluorescence. It also prevents penetration of the sample into membrane devices. To prevent these complications, mucous threads can be broken by repeated aspiration through a small bore pipette.

Urine

Urine is an important source for the detection of infections caused by CMV, enteroviruses, adenoviruses, BK virus, and HSV. Urine can be cultured (conventional or shell vial) or assayed using molecular techniques. Urine culture is the most common method for diagnosing CMV infection in neonates. In newborns, detection of CMV in urine within 21 days of birth confirms congenital acquisition of infection. Culture of enteroviruses from urine also establishes the diagnosis of enterovirus-induced disease. Mumps and rubella viruses were isolated from urine in the prevaccine era but are usually not seen today.

To collect urine specimens, the external genitalia are cleaned with a detergent-impregnated towelette. A volume of 5 to 10 ml of midstream-voided urine is collected in a sterile container. Collection in VTM is not recommended.

Urine must be processed for use in virus detection assays. Its acidic pH and the presence of microbial contaminants can inhibit virus growth. Urine also contains substances that inhibit PCR and other amplification techniques. To improve virus recovery, pH can be neutralized with sodium bicarbonate (7.5% solution) and bacteria can be removed by filtration (0.2-μm pore size) prior to culture. Attempts to improve virus recovery by culturing cell pellets versus supernatant after centrifugation have yielded variable results (3). For molecular assays, nucleic acids can be extracted from urine by a variety of manual or automated extraction methods.

Feces (Rectal Swab)

Many viruses that cause gastroenteritis such as enteric adenoviruses, caliciviruses (Norwalk group of viruses), astroviruses, and rotaviruses are noncultivatable in cell culture and require alternative methods for detection (9, 44, 60) (Table 2). Enteroviruses can be found readily by fecal culture or NA detection, but care must be taken in the interpretation of a positive result since asymptomatic shedding can occur in feces. Enveloped viruses are not commonly recovered in fecal specimens. One exception is CMV, which causes intestinal disease in immunosuppressed patients.

Fecal samples (2 to 4 g) are placed into a clean, dry, leakproof container, or samples are collected by inserting a swab 4 to 6 cm into the rectum and rotating the swab against mucosa. The swab is removed and placed in VTM. Fecal samples are preferred over rectal swabs since swabs often collect insufficient quantities of specimen.

Eye

HSV and adenovirus are the two viruses most often associated with keratitis and conjunctivitis. Diagnosis is made by conjunctival or corneal cultures. Enterovirus 70 and coxsackievirus A24 have been associated with hemorrhagic conjunctivitis and may be detected by PCR (54). Conjunctival swabs are collected from the lower conjunctiva

with a flexible, fine-shafted Dacron or rayon swab moistened with sterile saline and placed in VTM. Scrapings of the cornea or conjunctiva should be collected by an ophthalmologist or by other adequately trained personnel.

Viral causes of retinitis include CMV and VZV. These pathogens are detected in the aqueous and vitreous fluids by molecular techniques (amplification of viral genome) because they are not easily cultivated from these sites. These fluids have been shown to inhibit PCR (63); therefore, the original specimen must be extracted (see "CSF" above) to remove inhibitors. Vitreous and aqueous fluids are obtained from the eye during ocular surgery and placed in sterile containers for transport to the laboratory.

Tissue (Biopsy or Autopsy)

Many viruses can be isolated with ease from tissue. Lung is an ideal source for detecting lower respiratory tract infections due to viruses such as influenza, parainfluenza, adenovirus, HSV, and CMV. Other tissues that may yield positive viral results include liver, spleen, kidney, lymph node, and brain. In addition to culture, methods such as histology, AG detection (immunohistochemical stains), and NA detection can be used to detect viruses in tissue.

The major drawback of tissue specimens is the invasive nature of biopsy. However, for certain patients, biopsy is the only option. Tissue samples are obtained during surgery or autopsy and placed in VTM. An attempt should be made to excise the specimen from areas directly adjacent to the affected tissue. Tissue samples may also be obtained during endoscopy of the upper and lower gastrointestinal tract to detect viruses such as CMV, HSV, and adenoviruses.

Tissue specimens for culture are ground with a sterile mortar and pestle or a tissue grinder and resuspended in VTM. The tissue specimen is centrifuged (1,000 × g for 15 min at 4°C) to remove cell debris that may be toxic to cell culture, and the supernatant is inoculated onto cell monolayers. Fresh tissue specimens for NA detection are weighed (25 mg is optimal for most tissues), minced, treated with proteolytic enzymes, and extracted. NAs can also be obtained from formalin-fixed, paraffin-embedded tissues after deparaffinization and extraction.

Genital Specimens

The most common viral cause of external genital lesions in men and women is HSV-2. Although not as prevalent, HSV-1 is also sexually transmitted and can cause genital lesions (31). HSVs are easily cultured from these lesions, and growth usually requires only 24 to 48 h. HSV-1, HSV-2, and CMV are also frequently detected from the cervix, vagina, and urethra. Human papillomavirus (HPV) genotypes associated with a high risk of cervical cancer (genotypes 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, and 68) can be detected in cervical specimens by using molecular tests.

Genital specimens are collected with swabs that are then placed in VTM. Prior to collection of cervical specimens, mucus should be removed with a swab and discarded. Cervical specimens are collected by inserting a clean swab 1 cm into the cervical canal and rotating for 5 s. The swab is then removed and placed in VTM. Cells from the cervical os can also be obtained using a Cytobrush. Cervical samples collected in manufacturer-specific formats or as liquid-based cytology specimens are appropriate for HPV high-risk genotype detection (45). Cervical brush specimens in Standard Transport Medium for the hc2 High-Risk HPV DNA Test (Digene) may be stored for up to 2 weeks at room temperature, after which specimens can be stored for an additional week at 2 to 8°C. If testing is to be performed more than 3 weeks from collection, specimens should be placed at −20°C for up to 3 months. Cervical biopsy specimens must be placed into 1 ml of Standard Transport Medium and stored frozen at −20°C. Specimens in liquid-based cytology medium may be held for up to 3 weeks at temperatures between 4 and 37°C and cannot be frozen. To collect urethral specimens, exudates should be expressed and discarded. The patient should not have urinated for at least 1 h prior to collection. A flexible, fine-shafted swab is inserted 4 cm into the urethra, rotated 2 or 3 times, removed, and placed in VTM. Genital specimens are often contaminated with microbial flora. These specimens are usually centrifuged at 3,000 × *g* for 20 min to remove bacteria prior to culture.

Skin

Viruses can cause rashes with many different appearances including vesicular, maculopapular, and petechial. Vesicular lesions are commonly caused by HSV, VZV, and enteroviruses. Fresh vesicles should be sampled for optimal virus detection. Vesicles can rupture and ulcerate. Ulcers that have crusted may not contain viable virus or viral antigens. Samples are obtained by disrupting the surface of the lesion and collecting fluid with a swab or by aspirating with a 26- or 27-gauge needle attached to a tuberculin syringe (15). Specimens should be collected gently, without causing bleeding, since the presence of neutralizing antibody in blood can impair recovery. The base of the lesion should be scraped to collect cellular material for AG detection assays. Smears may be prepared at bedside. Swabs should be placed in VTM if the specimen is destined for NA detection, AG detection, and/or culture.

Viruses that cause maculopapular rashes include rubella, measles, adenoviruses, and enteroviruses. Viruses that cause petechial rashes include adenoviruses and enteroviruses. Recovery of viruses from these types of rashes requires a skin biopsy specimen, which is not routinely cultured by most clinical laboratories. Parvovirus B19 causes a maculopapular rash, but it is noncultivable in conventional tissue culture systems. Sources other than dermis are preferred for diagnosing these viral infections.

SPECIMEN TRANSPORT

Once a clinical specimen has been collected, it should be transported to the laboratory as soon as possible because virus viability decreases with time (some clinically important viruses are more labile than others). Overall diagnostic yield improves when specimens are expeditiously processed for viral culture. Viability is not required for antigen or NA detection techniques; therefore, transport time is not as much of an issue when these assays are to be performed. However, for timely diagnosis, delay should be avoided during transport of these specimens to the laboratory.

VTM should be used for all swabs and tissues, since they can dry during transport (Table 3). Specimens such as CSF, blood, urine, bronchoalveolar lavage fluid, vesicle fluid, amniotic fluid, and feces can be sent without transport medium (29).

Transport Conditions

Several steps may be taken to help preserve viruses during specimen transport to the laboratory, including the following: (i) transport of nonblood specimens at 4°C with wet ice or cold packs, especially if transit time is greater than 1 h; (ii) use

of VTM if appropriate, as described below; and (iii) avoiding freezing unless a delay of 24 h is anticipated (64). Specimens should be frozen at −60°C (dry ice). It is important to remember that recovery of RSV, CMV, and VZV may be seriously compromised by freezing.

Storage and transport conditions may vary somewhat based on the stability characteristics of specific viruses or viral NAs. A study to determine the feasibility of shipping adenovirus samples in M4RT showed that the virus is stable for up to 5 days at ambient temperatures (51). Severe acute respiratory syndrome coronavirus infectivity is maintained in serum, sputum, and feces for 96 h and in urine for 72 h (10a). CMV infectious titers in blood were decreased by up to 91% after storage at 4°C for 24 h (40). The data on CMV DNA quantification after storage are conflicting, with some studies reporting no decline in CMV DNA levels after 24 h (40) and 72 h (50) while another showed increased levels in blood stored at room temperature or at 4°C prior to plasma separation from lymphocytes (53). The increased levels of CMV DNA may be due to release of CMV from cells into plasma during storage. HSV DNA is stable in CSF specimens containing lymphocytes and monocytes for up to 30 days at temperatures ranging from 25 to −72°C (62). Temperature storage requirements for fluids, solid tissues, and extracted NA for diagnostic molecular testing have been described in a comprehensive review (13). RNAlater, an RNA stabilization buffer (Qiagen, Valencia, Calif.), has been shown to stabilize HCV and HIV RNA in plasma for up to 28 days at 37°C (33) as well as stabilizing virus infectivity of enveloped and nonenveloped viruses stored at room temperature for up to 50 days.

Transport Medium

The ideal transport medium maintains viability of a broad range of cultivatable viruses and is also compatible with the newer non-culture-based tests. VTM generally contains buffer to control pH, substances to maintain an appropriate osmotic environment, protein to stabilize the virus, and antibiotics to prevent growth of microbial contaminants. Many different transport media have been described and used successfully, including cell culture medium, bacteriologic broth-based media, buffered salt solutions with added protein, sucrose-based solutions, bentonite-containing media, and swab-tube combinations. Direct inoculation of cell monolayers and cell suspension at bedside has also been described (56). Some laboratories have reported that culturette swabs with Stuart's medium designed for collection and transport of bacteriology specimens are also acceptable for collection and transport of viral specimens. The swab-tube combination and liquid transport medium are two of the more common transport systems used today. VTM may be prepared in-house or purchased commercially. In most laboratories, commercial media have replaced "home-brew" transport solutions. Table 5 lists the different commercial media, as well as their sources, compositions, and storage conditions. Of note, CVM transport media contain no buffer to control pH, and the Viral Culturette contains no buffer, protein stabilizer, or antibiotics to control microbial contaminants. Therefore, delay in transport of viral specimens in these media should be avoided. Bartels ViraTrans contains fetal bovine serum, which may inhibit isolation of influenza viruses.

Unfortunately there have been no recent comprehensive comparisons of either commercially available or in-house prepared VTM. The most comprehensive reviews of transport systems for viruses appeared several years ago (27, 28), and many of these transport systems are no longer in use today. It is difficult to compare results of the few studies that have been performed because they were carried out in different laboratories under different conditions (with varying viral inocula and detection methods). Ideally, direct comparisons of several different transport media that support growth of multiple viruses should be performed in a clinical setting. However, the cost and logistics of performing these types of comparative studies remain problematic. One study comparing MicroTest M4 and Bartel's VTM for oral and genital specimens showed them to be equivalent for detection of HSV (42). A second study compared Copan VTM, BBL Viral Culturette, and Micro Test M4 (11). Copan VTM and Micro Test M4 were more effective than BBL Viral Culturette in maintaining low concentrations of viable virus that could be recovered in routine cell culture.

Manufacturers of commercial assays for NA or AG detection either supply transport media or make recommendations for transport systems that are compatible with their assays. The hybrid capture assay (Digene) for detection of high-risk HPV types is an example of the former, and Directigen assays (BD Diagnostic Systems) for influenza and RSV are examples of the latter. In addition to the Digene specimen transport medium and device, SurePath (TriPath Care Technologies, Burlington, N.C.) and ThinPrep (Cytyc, Marlborough, Mass.) liquid-based Pap tests have been evaluated for detection of high-risk HPV genotypes with favorable results (10, 45). Thus far, VTM has not been shown to inhibit amplification assays such as PCR (29) or interfere with AG detection tests (16).

Transportation Regulations

Few clinical virology laboratories can offer a complete battery of diagnostic tests for all human viruses. Therefore, shipment of samples to reference, specialty, state, or federal laboratories is common practice. A recent change in regulations has simplified the shipping process for most specimens. Currently, the majority of samples can be shipped as diagnostic or clinical specimens. Only specimens that have or may have a category A pathogen are classified as "Infectious Substance." Strict attention must be paid to specimen packaging and labeling for the transport of infectious substances. Shipping specimens through the mail or by commercial courier is regulated by federal and international agencies. Regulations are published by the U.S. Public Health Service and are also available from the U.S. Department of Transportation on the Internet (http://www.dot.gov). The International Civil Aviation Organization guidelines stipulate that training must be provided within 90 days of assuming a job involving the transport of dangerous goods. Retraining must take place every 24 months, and training records including time, place, instructor, and materials must be maintained. The International Air Transport Association 2005 dangerous goods regulations define infectious substances, containers, labels, and other packaging instructions required for shipping.

SUMMARY

Diagnosis of virus infection is based on likely etiologies, assay performance (sensitivity, specificity, positive predictive value, and negative predictive value), turnaround time, and cost. Viruses in and of themselves put limitations on test options (viruses that are noncultivatable must be identified directly in the specimen by electron microscopy, cytologic and histologic methods, AG detection, or NA detection or indirectly by serology). Regardless of the test method, the proper selection, collection, transport, and processing of specimens will

TABLE 5 Commercial sources and formulations of VTM

always be of the utmost importance. In some instances, a common sample can be collected and shared across diverse testing platforms. However, many commercial assays have specific sample requirements that must be followed. All aspects of "user-defined" assays, including specimen type, collection device, transport, and processing, as well as any changes to package insert specifications for commercial assays, must be verified. On the surface, the initial steps of viral detection appear simple and virtually static. However, as the field of diagnostic virology evolves, it is likely that new collection devices, transport systems, and processing methods that enhance detection will continue to emerge.

Reagents, Stains, Media, and Cell Lines: Virology*

KIMBERLE C. CHAPIN

81

Viruses are intracellular parasites requiring living cells to replicate. Thus, the description by Enders et al. in 1949 (7) of a cultivated mammalian cell line to isolate poliovirus and the subsequent cytopathic effect (CPE) was a critical development that opened the door for the practice of clinical virology. Subsequent discovery of host-sensitive animal and human tissue cell lines, as well as identification of virus-specific monoclonal antibodies and fluorescent-antibody (FA) techniques, resulted in the ability to isolate and identify many viruses infecting humans in a clinically useful time frame. Despite viral culture becoming technically more challenging with the current workforce available to the laboratory (http://www.asm.org/Policy/index.asp?bid=39060) and rapid immunologic antigen screening assays becoming the mainstay of most virology laboratories, cell culture remains a vital function that needs to be retained for a number of reasons (20). This chapter describes reagents, stains, media, and cell lines unique to virology used in association with culture techniques. The reader is referred to documents from the Clinical and Laboratory Standards Institute (CLSI) that provide guidelines for viral cell culture (3) and Appendices 2 and 3 in the 3rd edition of the *Clinical Virology Manual* (15) for listings of state public health laboratory virology services and virology laboratories offering diagnostic services that perform more esoteric testing. In addition, multiple websites, including http://www.virology.net, are available that also include international laboratories (8, 9). Appendix 1 of this chapter includes manufacturers and suppliers mentioned throughout this text for virology media and reagents.

Specimens containing viruses have transport requirements different from those of specimens for which bacterial or fungal diagnoses are being entertained. Viral transport media are designed to provide an isotonic solution containing protein, antibiotics to control bacteria, and a buffer to control pH. The media come in polypropylene centrifuge tubes that contain approximately 2 to 3 ml of medium, 1-dram freezer vials with up to 2 ml of medium, or a tube and swab with a gel or sponge base. Most often laboratories are using transport systems that can be used for the culture of *Chlamydia* and viruses, as well as *Ureaplasma* and *Mycoplasma*. The antibiotics used in these dual-purpose media are not inhibitory to either bacterial pathogens or viruses. In addition, some transport systems are available to be stored and/or allow transfer of specimens at room temperature instead of refrigeration. The reader is referred to chapter 80.

Cell culture systems are live cell monolayers that support the growth of viruses. Most viruses are detected by their production of a CPE, characteristic and visible morphological alterations in a susceptible cell line due to viral replication. Use of cell cultures is the most sensitive method for detecting many viruses and permits the detection of a wide variety of viruses or new viruses from a few media, in contrast to single-method detection systems such as enzyme immunoassay. Additionally, viruses isolated in culture can be analyzed for epidemiological purposes or to assess pathogenesis. For example, annual characterization of influenza virus isolates can direct vaccine development for the next influenza season.

Cell cultures may be propagated and/or maintained within the laboratory; however, monolayer cell cultures are more commonly prepared commercially (Appendix 1) and shipped to the laboratory every 1 to 2 weeks depending on the laboratory needs. Cells are typically provided in 16- by 125-mm screw-cap tubes or in 1-dram shell vials. Cell cultures come with the cell monolayer on one side of the lower half of the tube. The monolayer is covered with nutrient medium, and the manufacturer's label appears on the opposite side of the monolayer to aid in orientation of the tube for positioning and viewing.

Selection of cell lines varies for each laboratory and is dependent on the patient population and the most likely viruses that will be isolated. The most sensitive host system for the suspected virus should be included (refer to the specific chapters for individual viruses). The experience of the technologist with specific cell lines, cost, and availability of a cell line are also considerations for cell line selection. The reader should be aware that some traditional cell lines are not readily available (fetal cell lines) and are beginning to be replaced with cell lines of animal origin.

There are a multitude of special conditions that must be considered when inoculating cell cultures and identifying viruses. Some of these include the lack of CPE by certain viruses and the need to perform subsequent testing, such as hemadsorption; pretreatment of specific specimens with inherent toxicity, such as urine and stool; pretreatment of a cell line with trypsin to facilitate infection by a particular virus; and filter sterilization or treatment with antibiotics for respiratory specimens to limit bacterial or fungal contamination (chapter

* This chapter contains information presented in chapter 79 by Kimberle C. Chapin and Fred W. Westenfeld in the eighth edition of this Manual.

80). In addition, it should be noted that culture of certain viruses requires biosafety level 3 (BSL-3) or BSL-4 facilities, and any suspect specimen with a virus in this category should be referred to the appropriate facility.

Viral susceptibility testing is performed by phenotypic or genotypic assays. Readers are referred to chapter 114 for a more detailed discussion. Phenotypic assays may be performed using several methods such as plaque reduction, dye uptake, enzyme immunoassay, inhibition assays, and yield reduction assays or DNA hybridization. All methods employ cell cultures infected with virus, to which various dilutions of antivirals are added. Any decrease in viral activity is then measured. An approved standard for the plaque reduction assay is available as a document from the CLSI and standardizes antiviral susceptibility testing for herpes simplex virus (1).

Quality control of cell culture media and cell lines is an important consideration for virus isolation. Documentation of cell culture records such as cell type, passage number, source, age, receipt date, and maintenance medium lot and date are appropriate (2, 3, 21). Some of these parameters are documented on the shipping receipt from the vendor. In addition, culture media and additives should be checked for sterility and absence of toxicity. Correct storage at 35 to 37°C and rotation of media, using the oldest cell cultures first, ensure consistency in inoculation of fresh cell lines. Examining cells to confirm use of healthy cell cultures before inoculation and inoculating within 8 to 10 days of seeding are best for optimal performance (16, 21). Uninoculated cells of each lot should be maintained as negative controls to monitor toxic and/or nonspecific changes associated with cell age, as well as bacterial or fungal contamination that may be confused with CPE. Use of a pH indicator in the maintenance medium allows detection of changes in the condition of the monolayer. Changes in the maintenance medium color could be due to such factors as virus proliferation, cellular toxicity, or bacterial contamination. Microscopic examination is necessary to identify the specific cause. Finally, laboratories should be aware of possible changes in sensitivity of specific viruses to host cells and decreased sensitivity in continuous cell lines that have undergone multiple serial passages or have come from other laboratories (15). Readers are referred to the CLSI document on viral culture, M41-P, for further information (3).

REAGENTS

■ HEPES

HEPES is a serum-free medium used as a buffer in virology culture media.

■ Formalin for cell culture preservation

A formalin solution may be used to preserve viral CPE in cell culture, allowing the user to demonstrate viral CPE indefinitely and produce a useful teaching set.

Minimal essential medium with Earle's balanced salt solution	81 ml
37 to 40% Formaldehyde	30 ml

Note that formaldehyde is normally purchased as a 37 to 40% HCHO solution. Mix the minimal essential medium with the formalin in a suitable glass container. Fill cell culture tubes exhibiting CPE with the above mixture and store at room temperature.

■ Hemadsorption test

The hemadsorption test is used to detect orthomyxoviruses and paramyxoviruses in cell culture. Viruses such as influenza, mumps, and parainfluenza viruses may not produce CPE. These viruses possess a surface hemagglutinin that is expressed in the plasma membrane of virus-infected cells. These proteins have an affinity for erythrocytes and cause clumping of guinea pig red blood cells when introduced into the culture tube (22).

Basic procedure

The following is a basic descriptive procedure. Slight variations exist in preparation and inoculation of the guinea pig red blood cell suspension.

A guinea pig red blood cell suspension is produced by placing guinea pig cells in cold phosphate-buffered saline (PBS). A 4 to 10% stock solution of suspended cells is made depending on the working dilution required. A series of two or three washes with PBS and centrifugation with removal of the supernatant between each wash is performed. Remove the saline after the final wash in order to achieve the desired percent concentration solution (if the result is 0.4 ml of packed red cells, remove supernatant until 4 ml remains to acquire a 10% solution). The red cell suspension should be stored at 4°C and can be used for 1 week. From the 10% suspension, prepare a 0.4% suspension of guinea pig red blood cells. Remove medium from cell culture tubes and replace with 1 ml of cold PBS. Place 0.2 ml of the 0.4% suspension into each tube. Incubate at 4°C for 30 min. Shake the tube and examine microscopically for red blood cells that are adhering to the monolayer and/or clumping in the fluid, indicating a positive test (14).

■ PBS for 1-liter volume (10)

Solution A

NaCl	8.0 g
KCl	0.2 g
$CaCl_2 \cdot 2H_2O$	0.132 g
$MgCl_2 \cdot 6H_2O$	0.1 g
Distilled water	800 ml

Solution B

Na_2HPO_4	1.15 g
KH_2PO_4	0.2 g
Distilled water	200 ml

Dissolve each salt in demineralized water in the order listed. Sterilize by autoclaving for 20 min or by filtration. Mix solutions A and B when cool and adjust pH to 7.0. Store refrigerated.

■ Density gradient media

Density gradient media are used to fractionate a patient's leukocytes. The cells are subsequently cultured or used for direct staining. The reader is referred to chapter 80 for a listing of manufacturers and specific uses of the various media available.

■ Dulbecco's PBS (4)

PBS with glucose and sodium pyruvate. An early described maintenance-type medium.

■ Saline

Saline is used as a diluent in a variety of procedures. Normal or physiological saline is 0.85%.

Sodium chloride	8.5 g
Distilled water	1,000 ml

Other concentrations (e.g., 0.45%) are also used.

■ 10× Gentamicin-amphotericin B solution

10× gentamicin-amphotericin B solution is added to clinical specimens during tissue culture inoculation to reduce bacterial and fungal contamination. Use at a ratio of 1:10 (0.1 ml of 10× gentamicin-amphotericin B for every 1.0 ml of specimen) before centrifugation of the specimen. The supernatant is then inoculated to the appropriate cell culture line.

Eagle's minimal essential medium	89 ml
Gentamicin (50 mg/ml)	1 ml
Amphotericin B (250 μg/ml)	10 ml

Add all three ingredients and store frozen at –20 to –70°C in suitable working aliquots.

■ Trypsin solutions

Trypsin releases cells from the monolayer of a culture. Release of cells allows for subsequent passage of the cells or antibody-specific identification of cell-associated viruses such as varicella-zoster virus (VZV), adenovirus, and cytomegalovirus (CMV). Trypsin can be used instead of scraping cells from the culture vessel. Solution is made with either 2.5% PBS or Versene solution, which contains EDTA. Both are available commercially. See Appendix 1.

VIROLOGY STAINS

A rapid viral diagnosis may be made by directly examining stained clinical specimens. Specimens can be prepared in a number of ways, including direct application of mucous membrane scrapings onto a slide, concentration of bronchoalveolar lavage fluid by cytocentrifugation, or touch preps from unfixed tissue onto a slide. Papanicolaou (Pap), hematoxylin and eosin, and Wright-Giemsa stains are used to examine these preparations. A preliminary identification can be made when characteristic cell morphologies are observed (e.g., "smudge cells" or large basophilic inclusions consistent with adenovirus, or "owl's eye" nuclear inclusions consistent with CMV); however, a specific diagnosis is generally not possible unless virus-specific antibody staining methods are used (18, 20). For example, intranuclear inclusions and multinucleated cells are seen in both VZV and herpes simplex virus infections. Smears fixed in 95% alcohol or a cytological fixative are stable indefinitely at room temperature and can easily be transported in cardboard or plastic slide carriers to the laboratory (18).

Immunostaining

Specific immunostaining techniques using FA stains and horseradish peroxidase-labeled antibodies have become the most commonly used staining techniques for the detection of viruses (20). Viral antigen for the specific virus is sought using a monoclonal antibody specific for the virus. Fluorescein isothiocyanate (FITC)-labeled mouse monoclonal antibodies with Evans blue counterstain and tetramethylrhodamine isothiocyanate (TMIT) are the most commonly used markers. FITC yields an apple-green fluorescence and TMIT yields a reddish orange fluorescence when excited by the proper wavelength (13). FA staining is either direct or indirect depending on the antibody sandwiching technique used. Readers are referred to chapter 18 for specific details about the methodology. Immunostaining can be performed on slides obtained by direct preparation from a clinical specimen (such as with a VZV lesion scraping) or from virus-infected cells from a cell culture or spin amplification coverslip. Direct examinations using cytocentrifuged clinical specimens and leukocyte preparations are also common for respiratory viruses and CMV, respectively.

MEDIA AND CELL LINES

Cell culture media for viruses serve three general purposes: (i) short-term survival of cells such as during specimen transport, (ii) long-term survival such as when cell lines are passaged over an extended period, and (iii) rapid cell proliferation. The basic component of all of these media is a balanced salt solution with a CO_2-bicarbonate buffering system for maintaining pH within acceptable ranges. The solution contains inorganic ions, glucose, and a buffer (HEPES) with a phenol red indicator. The components allow maintenance of the osmotic pressure and the pH within the range of 6.8 to 7.6, which is optimal for mammalian cells, as well as aid in the detection of pH changes in the media. A carbohydrate source and inorganic ions are necessary for the regulation of osmotic pressure, pH, and the cells' enzymatic and metabolic activities. The addition of serum aids in the attachment and spreading of cells on the culture vessel. Amino acids and vitamins must be added to any media that will be used for other than short-term survival. There are 12 amino acids that are necessary for the development of protein and synthesis of nucleic acids. Amino acids also act as buffers. Vitamins, particularly the B vitamins, can act as vitamin supplements or as coenzymes for metabolism. Fat-soluble vitamins, such as vitamin A, are often added to media without serum. Other additives, such as antibiotics and hormones, commonly supplement the basic media. Most media are commercially available in liquid form. Serum, glutamine, and antibiotic solutions are filter sterilized (0.2-μm-pore-size filter) or purchased filter sterilized and typically added before use.

■ Balanced salt solutions (Hanks' and Earle's)

Balanced salt solutions are used alone for short-term survival, the transport of specimens, and the processing of viruses. Earle's and Hanks' salt solutions are the two most commonly used balanced salt solutions and have similar formulations. Earle's balanced salt solution has a better buffering capacity with CO_2, and Hanks' balanced salt solution has a better buffering capacity with air.

■ Basal medium Eagle cryoprotective medium (5)

Eagle's minimal essential medium with Hanks' balanced salt solution and 15% dimethyl sulfoxide (DMSO) is the original medium described for preserving virus. DMSO acts as the cryoprotective agent.

■ Buffered glycerol saline

Buffered glycerol saline is a multipurpose transport medium. The transport medium is used for the isolation of bacteria as well as viruses. Glycerol-containing media may also be used for long-term storage of isolates and transport or storage of biopsy specimens.

■ Growth medium with 10% fetal bovine serum

Growth medium is medium used to enhance the growth and multiplication of cell numbers. This medium is necessary in virology laboratories where cell cultures are prepared and transferred. Serum is added at a much greater concentration (8 to 20%) than that used in maintenance media. The serum component aids in promoting cell attachment and spreading on the surface of the culture vessel. Yeast extract and peptones also help cell proliferation. The colony sizes of the cells are larger in growth medium than in maintenance medium, but serum may contain inhibitors, toxins, infectious agents, or antibodies that interfere with cell growth. Typically, fetal bovine serum is preferred since it is less likely to contain these substances. Heat inactivation of serum may reduce some of its growth-promoting properties. Antibiotics and antifungal agents are typically added to reduce bacterial and fungal contamination. Fetal bovine serum (50 ml), L-glutamine (5 ml), gentamicin (0.5 ml; 50 mg/ml), and amphotericin B (5 ml; 250 μg/ml) are added to 500 ml of Eagle's minimal essential medium. The 10% growth medium is used when seeding a young monolayer or when greater confluency of the cell monolayer is desired.

■ HH medium

HH medium is a viral transport medium containing Hanks' balanced salt solution with 0.88% sodium bicarbonate, 0.2% bovine serum, 30 mM HEPES buffer, and 50 μg of gentamicin per ml. The pH should be adjusted to 7.2 by adding 1 N NaOH. HH medium was found to be an excellent transport medium for many viruses (11, 12).

■ Maintenance medium with 2% fetal bovine serum (6)

Eagle's medium is a maintenance medium suitable for growth and survival of a variety of cell lines for days to weeks at a low metabolic state. It contains the 12 essential amino acids, including glutamine, and vitamins in Earle's balanced salt solution. Antibiotics and antifungal agents are often added to the basic formula to control bacterial and fungal contamination. Fetal bovine serum is added at less than or equal to 2%. Serum supports life of the cell line but may contain inhibitors, toxins, infectious agents, or antibodies that interfere with cell maintenance. Typically, fetal bovine serum is preferred because it is less likely to contain these substances. Modifications include the addition of components to fortify the basic formulation for better support of cell lines. Fetal bovine serum (10 ml), L-glutamine (5 ml), gentamicin (0.5 ml; 50 mg/ml), and amphotericin B (5 ml; 250 μg/ml) are added to 500 ml of Eagle's minimal essential medium.

■ RPMI 1640 medium (15)

RPMI 1640 medium is an enriched medium used for the cultivation of cells in tissue culture. The medium is commonly used for the culture of human immunodeficiency virus and antiviral susceptibility testing. The base consists of glucose; essential amino acids, including glutathione (reduced); vitamins; and HEPES buffer. Additional enrichment is provided with incorporation of other amino acids. Antibiotics (e.g., penicillin and streptomycin) and a phenol red indicator are incorporated as well.

■ Sucrose-phosphate-glutamate medium

Sucrose-phosphate-glutamate transport medium is used for the maintenance and transport of *Chlamydia* species and viruses. Sucrose and two potassium phosphate buffer solutions are the base. Bovine serum and glutamic acid are additives. Glutamic acid is a stabilizing agent that is especially useful for enveloped viruses. The antibiotic combination may be the same as or slightly different from that in 2-sucrose-phosphate. Most commonly the antibiotic combination is vancomycin, streptomycin, and nystatin, which inhibit both gram-positive and gram-negative organisms, as well as yeasts.

■ 2-Sucrose-phosphate transport medium

2-Sucrose-phosphate medium is used for the transport of specimens for the purposes of culturing *Chlamydia trachomatis*. Sucrose (0.2 M) and two potassium phosphate buffers are the base. Fetal bovine serum allows the *Chlamydia* to maintain infectivity, and the antibiotics nystatin and gentamicin are added to inhibit yeasts and bacteria.

■ Transport medium (viral and universal)

Many viral transport media are available for the collection of viruses. The reader is referred to chapter 80 for specific company products. Most media are made for the isolation of *Chlamydia, Mycoplasma,* and *Ureaplasma* and are often called universal transport media. However, some are specific for viral isolation. In addition, some are able to be stored and shipped at room temperature, come with a variety of swab types, and contain from 1 to 5 ml of medium. The user should note each of these specific differences for any transport system being considered to optimize the most needed functions. The main components for these media are minimal essential medium with Hanks' balanced salts, bovine serum albumin, and sucrose with a phenol red pH indicator (pH 7.0 to 7.4). Microbial growth is inhibited by the incorporation of antibiotics, such as vancomycin, colistin, and amphotericin B, that inhibit gram-positive and gram-negative organisms as well as fungi.

CELL CULTURES

Sensitivity of the suspected viral pathogen for the host cell system and rate of CPE formation are two critical factors for virus isolation and identification. Thus, it may be appropriate to inoculate a specimen into a variety of cell systems to maximize recovery of a virus and/or recognize the characteristic CPE. Three general cell systems exist: primary, diploid, and continuous. Primary cell lines are those derived directly from human or animal tissues and are only subcultured once or twice. An example is rhesus monkey kidney (RhMK) cells. Subsequent subculture reduces the sensitivity to virus infection. Diploid cell lines are those which may support viral infection for up to 20 to 50 passages and are typically derived from fetal or newborn cells. An example is human diploid fibroblasts. Continuous cell lines are those typically derived from human or animal cancers or cells transformed in vitro; thus, the continuous cell lines have a heteroploid karyotype and can be subcultured indefinitely without loss of sensitivity to virus infection. An example is human epidermoid carcinoma of the larynx (HEp-2) (17). Decreased availability of fetal cell lines and contamination of monkey cell lines with endogenous virus have resulted in the use of more novel cell lines.

Cell lines may be used in conventional cell culture tubes and examined for CPE or grown on round coverslips in the bottoms of shell vials that are used in a spin-amplification technique.

Genetically altered cell lines and mixed cell lines have also been developed, as have lymphocyte preparations for the isolation of retroviruses. Unusual cell culture lines not listed may be available from vendors specializing in cell culture products. See Appendix 1.

■ A549 cells

A549 cell cultures originated from a human lung carcinoma. They are a continuous epithelial cell line. They are most commonly used to isolate adenovirus, herpes simplex virus, and VZV. Some have found A549 shell vials to be effective for diagnosing measles virus infections (13). This cell line is easily maintained in a laboratory with cell culture experience.

■ B95a or B95 cells

B95 or B95a is a lymphoblastoid cell line transformed by Epstein-Barr virus. The cell line is sensitive for measles and mumps virus isolation.

■ BGMK cells

BGMK cells are derived from Buffalo African green monkey *(Cercopithecus aethiops)* kidney cells. They are a continuous cell line most useful in isolating enteroviruses, specifically coxsackie B virus and polio virus, as well as *C. trachomatis*. Their range is quite narrow, making their regular use impractical for many clinical laboratories.

■ C6/36 and AP61 cells

C6/36 and AP61 are cell lines derived from mosquito cells for the isolation of arboviruses.

■ Genetically altered cell lines (ELVIS)

Genetically modified cell lines have been constructed to detect viruses by means other than CPE. Genetic elements derived from viral, bacterial, or cellular sources are introduced into a cell line where the end product (typically an enzymatic reaction) is dependent on presence of a specific virus. The original detector cell line was described by Stabell and Olivo (19). A baby hamster kidney cell line serves as the detector cell line and contains the genetic element of the *Escherichia coli* β-galactosidase gene. The gene is under the control of a promoter gene from herpes simplex virus and is activated only by the presence of herpes simplex virus proteins and thus viral replication. If the detector cells are exposed to the herpes simplex virus proteins, the promoter will be activated and cause production of the β-galactosidase enzyme. This, in turn, is recognized by a simple histochemical reaction or color reaction in the cells that is visible by light microscopy. The technology is described by the acronym ELVIS, which stands for enzyme-linked virus-inducible system. Cultures are typically evaluated within 16 to 24 h, making the assay rapid, simple, and able to be read by someone unfamiliar with CPE. Genetically altered cell lines have been developed for detection of both RNA and DNA viruses, as well as for antiviral susceptibility testing (15).

■ HEK cells

HEK cells are a primary cell culture line from human embryonic kidney. Human epithelial cell lines are optimal for isolation of adenoviruses. They are also used for BK virus. Embryonic cell lines are now less commonly available. Most enteroviruses, rhinovirus, measles virus, mumps virus, and herpes simplex virus will also grow in HEK cells.

■ HEK 293 or Graham 293 cells

HEK 293 cells are human embryonic kidney cells transformed with type 5 adenovirus. They are used only in specialized situations to isolate some of the more difficult-to-isolate enteric adenoviruses.

■ HeLa cells

HeLa cells are a continuous cell line derived from a cervical epithelioid carcinoma. HeLa cells may be used to isolate adenovirus, coxsackie B virus, herpes simplex virus, poliovirus, CMV, vesicular stomatitis virus, and VZV.

■ HeLa 229 cells

HeLa 229 cells are a HeLa variant used for isolation of *Chlamydophila pneumoniae.*

■ HELF cells (see WI-38 cells and MRC-5 cells)

Human embryonic lung fibroblasts (HELF cells) are diploid cell lines used especially for the isolation of rhinovirus and adenovirus.

■ HEp-2 cells

HEp-2 cells are commonly used in many laboratories because they support a broad range of viruses. A continuous human epidermoid carcinoma of the larynx cell line, it is used most for isolation of respiratory viruses such as respiratory syncytial virus and adenovirus. It may also grow herpes simplex virus, some enteroviruses, vesicular stomatitis virus, arboviruses, measles virus, and *C. pneumoniae*.

■ HFF cells

Human newborn foreskin cells are a diploid fibroblast line. Similar to other fibroblast lines, HFF cells are susceptible to herpes simplex virus and CMV.

■ HNK cells

HNK is a fibroblast line (human neonatal kidney) used for the isolation of VZV, herpes simplex virus, and adenovirus.

■ LLC-MK_2 cells

LLC-MK_2 is a serially propagated, continuous culture line of rhesus monkey kidney *(Macaca mulatta)* cells (RhMK cells). This cell line is most susceptible to enteroviruses, including strains of coxsackie A and B viruses, echovirus, and poliovirus, as well as influenza viruses A and B, mumps virus, and parainfluenza virus.

■ McCoy cells

McCoy cells are derived from a mouse fibroblast line and are used to isolate *C. trachomatis*. Fifteen serotypes of *Chlamydia* with at least 43 passages have shown satisfactory isolation.

■ MDCK cells

MDCK (Madin-Darby canine kidney) is a continuous polarized cell line. MDCK cells are used primarily for isolating influenza A, B, and C viruses. Exogenous protease must be added to the maintenance medium to cleave the viral hemagglutinin and produce infectious viral progeny. Some investigators have found MDCK cells to be superior to RhMK cells for isolating influenza virus (13). Coxsackie B-5 virus, adenoviruses, and reoviruses also are supported by this cell line.

■ Mink lung (Mv1Lu) cells

Mink lung cells are a continuous cell line used for isolation of herpes simplex virus, CMV, and influenza viruses A and B. Advantages include sensitivity equivalent to those of MRC-5 and WI-38 cells but with the ability for extended propagation in the laboratory and decreased effects from toxicity.

■ Mixed-cell cultures

A combination of cell lines within a single culture vessel is used to enhance recovery of viruses with fewer cell cultures and has been described by a number of investigators to be equivalent to and more cost-effective than routine single-cell-line tubes. Mixed-cell cultures have been developed for detection of respiratory viruses, herpesviruses, and enteroviruses by using a combination of cell lines that are sensitive to these specific viruses. Both conventional tube culture and the shell vial format have been described (15). Currently available mixed cell lines include the following: R-Mix (Diagnostic Hybrids), which includes A549 plus mink lung cells; H and V mix, which is African green monkey and MRC-5 cells; and E Mix, which contains BGMK and A549 cells. See individual cell line descriptions for permissiveness for specific viruses.

■ MRC-5 cells

MRC-5 cells are a diploid human fibroblast line propagated from embryonic lung. They are susceptible to a wide range of human viruses. The cell line is especially useful for growing CMV and VZV. Other viruses that may be isolated in MRC-5 cells include adenovirus, coxsackie A virus, echovirus, poliovirus, rhinovirus, respiratory syncytial virus, and herpes simplex virus. This cell line is also used for cytotoxicity testing for *Clostridium difficile*.

■ Rabbit kidney cells

Rabbit kidney cells (New Zealand White rabbits) are a primary cell line used for isolation of herpes simplex virus. CPE does not occur with VZV, which helps to differentiate VZV from herpes simplex virus. The cell line can also be used for the isolation of paramyxoviruses.

■ RD cells

RD is a continuous cell line derived from a human embryonic rhabdomyosarcoma cell line. RD cells are used to detect coxsackie A virus, herpes simplex virus, and poliovirus.

■ Rhesus monkey kidney (RhMK) cells

RhMK cells are an integral part of many diagnostic laboratories. RhMK cells are a primary cell line derived from the rhesus monkey *(M. mulatta)*. Although sometimes contaminated with simian viruses, RhMK cells are a general cell line used for primary isolation of enteroviruses, influenza virus, and parainfluenza virus. They will support the growth of many strains of coxsackie A and B viruses, echovirus, poliovirus, influenza A and B viruses, parainfluenza viruses 1, 2, and 3, measles virus, and mumps virus. Isolation of VZV may be enhanced by using both human diploid fibroblasts and RhMK cells (22).

■ SF cells

SF is a diploid cell line derived from human foreskin (at birth) by ViroMed Laboratories and is similar to the fibroblast lines MRC-5 and WI-38. SF supports the growth of a wide range of viruses, including adenovirus, coxsackie A virus, CMV, echovirus, herpes simplex virus, poliovirus, and VZV. This cell line is also used for *C. difficile* cytotoxicity testing.

■ Vero cells

Vero cells are a serially propagated continuous cell line derived from African green monkey kidney *(C. aethiops)*. Coxsackie B virus, herpes simplex virus, poliovirus, and mumps virus may be isolated in Vero cells. This cell line has also been successful in isolation of Marburg virus, Ebola virus, and lymphocytic choriomeningitis virus. Variant Vero line E-6 has been used to isolate hantavirus.

■ WI-38 cells

WI-38 cells are similar to other fibroblast lines. They are a diploid cell line derived from human embryonic lung fibroblasts. WI-38 cells support growth of a wide range of viruses and are useful for isolating enteroviruses such as coxsackie A virus, echovirus, and poliovirus. Respiratory viruses, such as rhinovirus, respiratory syncytial virus, and adenovirus, as well as herpes simplex virus, CMV, and VZV, are also supported. This cell line is also used for cytotoxicity testing.

Algorithms for Detection and Identification of Viruses

MARIE LOUISE LANDRY, ANGELA M. CALIENDO, YI-WEI TANG, AND ALEXANDRA VALSAMAKIS

82

Virology is a dynamic field that in recent decades has moved from the periphery to the mainstream of clinical laboratory practice. When the first edition of the *Manual of Clinical Microbiology* was published in 1970, diagnostic virology was practiced in a limited number of laboratories, primarily in public health, research, and academic settings. Methods focused on conventional cell cultures, classical serologic techniques, and light and electron microscopy. Time to result was slow, and it was often said that the patient was dead or better by the time the result was received. Over the intervening years, diagnostic advances have transformed the field by allowing accurate results in a clinically useful time frame. These include enzyme immunoassays for antigen and antibody detection, immunoglobulin M (IgM) assays, monoclonal antibodies for rapid identification of culture isolates, and direct detection in clinical specimens by immunofluorescence, shell vial centrifugation cultures, and nucleic acid amplification techniques.

Since the last edition of this Manual, the greatest growth has been in molecular methods, which are both rapid and sensitive, can be largely automated, and can detect viruses not amenable to routine culture. The greater variety of instruments for nucleic acid extraction and real-time amplification and detection and the increasing availability of commercial reagents and kits have facilitated this trend. Some molecular assays have now become standard of care. Furthermore, quantitative monitoring of viral load in blood has become more widely applied due to implementation of real-time PCR techniques. In addition to the advantages of molecular testing, however, some pitfalls are also becoming apparent as the tests are more widely used. For example, sensitivity and specificity can vary significantly between laboratories. In addition, despite targeting conserved regions of the genome, strain variability and mutations can lead to underquantification of viral load or even falsely negative results. Furthermore, as tests become more sensitive, low levels of clinically irrelevant viruses may be detected and can be misleading to clinicians. Requirements for staff training, test validation, and quality control can be challenging. At the other end of the spectrum has been the proliferation of rapid tests requiring minimal or no equipment or reagent additions. These tests often employ immunochromatographic detection for viral antigen or antibody and can be used at the point-of-care for immediate impact on clinical decisions.

Thus, with progress have come new challenges. Laboratories need to choose which tests to offer. Performance characteristics, staff expertise, and cost impact that choice. Laboratories must recognize the uses and also the limitations of each test in order to guide clinicians in interpreting the results. This Manual should serve as a key resource for accomplishing these tasks. Selecting the appropriate test depends on the virus(es) sought, sample site, clinical presentation, clinical purpose (e.g., screening, confirmation, diagnosis, or monitoring), patient characteristics, and disease prevalence. The methods available for each virus differ and continue to evolve. Table 1 provides a concise overview for each virus group; however, the reader is referred to the specific chapters for more detailed discussions.

While it can be daunting for laboratories to acquire and maintain expertise in the variety of test methods now available, it is extremely gratifying to witness the impact of state-of-the-art testing on patient care. As we move forward, it is critical that laboratorians communicate with each other to address problems, including the optimization and standardization of methods, and in addition encourage input and feedback from clinicians. Due to the speed of methodological change and the continuing discovery of new viruses and new therapies, keeping abreast of the most recent literature is strongly recommended.

TABLE 1 Methods for detection and identification of viruses[a]

Virus	Applicability[b] of:					Comments
	Virus isolation	Antigen detection	Nucleic acid detection	Electron microscopy	Antibody detection	
Adenoviruses	A	A	B	C	C	IFA and culture widely used for respiratory specimens. Rapid antigen assays used for enteric adenoviruses. NAAT used to monitor viral load in compromised hosts.
Arboviruses	C	D	B	C	A	Serology is primary diagnostic method. Most arboviruses are readily cultured; isolation of some agents may require BSL-3 or BSL-4 facilities.
Coronaviruses	C	C	A	C	A	Positive SARS CoV NAAT and antibody results require confirmation by a reference laboratory. NAAT becoming more widely used for non-SARS CoV.
Cytomegalovirus	A	A	A	C	B	Shell vial culture rapid and sensitive for nonblood specimens. Quantitative NAAT and pp65 antigenemia used to assess risk of disease and response to therapy. Serology primarily used to determine prior infection.
Enteroviruses	A	D	A	D	D	Enterovirus RNA detection preferred for CNS infection. Parechovirus detected primarily through virus isolation.
Epstein-Barr virus	D	B	A	D	A	Serology test of choice for routine diagnosis. NAAT useful for virus-related tumors. Quantitative NAAT useful for monitoring viral load in blood of transplant recipients. IHC or ISH can be used on tumor biopsy specimens.
Filoviruses and arenaviruses	A	A	A	C	B	Testing confined to specialized laboratories. Antigen and NAAT key to rapid diagnosis. BSL-4 facility needed for culture, except for LCM. Patients with severe disease may die without developing antibody. LCM diagnosed primarily by serology.
Hantaviruses	C	B	A	C	A	Testing confined to specialized laboratories. Serology and NAAT equally useful for diagnosis. IHC used in fatal cases. BSL-4 facility needed for culture. Isolation difficult.
Hendra and Nipah viruses	B	B	A	C	A	Testing confined to specialized laboratories. Serology and NAAT equally useful for diagnosis. IHC used in fatal cases. BSL-4 facility needed for culture. Patients with severe disease may die without developing antibody.
Hepatitis A virus	D	C	C	D	A	Serology is the standard diagnostic test. False-positive IgM problematic in low-prevalence areas.
Hepatitis B virus	D	A	A	C	A	Detection of specific viral antigens and antibodies allows for diagnosis and for monitoring the course of infection. NAAT used to monitor therapy.
Hepatitis C and G viruses	D	D	A	D	A	Serology is used for diagnosis. Qualitative NAAT used to confirm active infection. Quantitative NAAT used to monitor response to therapy. Genotyping helps determine duration of therapy.
Hepatitis D virus	D	B	B	D	A	Testing confined to reference laboratories. Diagnosis is relevant only in the presence of hepatitis B infection. IHC of biopsy tissue useful for diagnosis.
Hepatitis E virus	D	D	B	D	A	Serology is the standard diagnostic test. False-positive IgM problematic in low-prevalence areas. NAAT is specific for acute infection but lacks sensitivity.

(Continued on next page)

TABLE 1 Methods for detection and identification of viruses[a] *(Continued)*

Virus	Applicability[b] of:					Comments
	Virus isolation	Antigen detection	Nucleic acid detection	Electron microscopy	Antibody detection	
Herpes simplex virus	A	A	A	C	B	Shell vial used for rapid determination of viral replication. IFA used for rapid detection in skin or mucous membrane lesions or tissue specimens. NAAT is test of choice for CNS infection. Serology used to determine prior infection.
Herpesviruses 6 and 7	C	C	A	C	B	NAAT test of choice for diagnosis. MAbs available to differentiate virus isolates and for IHC. Serology can document primary infection in children.
Herpesvirus 8	D	B	B	C	A	Serology used to identify infected persons; sensitivity and specificity hampered by difficulty in setting cutoff values. NAAT of blood may be useful for monitoring KS risk. IHC more specific than NAAT for KS.
Human immunodeficiency virus	C	C	A	D	A	Serology is primary diagnostic method; rapid antibody testing becoming more widely available. Proviral DNA and plasma RNA tests used to diagnose neonatal infection. Quantitative RNA tests used to guide therapy and monitor response.
Human metapneumovirus	B	C	A	C	D	NAAT is the test of choice for diagnosis. Shell vial culture and antigen detection reagents not yet widely available. Conventional culture difficult.
Human T-cell lymphotropic virus	C	D	B	D	A	Serology is primary diagnostic method. NAAT useful for virus identification in HTLV Western blot-positive but untypeable specimens.
Influenza viruses	A	A	A	D	B	Rapid antigen tests widely used but suboptimal in sensitivity and specificity; IFA and rapid culture more sensitive. NAAT most sensitive but not yet widely used. Serology useful for epidemiological studies or retrospective diagnosis.
Measles viruses	B	B	C	C	A	Serology most useful for diagnosis and determination of immunity. Isolation useful only if attempted early (prodromal period to 4 days postrash).
Mumps virus	A	C	C	C	A	Serology used most commonly for diagnosis and determination of immunity.
Noroviruses	D	C	B	B	D	NAAT promising but challenging due to strain variability. EM useful in suitably equipped laboratories. Reagents for antigen detection not commercially available.
Parainfluenza viruses	A	A	B	D	C	IFA most common rapid detection method. NAAT more sensitive than isolation but not yet widely adopted.
Papillomaviruses	D	D	A	C	D	NAAT test of choice for detection and genotype differentiation. Cytopathology useful for diagnosis. Serologic diagnosis of exposure not available.
Parvoviruses	D	C	A	C	A	Serology used to diagnose B19 in immunocompetent individuals. NAAT test of choice for exposed fetuses and immunocompromised hosts. NAAT can be used to detect human bocavirus.
Polyomaviruses	C	B	A	B	C	JC virus DNA detection in cerebrospinal fluid useful for presumptive diagnosis of PML. BK virus DNA quantification in plasma or urine used for preemptive diagnosis of PVAN. IHC and EM useful for biopsy tissues.
Poxviruses	A	C	A	A	A	EM is the most useful routine test. NAAT allows virus inactivation and rapid detection. Smallpox isolation requires BSL-3 or BSL-4 and should be attempted only in WHO Collaborating Centers. Vaccinia virus requires BSL-2 and grows readily in cell culture.

Rabies virus	B	A	B	C	B	IFA performed on fresh and frozen tissue at the CDC. Serology used to confirm immunization status and confirm exposure in absence of RIG. NAAT most useful for non-CNS samples when fresh CNS tissue not available.
Respiratory syncytial virus	A	A	A	C	C	Rapid antigen tests, especially IFA, more sensitive than culture. NAAT most sensitive but not yet widely used. Serology useful only for epidemiological studies.
Rhinoviruses	A	C	B	D	D	Culture still most common test in clinical laboratories. NAAT more sensitive and most common test in research and epidemiological studies; cross-reaction with enteroviruses can occur.
Rotaviruses	D	A	B	C	D	Direct antigen detection is test of choice for diagnosis. EM useful in suitably equipped laboratories. NAAT is promising.
Rubella virus	A	D	B	D	A	Serology most useful for diagnosis and determination of immunity. Isolation useful for postnatal rubella if attempted early (prodromal period to 4 days postrash). In CRS, virus can be isolated for weeks to months after birth.
Transmissible spongiform encephalopathy agents	D	C	B	C	D	Histology most useful diagnostic test. Surrogate markers popular but lack specificity. Western blot for PrP performed in specialized laboratories. Human genome sequencing useful for diagnosis of genetic disorders.
Varicella-zoster virus	A	A	A	C	B	IFA and NAAT are most commonly used rapid tests. Culture less sensitive than IFA. Serology most useful for determination of immunity.

[a]Virus isolation includes conventional cell culture with detection of viral growth by cytopathic effects or hemadsorption; shell vial centrifugation culture uses immunostaining for detection of viral antigens. Viral antigens can be detected by a variety of immunoassays such as enzyme-linked immunosorbent assays, agglutination assays, immunofluorescence or immunoperoxidase techniques, and immunochromatography. Viral nucleic acids (DNA or RNA) can be detected and quantified by direct hybridization or by the performance of amplification methods such as PCR. Electron microscopy involves the visualization of viral particles by negative staining or immunoelectron microscopy or by thin-section techniques. Antibody detection involves measurement of total or class-specific immunoglobulins directed at specific viral antigens. Abbreviations: IFA, immunofluorescence assay; NAAT, nucleic acid amplification test; BSL, biosafety level; EM, electron microscopy; SARS, severe acute respiratory syndrome; CoV, coronavirus; CNS, central nervous system; LCM, lymphocytic choriomeningitis virus; IHC, immunohistochemistry; ISH, in situ hybridization; MAb, monoclonal antibody; KS, Kaposi's sarcoma; HTLV, human T-cell lymphotropic virus; PML, progressive multifocal leukoencephalopathy; PVAN, polyomavirus-associated nephropathy; RIG, rabies immune globulin; CRS, congenital rubella syndrome; PrP, prion protein.

[b]A, test is generally useful for the indicated diagnosis; B, test is useful under certain circumstances or for the diagnosis of specific forms of infection, as delineated in the right-hand column and in the text of the individual chapters; C, test is seldom useful for general diagnostic purposes but may be useful for epidemiological studies or for the diagnosis of unusual conditions; D, test is generally not used for laboratory diagnosis of infection.

Human Immunodeficiency Viruses*

TAXONOMY

Origin and Historical Perspective

The human immunodeficiency virus (HIV) is the etiologic agent of AIDS. AIDS was first recognized clinically in 1981 (93), although the first known case of AIDS has been traced to 1959 (136). HIV exists as two major viral species, HIV type 1 (HIV-1) and HIV-2. The more virulent of the two HIVs, HIV-1, is responsible for the worldwide AIDS pandemic, with over 39 million people living with HIV/AIDS as of the end of 2004. HIV-2, on the other hand, is less pathogenic and has a more limited geographic distribution.

HIV-1 was initially discovered in 1983 (3) and was confirmed the following year to be the cause of AIDS (55, 83, 123). Clavel et al. first isolated HIV-2 in 1986 (22). Both HIV-1 and HIV-2 are related to simian immunodeficiency viruses (SIV) (38, 69). Simian immunodeficiency virus strains have been found in over 25 species of nonhuman African primates (69). Chimpanzees and a number of species of Old World monkeys are the natural hosts for these primate lentiviruses, and it has been suggested that both the HIV-1 and HIV-2 epidemics are the result of simian-to-human transmissions. The HIV-1 epidemic appears to be the result of zoonotic virus transmissions from chimpanzee to human (56), while the sooty mangabey apparently is the source of HIV-2 infections in humans (136).

HIV Groups and Subgroups

Both types of HIV are members of the genus *Lentivirus* within the family of *Retroviridae*. Because of the mutation and recombination capabilities of HIV, various genetic clades have evolved (94, 119), and the genetic diversity of HIV-1 plays a significant role in the design and interpretation of HIV diagnostic assays. HIV-1 is subdivided into three genetic groups designated M (for major), O (for outlier), and N (for non-M, non-O), based on sequence diversity within the HIV-1 *gag* and *env* genes. HIV-1 group M is divided into nine subtypes (A through D, F through H, J, and K). Viruses belonging to different M subtypes have been isolated in distinct regions of the world. The initial epidemic in the early 1980s in North America and Europe was due to HIV-1 subtype B. Currently, subtype C dominates the global epidemic, although subtype B continues to be the major subtype in the United States, Europe, and Australia. Certain HIV-1 viral isolates appear to be recombinant, containing sequences from more than one subtype. Group O viruses are only rarely isolated and found mostly in persons from Cameroon, Gabon, and Equatorial Guinea. Group N viruses have been recovered from Cameroon. Seven subtypes of HIV-2 (A through G) have been defined, although HIV-2 groups C through G have each been recovered only from a single individual.

DESCRIPTION OF THE AGENTS

Structure and Genomic Organization

HIV viruses are enveloped plus-stranded RNA viruses. The HIV genome is organized similarly to other retroviruses. It contains the *gag, pol,* and *env* genes which encode structural proteins, viral enzymes, and envelope glycoproteins, respectively. These are flanked by long terminal repeats. In addition, the genome comprises open reading frames for *trans*-acting transcriptional activator (Tat), the regulator of viral expression (Rev), and several other proteins such as Vif, Vpr, and Nef.

Mature viral particles measure 100 to 150 nm in diameter and have a conical core surrounded by a lipid envelope (Fig. 1). The core contains two identical copies of single-stranded RNA, approximately 10 kb in length, which are surrounded by structural proteins that form the nucleocapsid and the matrix shell as well as by products of the *pol* gene. The lipid envelope is acquired as the virus buds from infected cells. The glycoprotein gp120/41 forms spikes protruding from this envelope. The glycoprotein, a product of the *env* gene, is synthesized as a precursor, gp160, which is cleaved into the heavily glycosylated gp120, forming the majority of the external portion and the transmembrane gp41 portion, which contains the membrane spanning domain. The major structural proteins that are encoded by the *gag* gene include p17, p24, p7, and p9. Products of the *pol* gene include the protease, reverse transcriptase, RNase, integrase, and ribonuclease.

HIV-2 is structurally analogous to HIV-1, but some of its protein components differ, most notably the outer envelope and transmembrane glycoproteins gp125 and gp36, as well as the core proteins p16 and p26. The major gene products that are of significance for the diagnosis of HIV-1 and HIV-2 are listed in Table 1.

* This chapter contains information presented in chapter 80 by Jörg Schüpbach in the eighth edition of this Manual.

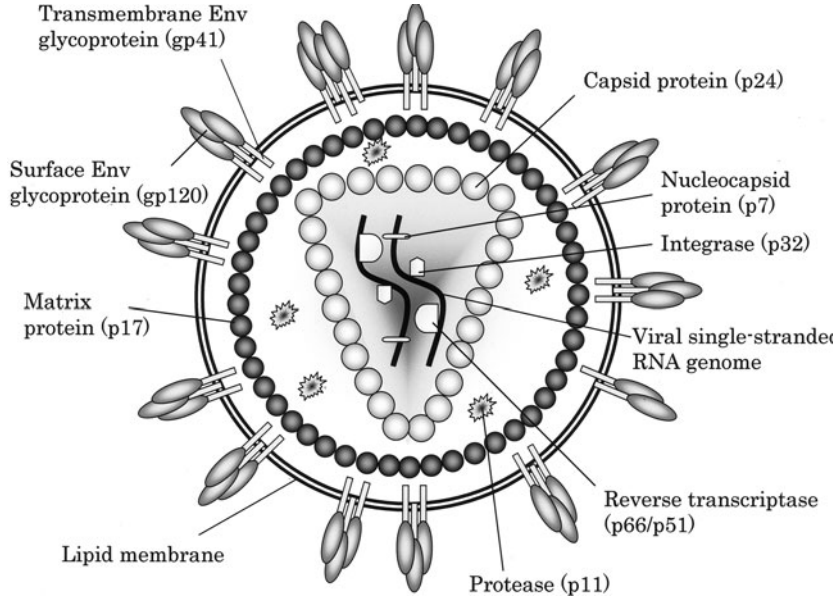

FIGURE 1 Schematic representation of a mature HIV virion showing the localization of viral proteins.

Replication Cycle

The replication cycle of HIV-1 is accomplished in vivo in approximately 24 h (120). Replication begins with the attachment of virus to the target cell via the interaction of gp120 and the cellular receptor CD4 (32). This binding results in gp120 conformational changes which allow the virus to interact with other cellular coreceptor sites, CXCR4 or CCR5. The interaction with CXCR4 occurs primarily with T-cell-tropic, syncytium-inducing viruses (51). In contrast, the β-chemokine receptor CCR5 is involved in macrophage-tropic non-syncytium-inducing HIVs (21).

Following fusion with the host cells, HIV enters the cell and RNA is released. HIV particles contain reverse transcriptase (RT), an enzyme that plays a crucial role in the replication process. RT possesses three distinct functions: RNA-dependent DNA polymerase, which serves to synthesize cDNA; RNase H, which degrades RNA from the cDNA-RNA complex; and a DNA-dependent DNA polymerase, which duplicates the cDNA strand. The reverse-transcribed genome is associated with several viral proteins and transported into the nucleus. The DNA copy becomes integrated into the genome of the infected cell by the virally encoded integrase; this integrated retroviral DNA genome is called the provirus. The cDNA then serves as a template for viral RNA. Activation of HIV transcription and gene expression is modulated by cellular transcription factors and by viral regulatory proteins, including Tat, Rev, Nef, and Vrp. The regulatory genes *tat* and *rev* greatly influence the rate of viral replication. The Tat protein increases transcription from the long terminal repeat. The Rev protein facilitates export of unspliced or partially spliced RNAs encoding the viral structural proteins. At the end of the replication cycle, the virion assembles and buds through the plasma membrane. Due to the infidelity of the RT, many errors are made during the replication cycle; thus, in an infected individual the virus exists as quasispecies of closely related viral genomes.

EPIDEMIOLOGY AND TRANSMISSION

Epidemiology

The AIDS pandemic has had an enormous toll throughout the world, and HIV-1 has been reported in virtually every country on earth. In contrast, HIV-2 has remained limited

TABLE 1 Major HIV-1 and HIV-2 gene products

Gene	Description of gene products	Gene products of:	
		HIV-1	HIV-2
Core *(gag)*	Precursor of Gag protein	p55	p53–55
	Capsid protein	p24	p26
	Matrix protein	p17	p16
Polymerase *(pol)*	RT component	p66	p68
	RT component	p51	
	Endonuclease component	p32	p33
Envelope *(env)*	Precursor of Env glycoprotein	gp160	gp125
	Outer Env glycoprotein	gp120	gp105
	Transmembrane Env glycoprotein	gp41	gp36

primarily to West Africa and to European immigrants from West Africa. Two African countries which are not in Western Africa, Angola and Mozambique, also have high HIV-2 seroprevalence rates, and additional spread of HIV-2 has been documented in Portugal, France, and India. Group M viruses are responsible for most HIV-1 infections, with a predominance of subtype C. Subtype B is most prevalent in the United States, Europe, and Australia but is rarely found in Africa. Subtypes A, C, and D predominate in Africa.

The HIV epidemic continues to grow and change (50). In 2003, an estimated 4.8 million people became newly infected with HIV, bringing to 37.8 million the number of individuals living with HIV. In addition, the AIDS epidemic killed 2.9 million people in 2003 and has killed over 20 million people since the first cases of AIDS were identified in 1981. Over 60% of HIV-infected individuals live in sub-Saharan Africa. Globally, the overall proportion of HIV-positive women has increased steadily in recent years; and women represented 50% of people living with HIV in 2002 (151). This trend is most obvious in sub-Saharan Africa and the Caribbean.

In the United States, the cumulative estimated number of AIDS cases diagnosed through 2003 is 929,985 and the cumulative estimated number of AIDS-related deaths is 524,060 (15). The demographic characteristics of the epidemic have changed significantly since the 1980s. In the early days of the epidemic, populations most affected in the United States included mostly homosexual and bisexual men (50). During the past decade, an estimated 40,000 people have been infected with HIV every year, but the epidemic now affects a large proportion of African-Americans and greater numbers of women (15), with approximately one-half of new infections reported among African-Americans. Most HIV infections in men occur during injecting-drug use or sex between men. The main risk factor for women is heterosexual transmission from a male partner with undisclosed risk behaviors. AIDS-related deaths have steadily decreased since the introduction of antiretroviral therapy in 1995–1996. However, African-Americans have the poorest survival rates among individuals diagnosed with AIDS in the United States.

Transmission

HIV-1 and HIV-2 have the same modes of transmission. The most common mode of HIV infection is sexual transmission at the genital mucosa through direct contact with infected blood fluids, including blood, semen, and vaginal secretions (74, 130, 157). Infection may also occur through inoculation of infected blood, via transfusion of infected blood products, transplantation of infected tissues, or reuse of contaminated needles. The risk of HIV-1 infection following occupational percutaneous exposure to HIV-1-infected blood has been estimated to be 0.3% (57).

The vast majority of HIV transmission from mother to child occurs in resource-poor countries. Maternal HIV-1 RNA in blood and genital fluids has been documented to correlate strongly with mother-to-child transmission (102). HIV transmission can occur in utero, during labor and delivery, and during breast-feeding. In the absence of therapeutic intervention, the risk of mother-to-child transmission can range from 15 to 30% and is further increased in the setting of breast-feeding. However, the risk can be significantly reduced to below 2% if antiretroviral therapy is administered to women during pregnancy and labor (25). Antiretroviral treatment of the mother and infant after birth can also significantly decrease the risk of HIV infection in the newborn.

CLINICAL SIGNIFICANCE

Virological Parameters during the Course of HIV Infection

The natural history of HIV-1 infection can be divided into three phases: a transient acute retroviral syndrome, a period of clinical latency, and finally progression to AIDS. Each of these stages is associated with specific changes in virologic and immunologic parameters. Following HIV infection, HIV-specific markers appear in the blood in the following chronological order: HIV RNA, p24 antigen, and HIV antibody (Fig. 2). The exact time when each of these three markers can be detected depends on a number of factors including the type of test used, characteristics of the infecting virus, and host immune responses of the individual. During the first week after infection, HIV RNA, antigen, and antibody are generally not detectable, although viral replication is occurring. Within 1 to 4 weeks after infection, viral RNA increases rapidly and viral antigen is detectable, but HIV antibody is usually not detectable. The time period when HIV antibody is not detectable is referred to as the window period. In most infected persons, HIV antibody is detected within 1 to 2 months, but in a small percentage of individuals, seroconversion may require up to 6 months. Following the initial HIV RNA peak, viremia generally decreases to a lower comparatively stable level, which reflects ongoing viral replication and immune system damage. The HIV RNA pattern in perinatally infected infants differs from that in infected adults, since high HIV RNA levels may persist in HIV-infected children for prolonged time periods.

Acute Retroviral Syndrome

Acute HIV-1 infection is a transient symptomatic illness which is associated with high levels of HIV-1 replication and a developing virus-specific immune response. The diagnosis of acute HIV-1 infection is often missed because symptoms tend to be nonspecific and HIV-1-specific antibodies are not detectable. Symptoms present in 40 to 80% of the cases within 3 to 6 weeks after primary infection and usually last 7 to 14 days. The clinical symptoms of acute HIV-1 infection were first described as a mononucleosis-like syndrome in 1985 (29). Most commonly, fever, maculopapular rash, oral ulcers, lymphadenopathy, malaise, weight loss, arthralgia, pharyngitis, and/or night sweats are seen (31, 70).

During acute HIV-1 infection, there is an initial rise in plasma viremia, reaching levels of up to 100 million copies of HIV-1 RNA per ml of plasma (79). In addition, destruction of HIV-1-specific $CD4^+$ T lymphocytes as well as widespread dissemination of the virus, with seeding of lymphoid organs and other tissue reservoirs, occurs. During resolution of primary infection, $CD4^+$ T-cell counts rebound, and viremia declines before reaching a steady level, which has been shown to be an important predictor of disease progression (96, 97).

Clinical Latency

The asymptomatic period, which usually lasts several years, is the period between primary infection and the development of clinical immunodeficiency. During that period, the number of $CD4^+$ lymphocytes declines slowly, and the virus continues to replicate, albeit at a relatively stable level. During this clinical latency period, high titers of virus can be found in lymphoid and other tissue compartments (116). The length of the clinical latency period can vary considerably but is on average 10 years. In rapid progressors, AIDS develops within 1 to 2 years, but the clinical latency period

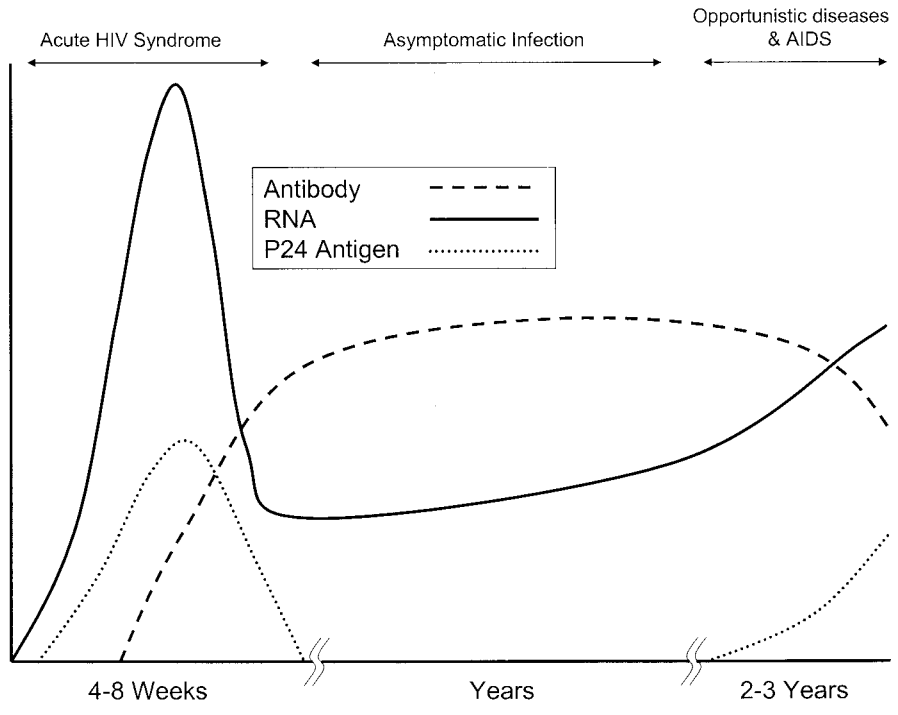

FIGURE 2 Time course of appearance of markers of HIV infection during the course of HIV infection.

can be short, as in the recent well-publicized New York case, where the infection was reported to result in symptomatic AIDS in 4 to 20 months (91). In contrast, 5 to 10% of HIV-infected individuals are long-term nonprogressors and remain symptom-free for longer than 20 years (104). Several factors influence the steady-state level of viral replication and the rate of disease progression, including host immune responses, host genetic factors, and the fitness of the infecting virus. One of the most important host genetic factors reported to affect virus replication rates is the deletion of CCR5; most individuals homozygous for a 32-bp deletion in CCR5 are resistant to HIV-1 infection (133) and showed slower HIV-1 replication (122). In addition to mutations in chemokine receptor genes, a number of HLA class I alleles have been found to be associated with lower steady-state viral levels and slow disease progression (1), and it has been suggested that rates of disease progression may also be influenced by other concurrent infections (143).

Disease Progression to AIDS

The continuous replication of HIV-1 in productively infected cells together with the elimination of host cells and chronic immune activation results over the years in deterioration of the immune system. Studies of HIV-1 replication dynamics have shown that, in productively infected lymphocytes, the interval between infection, virus production, and cell death is very short. The half-life of HIV-1 in plasma is thought to be 6 h, the length of the replication cycle in $CD4^+$ lymphocytes has been estimated at 2.6 days, and 35 million $CD4^+$ cells are thought to be lost daily (73). As the ability of the host to eliminate productively infected cells declines, $CD4^+$ lymphocytes with integrated provirus accumulate. These resting memory $CD4^+$ lymphocytes serve as a long-lived reservoir for HIV-1. The mean half-life of this latent reservoir has been reported to be as long as 40 months for many patients (52).

Clinical manifestations can affect nearly every organ system. In addition, destruction of the immune system is clinically manifested by the occurrence of opportunistic infections and tumors, and central nervous system involvement can be seen, most commonly the HIV-associated dementia complex (124). Conditions listed in the 1993 AIDS surveillance case definition include a CD4 T-cell count of <200; opportunistic infections caused by viruses, bacteria, fungi, and protozoa; neoplastic disease; HIV encephalopathy; wasting syndrome; and progressive multifocal leukoencephalopathy. These conditions complicate the clinical course of HIV-1 infections and are often the cause of death.

Several public health organizations, including the CDC and the WHO, have published HIV-1 disease classification systems for both public health purposes and HIV disease staging. HIV-1 disease staging classifies disease according to prognosis and is useful in guiding treatment decisions. The current CDC classification system for HIV-infected adolescents (>13 years) and adults combines three categories of CD4 counts (categories 1, 2, and 3, corresponding to >500, 200 to 499, and <200 cells/mm^3, respectively) with three symptom categories (categories A, B, and C) (12).

The course of HIV infection and the clinical characteristics of AIDS in children differ from those in adults, and the CDC has developed a separate classification system to describe the spectrum of HIV-1 disease in children less than 13 years of age born to HIV-infected mothers (13). The disease progresses rapidly in infants with vertically acquired HIV infection. The most common AIDS defining conditions include *Pneumocystis jirovecii* pneumonia, lymphoid interstitial pneumonia/pulmonary lymphoid hyperplasia, and recurrent bacterial infections.

Therapy and Vaccination

Significant scientific advances in the development of effective antiretroviral therapy have occurred in the past 20 years. The first effective drug against HIV-1, zidovudine (AZT), was approved by the FDA in March 1987. Currently, a total of 24 antiretroviral drugs or combinations of antiviral drugs have been approved by the FDA for the treatment of HIV infections (Table 2). Approved antiviral agents used to treat HIV-1 fall into four classes: nucleoside RT inhibitors (NRTIs), nonnucleoside RT inhibitors (NNRTIs), protease inhibitors (PIs), and fusion inhibitors. The combination of three or more of the anti-HIV drugs, also referred to as highly active antiretroviral therapy (HAART), is the recommended treatment for HIV-1 infection. Guidelines for the use of antiretroviral agents in adults and in children evolve rapidly; these are updated on a regular basis, and the most recent guidelines can be obtained from the AIDS information website (http://AIDSinfo.nih.gov). Not all drugs used to treat HIV-1 infection are effective against HIV-2 infection. HIV-2 is resistant to NNRTIs and thought to be less susceptible to zidovudine and some of the protease inhibitors.

Although currently available therapies have been shown to slow down progression to AIDS, the activity of these powerful combination therapies can be altered by a number of factors including adherence, drug toxicity, and the development of antiviral resistance. Therefore, proper management of HIV-infected patients must include systematic monitoring of the efficacy of antiviral treatment through use of sensitive and accurate tests to measure viral load changes during therapy and to detect the emergence of antiviral resistance.

Several obstacles have slowed down the progress towards the development of effective vaccines against HIV (38, 105). These include the inability of HIV-1 to produce neutralizing antibodies, the lack of understanding of correlates of protective immunity, the genetic diversity of the virus, and the limitation of animal models. A variety of vaccine strategies have been investigated, including live attenuated subunit, recombinant vector, and DNA vaccines (132). Various adjuvants have been tried, and alternate sites of delivery have been explored. Although results of trials of subunit vaccines showed no protection against infection and did not lower viral loads, newer strategies combining DNA vaccines and recombinant vector vaccines are under investigation.

COLLECTION, STORAGE, AND TRANSPORT OF SPECIMENS

Serum samples are used routinely for standard HIV antibody and antigen determinations, although plasma samples are also acceptable. The serum/plasma should be promptly separated from the clot/cellular elements and refrigerated at 2 to 8°C. If testing is not to be performed within 7 days, the serum specimens should be frozen at −20°C or lower. Serum/plasma specimens can be transported either refrigerated (if transport takes places within 7 days of collection) or frozen in screw-capped plastic vials.

Dried blood spots, as well as noninvasive specimens such as urine or oral fluid, are approved for use in some of the HIV antibody kits. The Orasure HIV-1 specimen collection device (Epitope Inc., Beaverton, Oreg.), which increases the flow of mucosal transudate across the mucosal surfaces onto an absorbent cotton pad, is available for collection of oral fluids. Rapid, point-of-care HIV assays usually require finger stick or venipuncture whole blood, although one of the assays is approved for use with oral fluid, and some of the assays have been validated for use with serum samples.

TABLE 2 Antiretroviral formulations approved for use by the FDA (as of March 2006)

Type of antiretroviral agent	Generic name (approval yr)	Other name(s)
NRTIs	Zidovudine (1987)	Retrovir, AZT, ZDV
	Didanosine (1991)	Videx, ddI
	Zalcitabine (1992)	HIVID, ddC
	Stavudine (1994)	Zerit, d4T
	Lamivudine (1995)	Epivir, 3TC
	Abacavir (1998)	Ziagen, ABC
	Tenofovir (2001)	Viread, TDF
	Emtricitabine (2003)	Emtriva, FT
NRTI coformulations	Zidovudine-lamivudine (1997)	Combivir
	Zidovudine-lamivudine-abacavir (2000)	Trizivir
	Tenofovir-emtricitabine (2004)	Truvada
	Abacavir-lamivudine (2004)	Epzicom
NNRTIs	Nevirapine (1996)	Viramune, NVP
	Delavirdine (1997)	Rescriptor, DLV
	Efavirenz (1998)	Sustiva, EFV
PIs	Saquinavir (1995)	Invirase, Fortonase, SQV
	Ritonavir (1996)	Norvir, RTV
	Indinavir (1996)	Crixivan, IDV
	Nelfinavir (1997)	Viracept, NFV
	Atazanavir (2003)	Reyataz, ATV
	Fosamprenavir (2003)	Lexiva, FPV
	Tripranavir (2005)	Aptivus
PI coformulation	Lopinavir-ritonavir (2000)	Kaletra, LPV/r
Fusion inhibitors	Enfuvirtide (2003)	Fuzeon, T-20

TABLE 3 Comparison of HIV-1 viral load assay characteristics

Assay characteristics	Amplicor HIV-1 Monitor Test Version 1.5		VERSANT HIV-1 RNA 3.0 bDNA assay	NucliSens HIV-1 QT assay
	Standard	Ultrasensitive		
Specimen requirements				
Anticoagulant	EDTA, ACD	EDTA, ACD	EDTA, ACD	EDTA, ACD, heparin
Plasma vol	0.2 ml	0.5 ml	1.0 ml	50 μl-2 ml
Kit characteristics				
RNA isolation method	Precipitation	Ultracentrifugation, precipitation	Ultracentrifugation	Binding to silica particles
Amplification method	RT-PCR	RT-PCR	bDNA	Isothermal
Amplified product	DNA	DNA	Signal	RNA
Detection method	ELISA	ELISA	Chemiluminescence	Electrochemiluminescence
Standards and controls	1 internal QS,[a] 3 external controls	1 internal QS,[a] 3 external controls	6 external standards, 3 external controls	3 internal calibrators
Dynamic range (copies/ml)	400–750,000	50–100,000	75–500,000	176–3,400,000[b]

[a] Quantitation standard RNA.
[b] Use of a 2 ml input volume instead of 1 ml improves the lower limit of sensitivity to 80 copies/ml.

HIV RNA viral load assays are most commonly performed with plasma specimens. To ensure accurate HIV RNA quantitation in plasma, proper collection, processing, storage, and transport of plasma specimens are essential to avoid RNA degradation. The same collection system and procedures should be used to follow up patients over time, because different collection systems may produce discrepant values. In addition, if a change in the collection system or technology is planned, baseline HIV values should be determined with two specimens obtained less than 2 weeks apart. Each of the three FDA-approved kits available for determination of HIV viral load in plasma has specific volume and collection tube requirements (Table 3). These assays have also been used to measure HIV viral loads in specimens other than plasma, including dried blood spots, cerebrospinal fluid, cervical secretions, seminal plasma/semen, and serum. The RNA content in serum has been found to be lower than in the paired plasma sample (66). In addition, acid citrate dextrose (ACD) anticoagulated specimens have also been shown to yield results that are approximately 15% lower than results obtained with EDTA plasma (61, 84). For all assays, plasma must be separated from blood cells within 6 h of collection, because delays in the separation of plasma from cellular elements can result in RNA degradation. HIV RNA is generally stable in cell-free plasma at refrigerated temperature for several days and remains stable for at least three freeze/thaw cycles (66). For long-term storage, plasma samples should be stored at −70°C. Plasma preparation tubes (PPT) (BD Vacutainer PPT tubes; Becton Dickinson, Franklin Lakes, N.J.), which contain dried EDTA and a gel separator that after centrifugation forms a barrier between the plasma and cellular elements, have become available in recent years. PPT tubes provide a closed collection system for the preparation and transport of plasma specimens; plasma samples do not need to be poured off from PPT tubes after centrifugation, and plasma transfer and relabeling steps are eliminated. This improves convenience, decreases risks of errors, and improves safety. Initial recommendations from the manufacturer allowed for either refrigerated or frozen transport of centrifuged PPT tubes. However, recently, minor discrepancies have been reported to occur in plasma samples that were frozen in situ (64, 142). The differences were noted only for samples with viral loads close to the limits of detection; a large proportion of samples with undetectable viral load in the standard EDTA aliquot were found to have detectable HIV RNA in the corresponding PPT tube. As a result, the manufacturer has recently recommended that plasma in PPT tubes should be stored without freezing and that plasma from PPT tubes should be transferred to a secondary tube if plasma samples need to be stored frozen.

For HIV resistance assays, genotypic and phenotypic, plasma collected from EDTA, ACD, or PPT/EDTA tubes can be used. The plasma must be separated from the cellular elements within 6 h of collection and frozen immediately. Plasma specimens should be transported frozen. For HIV DNA and viral culture assays, whole blood is commonly used. It should be collected on EDTA, ACD, or cell preparation tubes. HIV can be cultured from plasma or from peripheral blood mononuclear cells (PBMCs), but HIV DNA assays require whole blood or PBMCs. For preparation of PBMCs, the blood specimen should not be refrigerated or frozen, but instead should be kept at ambient temperature for no longer than 4 days.

DIRECT DETECTION

p24 Antigen Assays

In the early days of the AIDS epidemic, p24 antigen testing played an important role as a tool for the diagnosis, prognosis, and evaluation of antiretroviral activity and for monitoring of HIV-1-infected cultures. In 1996, the FDA approved the Coulter HIV-1 p24 Ag assay (Coulter Co., Miami, Fla.) for screening blood products. This test was used for screening blood and plasma donors in the United States for a few years until it was replaced with more sensitive nucleic acid tests in 1999. At present, use of this assay is very limited in the United States, and only one kit (Coulter HIV-1 p24 antigen assay) is commercially available, for research use only. HIV-1 antigen assays are utilized more commonly in areas with limited resources for the detection of early HIV-1 infection and for the diagnosis of HIV-1 infection in the newborn, as well as for monitoring antiretroviral therapy, because of its reduced cost and ease of performance.

The test is of diagnostic value during early infection. p24 antigen is usually not detectable during the first week after infection, but it is detectable thereafter during acute infection before HIV-1 antibody (Fig. 2). After HIV-1 antibody

seroconversion, p24 antigen forms immune complexes with HIV-1 antibody and becomes undetectable. Therefore, p24 antigen is found in the blood either in a free form or in a complex with HIV-1 antibody. The presence of HIV-1 p24 antigen can be detected in plasma or serum by antigen capture enzyme-immunosorbent assay (EIA). Because p24 antigen tests can produce false-positive reactions due to interfering substances, positive samples need to be confirmed by a neutralization procedure.

Standard EIA procedures for HIV-1 antigen determination are insensitive, and modifications to the HIV-1 antigen test have been made in recent years to boost the sensitivity of the assay including acid or heat treatment for dissociation of antigen antibody complexes (107, 134), and increased sensitivity has been achieved by the addition of signal amplification (6, 82, 106, 118, 125, 137). These variants of HIV-1 antigen assays are of interest because they provide highly sensitive yet inexpensive and easy to use tools for use in settings with limited resources. The enzyme-linked immunosorbent assay (ELISA) amplification system tyramide (ELAST; Perkin-Elmer) is designed to amplify the signal generated by horseradish peroxidase when applied to solid-phase EIA, and Perkin-Elmer has developed a kit, the ultrasensitive p24 antigen assay (Up24), that combines heat denaturation and signal amplification-boosted detection of HIV-1 antigen (125). These assays have been evaluated for their use in pediatric diagnosis (106, 137) and therapeutic monitoring (7) and appear to be able to detect non-B as well as B subtypes (121). Heat denaturation combined with tyramide signal amplification has been reported to increase the sensitivity of p24 antigen detection to levels comparable to detection of viral RNA by PCR and has been found to be effective for the monitoring of responses to antiretroviral therapy (6, 82, 118, 125, 135) as well as for pediatric diagnosis (30).

Recently, real-time immuno-PCR (IPCR), a procedure combining EIA and real-time PCR, was reported to be as sensitive for the detection of HIV-1 antigen as other available viral load methods and allowed for the detection of ultralow levels of HIV-1 p24 antigen (2). In the IPCR procedure, anti-HIV-1 p24 antibody adsorbed to the microwell plate is used to capture the antigen. Streptavidin-horseradish peroxidase serves as a bridge between a biotinylated detector anti-HIV-1 p24 antibody and biotinylated reporter DNA. The reporter DNA is amplified by PCR using a fluorescent probe for real-time analysis. In their study, Barletta et al. found that IPCR detected 42% of patient samples that had HIV-1 RNA viral loads of <50 copies/ml, although the specificity of the assay has not been adequately assessed (2).

HIV-1 DNA Qualitative Assays

Detection of HIV-1 DNA assays can be used to supplement or substitute antibody testing for the diagnosis of HIV-1 infection in special situations such as primary infection during the diagnostic window period or in newborns of infected mothers. HIV-1 DNA qualitative assays make use of PCR to amplify conserved regions of the HIV-1 genome to detect proviral HIV-1 DNA in blood mononuclear cells. Only one qualitative HIV-1 DNA PCR assay is commercially available (Roche Amplicor HIV DNA assay, version 1.5; Roche Diagnostics, Indianapolis, Ind.), but it is not approved by the FDA. Several laboratories have also developed home brew assays including nested as well as real-time PCR procedures (36, 54, 87).

The sensitivity and specificity of standard HIV-1 DNA PCR assays have been reported to be 96 and 99%, respectively, at 1 month of age for HIV-1 subtype B (43). The potential utility of qualitative DNA PCR assays in the diagnosis of vertical HIV-1 transmission has been greatly increased with the development of simple and sensitive procedures using dried blood spots (54, 87); a sensitivity of 98.1% and a specificity of 100% were reported with use of real-time PCR assays (87). False-negative HIV-1 DNA results have been reported for infants with non-B subtypes (81), although the latest 1.5 version of the Amplicor assay appears to allow for the detection of most HIV-1 subtypes.

HIV-1 RNA Viral Load Assays

Viral load assays which measure the quantity of HIV-1 RNA in plasma are used as prognostic markers, to monitor therapy, and to determine infectiousness. HIV-1 plasma viral load is a strong predictor of the rate of disease progression (96, 110). But HIV-1 RNA load assays are most commonly used to guide HIV-1 treatment decisions (77, 131). In the United States, three commercial assays are FDA approved for the quantification of HIV-1 RNA in plasma. A comparison of the plasma specimen requirements and characteristics of the assays is shown in Table 3. These assays are not reliable for use in HIV-2 and HIV-1 type O individuals because they have not been optimized for these viruses and will likely underestimate HIV RNA levels.

The Amplicor HIV-1 Monitor Assay (Roche Diagnostics) is based on reverse transcription of the target HIV-1 RNA and on PCR amplification of the resulting cDNA (103). After the viral RNA extraction step, reverse transcription and PCR amplification occur in a single step using the thermostable enzyme *Thermus thermophilus* DNA polymerase. With repeated cycles of heating and cooling in the presence of biotinylated oligonucleotide primers specific for a conserved region of the HIV-1 *gag*, segments of the viral cDNA are amplified exponentially to generate high numbers of amplicons. These amplicons are denatured into single-stranded DNA which are then bound to a solid phase coated with HIV-specific oligonucleotide probes. Avidin-horseradish peroxidase conjugate is added, and the amount of bound amplicon is measured after a colorimetric substrate is added. An internal quantitation standard RNA, consisting of a known concentration of RNA identical in size to the target amplicon, is added to each sample before the RNA extraction step. It allows for the quantification of HIV-1 RNA and compensates for plasma inhibitors that may affect extraction and amplification. The HIV-1 RNA copy number is calculated based on the input copy number of the quantitation standard RNA. The version of the assay currently in use (version 1.5) can adequately quantitate all group M subtypes of HIV-1, in contrast to older versions of the assay. Version 1.5 differs from version 1.0 in test primers, thermocycling conditions, and composition of the RT PCR buffer (100). One disadvantage of the Amplicor HIV-1 Monitor assay is that it has a limited dynamic range, requiring performance of both the standard and ultrasensitive assays for samples that fall outside the dynamic range. One advantage of the assay is that there is minimal risk of amplicon contamination because the kit includes UTP and uracil-*N*-glycosylase. Two FDA-approved versions of this assay exist, both of which are needed to cover the clinically relevant range of viral load values. The standard assay has a dynamic range of 400 to 750,000 copies/ml, and the ultrasensitive assay has a dynamic range of 50 to 100,000 copies/ml. Modifications that are included in the ultrasensitive assay include an increase in the initial input volume (500 μl), an ultracentrifugation step, and a lower resuspension volume (148). Two variations of these assays exist: the Amplicor HIV-1 Monitor

assay, which is performed in microwell plates, and the Cobas Amplicor HIV-1 Monitor assay, in which amplicons are captured on magnetic beads, and the Cobas analyzer is used to automate most of the assay.

The VERSANT HIV-1 RNA 3.0 Assay (Bayer Nucleic Acid Diagnostics, Norwood, Mass.) is a branched DNA (bDNA) method which quantifies HIV-1 RNA by signal amplification instead of target nucleic acid amplification (40). In this assay, virions are pelletted by centrifugation and disrupted by detergent and proteinase K to release the RNA. HIV-1 RNA is captured on microwells by specific synthetic oligonucleotide probes containing capture extenders. Target probes, which have numerous target extenders, hybridize to both the viral RNA and preamplifier probes. These then bind to the amplifier probe to form bDNA complexes. Multiple copies of alkaline phosphatase-labeled probe are then hybridized to the bDNA complexes. Detection is accomplished by chemiluminescence. Quantitation is determined from an external standard curve run on the same plate; six kit standards of know viral concentration are used. When compared to other viral load assays, the reproducibility of the bDNA assay has been reported to be superior, particularly at the low end of the dynamic range (85, 108). The VERSANT HIV-1 RNA 3.0 bDNA assay offers the advantages of high throughput; in the current version, 84 specimens can be run on one plate. In addition, the assay can reliably quantify all subtypes of HIV-1. Disadvantages of the bDNA assay include the requirement for a large volume of plasma and the absence of an internal quantitation standard for each sample tested. The Bayer System 340 bDNA Analyzer provides semiautomation of the assay.

The NucliSens HIV-1 RNA QT assay (bioMerieux, Inc., Durham, N.C.) uses nucleic acid sequence-based amplification (155). In a first step, HIV RNA is isolated from the patient's plasma sample, together with three internal calibrators (Qa, Qb, and Qc), by binding to a solid phase consisting of silicon dioxin particles. The three synthetic RNA calibrators differ from the wild-type RNA sequence by only a small number of bases; this allows for independent quantification and detection of the three calibrators and the patient's RNA. Second, coamplification of the patient and calibrator RNAs is performed in the presence of avian myeloblastosis virus RT, RNase H, and T7 RNA polymerase under isothermal conditions for 90 min. Finally, to detect the amplification products (HIV-1 RNA from the patient, Qa, Qb, and Qc) aliquots of the amplified sample are added to four hybridization solutions, each containing a probe specific for one of the four products. The amplified products are hybridized to an oligonucleotide fixed to a magnetic bead and a ruthenium labeled probe. The magnetic beads are captured on the surface of an electrode by a magnet, and the light emitted by the ruthenium labeled probe is quantified by electrochemiluminescence. The second-generation assay currently in use cannot reliably quantify subtypes A and G (59). Advantages of the NucliSens HIV-1 QT assay include a wide dynamic range (176 to 3,400,000 copies/ml) when a 1-ml input plasma volume is used. In addition, the assay can be used for measuring viral loads at other body sites because the RNA extraction procedure consistently generates RNA products that are free of interfering substances (53).

Numerous other types of HIV RNA viral load assays are in use including a number of real-time assays (58, 113, 129), some of which can be utilized for HIV-2 and HIV-1 group O viruses (33, 67). The commercial development of real-time HIV-1 assays is ongoing. In these assays, amplification and detection are performed in a single closed tube; this eliminates the risk of amplicon carryover contamination. The next generation of assays for measuring HIV viral load such as TaqMan or molecular beacon technology is likely to soon replace current assays (9).

The high cost and complex technical requirements of nucleic acid-based testing strategies have resulted in the development of other types of viral load assays for use in settings with limited resources. Two of these assays have received recent attention: the heat-denatured signal-boosted p24 antigen assays (Perkin-Elmer, Wellesley, Mass.) and the RT assay (Exa Vir Load assay; Cavidi Tech AB, Uppsala, Sweden) (7, 144). Although both methods remain less sensitive and reproducible than the nucleic acid-based assays, they are affordable alternatives to HIV RNA quantitation. Furthermore, an automated, low-cost real-time reverse transcription-PCR test is routinely used for diagnosis and monitoring of HIV-1 infection in a West African setting where resources are limited (129).

ISOLATION PROCEDURES

Because HIV can be isolated from the blood of the majority of HIV-infected individuals, HIV culture was frequently utilized in the early years of the epidemic as a diagnostic or prognostic marker or for assessing the efficacy of antiviral therapy (75, 96). Although a positive culture provides direct evidence of HIV infection, HIV culture is no longer used for routine diagnosis but is utilized primarily in research laboratories. The procedure for HIV culture is elaborate and time-consuming (63, 75). To isolate HIV, the patient specimen is first cultured by mixing patient cells with cells from healthy donors stimulated with phytohemagglutinin and interleukin-2; fresh stimulated donor cells must be added weekly, because HIV-1 produces cell death. In the second step, the presence of RT or p24 antigen released in the culture supernatants is assayed periodically.

Viral culture assays based on recombinant technology are now used in resistance assays and to determine the viral replicative capacity (RC assay) of HIV-1. The RC assay, also referred to as viral fitness assay, has been developed by Monogram Biosciences (formerly Virologic, South San Francisco, Calif.). It measures the ability of HIV-1 from a patient undergoing antiretroviral treatment to replicate in vitro compared to that of a wild-type reference virus. The patient RC value is expressed as a percentage of the replication capacity of the wild-type reference standard. The assay uses a retroviral vector constructed from an infectious clone of HIV-1. The vector contains a luciferase expression cassette inserted within a deleted region of the envelope gene (121). HIV-1 protease and RT sequences are amplified from the patient plasma samples and inserted into the vector. The amount of luciferase produced by patient-derived viruses is then compared to the amount of luciferase produced by well-characterized wild-type reference virus. RC has been suggested as an additional parameter for making decisions regarding antiretroviral therapy. Patients who do not experience increases in viral loads despite the accumulation of multiple resistance mutations have been shown to harbor virus with decreased RC (35). In addition, certain drug resistance mutations have been shown to reduce RC (39, 91), and low replicative capacity has been correlated with a slower rate of CD4 cell loss in individuals who have experienced viral rebound on treatment (147).

TABLE 4 Major FDA-approved HIV-1/HIV-2 standard EIAs[a]

Test name	Antigens used for detection	Antibodies detected
Abbott HIV AB HIV-1/HIV-2[b]	Recombinant gp41, recombinant gp120, recombinant gp36	IgG and IgM
Bio-Rad Genetic Systems HIV-1/HIV-2[c]	Synthetic gp41, synthetic p32, recombinant gp36	IgG

SEROLOGIC TESTS

The diagnosis of HIV infection is commonly accomplished via detection of HIV antibody by using a screening test and then confirmation using a subsequent confirmatory or supplementary test. Screening tests are highly sensitive and easy to perform; confirmatory tests are more specific (and generally, less sensitive than screening tests) and are more complex and difficult to perform and interpret (27). Because HIV causes a chronic infection which typically lasts for years and the initial infection may be minimally symptomatic, most patients who are identified with HIV are identified by antibody detection. In recent years, rapid assays for detection of HIV antibody have played an increasingly important role in situations in which rapid provision of antiretroviral therapy may prevent HIV, including labor and delivery (24) and employee exposures, for which current guidelines call for post exposure prophylaxis within 2 h of exposure.

Serological testing for HIV antibody is used for various purposes, including primary diagnosis, screening of blood products, management of untested persons in labor and delivery, evaluation of occupational exposures to blood/body fluid, and epidemiological surveillance. Screening of blood products for HIV and other viral transfusion-transmitted diseases has nearly eliminated a major source of HIV transmission in parts of the world where such screening has been implemented (145, 146).

Antibody Screening Tests: Standard EIAs

Considerable progress has been made over the past 3 decades in the development of HIV antibody screening tests. The first generation of HIV antibody assays relied on the detection of antibody to HIV viral protein lysates. The second generation assays utilized HIV recombinant antigens as the source of antigen bound to the solid phase and included recombinant antigens for detection of HIV-2. Relative to first-generation tests, second-generation methods provided fewer false-positive results and the ability to detect HIV-2. Third-generation assays utilize solid phases coated with recombinant antigens and peptides, and HIV antibody in the patient's sample is detected with labeled recombinant antigens. Relative to second-generation assays, third-generation methods provide earlier detection during seroconversion, since these antigen-antigen sandwich assays efficiently detect immunoglobulin M (IgM) and other non-IgG antibodies. Fourth-generation assays combine antibody and antigen detection, further decreasing the time to detection during seroconversion (88, 89, 90). At present, most of the commonly used assays provide for the simultaneous detection of antibodies to both HIV-1 and HIV-2 (Table 4). In addition, numerous standard EIA kits are also available for the detection of HIV-1 antibody only, and two kits are approved for the detection of HIV-2 antibody.

The shortage of trained medical laboratory workers and increasing fiscal pressures on laboratories have driven increasing automation in clinical laboratories. Modern random-access immunochemistry platforms provide substantial labor savings over automated EIA approaches. Methods for performing HIV antibody testing are being developed on at least three major platforms, but none is as yet FDA approved. The Abbott Axsym uses a fluorescent EIA method and combines antigen-antibody detection (138); the Bayer Advia-Centaur (45, 156) and the Ortho Vitros-ECi use chemiluminescent assay formats. All have the potential to make laboratory-based HIV testing simpler, faster, and more widely available.

Antibody Screening Tests: Rapid Assays

HIV prevalence continues to increase in the United States, and many at-risk persons are unaware that they are infected (15). CDC goals for HIV prevention include making HIV testing a routine part of medical care, and recent publications suggest that expanded screening for HIV is a cost-effective health intervention (5, 115, 127). Serving hard-to-reach populations has been limited by the logistics of conventional HIV testing, which require a follow-up visit before results of testing are available, even for seronegative patients. In addition, an immediate result is medically desirable in certain settings, for example, in assessment of the source patient in occupational blood and body fluid exposures, and in labor and delivery settings with women of unknown HIV serostatus.

To address these problems, rapid HIV tests have been under development and in active use for over a decade (78, 141). Performed both in clinical laboratories and at the point of care, rapid HIV tests have a role when rapid results are necessary and when HIV testing is provided to previously inaccessible populations and situations. Rapid HIV tests fall mostly into two categories; membrane EIAs and immunochromatographic assays. Membrane EIAs typically involve a series of steps, including addition of sample, wash, addition of conjugate, wash, addition of substrate, and stop reagent. The result is read as a colored spot or triangle on a solid surface. Most of these tests include a built-in control.

If the test differentiates two analytes, such as HIV-1 and HIV-2, two controls are included. Immunochromatographic or lateral-flow assays require the addition of only one or no reagent and thus are extremely simple to perform. They are especially well-suited for testing outside traditional laboratory settings. These tests utilize antibodies spotted onto nitrocellulose membranes with lateral or vertical flow of sample or reagents to interact with immobilized antibody. The sample is added at one end and moves along the membrane by capillary action to reach the immobilized antibody stripes.

Four rapid HIV antibody tests were available in the United States as of March 2006 (Table 5). The Abbott Oraquick and Trinity Uni-gold Recombigen both have waived status, while MedMira Reveal and Bio-Rad Multispot HIV-1/HIV-2 are nonwaived. Waived tests are simple methods approved for use in settings outside dedicated clinical laboratories. Laboratories operating under a "certificate of waiver" are subject to minimal regulations, and waived tests are required to be simple and have minimal chance of error. Uniquely, the Multispot allows discrimination between HIV-1 and HIV-2 reactivity. Many other tests are in development and in use outside the United States; and an older kit, Abbott's Single Use Diagnostic System HIV-1 (SUDS), has been removed from the market, but not before extensive experience was gained with its use.

Disadvantages of rapid assays include subjective interpretation, lack of automation, and possible errors if the reader has vision problems such as color-blindness. Although these kits are easy to use, lack of attention to technique and less-skilled personnel can lead to errors (62). Samples must be dispensed within specified time limits, and pipettes must be held vertically for correct delivery of reagent volumes. These formats are useful primarily for small-volume testing. Accurate timing of steps can be adversely affected when multiple samples are tested, and conventional EIAs and similar methods scale up to larger sample volumes more efficiently.

Numerous published studies support the manufacturer's validation data suggesting that rapid tests perform similarly to laboratory-based standard EIA methods when performed by skilled staff. In the largest such study, the MIRIAD trial, HIV testing with Oraquick in point-of-care settings had equal sensitivity to a laboratory-based EIA and had fewer false positives (8). In this trial, testing was performed at the point of care by labor and delivery nurses, midwives, and obstetrics and gynecology residents. This represents the most extensive trial to date documenting the accuracy of the rapid test when used by nonlaboratorians. Unfortunately, the procedures used for training, certifying, and assessing the testing personnel were not specified in the publication. The Oraquick was also found to perform as well as a laboratory-based EIA in a region with transmission of multiple HIV subtypes (126). Other rapid tests have also been evaluated for patients with non-B subtypes (76), but the existing data are limited relative to the large number of tests and HIV subtypes. No data are available on the accuracy or impact of rapid tests in a home environment, although the FDA is considering approval of one rapid HIV kit as a home test.

Other Types of Antibody Screening Tests

Alternative specimens for HIV antibody testing include oral fluid and urine. Either may be useful in testing of patients who are reluctant to undergo phlebotomy or who have poor vascular access, as well as in mass screening settings and in locations in which phlebotomy is impossible. Since there are no sharps involved, collection is also safer. Oral fluid has also been used for home testing, whereby a patient collects the specimen and sends it for analysis; counseling is provided when the result is communicated to the patient. Fluids in the oral cavity come from several sources, from the secretions of multiple different glands, and also from transudated plasma derived from the capillaries of the gum. The former contains primarily secretory IgA, which may have a role in protection against infection but is not a reliable target for diagnostic testing. In contrast, the transudated gingival fluid contains primarily blood-derived IgG. Collection devices such as the Orasure specimen collection device are specifically targeted to enhance collection of this component of the oral fluid. Oral-fluid-based HIV EIA, Western blot, and waived rapid tests are FDA approved; indeterminate Western blots appear to be more common from oral fluid than from serum samples (27, 140, 149). IgG is found, usually in small quantities relative to serum, in the urine, and FDA-licensed EIAs and Western blots are available for urine (153).

Detuned EIAs allow for the distinction between recent and distant HIV infections. This type of assay is used to estimate the incidence of new infections by assessing the titer or affinity of HIV antibody. This is done by comparing the results of a standard, sensitive HIV antibody test with one whose sensitivity has been intentionally decreased—a "detuned" assay. Patients positive for both the standard and detuned test are considered to have long-standing infections; patients positive on the standard test but negative on the detuned tests are considered to have recent infection. Variations have been seen in the performances of these methods in different geographic regions and with different HIV subtypes. Approaches to detuning HIV tests include sample dilution, shortened incubation times, and chaotropic agents (41, 117).

TABLE 5 Rapid and point-of-care HIV tests approved for use in the United States

Test	Antigens used for detection of:		Approved for detection of HIV type:
	HIV-1	HIV-2	
Abbott/Orasure Oraquick Advance Rapid HIV 1/2[a]	gp41	gp36	HIV-1 and HIV-2
Bio-Rad Multispot HIV-1/HIV-2 Rapid[b]	Recombinant and synthetic gp41	gp36	HIV-1 and HIV-2 (separate result for each)
Trinity Unigold Recombigen HIV[c]	gp41, gp120		HIV-1
MedMira Reveal G2 Rapid[d]	gp41, gp120		HIV-1

HIV Antibody Confirmation Assays

Both standard and rapid HIV screening tests require confirmation if the initial test result is positive (see Fig. 4 and 5). Screening HIV tests are optimized to provide very high sensitivity, at the expense of specificity. HIV testing algorithms therefore incorporate highly specific, but less sensitive, confirmatory tests. The most commonly used confirmation test is the Western blot, but other confirmation methods and strategies are available, including IFA (indirect fluorescent antibody) and LIA (line immunoassay). In addition to the traditional EIA screening/Western blot confirmation algorithm, a number of alternative algorithms have been proposed which include the use of a second, different EIA or rapid test as the confirmatory method. Such a scheme has been modeled for cost-effectiveness, even recommended, but has not been extensively studied in practice (47, 162, 163). Results of pilot projects using varying strategies for accelerated confirmatory testing have been encouraging (98, 128, 152).

The Western blot is considered by many to be the "gold standard" for the validation of HIV antibody initially reactive samples. Commercially available Western blots are supplied in kit form with HIV antigens separated by molecular weight by electrophoresis and blotted onto a membrane which is then cut into strips. The testing laboratory incubates the strips with patient serum and washes and then develops the reaction with an enzyme-labeled anti-human antibody, which detects patient antibodies bound to the specific viral proteins. Antibodies to the following HIV-1-associated antigens can be detected: gp 160, gp 120, p66, p55, p51, gp41, p31, p24, p17, and p15. Western blots are specific for HIV species and often subspecies. Therefore, it is necessary to use separate Western blots for HIV-1 and HIV-2, and results with subtypes other than M have been variable (19, 28). HIV-1 Western blot kits approved for use in the United States can be purchased either from Biorad/Genetic Systems (Hercules, Calif.) or from Calypte/Cambridge Biotech (Lake Oswego, Oreg.). Western blots are prepared from HIV grown on cell culture; therefore, nonviral proteins may be present on the nitrocellulose strip and lead to nonspecific reactions.

An indirect fluorescence assay (Fluorognost; Sanothemia, Westport, Conn.) has also been used as both a screening and a confirmatory test for HIV-1 infection. HIV-infected and -uninfected lymphocytes are fixed on a slide. The slide is incubated first with patient serum and then with a fluorescent-labeled anti-human antibody. For interpretation, patterns of fluorescence in infected and uninfected cells are compared for each patient sample. LIAs employ a strategy similar to that of the Western blot. Recombinant or synthetic antigens are placed on a strip rather than transferred from an electrophoresed gel. This approach has the advantage of placing only viral antigens in the reaction, eliminating the background from cross-reactivity with nonspecific cell proteins. The manufacturer has control over the quantity and type of antigens represented and can include HIV-2 and type O antigens to confirm these infections in a single test (19, 20, 101). The INNO-LIA HIV1/11 Score test (Innogenetics, Alpharetta, Ga.) is widely available outside the United States and can be used for confirmation of HIV-1, HIV-2, and HIV-1 type O infections.

Similar to the LIA, rapid confirmatory tests have been developed which incorporate multiple, separate diagnostic antigens in a rapid test format. Methods include the Quix HIV-1 Rapid Antibody Confirmation Test (Universal Healthwatch, Guardian Scientific Africa, Monmouth Beach, N.J.), the Bionor HIV-1&2 Confirmatory Rapid EIA (Bionor A/S, Skien, Norway), and the HIV 1 & 2 CombFirm (Orgenics, Inverness Medical Innovations, Waltham, Mass.). These tests may provide a robust confirmatory testing capability to settings where rapid screening tests are valuable. This would eliminate the need for collecting a specimen for off-site confirmation and awaiting the result prior to initiating treatment (26, 139).

ANTIVIRAL SUSCEPTIBILITIES

Resistance testing has become a crucial element in the management of antiretroviral-treatment-experienced patients, because it is useful for the selection of the antiretroviral treatment in patients who are failing their current regimen due to the development of antiviral resistance. In addition, given the high rates of transmission of resistant viruses, resistance testing is also taking an increasingly important role in the choice of the initial antiretroviral therapy (86). The clinical utility of HIV-1 resistance testing has been evaluated in a number of prospective randomized clinical trials (4, 23, 44, 99, 150). Although not all of the trials demonstrated a clear benefit for using resistance testing (99), several of the studies showed that patients for whom the antiretroviral treatment was based on the results of resistance testing had greater decreases in viral load than did patients in whom the antiretroviral regimen was based on prior antiretroviral usage (4, 23, 44, 150). One of these studies showed that expert advice further improved the benefit of using genotyping resistance testing (150). In addition, use of resistance testing to guide antiretroviral treatment has been reported to be cost-effective (159). Two types of methods are available to assay for HIV-1 resistance. Genotyping tests examine the population of viral genomes in the patient sample for the presence of mutations known to confer decreased sensitivity to antiretroviral drugs. Phenotypic assays measure viral replication of the patient's virus in the presence of antiretroviral drugs.

Genotyping Assays

Genotyping assays determine the sequence of nucleotides in the viral genome and compare the sequence to that of wild-type virus. Mutations that appear during the course of antiretroviral therapy are considered to cause drug resistance if in vitro studies confirm that the presence of these mutations decreases the susceptibility of HIV to a specific drug.

The initial steps of genotypic assays include extraction of viral RNA from plasma and RT-PCR to amplify viral RNA sequences which code for the patient RT and protease, the targets of most available antiretroviral drugs. Next, the nucleotide sequence of amplified sequences is determined and examined for the presence of known resistance mutations. This can be accomplished most commonly in the clinical laboratory setting by using automated sequencing technology. In this technology, the nucleotide sequence of the gene of interest is obtained and translated into the predicted amino acid sequence in order to assess for the presence of specific mutations. The process requires alignment and editing of the sequence, a comparison to the wild-type sequence, and final interpretation linking the mutations to specific antiretroviral drugs. Two FDA-approved kits, containing sequencing reagents as well as the software programs required for sequence alignment and interpretation, are commercially available. The two assays, i.e., the Trugene HIV-1 Genotyping Kit and OpenGene DNA Sequencing System (Bayer Diagnostics Co., Tarrytown, N.Y.) and theViroSeq HIV-1 Genotyping System (Abbott Diagnostics,

Abbott Park, Ill.), have been found to perform in an equivalent manner (49).

One limitation of both assays is that they are able to detect only mutants comprising major fractions of patient's virus; resistant variants must constitute at least 25 to 30% of the virus population (68). In addition, the assays do not detect the ENV gene mutations resulting from use of the fusion inhibitor T-20. Although the clinical significance of resistant mutations present at low levels remains to be fully elucidated, there is evidence that minor mutations which are missed by standard genotyping assays can lead to failure of subsequent treatments (18, 95). Because of the lack of sensitivity of standard genotyping assays for detection of low-frequency drug resistance mutations, efforts are under way to increase the sensitivity of detection of mutations through single-genome sequencing (114). Single-genome sequencing involves serially diluting the cDNA until there is a single copy present for amplification and sequencing. This is not presently a practical clinical tool as the process is expensive and labor-intensive.

Another genotypic assay, the HIV PRT GeneChip assay (Affymetrix, Santa Clara, Calif.), is used mostly in research settings. In this assay, the HIV sequencing is accomplished by DNA hybridization of the amplified viral genes to oligonucleotide probes on high-density microarrays followed by automated base calling and mutation detection (160). The HIV LiPA line probe assay is no longer available commercially. This reverse hybridization-based method used probes immobilized on a carrier surface to identify selected drug resistance mutations and provided limited information on the presence or absence of specific mutations at particular positions.

Phenotyping Assays

In phenotyping assays, the ability of HIV-1 to grow in the presence of various concentrations of a given antiretroviral agent is measured. The amount of drug required to inhibit virus replication by 50 or by 90% is determined and given as a 50 or a 90% inhibitory concentration (IC_{50} or IC_{90}), respectively. The IC_{50} or IC_{90} obtained with the patient sample is compared to a control wild-type virus, and the result is reported as a "fold" difference. Early phenotypic resistance assays were labor-intensive because they necessitated the isolation and culture of HIV-1 from the patient's specimen. Currently, commercially available methods use HIV-1 RNA amplified from plasma and are based on recombinant DNA technology. These phenotypic assays are automated but remain labor-intensive and technically complex. They have not been developed in a kit format and are performed at only two commercial laboratories: Virco (Mechelem, Belgium) and Monogram Biosciences, formerly ViroLogic (San Francisco, Calif.). The first step involves extraction of HIV-1 RNA from plasma. Reverse transcription and PCR amplification of the protease and RT genes follow. The amplified genes from the patient's specimen are then inserted into vectors. The PhenoSense assay (Monogram BioSciences) uses an HIV-1 vector with a luciferase reporter gene replacing the viral envelope gene. In the AntiVirogram assay (Virco), patient and HIV-1 vector sequences are combined by recombination in vitro, and viral replication is measured using a reporter gene system. The virtual phenotype, an approach developed by Virco, can be used as an alternative to phenotypic testing, although it is really a genotyping resistance interpreted with the aid of a large database of samples with paired genotypic and phenotypic data. The virtual phenotype is determined by entering the genotype into the database and by finding the closest matching phenotyping results.

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

Use and Interpretation of Antibody Assays

Currently available standard EIAs are exquisitely sensitive and specific. Causes of false-negative and false-positive screening tests are listed in Table 6. The currently approved rapid methods appear to have sensitivity comparable to that of conventional EIA methods, although occasional false-positive and false-negative results were seen in large panels, but never in numbers sufficient to discriminate between different kits in a significant manner (154, 154a–154c).

In the rapid HIV antibody tests, only one or occasionally two antigens are used for detection of HIV-1 and HIV-2 antibody. In theory, this should limit sensitivity in some patients. A report of a series of patients who were treated

TABLE 6 Causes of false-positive EIA, false-negative EIA and indeterminate Western blot HIV antibody results

Result	Nonspecific causes	HIV-specific causes
False-negative EIA	Hypogammaglobulinemia, immunosuppressive therapies	Acute infection during the window period, seroreversion[a], advanced AIDS, HIV-2 (if EIA kit detects only HIV-1), HIV-1 subtype O (if EIA kit does not detect HIV-1 subtype O), other HIV strain variations
False-positive EIA	Multiple transfusions, hypergammaglobulinemia, recent vaccinations, hemodialysis, antibodies to HLA antigens, autoantibodies associated with autoimmune disease, cross-reactivity with vector proteins	Experimental HIV vaccination
Indeterminate HIV-1 Western blot	Multiple transfusions, hypergammaglobulinemia, recent vaccinations, hemodialysis, antibodies to HLA antigens, autoantibodies associated with autoimmune disease, idiopathic	Early seroconversion, incomplete HIV-1 antibody evolution[a], cross-reactivity with HIV-2 proteins, cross-reactivity with HIV-1 subtype O proteins, experimental HIV vaccination

[a] In acutely infected individuals treated with antiretroviral therapy.

with HAART early after a known HIV exposure has been published. These patients developed HIV infection with low viral loads and a declining gp41 antibody response which was not detected by the Oraquick method (111). While this is not a patient population for which rapid testing would be appropriate currently, this report points to a potential sensitivity issue with rapid tests, particularly if used for two-stage confirmatory testing. The quality of testing is of concern at all times, but particularly for rapid HIV assays when testing is performed outside standard laboratory settings and by personnel whose chief expertise is not performing laboratory tests. The CDC has issued extensive performance and quality assurance guidelines for use of rapid HIV tests (16). In addition, it should be recognized that no laboratory test is 100% accurate, and results inconsistent with clinical findings should be repeated or assessed with different tests (27, 28).

Two types of criteria are used worldwide for the interpretation of HIV-1 Western blots. Criteria from the WHO require the detection of at least two envelope products (161). In the United States, HIV-1 Western blots are usually interpreted following the CDC guidelines, which require detection of at least two of three antigens: p24, gp41, or gp120/160 (10, 11). The absence of all bands is a negative result. HIV-associated bands that are present but do not meet the criteria for positivity are an indeterminate pattern (Fig. 3). Causes of indeterminate HIV-1 Western blots are listed in Table 6. p24 reactivity is most commonly seen with indeterminate HIV-1 Western blots; this is often due to nonspecific reactivity, but it is important to note that p24 is also the first positive band seen during HIV-1 seroconversion. Indeterminate HIV-1 Western blots should be followed with a repeat screening test and Western blot after 2 weeks to 6 months. HIV-2-infected

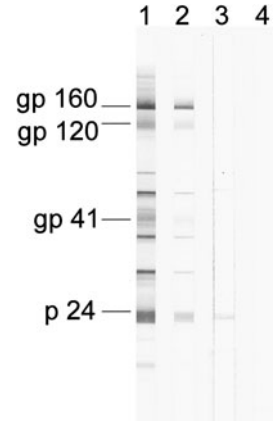

FIGURE 3 Examples of HIV-1 Western blot results interpreted according to CDC guidelines. High positive, low positive, indeterminate, and negative results are shown in lanes 1, 2, 3, and 4, respectively.

patients sometimes exhibit unusual indeterminate patterns on HIV-1 Western blot, consisting of reactivity to *gag* (p55, p24, or p17) and *pol* (p66, p51, or p32) gene products, in the absence of reactivity to envelope proteins. In addition, reactivity to p65, p51, p31, and gp160 can be seen on HIV-1 Western blots with samples from patients infected with HIV-1 type O. Samples from patients with HIV-2 or HIV-1 type O epidemiological risk factors should be further tested when the screening HIV-1/HIV-2 plus O EIA is positive and the confirmatory test is negative or indeterminate (Fig. 4). RNA or DNA testing may be used to further assess cases in which the

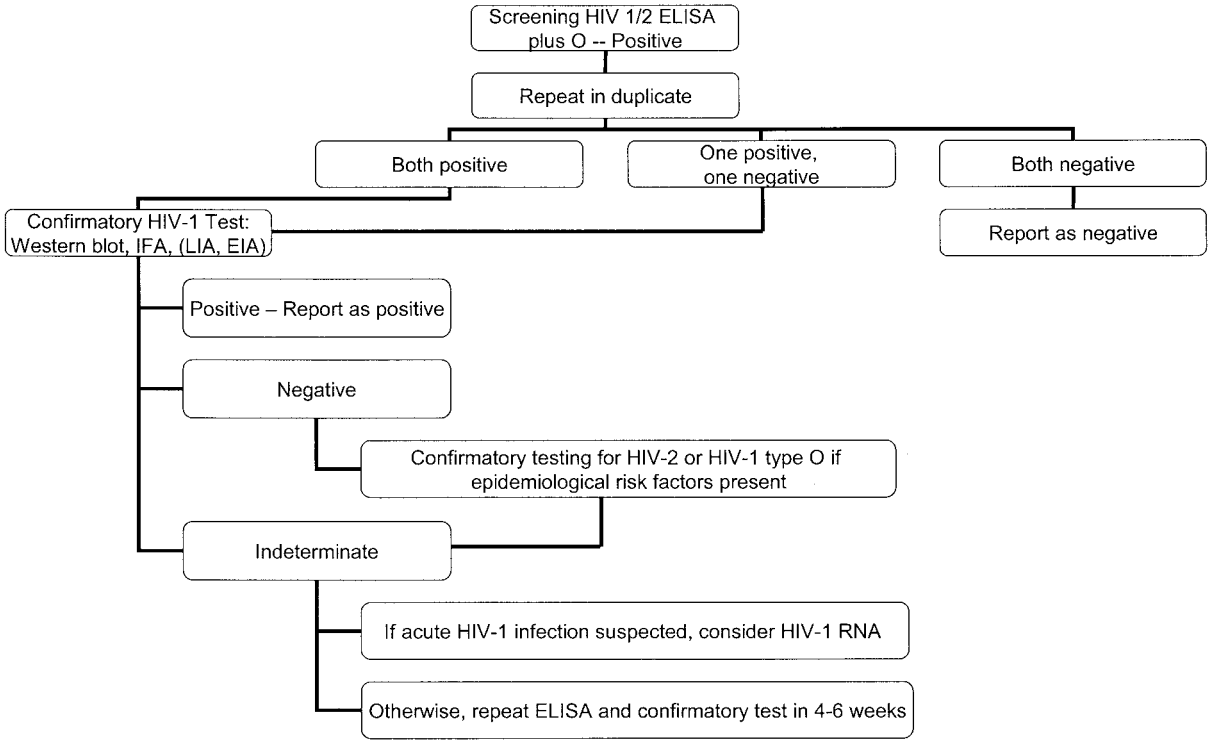

FIGURE 4 HIV antibody testing algorithm for samples initially reactive in a standard HIV-1/HIV-2 PLUS O assay showing the sequence of suggested follow-up confirmatory testing.

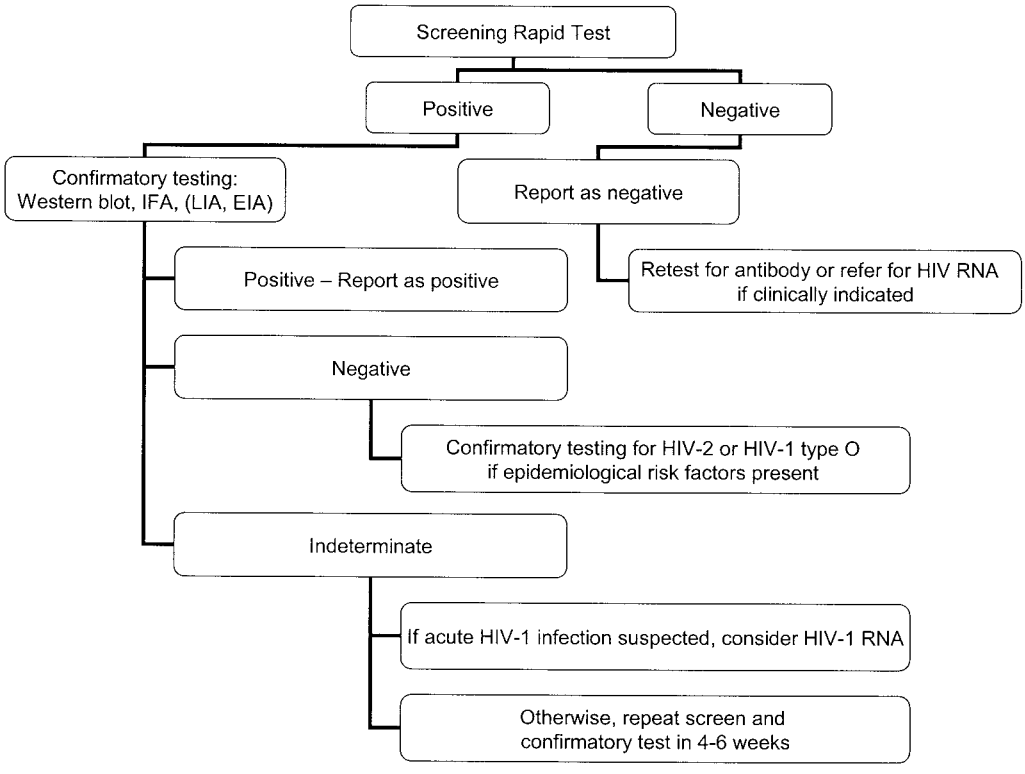

FIGURE 5 HIV antibody testing algorithm for samples tested with rapid HIV assays. Note that for rapid tests, as opposed to conventional screening assays, there is no recommendation to repeat an initial positive in duplicate prior to performing confirmatory testing. It is *not* recommended to perform a second EIA on a positive rapid test result prior to confirmatory testing; if a second screening test is used, confirmatory testing should be performed even when the result is negative.

HIV-1 serological results are inconclusive, although these tests are not approved for diagnosis of HIV-1 infection.

The algorithm for confirmation of rapid HIV tests is shown in Fig. 5. All reactive rapid HIV test results require confirmatory testing, regardless of EIA results. Samples reactive by rapid tests and negative by standard EIA have been subsequently confirmed as HIV positive. Therefore, retesting of samples by standard EIA prior to Western blot testing is not recommended (16, 17).

Use and Interpretation of HIV-1 DNA Qualitative Assays

The clinical usefulness of HIV-1 DNA testing in adults is very limited. However, HIV-1 DNA PCR is the preferred method in the United States for determining an exposed infant's HIV-1 infection status. Indeed, serological tests are not useful for the detection of HIV-1 infection in infants since maternal antibodies can be present in children until 18 months of age. The DNA test can be performed on whole blood or on dried blood spots, but the specimen collected at birth must be a neonatal and not a cord blood sample; cord blood samples yield a high rate of false-positive results (80). To exclude HIV-1 infection in an exposed infant, HIV-1 DNA PCR testing should be performed at birth, at weeks 4 to 7, and at weeks 8 to 16 (80). The sensitivity of the assay is 38% at 48 h of life and 99% at 4 weeks of age (43). Several studies have shown that HIV-1 RNA assays are at least as sensitive as HIV-1 DNA assays, especially for the detection of non-B subtypes (30, 164). It should be noted, however, that the sensitivity of the HIV-1 DNA and RNA assays may be affected by the use of prophylactic antiviral regimens and that HIV-1 RNA assays have not been approved for the diagnosis of HIV.

Use and Interpretation of Viral Load Assays

The clinical utility of HIV-1 viral load testing has been well established (14), and details can be found on line at http://www.hivatis.org and http://www.iasusa.org. Indications for use of HIV-1 RNA testing are listed in Table 7. Viral load assays are used widely to monitor changes in plasma viremia during antiretroviral therapy because they are useful for predicting time to progression to AIDS, determining when to initiate therapy, and monitoring responses to therapy. The magnitude of the decrease in viral load is dependent on the effectiveness of the antiretroviral therapy, and the optimum goal of therapy is to achieve viral loads below the detection limit of the assay. Baseline testing as well as repeated levels of HIV-1 RNA should be obtained before initiating or changing antiretroviral therapy regimens.

Guidelines for the proper use and interpretation of HIV-1 RNA load assays are listed in Table 8. Biological variation of HIV-1 RNA among clinically stable patients has been estimated to be approximately 0.3 $\log_{10}$ (34). In addition, commercial tests show assay reproducibility ranges from 0.2 to 0.5 $\log_{10}$ depending on the region of the assay's dynamic range. Generally, a change in viral load greater than 0.5 (threefold)

TABLE 7 Indications for use of HIV-1 RNA load assays

Prediction of HIV disease progression
To offer better prognostic information
To identify patients whose disease is becoming more active
To decide when to initiate or change antiretroviral therapy
Measure of response to antiretroviral therapy
To find out whether a particular drug combination is working well in an individual patient
To determine whether therapy should be changed
Aid in establishing diagnosis (when HIV antibody test is negative or indeterminate)
Syndrome consistent with acute HIV infection[a]
Infants from HIV-infected mothers[a]
Screening of blood products

[a] HIV-1 RNA assays are not FDA approved for diagnosis; standard antibody methods should first be used to confirm diagnosis.

log is considered to be significant. Viral load changes for samples close to the 50-copies/ml low detection limit of assays should be interpreted with particular caution because at the low end of the dynamic range, assay variability has a greater impact on assay interpretation. For borderline viral load values in patients with no prior data, it may be indicated to verify patient status, scrutinize laboratory results, and consider repeat testing.

Numerous studies comparing the performances of the three FDA-approved assays have been done (46, 48, 60, 71). Overall, high correlations between assays have been shown, and net changes in plasma RNA levels after antiretroviral therapy are similar. The current-generation assays have been standardized so that the differences in viral load are narrowing among assays. However, values do differ, and for a given sample, the viral loads obtained with the Bayer Versant 3.0 assay are consistently lower than the viral load values generated by the other two assays. It is therefore optimal for patients to be monitored over time with a single assay.

HIV-1 RNA load testing is sometimes requested to resolve equivocal serologic findings or to facilitate the diagnosis of HIV-1 infection during the acute phase or in a pediatric setting. In these settings, it is important to keep in mind that these molecular methods are not approved by the FDA for the diagnosis of HIV-1 infection. In addition, false-positive results can be obtained because of contamination during specimen processing, carryover of amplified products, or incorrect thresholds. With the bDNA assay, nonspecific hybridization can also lead to false-positive results. In CDC proficiency surveys, false-positive results as high as 5,000 copies/ml have been reported. Furthermore, herpes simplex virus infections, acute respiratory infections, and vaccinations can cause transient increases in viral load; HIV-1 RNA viral loads usually return to baseline within 1 month (42, 109).

TABLE 8 Guidelines for use and interpretation of HIV-1 RNA load assays

The same assay and the same laboratory should be used to monitor viral load changes.
A change in viral load is significant only if there is a threefold or 0.5 log increase or decrease *at a minimum*.
Changes in viral loads for samples with viral load at the low end of the dynamic range should be interpreted with extreme caution.
Infections and immunizations may produce transient nonspecific changes in viral load level.
To establish a baseline, viral load must be measured in two separate samples collected 1 to 2 weeks apart.
Patients should be tested 2 to 8 weeks after initiation of therapy for initial assessment of drug efficacy.
To evaluate the durability of antiretroviral efficacy, viral load assays should be performed every 3 to 4 months for patients on antiretroviral therapy.

Use and Interpretation of Resistance Assays

Clinical guidelines for the use of HIV-1 resistance testing in adults are published and updated on a regular basis (72), and a list of general suggestions for the use and interpretation of resistance assays is provided in Table 9. In contrast to phenotypic tests, genotyping assays are widely available, technically easier to perform, faster, and less expensive. In some cases, a resistance mutation may be detectable before a change in the phenotype has occurred, and therefore, genotypic and phenotypic results are not always correlated. One limitation of genotyping assays originates from the complexity of data generated by the genotyping assays. In the face of the rapid development in new drugs and new information of HIV-1 resistance, it remains a challenge to keep updated on which mutations are associated with each specific drug combination. Another problem with resistance testing is that drugs are used in combination but are not tested in combination. Phenotyping assays offer the advantage that they provide results in a format that is more familiar to clinicians. In addition, there appears to be less need for expert interpretation because susceptibility is measured directly. However, clinically significant cutoffs for distinguishing sensitive from resistant isolates have not been clearly defined for all of the available drugs.

Both types of assays will yield results only if the plasma used for testing contains at least 500 to 1,000 HIV-1 RNA copies per ml. In addition, for both assays, the resistant viral mutant must constitute at least 20 to 30% of the viral quasispecies to be detected. Also, cross-contamination can occur with both resistance assays, because both procedures rely on an RT-PCR step to amplify the HIV-1 gene sequences. In general, genotyping assays appear to show more evidence of clinical efficacy than phenotyping assays. Phenotyping assays, on the other hand, can help in defining the significance of

TABLE 9 Guidelines for use and interpretation of resistance testing

Resistance testing is recommended:
For patients failing therapy (to aid in the selection of salvage therapy)
For patients with recent infection, before initiation of therapy (to determine if a resistant virus was recently acquired)
For pregnant women (to optimize therapy)
Results of test are most reliable if test is performed when patient is taking antiviral therapy.
Genotype and phenotype results are not always correlated.
Genotype and phenotype assays require 500 to 1,000 HIV-1 RNA copies/ml in plasma.
Genotype and phenotype assays are insensitive to minor variants (resistant mutant must make up at least 25 to 30% of the virus population).

newly recognized resistance mutations and in elucidating the effects of complex mutation interactions.

The interpretation of HIV-1 genotyping results is complex. It requires knowledge of the identity of mutations associated with each specific drug, of the interactions of resistance mutations, and of the genetics of cross-resistance. This problem has been addressed by the development of several systems for facilitating the interpretation of HIV genotypes. Most systems use a rules-based approach; a group of experts establish interpretation algorithms based on the type of mutations or combination of mutations that are associated with resistance to specific drugs. As new information becomes available, the algorithms must be updated. In the Trugene and ViroSeq assays, these algorithms are used to generate automated HIV-1 genotyping reports. Depending on the mutations detected, the report indicates, for each drug in each of the antiviral categories, whether virus contained in the sample shows no evidence of resistance, resistance, or possible resistance, or if there is no sufficient evidence to place the virus in one of the three other categories. The Virtual Phenotype circumvents the complexity of HIV-1 genotyping data but provides only an estimate of the probable phenotype. Further, the correlation between actual and virtual phenotype is likely to be lower when there are few matches in the database as well as for newer drugs.

For HIV-1 phenotyping, thresholds to distinguish sensitive from resistant isolates can be defined as either biological cutoffs or clinical cutoffs. Biological cutoffs are based on biological variations measured in treatment-naïve patients, and the standard interpretation is that the isolate is susceptible if it is within the mean plus 2 standard deviations of the cutoff. Clinical cutoffs are based on the distinction between diminished and full clinical responses. These cutoffs vary from drug to drug and with the two different assays.

Human T-Cell Lymphotropic Virus Types 1 and 2

ANTOINE GESSAIN, CHARLENE S. DEZZUTTI, ELLIOT P. COWAN, AND RENU B. LAL

84

TAXONOMY

Human T-cell lymphotropic virus types 1 and 2 (HTLV-1 and HTLV-2) are members of the *Delta retrovirus* genus, different from the *Lentivirus* genus that includes human immunodeficiency virus types 1 and 2 (HIV-1 and HIV-2).

DESCRIPTION OF THE AGENT

HTLV is a complex retrovirus with regulatory genes in addition to the structural and enzymatic *gag, pol,* and *env* genes found in all classical retroviruses. HTLV-1 and HTLV-2 appear to use the ubiquitous glucose transporter, GLUT-1, for cellular entry (26). HTLV has made numerous cross-species jumps from nonhuman primates into humans and between nonhuman primate species (5, 8, 44, 61).

HTLV-1 and HTLV-2 are typical C-type retroviruses; they contain an electron-dense, centrally located nuclear core and bud from the cell surface. Within the core are two positive-sense single-stranded RNA genomes. Once a cell is infected, the RNA genome is converted by reverse transcriptase to DNA and integrates into the host genome. HTLV-1 and HTLV-2 have similar genomic organization: *gag, pro/pol, env, pX,* flanked by the long terminal repeats (LTRs) (Fig. 1). Further, they share approximately 60% of their nucleotide sequences. The *gag* gene encodes the structural proteins, p19, p24, and p15. The *pro/pol* genes encode the protease and the reverse transcriptase, respectively. The *env* gene encodes the transmembrane and external envelope glycoproteins, gp21 and gp46. HTLV-1 and HTLV-2 use alternative splicing and internal initiation codons to produce several regulatory and accessory proteins encoded by four open reading frames (ORFs) located in the pX region of the viral genome between *env* and the 3′ *LTR.* The *pX* gene encodes the spliced, regulatory proteins Tax and Rex and several additional ORFs (Fig. 1).

EPIDEMIOLOGY AND TRANSMISSION

HTLV-1 infects 15 to 20 million people worldwide, with foci of endemicity in southern Japan, the Caribbean, large parts of sub-Saharan Africa and Central and South America, and some rare areas in Melanesia and the Middle East (northern part of Iran) (13, 28). The seroprevalence rate in adults ranges from 1 to 5% in the Caribbean islands to approximately 5 to 25% in southern Japan (13). HTLV-2 is endemic in Amerindian tribes throughout the Americas, as well as in a few Pygmy tribes in Central Africa with seroprevalence ranging from 1 to 30% in adults (13, 37). In all areas of endemicity, HTLV-1/2 seroprevalence increases with age, especially in women. In the United States and Europe, the seroprevalence for both HTLV-1 and HTLV-2 among low-risk populations is less than 1% (28, 48). However, high-risk populations such as intravenous drug users (IDUs), in which HTLV-2 infection predominates over HTLV-1 infection, are reported to have a seroprevalence of up to 20% (13, 37).

HTLV-1 and HTLV-2 infections are spread through sexual (mainly male-to-female), vertical (mother-to-child by prolonged breast-feeding), and parenteral (drug use and blood transfusion) transmission (13, 28, 48). IDU and sex with IDUs are the most important risk factors for HTLV-2 transmission (13, 37). Both cross-sectional and prospective studies support sexual transmission, and there was a strong concordance of seropositivity between spouses in an area where HTLV-2 is endemic (38). A study has indicated that the mode of transmission can impact the rate of viral evolution (42). Lineages of the HTLV-2 virus evolve at a rate 150 to 350 times faster when the virus is transmitted between IDUs than when it is propagated by mother-to-infant transmission. Salemi et al. (42) postulated that the increase in viral transmission rate between IDUs, which can be many transmissions per year, accounted for the increase in the HTLV-2 evolution rate, whereas vertical transmission would be expected to occur just once every 14 to 30 years for a given viral lineage. This change in the mode of virus spread creates a possible risk for emergence of HTLV-2 strains with higher virulence.

Highly effective screening programs for volunteer blood donors have been implemented in Japan, Australia, the United States, Canada, and several Caribbean and European countries to reduce the risk of transfusion-related HTLV-1 and HTLV-2 transmission (11, 16, 43, 48, 50). In the United States, the incidence rate of seroconversion associated with HTLV in blood donors is estimated to be 1.59 per 100,000 persons per year (16), and the residual risk of transmitting HTLV infection by transfusing screened blood is estimated to be 1 in 641,000 (43).

Both HTLV-1 and HTLV-2 are the result of zoonotic transmission of simian retrovirus from simian to human hosts. The phylogeny of primate T-lymphotropic viruses (PTLV) indicates that both HTLV-1 and HTLV-2 emerged from respective primate lineages, PTLV-1 and PTLV-2, but their subsequent

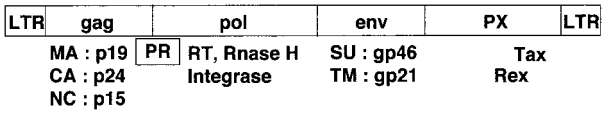

FIGURE 1 Organization of the HTLV-1 (9,046 bp) and -2 (8,952 bp) proviral genomes. MA, matrix; CA, capsid; NC, nucleocapsid; SU, surface; TM, transmembrane; RT, reverse transcriptase; PR, protease. Regions I to V correspond to ORFs of the pX region, located between the *env* gene and the LTR region of the HTLV-1/2 proviruses. ORF 1 and II encode P12, P13, and P30 for HTLV-1, and P10, P11, and P28 are for HTLV-2. ORF III and IV encode Rex and Tax regulatory proteins for HTLV-1 and -2. The gag and env proteins are most immunogenic, and antibodies to these proteins are commonly detected by serological tests (EIA and Western blotting). PCR assays are designed to detect regions within the LTR region and *gag*, *pol*, *env*, and/or *tax* genes.

evolution continued in different patterns (44). HTLV-1 includes at least four main subtypes, which evolved from PTLV-1 through several independent interspecies transmissions between simian and human hosts at different geographic locations (44, 56, 60). HTLV-2 includes three subtypes, which appear to originate from a common human ancestor virus that emerged possibly from only one simian-to-human transmission (5, 44). The possibility of additional zoonotic transfer of primate retroviruses from simian to human hosts and the impact that can result from such primate zoonotic transmission events remain a public health challenge (5, 44).

Molecular epidemiologic studies have shown HTLV proviruses to be remarkably stable genetically (34, 60). The different rates of evolution of HIV-1 and HTLV-1 are due to clonal expansion of HTLV-infected cells versus active replication of HIV-1 (58). While the overall genome of HTLV is highly conserved, nucleotide divergence in the LTR and the *gp21 env* gene has been exploited to genotypically subtype both HTLV-1 and HTLV-2 (44). The impact of diversity and emerging variants continues to challenge retroviral serology. An understanding of phylogenetic relationships is therefore useful (Fig. 2). There are at least four major geographic HTLV-1 subtypes: cosmopolitan (subtype A), Central African (subtype B), Australo-Melanesian (subtype C), and Central African (subtype D, mainly among Pygmy tribes) (44). Likewise, HTLV-2 has three subtypes: 2a, 2b, and 2d (5, 37, 44). Subtype 2a is commonly found among IDUs worldwide, whereas subtype 2b is found primarily among Amerindians and in some Pygmies from Cameroon. Subtype 2d has been found in only one Pygmy, from Zaire. Earlier studies had identified a molecular subtype 2c; however, subsequent analysis confirmed this to be subtype 2b (54). This genetic heterogeneity within HTLV-1 and HTLV-2 has provided valuable information on geographic clustering, movement of ancient populations, and viral transmission (37, 44).

CLINICAL SIGNIFICANCE

HTLV-1 has been associated with two major diseases: adult T-cell leukemia (ATL) and HTLV-1-associated myelopathy/tropical spastic paraparesis (HAM/TSP) (13, 24, 36, 47). ATL is a severe malignant lymphoproliferation of CD4-positive cells diagnosed biologically by seropositivity for HTLV-1, the presence of morphologically distinct $CD3^+/4^+/25^+$ lymphocytes with cleaved nuclei (flower cells), and clonal integration of HTLV-1 provirus(es) in the tumor cells, as detected by Southern blotting or inverse PCR (24, 36).

The clinical features of the chronic neuromyelopathy HAM/TSP are muscle weakness in the legs, hyperreflexia, clonus, extensor plantar responses, sensory disturbances, urinary incontinence, impotence, and low-back pain (47). Biological diagnosis includes the presence of high titers of HTLV-specific antibodies in the serum and cerebrospinal fluid. The estimated lifetime risk of developing HAM/TSP among HTLV-1 infected persons is less than 2% (13, 28) but can vary according to the geographical area. Other uncommon inflammatory disease associations include infective dermatitis, uveitis, myositis, and HTLV-associated arthropathy.

HTLV-2 has not been associated with malignancies; however, it has been associated rarely with a neurological disease resembling HAM/TSP (4, 37). The estimated lifetime risk of disease development for HTLV-2-infected persons is unknown but appears to be less than that estimated for persons with HTLV-1 infection. While the majority of HTLV-2-infected persons remain asymptomatic (>95%), recent studies report an increased incidence of infectious diseases (such as bronchitis and kidney and/or bladder infections) in HTLV-1- and HTLV-2-infected persons (4, 37).

COLLECTION AND STORAGE OF SPECIMENS

Serum or plasma is suitable for use in serologic assays for HTLV-1 and HTLV-2 detection. These specimens can be drawn at the time of presentation. Seronegative patients who are suspected of having HTLV-1 or HTLV-2 or those with seroindeterminate Western blot patterns should be redrawn at 6 months and retested to capture persons during the seroconversion window period. Serum and plasma specimens can be stored at 4°C or frozen for later use. Package inserts should be consulted for storage limitations and limitations on the number of freeze-thaw cycles permitted. Peripheral blood mononuclear cells (PBMCs) are appropriate specimens for nucleic acid detection and virus isolation since HTLV-1 and HTLV-2 are cell-associated viruses. Whole blood is collected, and PBMCs are typically isolated on a Ficoll-Hypaque gradient (discussed in chapter 80). DNA is prepared using standard methods, and it can be stored at −20°C until needed.

DIRECT DETECTION

Nucleic Acid Detection

Amplification of proviral DNA by PCR is the preferred method for determining infection status, testing the validity of serologic assays, distinguishing between HTLV-1 and HTLV-2, and studying tissue distribution in vivo. Two qualitative PCR procedures, utilizing primers in the *pol* or *tax* gene regions, have been used to confirm and differentiate between HTLV-1 and HTLV-2 infections (Table 1) (17, 23). The first uses HTLV consensus primers that allow amplification of both viruses; typing is achieved either by hybridizing the product to an HTLV-1-specific or HTLV-2-specific probe or by specific restriction digestion patterns (17, 23). A second approach employs type-specific primers and probes in separate amplifications. The PCR products can be detected with labeled internal probes by Southern blot hybridization (17). Most of these assays are performed for research use only.

Viral load assays are based on proviral DNA amplification; RNA viral loads are not feasible in the plasma for

TABLE 1 Summary of serological and supplemental confirmatory tests for HTLV-1 and HTLV-2 infections

Detection method	Description	Reference(s)	Availability in United States[a]
Serological screening tests			
EIA	HTLV-1- and HTLV-2-infected cell lysates and/or recombinant antigens used to detect HTLV antibodies by colorimetric readout. Excellent sensitivity and specificity.	2, 23, 35	Two FDA-licensed tests
ChLIA	Similar to EIA but with chemiluminescent readout.		Research use only
Particle agglutination	Viral lysate coats gelatin or latex particles. Antigen-specific antibodies bind, which results in agglutination of particles. Visual readout by operator.		Research use only
Serological supplementary tests			
WB	HTLV-1 viral lysates ± recombinant antigens used to detect HTLV-1- and -2-specific antibodies. May contain recombinant antigens to differentiate antibodies to HTLV-1 and HTLV-2.	57	Research use only
LIA	Recombinant or peptide HTLV-1 and HTLV-2 antigens painted onto membrane. Antibodies to individual viral proteins are visualized.	40	Research use only
IFA	Antibodies bind to HTLV-1- and HTLV-2-infected cells. Detected by secondary anti-human antibody with fluorescent label. Differentiates between antibodies to HTLV-1 and HTLV-2.	15	Research use only
Nucleic acid detection tests			
Qualitative PCR	Distinguishes between HTLV-1 and HTLV-2 either by using HTLV consensus primers with typing done by HTLV-1- or HTLV-2-specific primers and probes in separate tests, or by differential patterns using restriction enzyme fragment length polymorphisms.	17, 44	Research use only
Quantitative PCR	Determines proviral DNA copy number by limiting dilution, quantitative competitive PCR, or real-time PCR using gene- and type-specific primers.	1, 18, 31, 52	Research use only

[a] FDA licensed: may be used for blood donor screening and as an aid in clinical diagnosis of HTLV-1 or HTLV-2 infection and related diseases. Research use only: not for clinical use.

HTLV due to the cell-associated nature of these viruses (12). Quantitative nucleic acid amplification tests have been developed to determine HTLV-1 and HTLV-2 proviral DNA load using quantitative competitive PCR (1) or real-time PCR (18, 21, 31, 52). The real-time noncommercial PCR assay has excellent sensitivity and a broad dynamic range, from 10 to 10^6 copies/reaction (21), and has been used to study the relationship between proviral load and pathogenesis. Studies using these methods demonstrate that the proviral load is higher among HAM/TSP patients than among asymptomatic carriers (28, 47), suggesting that proviral load may be an indicator for future disease development (47). Follow-up of the proviral load or of the presence of a specific clone can also be done during ATL treatment (6, 36). Further, recent studies suggest that sexual transmission and mother-to-child transmission are associated with higher HTLV proviral load in the index case (22, 32, 38). Thus, quantification of HTLV proviral load is providing a better understanding of correlates of transmission and disease progression (32, 38, 47).

PCR also has been used to genetically subtype HTLV-1 and HTLV-2 based on the LTR region. Earlier studies used restriction endonuclease digestion of PCR products; separation through an agarose gel with visualization of the bands by ethidium bromide allows for subtype determination (44). However, most recent studies now perform direct sequencing of the PCR products (44, 56). Likewise, sequence and phylogenetic analyses of *env* and LTR regions have resulted

FIGURE 2 Unrooted phylogenetic tree generated by the neighbor-joining method using a fragment of the LTR region (622 bp) of representative sequences of the different subtypes of HTLV-1 and HTLV-2 strains. Bootstrap support (1,000 replicates) is noted on the branches of the tree. The branch lengths are drawn to scale, with the bar indicating 0.1 nucleotide replacement per site. The four main HTLV-1 subtypes (a, b, c, and d) are represented as well as the three main subtypes of HTLV-2 (a, b, and d). HTLV-1e and HTLV-1f represent the two other rare HTLV-1 subtypes, which have so far been found in few inhabitants of Central Africa.

in elucidation of the molecular epidemiology and the geographical distribution of virus-carrying populations (5, 44).

VIRUS ISOLATION AND IDENTIFICATION

Viral isolation of HTLV-1 or HTLV-2 has been difficult due to the cell-associated nature of this virus (12). Nevertheless, cocultivation of HTLV-1- and HTLV-2-infected PBMCs with activated, allogeneic HTLV-negative PBMCs or cord blood cells is used to obtain viral isolates. The culture supernatants are collected weekly for up to 4 weeks, and the presence of p19 gag antigen in the supernatant is tested using a research use antigen capture assay (Zeptometrix Corp., Buffalo, N.Y.). Because of the time required and labor- intensive nature of this method, virus isolation and antigen detection are generally not done for diagnosis of HTLV infection but rather serve as a research tool.

SEROLOGIC TESTS

Testing for antibodies to HTLV-1 and HTLV-2 should be performed for all blood donors and any patients presenting with relevant clinical signs and symptoms. In the United States, all blood donors have been screened for antibodies to both HTLV-1 and HTLV-2, using assays that include both HTLV-1 and HTLV-2 antigens (14; http://www.fda.gov/cber/gdlns/htlv-ii.pdf) since 1997. Testing for HTLV-1 and HTLV-2 should also be offered to persons who are from areas where HTLV is endemic, who engage in high-risk behaviors such as needle sharing, and who have had sexual contact with persons from either group. Currently, HTLV-1 and HTLV-2 testing is not routinely performed for fertility or pregnancy testing in the United States. This is different in some European countries, including some islands in the West Indies, where recommendations have been made to test pregnant and breast-feeding women originating from areas of HTLV-1 endemicity (48, 50).

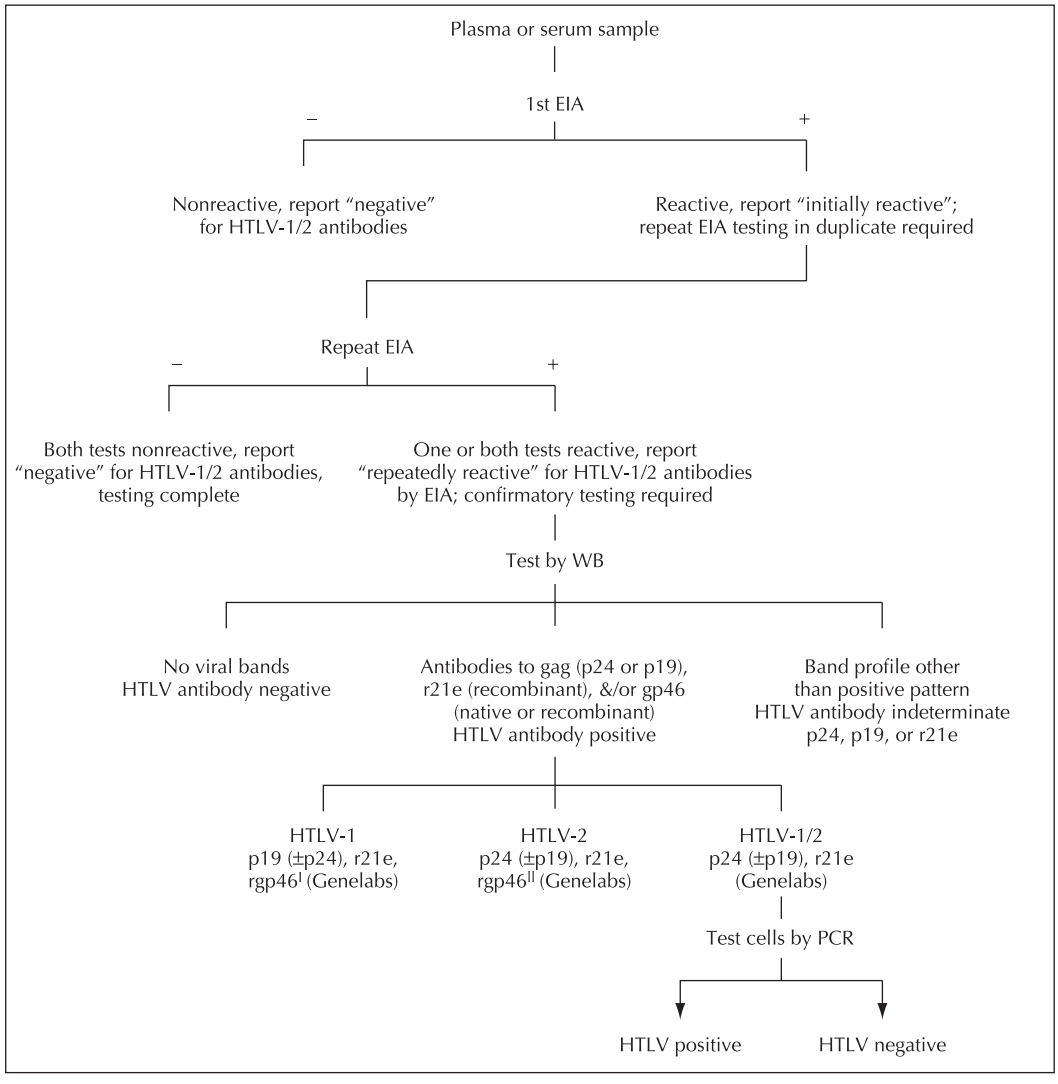

FIGURE 3 Serologic testing algorithm for the detection and confirmation of HTLV-1 and -2 infection. If the initial screening EIA is reactive, a repeat assay with the same specimen is performed in duplicate. If one or both of the repeat tests are reactive, the specimen is classified as repeatedly reactive and supplemental testing is done for the purpose of confirmation. Western blot criteria shown are those used by the manufacturer and not the PHS working group. In some cases, further follow-up is done using PCR.

The most common screening assays detect antibodies in serum or plasma (11, 14, 51). The immunodominant regions of structural and regulatory proteins are well characterized (20) and are used in diagnostic assays that detect and differentiate HTLV-1 and HTLV-2. The major tests for HTLV-1 and HTLV-2 are described in Table 1. The serologic testing algorithm is comprised of a primary screening assay followed by testing for confirmation and identification of HTLV type (Fig. 3).

Primary screening assays include enzyme immunoassay (EIA), particle agglutination (Fujirebio America, Fairfield, N.J.), and immunofluorescence assays (Table 1). The EIA is a sensitive and simple colorimetric test that uses purified infected cell lysates and/or recombinant antigens or synthetic peptides (2, 11, 51). The addition of HTLV-2 antigens to screening test kits significantly improved the detection of antibodies to HTLV-2, compared with results using kits that contained only HTLV-1 antigens (2, 23, 35). The EIA and next-generation versions that use chemiluminescent technology (chemiluminescent immunoassays [ChLIAs]) can be automated and performed on a large scale. While this test is not yet licensed in the United States, it is being routinely used outside the United States. However, neither EIAs nor ChLIAs can differentiate between HTLV-1 and HTLV-2 infections because of the significant homology in structural proteins between the two viruses; therefore, these screening assays are referred to as tests for HTLV-1/2 (2, 11, 51).

Comparative analysis of various commercial screening assays containing both HTLV-1 and HTLV-2 antigens indicates that sensitivity ranges from 98.9 to 100% for confirmed HTLV-1-positive specimens and 91.5 to 100% for confirmed HTLV-2-positive specimens. Specificity ranges from 90.2 to 100% (2, 11, 23, 35, 51). Currently, two HTLV-1/2 EIAs are FDA licensed for use in the United States (Vironostika HTLV-I/II Microelisa System [BioMerieux, Durham, N.C.] and Abbott HTLV-I/HTLV-II EIA [Abbott Laboratories, Abbott Park, Ill.), with reports of overall sensitivity of 99.76 to 100% and specificity of 99.63 to 99.98%. These ranges reflect differences in the source of antigen and assay configuration among the various tests, as well as the source of the specimens (2). These licensed assays are used both for blood donor screening and as an aid in clinical diagnosis of HTLV-1 and HTLV-2 infection and related diseases. Further attempts have been made to develop a dual EIA algorithm to increase the predictive values of HTLV tests (46). Pooling of samples for seroepidemiologic studies has been proposed; however, pooled testing is not recommended for blood donor testing (3).

While most screening assays are highly sensitive, specimens containing low titers of antibodies to HTLV-1 and HTLV-2 from certain areas of HTLV-2 endemicity or specimens from early seroconverters can be missed by current EIAs (27, 35). Nucleic acid assays can be used to detect infected individuals either with low antibody titers or within their window period prior to the development of an antibody response (median window period, 51 days; range, 36 to 72) (27). However, these assays are used mainly for research and are not in routine clinical use.

Supplemental confirmatory or differentiation tests for HTLV-1 and HTLV-2 infection include Western blots (WB) containing the viral lysates supplemented with recombinant proteins (57), line immunoassays (LIAs), (Innogenetics, Ghent, Belgium) (40), and immunofluorescence assays (IFAs) (15) (Table 1). Although WB assays using purified viral lysates are highly sensitive for detecting p24 and p19 gag antibodies, they do not always detect antibodies to native envelope glycoproteins. An alternative approach used in a second-generation confirmatory assay is a modified WB that contains type-specific gp46env recombinant proteins from both viruses and a truncated form of r21e that reduces nonspecific reactivity, improves performance (specificity and sensitivity), and allows differentiation between HTLV-1 and HTLV-2 (Genelabs WB 2.4; Genelabs Diagnostics/ZeptoMetrix Corp.) (Fig. 4) (23, 57).

Another supplementary test is the LIA, consisting of recombinant and synthetic HTLV-1 and HTLV-2 antigens painted onto strips (Innogenetics) (40). Some of these antigens are specific for HTLV-1 or HTLV-2; therefore, this assay can differentiate between HTLV-1 and HTLV-2 infections. IFAs that detect binding of antibodies from a specimen to HTLV-1- or HTLV-2-infected cells can be used to discriminate HTLV-1/2 infections and to determine antibody titer (15). No assay has been approved or licensed as a confirmatory test for clinical use by the U.S. Food and Drug Administration; however, WB and LIA have been certified for use in Europe and other areas of endemicity (Brazil, Argentina, West Indies, Iran, and Japan) to confirm any EIA repeatedly reactive sample (48, 50).

ANTIVIRAL SUSCEPTIBILITIES

There are limited treatment options for HTLV-associated diseases. Although zidovudine (AZT) and alpha interferon (IFN-α) yield some responses and improve ATL prognosis, alternative therapies are needed. New drugs such as arsenic trioxide, proteasome inhibitors, retinoids, and angiogenesis inhibitors, as well as cellular immunotherapy, are under investigation (6). Antiretroviral treatment such as lamivudine and high-dose IFN-α and IFN-β have recently showed some clinical benefit among HAM/TSP patients (33, 41, 49). However, no randomized trials have been done to compare the effectiveness of these therapies for ATL or HAM/TSP treatment. For uveitis, topical and systemic corticosteroids appear to improve sight whereas infective dermatitis responds well to antibiotic treatment.

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

A typical algorithm for HTLV testing for diagnostic purposes is outlined in Fig. 3. If the initial screening EIA is reactive, a repeat assay on the same specimen is performed in duplicate. If one or both of the repeat tests are reactive, the specimen is classified as repeatedly reactive. The repeatedly reactive specimens are subjected to confirmatory supplemental testing that is typically done by WB, even though these tests have not been licensed by the FDA (Fig. 4 and Table 1). Based on the data available in 1992, the U.S. Public Health Service (PHS) recommended that the diagnostic criteria for confirmation of HTLV-1 or HTLV-2 seropositivity by supplemental tests include demonstration of antibodies to p24gag and to native gp46env and/or r21e (9). Subsequent data with more-sensitive assays suggest that alternative patterns of WB reactivity may be considered. The second-generation modified WB is the most commonly used WB assay worldwide (Genelabs WB 2.4). Specimens with reactivity to p19gag (with or without p24gag), r21e, and rgp46^{I} are referred to as HTLV-1 (Fig. 4A). Sera with reactivity to p24gag (with or without p19), r21e, and rgp46^{II} are referred to as HTLV-2 (Fig. 4B). Specimens with no immunoreactivity to any bands are considered negative for antibodies to HTLV-1 and HTLV-2 (false-positive EIA specimens). Specimens reacting with p24gag (with or without p19gag) and r21e, but with no reactivity to either rgp46^{I} or rgp46^{II}, are referred to as untypeable and are considered to be

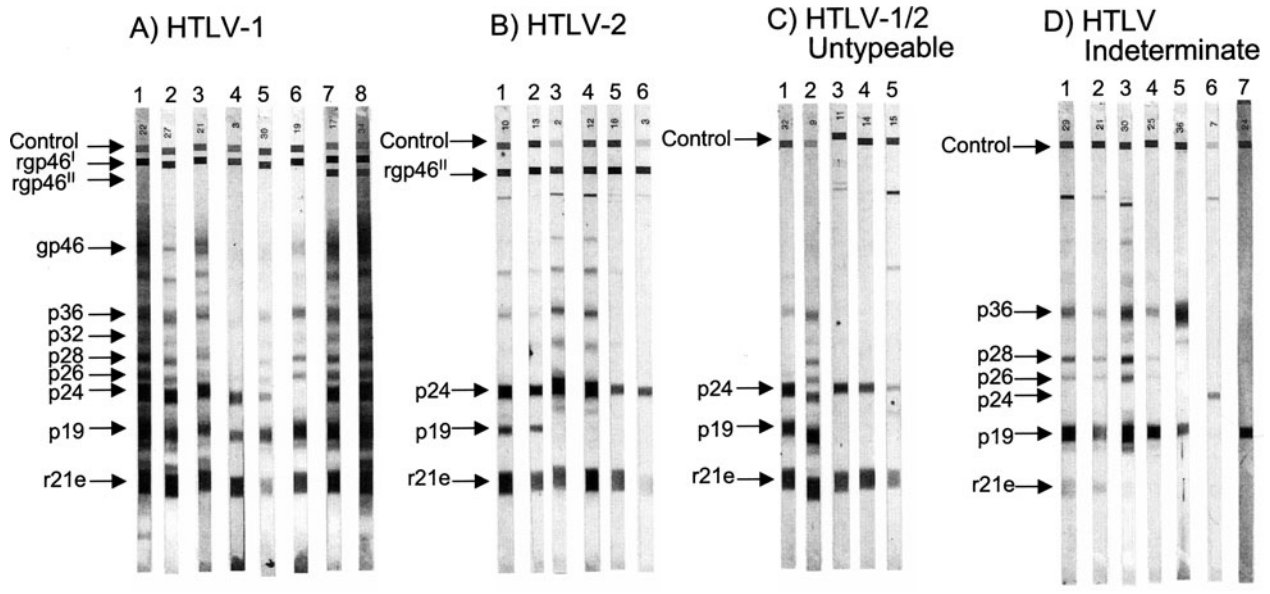

FIGURE 4 Western blot analysis of representative plasma or serum specimens from persons infected with HTLV-1 (A), HTLV-2 (B), and HTLV-1/2 untypeable (C). Representative seroreactivity patterns are shown for Western blots from Genelabs Diagnostics (HTLV-2.4 version), which contain HTLV-1 antigens spiked with recombinant r21e (common to HTLV-1 and HTLV-2) and two external envelope recombinant proteins specific for HTLV-1 (rgp46^{I}) and HTLV-2 (rgp46^{II}). Panel A shows typical patterns for HTLV-1 reactivity (lanes 1 to 5), atypical reactivity lacking p24 response (lane 6), and specimens with high antibody titers showing dual reactivity to both rgp46 proteins (lanes 7 and 8; titration of sera results in reactivity only to rgp46^{I}). Panel B shows typical patterns for HTLV-2 reactivity (lanes 1 to 6; note that the p24 band is stronger than p19 reactivity, which is usually absent from HTLV-2-infected sera). Panel C shows HTLV-1/2-positive but untypeable specimens, with reactivity to gag (p24, with or without p19) and r21e but not gp46^{I} or gp46^{II}. Lanes 1 and 2: characteristic patterns of specimens that are usually found to contain HTLV-1 after additional testing; lanes 3 to 5: characteristic patterns of specimens that are usually found to contain HTLV-2 after additional testing. Panel D demonstrates typical patterns from HTLV indeterminate specimens. Shown are typical HTLV gag indeterminate profiles frequently found in plasma or sera from individuals originating from tropical regions (Central Africa, Papua New Guinea, etc.) (lanes 1 to 4) and those from low-risk populations (lanes 5 to 7). In the great majority of the cases, neither HTLV-1 nor HTLV-2 infection could be demonstrated in samples with such seroreactivity.

HTLV positives (Fig. 4C). PCR analysis of these untypeable specimens has identified the presence of HTLV-specific sequences (55). Similar criteria are used for LIA (see manufacturer's instructions).

Both the WB assays and LIA can give indeterminate results (immunoreactivity to a single HTLV gene product or multiple bands, conditions that do not meet the criteria for seropositivity [Fig. 4D]) (51, 57). Antibody to only gag proteins (p24, p19) is the most common indeterminate pattern that is observed in EIA-reactive specimens and is an area of intense investigation (7, 10, 19, 25, 29, 30, 39, 53, 55). Extensive PCR analyses using primers to detect multiple gene regions have failed to detect HTLV-1 or HTLV-2 proviral sequences in low-risk seroindeterminate persons, thus indicating that these individuals are not likely to be infected with HTLV-1 or HTLV-2 (7, 10, 19, 30, 39, 55). The possibility that such indeterminate WB results may represent a novel retrovirus with partial homology to HTLV has been explored; however, no DNA amplification was observed using generic PCR primers that would detect HTLV-related viruses (7, 55), with the exception of HTLV-3 and HTLV-4 (8, 61), two novel human retroviruses closely related to HTLV-1 and HTLV-2 isolated from individuals living in Central Africa. Limited studies have established that individuals with indeterminate WB profiles generally do not have risk factors for HTLV infection (10, 29, 30, 39). Such indeterminate WB results among low-risk persons appear to represent antibodies to different viral and cellular antigens that cross-react with HTLV proteins (25).

In rare instances, specimens with confirmed HTLV infection have an indeterminate WB pattern of reactivity to p19gag (in the absence of p24gag) and r21e (10, 39). Likewise, in some instances, antibody to r21e may represent an early antibody response during seroconversion (28). Individuals with such reactivity should be retested in 6 months by EIA and/or PCR.

Recent data suggest that a very small number of patients with chronic progressive neurological disease from the United States with HTLV-indeterminate WB patterns may be infected with a defective HTLV or have HTLV-1 in low copy numbers (45, 59). Persons who have clinical neurological symptoms or are from high-prevalence areas (e.g., African, Asian, South American, and Caribbean countries) with HTLV-1/2-indeterminate reactivity should be further investigated for possible retroviral infection, including infection with the recently identified viruses HTLV-3 and HTLV-4.

Further testing could include PCR in conjunction with serologic testing.

In the United States, decisions to accept blood donations and defer blood donors are currently based on only screening test (EIA) results because of the lack of FDA-licensed supplemental tests. Persons who are ultimately confirmed to be antibody positive to HTLV-1 or HTLV-2 (i.e., when licensed supplemental testing becomes available) are permanently deferred from donating blood. Blood donors with plasma specimens that are repeatedly reactive on screening but not confirmed as seropositive for HTLV-1 or HTLV-2 (including false EIA-reactive and supplemental test indeterminate specimens and specimens for which supplemental testing was not performed) should be notified and deferred if the same test result is obtained on two separate donations or if the same donation repeatedly tests reactive on screening tests from two different manufacturers (14). Screening tests are weighted toward better sensitivity than specificity because of the public health implications of false-negative results. Therefore, in the absence of known risk factors for a given blood donor, repeatedly reactive results from a single-test kit or discrepant results between multiple test kits most likely represent false-positive reactions. Reactivity in a dual-screening test algorithm increases the probability of infection (46).

Persons with HTLV-1- or HTLV-2-positive or -indeterminate test results are counseled according to the guidelines established by the PHS Working Group (CDC). These guidelines state that persons should be informed that HTLV is not the AIDS virus and that their risk of developing HTLV-related diseases is low. HTLV-1- or HTLV-2-infected persons are asked not to donate blood, semen, organs, or other tissues and not to share needles or syringes. To prevent transmission of HTLV, the infected person is counseled to use protective measures during sexual relations and women are counseled to refrain from breast-feeding. Persons who have indeterminate results on two separate occasions at least 3 months apart should be advised that their specimens were reactive in screening for HTLV-1/2, but these results could not be confirmed by more-specific tests. Further, they should be reassured that indeterminate results are very rarely caused by HTLV-1 or HTLV-2 infection. Repeat testing should be offered.

The authors employed by the U.S. Government are writing as individual experts whose views should not be taken to represent those of the U.S. Government agencies by which they are employed.

Influenza Viruses*

ROBERT L. ATMAR

85

TAXONOMY

The influenza viruses are members of the family *Orthomyxoviridae*. Antigenic differences in two major structural proteins, the matrix protein (M) and the nucleoprotein (NP), are used to separate the influenza viruses into three genera within the family: *Influenzavirus A*, *Influenzavirus B*, and *Influenzavirus C*. Members of these three genera are also referred to as influenza type A, B, and C viruses, respectively. The influenza A viruses are further classified into subtypes based upon characteristics of the two major surface glycoproteins, hemagglutinin (HA) and neuraminidase (NA). Subtypes are recognized by the lack of cross-reactivity in double immunodiffusion assays with animal hyperimmune sera corresponding to each antigen (58). Sixteen HA subtypes and nine NA subtypes are now recognized (23). The following information is used in the naming of individual virus strains: type, species of origin (if nonhuman), geographic location of isolation strain or laboratory identification number, year of isolation and subtype (influenza A viruses only). Thus, a human strain of influenza is A/California/7/2004 (H3N2), while an avian strain isolated in the current Asian epizootic is A/quail/Vietnam/36/2004 (H5N1).

DESCRIPTION OF THE AGENTS

Orthomyxoviruses are enveloped, single-stranded-RNA viruses with segmented genomes of negative sense. Influenza A and B viruses have eight RNA segments, and influenza C viruses have only seven segments. Each segment ranges from ~800 to ~2,500 nucleotides in length, and the entire genome ranges from 10 to 14.6 kb. Viruses are spherical and pleomorphic, with diameters of 80 to 120 nm after serial passage in culture. Filamentous forms also occur and may be up to several micrometers in size. The lipid envelope is derived from the host cell membrane through which maturing virus particles bud, and HA and NA form characteristic rod-like spikes (HA) and spikes with globular heads (NA) on the virus surface. As its name implies, the HA can agglutinate red blood cells from both mammalian (e.g., human [type O] and guinea pig) and avian (e.g., chicken and turkey) species by binding to sialic acid residues, and this characteristic is used for virus identification. The lipid envelope surrounds the nucleocapsid which has helical symmetry and consists of the genomic RNA segments, several copies of the polymerase proteins, and the NP. The matrix-1 (M1) protein is present between the nucleocapsid and the envelope, and the matrix-2 (M2) protein forms an ion channel across the envelope in influenza A viruses.

EPIDEMIOLOGY AND TRANSMISSION

Influenza viruses cause annual epidemics in areas with temperate climates; in tropical climates, seasonality is less apparent and influenza viruses can be isolated throughout the year. In the temperate regions of the Northern Hemisphere, epidemics generally occur between December and March, and in the Southern Hemisphere, the epidemic period is usually between May and August. Epidemics are characterized by a sudden increase in febrile respiratory illnesses and absenteeism from school and work, and within a community the epidemic period usually lasts from 3 to 8 weeks. A single subtype (A) or type (B) of influenza virus usually predominates, but epidemics have occurred in which both A and B viruses or two influenza A virus subtypes were isolated (13). Global epidemics, or pandemics, occur less frequently and are seen only with influenza A viruses. Pandemics occur following the emergence of an influenza A virus that carries a novel HA and that can be readily transmitted from person to person. The pandemic strain may develop due to gene reassortment following coinfection of a susceptible host with human and avian influenza viruses or through gradual adaptation of an avian strain to mammalian hosts.

Influenza viruses are transmitted from person to person primarily via droplets generated by sneezing, coughing, and speaking. Direct or indirect (fomite) contact with contaminated secretions and small-particle aerosols is another potential route of transmission that has been noted. The relative importance of these different routes has not been determined for influenza viruses (6). For avian strains of influenza virus, direct contact with infected birds has been the most common route of transmission, but direct inoculation into the pharynx or gastrointestinal tract may also lead to infection (3).

Concern is increasing about the pandemic potential of avian strains of influenza A/H5N1 viruses. In 1997, several human cases occurred in Hong Kong in association with a large poultry outbreak. This outbreak was controlled by

* This chapter contains information presented in chapter 87 by Nancy J. Cox and Thedi Ziegler in the eighth edition of this Manual.

slaughtering all poultry in Hong Kong, but H5N1 viruses again caused outbreaks in poultry in China in 2003 and in several southeast Asian countries in 2004 and 2005. By late 2005 and early 2006, the virus had spread to poultry in other parts of Asia, as well as to parts of Europe, Africa, and the Middle East. More than 150 human infections have been documented; most cases have been in southeast Asia, but several cases have also occurred in Turkey and Iraq. Most human cases have been due to direct contact with infected birds, but limited human-to-human transmission has also occurred (3). The virus continues to evolve, raising the possibility that it may acquire the ability to spread efficiently among humans (49).

CLINICAL SIGNIFICANCE

Influenza A and B virus infections typically cause a febrile respiratory illness characterized by fever, cough, upper respiratory tract symptoms (including sore throat, rhinorrhea, and nasal congestion), and systemic symptoms (including headache, myalgia, and malaise). This constellation of symptoms is called influenza, although other clinical presentations, from asymptomatic infection to viral pneumonia, also occur. Illness begins abruptly after a 1- to 5-day incubation period (average, 2 days). Fever generally lasts for 3 to 5 days, but symptoms of dry cough and malaise may persist for several weeks. Complications include otitis media in children, sinusitis, viral pneumonia, secondary bacterial pneumonia, exacerbation of underlying cardiac or pulmonary disease, myositis (including rhabdomyolysis), neurologic problems (seizures, acute encephalitis, and postinfectious encephalopathy), Reye's syndrome (associated with aspirin use), myopericarditis, and death (27, 53). In contrast, influenza C viruses cause mild respiratory illnesses that clinically are not distinguishable from common colds.

Influenza A/H5N1 virus causes a similar clinical syndrome, with fever (>38°C) and lower respiratory tract symptoms. Upper respiratory tract symptoms may be absent, and gastrointestinal symptoms (watery diarrhea, vomiting, and abdominal pain) occur in some patients (3). Acute encephalitis may occur (14). Infection is associated with a high mortality (~50%), with most patients dying of progressive pneumonia. Viral replication is prolonged, and levels of several inflammatory mediators (e.g., interleukin-6, interleukin-8, and interleukin-1beta) in plasma have been higher in fatal than in nonfatal cases. Surviving patients develop measurable serum antibody responses 10 to 14 days after symptom onset (3).

Influenza A and B virus infections spread rapidly through the community, with clinical attack rates having been documented to be as high as 70% following a common source exposure in an enclosed space (42). Epidemic disease is associated with an increase in hospitalization rates, especially in young children and in the elderly, and an increase in mortality rates in the elderly. Mortality rates have been higher in epidemics caused by influenza A/H3N2 viruses than in those caused by A/H1N1 or B viruses in the past 20 years. Additional information on the clinical presentation, manifestations, and complications of the diseases can be found in clinical textbooks (27, 53).

There are four licensed antiviral medications available for the treatment of influenza virus infection. Treatment with any of these medications must be initiated within 2 days of symptom onset to have demonstrable clinical benefit. Amantadine and rimantadine block the M2 ion channel and are active against only influenza A viruses, and zanamavir and oseltamivir are NA inhibitors and are active against both influenza A and B viruses. Clinically significant resistance has been seen following treatment of children or immunocompromised patients with amantadine and rimantadine, and the prevalence of resistance is increasing among all influenza A/H3N2 virus isolates (7). These drugs have also been used for prophylaxis, but annual immunization with a trivalent influenza vaccine is the primary means of prevention of influenza.

Both vaccines using inactivated virus and those using live, attenuated virus are available (25). Influenza vaccines used in the United States are derived from viruses grown in embryonated chicken eggs. For inactivated-virus vaccines, virus is harvested and then inactivated. Viral proteins are partially purified and standardized to contain 15 μg of HA. The vaccine is trivalent, containing HAs of influenza A/H1N1, A/H3N2, and B virus strains. The strains to be included in the vaccine are selected in January and February to make a vaccine for use in September. The vaccine with live, attenuated virus is also trivalent, and strain selection occurs at the same time as that for inactivated-virus vaccines. A reassortant vaccine virus for each strain to be included is derived to contain six internal genes from a parental attenuated influenza (A or B) virus and the HA and NA from the strain selected in January or February. The vaccine is licensed for use in persons 5 to 49 years of age (25). It is given topically into the nose, and virus replicates in the upper respiratory tract. Vaccines derived from viruses grown in mammalian cells and those containing higher amounts of HA or additional viral proteins are currently under evaluation to improve the efficacy of current influenza vaccines.

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

Influenza viruses infect the respiratory epithelium and can be found in respiratory secretions of all types. The level of virus shedding parallels the severity of clinical symptoms in uncomplicated influenza and is maximal in the first several days of illness. Samples should be collected during this time (first 2 to 3 days) to maximize the likelihood of virus detection. A variety of upper respiratory tract samples alone or in combination are routinely used for virus identification, including nasal aspirates, nasal wash fluids, nasal or nasopharyngeal swabs, throat swabs, and throat wash fluids. Virus titers tend to be lower in samples collected from the throat, so assays of these samples alone tend to be less sensitive. However, recent reports of human infection with H5N1 strains suggest that throat samples may have better diagnostic yields than samples collected from the nose (3). Lower respiratory tract samples, including sputa, tracheal aspirates, and bronchoalveolar lavage fluids, also may yield virus and can be assayed when indicated. Virus can occasionally be identified in nonrespiratory clinical samples (3, 36).

Once collected, the clinical samples should be placed in viral transport medium. A number of transport media are suitable for influenza viruses, including veal infusion broth, Hanks balanced salt solution, tryptose phosphate broth, sucrose phosphate buffer, and commercially available cell culture medium. All of these media are supplemented with 0.5% bovine serum albumin or 0.1% gelatin to stabilize the virus and antimicrobials (antibiotics and antifungals) to inhibit the growth of other respiratory flora. However, the use of transport medium may interfere with the test performance for certain commercially available virus detection assays; the package inserts of these assays should be consulted if they are to be used for diagnosis (Tables 1 and 2). Influenza virus

TABLE 1 Commercially available kits for detection of influenza A and B viruses by FA staining[a]

Test (manufacturer)	Assay format	Acceptable clinical sample(s) for direct detection[b]	Comment	Assay sensitivities (%)/ specificities (%) for direct detection of virus types[c]	Assay sensitivities (%)/ specificities (%) for identification of type A and B isolates[c]	Other virus(es) detected
Bartels respiratory viral detection kit (Trinity Biotech)	IFA	NA, NPA, NPS, NW, TS	Also available as individual components for influenza A or B virus	A, 86/99; B, 65/98	A, 100/99.9; B, 100/100	Adenovirus, P1, P2, P3, RSV
D^3 DFA respiratory virus screening and identification kit (Diagnostic Hybrids, Inc.)	DFA	NA, NPA, NW	Also available as individual components for influenza A or B virus	A, 96.6–100/100; B, 100/100	A, 100/99.5–100; B, 100/99.5–100	Adenovirus, P1, P2, P3, RSV
Imagen influenza virus A and B (DakoCytomation)	DFA	NPA		A, 96.2/100; B, 86.7/99.5	A, 100/100; B, 100/100	None
PathoDx respiratory virus panel (Remel)	DFA	Cell culture only	Not approved for direct use on clinical specimens	Not applicable	A, 100/100; B, 100/100	Adenovirus, P1, P2, P3, RSV
Light Diagnostics Simulfluor viral diagnostic screen (Chemicon)	DFA	NPA, NPS, NW, TS	Also available as flu A/flu B kit	A, 80/98.6; B, 50/100	A, 97.8/100; B, 100/100	Adenovirus, P1, P2, P3, RSV

[a] Abbreviations: NA, nasal aspirate; NPA, nasopharyngeal aspirate; NPS, nasopharyngeal swab; NW, nasal wash fluid; TS, throat swab; RSV, respiratory syncytial virus. All kits listed can be used to detect influenza virus types A and B.
[b] All kits can be used to identify virus type from positive cell cultures.
[c] Sensitivities and specificities are per the manufacturers' brochures.

infectivity is maintained for up to 5 days when samples are placed in transport media and maintained at 4°C (2). The clinical sample should be transported to the diagnostic laboratory as rapidly as possible after collection under these conditions. If a sample cannot be cultured during this time frame, it should be stored immediately at −70°C; storage at higher temperatures (e.g., −20°C) leads to the loss of virus viability. Immediate transport and processing of samples after collection are necessary for immunofluorescence detection of virus antigen in exfoliated epithelial cells.

DIRECT DETECTION

Microscopy

Influenza viruses have been detected in clinical specimens by direct and indirect visualization of their typical morphological appearance by electron microscopy (EM). Immune EM has been the most sensitive EM method and allows differentiation of viruses as to type and subtype when specific hyperimmune sera are used in the assay (44). However, large numbers of viruses ($>10^5$ to 10^6 per ml) must be present in the clinical sample for successful detection using this diagnostic approach. Because of the need for an experienced microscopist and access to an electron microscope, the relatively high costs of assay performance, and the greater sensitivity of other diagnostic approaches, EM is not routinely used for the diagnosis of influenza virus infection.

Antigen Detection

Antigen detection assays are used in a variety of formats to rapidly detect influenza viruses in clinical specimens and to confirm the identity of isolates grown in culture. These assays are based upon detecting the interaction of viral proteins with specific antibodies. A variety of different formats is used and include direct and indirect fluorescent-antibody (FA) staining, radioimmunoassay, enzyme immunoassay, immunochromatographic assay, and fluoroimmunoassay.

FA assays identify viral antigens present on infected, exfoliated epithelial cells present in respiratory secretions. Cells are collected on swabs or in aspirates or wash fluids and are washed in cold buffer to remove mucus before being applied and fixed to a microscope slide. Use of cytocentrifugation for application of the cells to slides can improve the number and morphology of cells for evaluation and enhance the accuracy of interpretation (33). Virus-specific antibodies are applied to the fixed cells; monoclonal antibodies directed against viral proteins that are conserved and expressed in large quantities (e.g., M and NP) are used because of their greater specificity compared to polyclonal sera and are available from a number of manufacturers (63). A fluorochrome is conjugated to the virus-specific antibody in direct FA (DFA) assays, and it is conjugated to a second antibody that reacts with the virus-specific antibody in indirect FA (IFA) assays. Antibody staining of cells is detected with a fluorescent microscope. Contaminating mucus can cause nonspecific fluorescence that can be reduced by treating the samples with

N-acetylcysteine or dithiothreitol and by centrifuging cells through Percoll (38, 54). DFA and IFA assays take 2 to 4 h to perform, although some diagnostic laboratories batch samples and do not perform tests as soon as the sample is received, delaying the availability of results. In theory, IFA assays should be more sensitive and less specific than DFA assays, but there is significant overlap in the sensitivities (50 to 90%) and specificities (generally >90%) of these assays noted in published reports (55). An advantage of FA assays is that sample quality can be determined by observing whether an adequate number of epithelial cells are present. In addition, kits are available to screen for other respiratory viruses (e.g., respiratory syncytial virus, parainfluenza viruses, and adenovirus) as well as for influenza A and B viruses (Table 1). These multiplex assays allow for efficient screening for other viral causes of febrile respiratory disease. Disadvantages include the need for specialized equipment (a fluorescent microscope) and the impact of technician expertise on assay performance characteristics (i.e., sensitivity and specificity). Each laboratory should establish its own performance characteristics compared to those of cell culture.

A variety of immunoassays that utilize different reporter formats (isotopic, colorimetric, fluorometric, and chromatographic) have been developed for the detection of influenza virus antigen in clinical specimens. Many of these assays take at least 2 h to perform and have 50 to 80% sensitivity compared to culture methods (63). A number of commercially available kits utilize the immunoassay format for rapid (≤30-min) detection of influenza A and B viruses in clinical specimens (Table 2). The kits utilize monoclonal antibodies to detect the presence of the influenza A or B NP by enzyme immunoassay or chromatographic immunoassay. All of the kits provide results within 30 min, and some of them can be used as point-of-care tests (i.e., those classified by the Clinical Laboratory Improvement Amendments [CLIA] as waived). The types of specimens that are appropriate for testing vary among the kits, and specific instructions for sample collection and processing must be followed for optimal results. Assay performance characteristics (sensitivity and specificity) in clinical settings often differ from those described in the manufacturers' brochures (Table 2) (55, 61).

NA Activity Assay

The determination of the three-dimensional structure of the influenza virus NA by Peter Colman and colleagues in the 1980s led to the development of specific substrates that can block or be catalyzed in the enzyme's catalytic site (12). An influenza virus-specific diagnostic assay was developed using a small-molecule derivative of sialic acid coupled to a reporter chromogen detectable only after it is cleaved from the sialic acid substrate (ZStatFlu; ZymeTx). The presence of influenza A or B virus NA in the clinical sample (throat swab) leads to the enzymatic cleavage and release of the reporter that is then identified visually. The assay does not distinguish influenza A virus from B virus strains, and it does not identify influenza C viruses, which lack NA (Table 1). The NAs of other viruses (e.g., paramyxoviruses) and bacteria do not recognize the sialic acid derivative-reporter complex as a substrate and thus do not catalyze the release of the reporter molecule. A modified version of the test, in which the reporter gives a chemiluminescent rather than a colorimetric signal, is under development (50).

Nucleic Acid Analyses

Molecular methods are increasingly being used both for the detection and for the characterization (see below) of influenza viruses. The most commonly used molecular method is reverse transcription-PCR (RT-PCR). Viral nucleic acids are first extracted from clinical samples. The use of guanidinium thiocyanate with silica particles or commercial kits based upon this approach reliably removes inhibitors of the enzymatic amplification that are often present in clinical specimens (5, 20). cDNA is then synthesized by using random hexamers or a virus-specific oligonucleotide. The cDNA is amplified by using virus-specific oligonucleotides as primers and a heat-stable DNA polymerase. Resulting amplicons are identified as virus specific by using a variety of different methods (identification by size, hybridization, restriction enzyme mapping, and sequencing).

A large number of different RT-PCR assays have been developed since the initial description in 1991 of an RT-PCR method to detect and distinguish influenza A, B, and C viruses (65). Assays that identify and distinguish different influenza virus types have targeted conserved genes, such as the M gene, and subtype-specific assays have amplified a portion of the HA gene (15, 17). RT-PCR assays can be used in a multiplex format to simultaneously detect multiple strains or to identify different genes (e.g., those for HA and NA) (62). A disadvantage of multiplex assays is that the limit of detection for each substrate is often increased, which may lead to false negatives when small amounts of viral RNA are present. Nested PCR assays have been developed to improve assay sensitivity, but the inherent problem of carryover contamination associated with the use of this assay format limits its utility for most diagnostic laboratories. When a nested PCR format has been used, assay sensitivity has been better than that achieved with cell culture (64). Real-time RT-PCR assays can directly and rapidly detect influenza viruses in clinical specimens with a sensitivity approaching or exceeding that of culture (56). A real-time RT-PCR for the Asian lineage avian H5 virus causing the panzootic and human cases has recently been approved by the Food and Drug Administration for distribution by the Centers for Disease Control and Prevention (CDC) to the Laboratory Response Network-designated laboratories (11).

Another molecular method for direct detection of influenza viruses in clinical samples is nucleic acid sequence-based amplification (NASBA). NASBA is an isothermal method that amplifies a portion of the RNA genome by using avian myeloblastosis reverse transcriptase, T7 RNA polymerase, and RNase H. RNA amplicons complementary to the genomic RNA are generated and are detected by using a virus-specific probe, and when the probe is a molecular beacon, results can be obtained in real time. NASBA can be more sensitive than culture or immunofluorescent-antibody staining for the diagnosis of influenza virus infection, but additional experience with this method is needed (41).

ISOLATION PROCEDURES

Influenza virus isolation procedures should be performed under biosafety level 2 (BSL-2) conditions. When the clinical sample comes from a patient suspected to be infected with a highly pathogenic avian influenza (HPAI) virus strain, attempts at virus isolation should be performed under BSL-3 or higher conditions (9). Human clinical samples should be processed in separate laboratories and by staff members other than those handling clinical material from swine or birds (59).

TABLE 2 Commercially available kits for rapid (≤30-min) detection of influenza A and B viruses[a]

Test (manufacturer)	Assay format (viral protein detected)	Acceptable clinical sample(s)	Sample collection restrictions	Virus type(s) detected (differentiation of A and B)	Assay sensitivity(ies) (%)/ specificity(ies) (%)[b]	Assay performance time (min)	Assay complexity[c]
Directigen flu A (Becton-Dickinson)	Immunochromatographic membrane assay (NP)	NA, NPS, NW, TS	For swab samples, use polyester- or rayon-tipped swabs with aluminum wire; do not use calcium alginate	A only	67–96/92–100	15	Moderate
Directigen flu A + B (Becton-Dickinson)	Immunochromatographic membrane assay (NP)	BAL, NA, NPS, NS, NW, TS	For swab samples, use polyester- or rayon-tipped swabs with aluminum wire; do not use calcium alginate	A and B (yes)	A, 86/91; B, 81/99	15	Moderate
Directigen flu A + B/EZ (Becton-Dickinson)	Immunochromatographic membrane assay (NP)	NA, NW, TS	For swab samples, use polyurethane foam swabs	A and B (yes)	A, 77–86/86–99; B, 69–80/99–100	15	Moderate
FLU optical immunoassay (Thermo Electron)	Optical immunoassay (NP)	NA, NPS, sputum, TS	NPS, use polyester swab; TS, use cotton swab; do not use transport media prior to testing	A and B (no)	Combined, 62–88/52–80	15	Moderate
FLU optical immunoassay A/B (Thermo Electron)	Optical immunoassay (NP)	NA, NPS, sputum, TS	NPS, use polyester swab; TS, use cotton swab; do not use transport media prior to testing	A and B (yes)	Equivalent to those of FLU optical immunoassay	15	Moderate
NOW influenza A (Binax)	Immunochromatographic membrane assay (NP)	NA, NPS, NW	For swab samples, use cotton, rayon, foam, or polyester flexible-shaft swabs; do not use calcium alginate	A only	78–82/92–94	15	Waived
NOW influenza B (Binax)	Immunochromatographic membrane assay (NP)	NA, NPS, NW	For swab samples, use cotton, rayon, foam, or polyester flexible-shaft swabs; do not use calcium alginate	B only	58–71/97	15	Waived
NOW influenza A and B (Binax)	Immunochromatographic membrane assay (NP)	NA, NPS, NW	For swab samples, use cotton, rayon, foam, or polyester swabs; do not use calcium alginate	A and B (yes)	Equivalent to those of individual NOW influenza A and NOW influenza B tests	15	Waived
QuickVue influenza test (Quidel)	Immunochromatographic membrane assay (NP)	NA, NS, NW	Do not use any kind of transport medium to store or transport sample	A and B (no)	Combined, 73–81/96–99	10	Waived
QuickVue influenza A + B test (Quidel)	Immunochromatographic membrane assay (NP)	NA, NS, NW	Do not use any kind of transport medium to store or transport sample	A and B (yes)	A, 72–77/96–99; B, 73–82/96–99	10	Waived
Influenza A test (SA Scientific, Inc.)	Immunochromatographic membrane assay (NP)	NA, NW		A only	76/98	30	Waived
Influenza B test (SA Scientific, Inc.)	Immunochromatographic membrane assay (NP)	NA, NW		B only	91/100	30	Waived

Wampole Clearview influenza A/B (Fisher)	Immunochromatographic membrane assay (NP)	NS, NW, TS	For swab samples, use cotton, rayon, foam, or polyester swabs; do not use calcium alginate	A and B (yes)	Equivalent to those of individual NOW influenza A and NOW influenza B tests	15	Moderate
Xpect flu A and B (Remel)	Immunochromatographic membrane assay (NP)	NS, NW, TS	For swab samples, use rayon- or Dacron-tipped swabs with aluminum or plastic shafts; do not use calcium alginate	A and B (yes)	A, 89–100/100; B, 83–100/100	15	Moderate
ZstatFlu (ZymeTx)	Colorimetric detection of viral NA activity	TS	Use foam swab included in kit for TS collection	A and B (no)	Combined, 62/99	30	Waived

[a] Data are from references 25, 55, and 61. Abbreviations: BAL, bronchoalveolar lavage fluid; NA, nasal aspirate; NPS, nasopharyngeal swab; NW, nasal wash fluid; NS, nasal swab; TS, throat swab.
[b] Sensitivities and specificities are per the manufacturers' brochures.
[c] CLIA-waived laboratory assays employ methodologies that are so simple and accurate as to render the likelihood of erroneous results negligible. CLIA moderate-complexity assays require some knowledge, training, reagent preparation, processing, proficiency, ability to troubleshoot, or interpretation and judgment in the performance of the tests.

Cell Culture

Influenza viruses can be grown in a number of different cell lines, including primary monkey kidney cells, Vero cells, human diploid lung fibroblasts, and Madin-Darby canine kidney (MDCK) cells (24, 46). Although some variability can be seen from season to season, MDCK and primary monkey kidney cell lines have similar isolation frequencies (24), and MDCK cells are more sensitive than Vero or diploid lung fibroblast cells (46). Thus, MDCK cells (CCL 34; American Type Culture Collection, Manassas, Va.), a continuous polarized cell line, are the most common cell line used for isolation of influenza viruses and will support the growth of type A, B, and C strains. Continuous cell lines do not produce proteases that will cleave the viral HA, a step necessary to produce infectious viral progeny, so exogenous protease must be added to the maintenance medium. L-(Tosylamido-2-phenyl) ethyl chloromethyl ketone (TPCK)-treated trypsin at a concentration of 1 to 2 μg/ml provides the necessary proteolytic activity and is the recommended protease for virus isolation. Chymotrypsin cleavage of the HA prevents the trypsin-mediated enhancement of viral infectivity, and TPCK treatment inactivates chymotrypsin activity which may contaminate pancreatic extracts of trypsin (32, 34).

MDCK cells are propagated in growth medium that contains 5 to 10% fetal calf serum (FCS). FCS contains inhibitors that prevent the production of infectious virus, so the FCS must be removed prior to inoculation of the clinical sample (16, 63). The inhibitory effects of FCS can be prevented by washing the cell sheet with Hanks buffer or serum-free medium sufficiently to remove the protein-containing growth medium and then adding serum-free medium to cover the cell sheet. The clinical sample is then inoculated into the medium. After a 2-h incubation, the inoculum-medium mixture is removed and replaced with serum-free medium supplemented with TPCK-treated trypsin. Alternatively, the sample can be inoculated directly onto cells with serum-free medium supplemented with TPCK-treated trypsin and incubated overnight prior to changing of the medium the next day. The cultures are maintained at 33 to 34°C and monitored for virus growth.

The replication of influenza viruses typically leads to cytopathic effects (CPE) and destruction of the cell sheet within a week following inoculation. CPE may be inapparent or absent in the presence of viral replication, but viral replication can be identified by the ability of the viral HA to bind to sialic residues on the erythrocytes of different animal species. Cultures should be screened every 2 to 3 days by hemadsorption (binding of erythrocytes to the viral HA of infected cells) or hemagglutination (cross-linking of erythrocytes by virus in the culture medium) for evidence of viral replication. To evaluate hemadsorption of cells grown in a tissue culture tube, CPE are first determined by microscopic examination (Fig. 1A), and then the medium is removed and stored. The cell sheet is rinsed three times with 1 ml of 0.05% guinea pig red blood cells. One milliliter of 0.5% guinea pig red blood cells is then added, and the tube is stored at 4°C for 20 min, with the red blood cell suspension covering the cells. The tube is then shaken, and adherence of red blood cells to the cell sheet is determined microscopically (Fig. 1B). If cytopathic changes are scored as less than 4+ (i.e., less than 75% of cell sheet with CPE), the tissue culture tubes are rinsed with phosphate-buffered saline and refed with culture medium. The media collected initially from tubes with 4+ cytopathic changes can be used for further characterization. All procedures are performed in a BSL-2 safety cabinet, and care must be taken to prevent

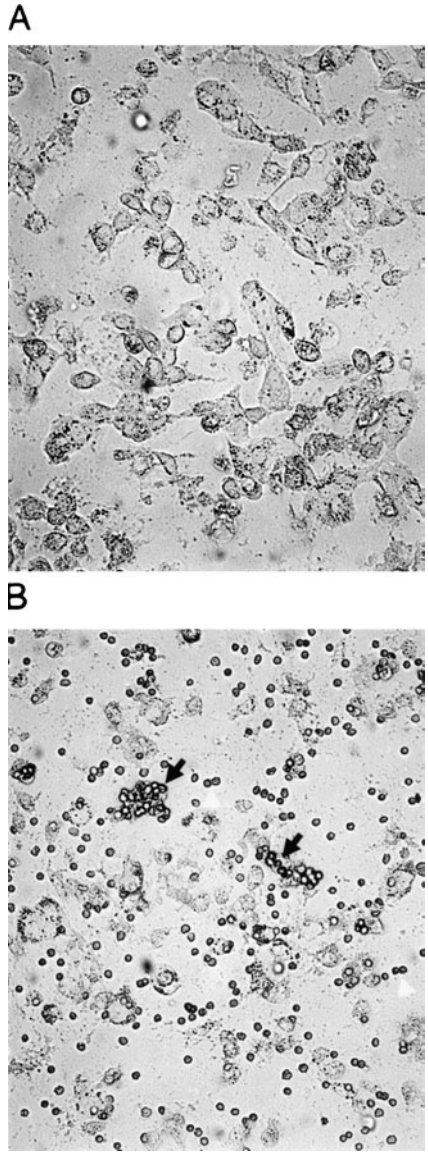

FIGURE 1 Influenza virus-infected MDCK cells. (A) Cytopathic changes. (B) Hemadsorption with guinea pig red blood cells. Red blood cells adsorb to both infected cells (black arrows) and the plastic previously occupied by infected cells (white arrowheads).

cross-contamination between cultures. Guinea pig red blood cells are more sensitive for detection of influenza virus than are avian cells, but influenza C virus does not agglutinate guinea pig red blood cells. Chicken red blood cells can be used in agglutination assays to identify influenza C viruses. Although most isolates will be identified within 1 week after inoculation, additional strains can be detected by maintaining the culture for 10 to 14 days and by blind passaging of negative cultures. Presumptive isolates are characterized further, as outlined below.

A disadvantage of traditional cell culture methods is the time needed to obtain a positive result (average, 4 to 5 days). More rapid methods have been developed by inoculating samples onto cell culture monolayers maintained in shell vials or multiwell plates. This approach can utilize either cell lines employed in traditional cell culture for identification of influenza virus (e.g., MDCK cells) or cell mixtures (A549 cells plus mink lung cells) to screen for multiple respiratory viruses (R-Mix FreshCells; Diagnostic Hybrids, Athens, Ohio) (19, 21, 39). The cells are fixed after 24 to 72 h, and type-specific monoclonal antibodies are used to detect viral antigen. Sensitivity is generally lower than that achieved by using standard isolation methods (56 to 100%), and this approach has the disadvantage of not producing virus for additional studies (e.g., antigenic characterization) (63). Screening for viral antigen by immunofluorescence also can be used at the end of the 10- to 14-day incubation period for standard culture prior to discarding of cells (57). This step is usually not necessary if screening by hemadsorption is being performed, but it may detect virus in the absence of cytopathic changes if other strategies for virus detection are not utilized.

Isolation from Embryonated Chicken Eggs

The amniotic and allantoic cavities of 10- to 11-day-old embryonated chicken eggs are inoculated with the clinical sample for isolation of influenza A and B viruses. Seven- to eight-day-old eggs are used for isolation of influenza C viruses, although these viruses are also isolated by using 10- to 11-day-old-eggs. Embryonated eggs have endogenous proteases that are able to cleave the viral HA to yield infectious virus, so exogenous administration of proteases is not necessary. Inoculated eggs are incubated at 33 to 34°C for 2 to 3 days (5 days for influenza C viruses), and then both amniotic and allantoic fluids are collected and assayed for hemagglutination activity. Influenza A and B viruses can grow both in cells lining the allantoic cavities and in those lining the amniotic cavities, whereas influenza C virus grows only in cells lining the amniotic cavities of embryonated eggs. If no hemagglutination activity is detected, influenza viruses may still be recovered by performing one or two blind passages. A pool containing equal volumes of the amniotic and allantoic fluids is inoculated into eggs as described above (16).

IDENTIFICATION AND TYPING SYSTEMS

A variety of methods are used to identify and characterize influenza virus isolates. The most common are shown in Table 3 and are based upon immunologic or molecular approaches. The initial step is to identify the isolate as an influenza virus and to distinguish it from other respiratory viruses that have the ability to agglutinate or adsorb red blood cells (e.g., parainfluenza viruses and mumps virus). In many instances, it is sufficient to identify the virus by type, and this may be accomplished by using immunofluorescent or immunoperoxidase stains or an enzyme-linked immunosorbent assay (ELISA) using commercially available, type-specific antibodies targeting the viral NP or M. These assays are particularly useful for working with cell culture isolates. The rapid immunochromatographic assays described in Table 2 may be able to identify isolates and type them, but there are limited data on the use of these assays for this purpose, and these assays are not approved for this use. Importantly, the immunochromatographic assays may give false-negative results when the quantity of virus in a cell culture harvest is low.

Hemagglutination inhibition (HAI) assays have been performed for more than 60 years and are still used for identification (28, 59). HAI assays can be type, subtype, or strain specific, and they are particularly useful for examining antigenic relationships among strains of the same subtype. Immune sera are usually produced in ferrets, sheep, or chickens (63). The hemagglutination activity of the virus is quan-

TABLE 3 Methods to identify and characterize influenza virus isolates

Assay	Advantage(s)	Limitation(s)
Assays using type- or subtype-specific antisera		
ELISA	Standard assay with known performance characteristics; most labs experienced with assay format	For subtyping of influenza A virus strains, need to update sera periodically to detect circulating strain
HAI	Standard assay with known performance characteristics; no special equipment needed	For subtyping of influenza A virus strains, need to update sera periodically to detect circulating strain; many clinical labs not experienced with this method
Immunofluorescence or immunoperoxidase staining of infected cells	Standard assay with known performance characteristics; most labs experienced with assay format	For subtyping of influenza A virus strains, need to update sera periodically to detect circulating strain
Molecular methods		
RT-PCR	Very sensitive	Potential for carryover contamination; need for stringent laboratory controls
Identification by amplicon size	Ease of performance	Potential for false-positive results due to nonspecific amplification
Hybridization	Most commonly used approach for confirmation of PCR results	Depending on hybridization format used, may add time to performance of assay
Restriction analysis	Ease of performance	Need to know specific sequence; increased handling of post-PCR samples relative to that in other methods
Sequencing	Sequence data obtained may be used in other studies	Need for specialized equipment; increased cost relative to those of other methods
Microarray analysis	Potential to analyze multiple genetic sequences simultaneously	Investigational; limited experience

titated, and a standard amount of viral HA (4 HA units) is mixed with serial dilutions of the immune serum. A fourfold or greater difference in HAI activities between the isolate and the reference strain is an indication that the isolate may be an antigenic variant (Table 4). Because the HA undergoes antigenic change over time, subtype-specific antisera for interpandemic strains must be prepared and standardized every few years (1). Thus, subtype identification is usually performed only as part of surveillance activities or investigation of a case in which there is a strong epidemiologic suspicion of infection with a nonhuman strain.

Molecular assays are increasingly being used for virus identification and characterization. The same RT-PCR assays used for detection of viruses in clinical samples also can be used to identify clinical isolates. An advantage that molecular assays have over immunology-based assays is that the molecular assays can identify influenza A virus subtypes even after significant antigenic variation has occurred because there are well-conserved regions of the HA gene that serve as targets for the primers and probes used for identification (1). Multiplex assays can also be used to distinguish influenza A and B viruses or to identify HA and NA subtypes (52, 62). Results are determined by identification of amplicon size, by hybridization to type- or subtype-specific probes, and by direct sequencing of the amplicons. If the sequences of different variants are known, it may be possible to identify restriction fragment length polymorphisms unique to each strain. For example, this method was used to distinguish two H3N2 variants that cocirculated during a single season (43). Influenza A/H3N2/Wuhan/359/95 virus-like variants generated amplicons that could be digested with the BstF5I restriction enzyme, whereas amplicons from influenza A/H3N2/Sydney/05/97 virus-like variants could be digested by HindIII. Direct sequencing of amplicons, or even entire genes, is a more common way to track and characterize specific strains.

DNA microarrays are being used increasingly in diagnostics for identification of specific pathogens. Oligonucleotide probes are arrayed on a chip or membrane, and hybridization of virus-specific sequences is then detected. The viral sequences can be generated by cDNA synthesis from viral

TABLE 4 Antigenic variation of influenza A/H3N2 virus strains detected by HAI assays using guinea pig red blood cells[a]

Reference antigen	Value[b] for reference ferret antiserum raised against:	
	A/Wyoming/03/2003	A/California/07/2004
A/Wyoming/03/2003	**640**	80
A/California/07/2004	80	**320**

[a] Data are from the CDC (10).

[b] Values are reciprocals of the highest serum dilutions that inhibit hemagglutination. Boldface indicates interaction of the virus with its homologous antiserum. The differences led to a recommendation for a change in the A/H3N2 virus used for the 2005–2006 influenza virus vaccine (10, 25).

genomic RNA or by amplification of fragments of genomic RNA by RT-PCR. Microarray analysis strategies have been developed that distinguish influenza virus types (A versus B) and subtypes (H1, H3, H5, N1, and N2) (30, 35) but at the present time are too costly for most individual laboratories to develop. Nevertheless, this technology has the promise of being able to more fully characterize strains in surveillance studies and to provide rapid and accurate identification of influenza virus strains.

SEROLOGIC TESTS

Influenza virus infections are also identified by using serologic methods. Most persons have been infected previously with influenza viruses, so detection of virus-specific immunoglobulin M or other immunoglobulin subclasses has not been particularly useful (47). An exception may be detection of immunoglobulin M responses to novel HAs from avian strains (29). Instead, paired acute- and convalescent-phase serum samples collected at least 10 days apart are needed to detect a significant (fourfold or greater) increase in serum antibody levels. The requirement for paired sera to identify infection makes serology an impractical method for identification of influenza virus infection in the acutely ill individual. Instead, serology is used primarily in surveillance and in epidemiologic studies. The most widely used assay formats include complement fixation, HAI, neutralization, and enzyme immunoassay. Complement fixation identifies type-specific antibodies to the NP, but it is not as sensitive as the other commonly used serologic assays in detecting significant rises in antibody levels. HAI and neutralization antibodies in serum are functionally significant in that higher serum antibody levels correlate with protection from infection and illness, and these antibody levels are used to measure responses to vaccination as well as to identify infection (13). HAI antibodies block the binding of the viral HA to sialic acid residues on red blood cells and thus inhibit hemagglutination. Each of the components in the HAI assay may affect the outcome of the test. Human and animal sera may contain nonspecific inhibitors of hemagglutination, but methods to remove these inhibitors have been developed (16). The source of the viral antigen can affect results in that virus initially isolated in cell culture may detect a greater frequency of antibody rises than egg-grown virus (45). The species from which the red blood cells are derived can affect assay results. Chicken and turkey red blood cells are commonly used to measure HAI antibody to human strains of influenza viruses, but they may fail to detect HAI antibodies to avian strains (such as H5N1). Substitution of horse red blood cells can improve HAI assay sensitivity for detection of antibodies to avian influenza virus strains (51). Neutralizing antibodies block viral infectivity and provide a more sensitive assay for detection of antibodies to influenza A and B viruses (60). Although neutralization assays have been available for more than 35 years, they are less standardized than are HAI antibody assays (48, 59). Nevertheless, neutralization assays are the preferred method for detection of antibody to HPAI virus strains (48). Because these assays require the use of live virus, their use with HPAI virus strains is restricted to those laboratories with BSL-3 or higher facilities (63). Enzyme immunoassays are also used for detection of antibody responses to whole virus antigen or to specific viral proteins. The conjugate and the antigen used in the assay are factors that affect the performance characteristics (sensitivity and specificity) of these assays. Enzyme immunoassays are used to measure specific immunoglobulin responses in a variety of clinical specimens (serum samples and respiratory secretions) (8).

ANTIVIRAL SUSCEPTIBILITIES

Plaque inhibition assays are the "gold standard" for measuring susceptibility to amantadine and rimantadine, but the assays are cumbersome and time-consuming to perform (26). ELISA methods have also been used to measure decreases in the expression of viral antigens in the presence of these drugs. These assays can be used in combination with genotypic characterization of the M2 gene since in vitro and in vivo resistance to these drugs is associated with specific M2 gene mutations (4). RT-PCR amplification followed by restriction fragment length polymorphism analysis or direct sequencing of amplicons is a genotypic method used to identify resistant viruses (18, 31).

Cell culture assays do not reliably identify antiviral susceptibility to the NA inhibitors, zanamivir and oseltamivir. Instead, NA enzyme inhibition assays with chemiluminescent or fluorescent substrates are used to identify resistance (37). The results of these assays also correlate with mutations in the NA gene that can be identified by sequencing. Mutations in the HA gene may also lead to a resistance phenotype through decreased binding affinity of HA to cell surface receptors and decreased reliance on NA function to release budding viruses from infected cells. No reliable cell culture system currently exists for identifying HA resistance mutations, so identification relies upon sequencing of the receptor binding site of the HA gene.

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

The results of a diagnostic test must be considered in the context of the overall setting in which the test is ordered. Clinicians play a critical role in assessing the plausibility of a test result, but the laboratory also can contribute to this appraisal. Seasonal, epidemiologic, and clinical factors are elements that must be evaluated in addition to the type of assay used. Unexpected laboratory results can be recognized by the laboratory as well as by the clinician. For example, a positive influenza test result when influenza is not recognized to be circulating in the community should prompt an assessment as to whether epidemiologic (e.g., travel history) or clinical (e.g., immunocompromised host) factors support the diagnosis of influenza virus infection. Close interactions between the laboratory and clinician are a vital component of a quality control program.

No diagnostic assay has 100% sensitivity and specificity, so false-negative and false-positive results can be expected to occur. Many factors that contribute to lowered sensitivity and specificity are known and can be addressed in ongoing quality control programs. False-negative results may be due to poor quality or inappropriate clinical sample collection, delays in sample transportation or processing, inadequate sample storage (e.g., wrong temperature or transport medium), the time of sample collection during the clinical illness (e.g., later in the illness than recommended, when viral shedding has decreased), and the performance characteristics of the diagnostic assay (i.e., lower sensitivity). False-positive results may also be due to other characteristics of the diagnostic assay (i.e., nonspecific reactions), as well as to cross-contamination within the laboratory, mislabeling of specimens, and microbial contamination. Standard operating procedures in the collection, transportation, and pro-

cessing of clinical samples should be established and followed to minimize the occurrence of the inaccurate test results. Reagents should be standardized, and periodic assessments of assay performance should be performed with known positive and negative controls. The timing of these assessments will be based upon the type and number of tests being performed and the sources of reagents.

Each laboratory must decide upon the goals of its influenza virus diagnostic program in selecting the diagnostic assays to be performed. Rapid and sensitive assays can favorably impact patient management by allowing the prescription of targeted antiviral therapy and the institution of appropriate infection control isolation procedures. Positive test results may form the basis for offering prophylactic therapy to close contacts of infected patients, especially those contacts with high-risk medical conditions. Early and rapid laboratory diagnosis also can be important for evaluating influenza-like illnesses in the setting of a nosocomial outbreak, at the beginning of the influenza season (before influenza is recognized to be circulating in the community), and in persons with a history of contact with pigs or birds or travel to an area where influenza virus is circulating. The laboratory's expertise, staffing, and available equipment also will influence test selection. For example, a fluorescent microscope and an experienced technician are necessary for the performance of immunofluorescence assays, and a thermal cycler along with other equipment is needed for RT-PCR assays. If the clinical specimen being tested comes from a patient who may be infected with an HPAI virus strain (e.g., H5N1), non-culture-based assays are currently recommended for laboratories that do not meet the BSL-3 or higher conditions recommended for growth of these strains (9). Commercially available antigen detection assays or the more sensitive H5-specific RT-PCR assays may be performed by using BSL-2 work practices. In the United States, influenza A virus-positive samples from patients meeting the clinical (febrile [>38°C] respiratory illness [cough, sore throat, or dyspnea]) and epidemiologic (contact with poultry or domestic birds or with a patient with known or suspected H5N1 virus infection in an H5N1-affected country) parameters for suspected A/H5N1 virus infection are referred to the CDC for further evaluation. Selected negative samples may also be sent to the CDC for analysis in consultation with the local public health department (9).

As new strains of influenza virus emerge, the sensitivities of established methods to detect these strains may change. For example, cell lines may have diminished sensitivity to new strains, or the ability to detect influenza virus antigen in infected tissue culture cells (e.g., by hemadsorption) may decrease (57). Thus, it is prudent to reevaluate periodically the performance characteristics of established methods, especially if results do not correlate with those expected based upon clinical and epidemiologic criteria.

Influenza diagnosis is also performed for reasons other than patient management. On the local level, knowledge that influenza is circulating in a community allows diagnosis of influenza based upon clinical symptoms (febrile respiratory illness with cough) with a sensitivity (60 to 80%) similar to that of many rapid antigen tests (40, 63). Influenza viruses isolated in national and global surveillance systems are characterized antigenically and genetically to identify variants. Information gained from these surveillance activities is used in the annual selection of strains for inclusion in updated trivalent influenza vaccines. Surveillance and characterization of isolates also allow the identification of infection with novel subtypes, as has occurred with influenza A/H5N1 viruses in southeast Asia and A/H7N7 strains in The Netherlands (22).

Parainfluenza and Mumps Viruses*

DIANE S. LELAND

86

TAXONOMY AND DESCRIPTION OF AGENTS

The human parainfluenza viruses (HPIVs) and mumps virus are members of the *Paramyxoviridae* family. This family includes the *Paravirinae* subfamily, of which both HPIV and mumps virus are members. However, within this subfamily, HPIV type 1 (HPIV-1), -2, -3, and -4 and mumps virus are classified into different genera. The *Respirovirus* genus is home for HPIV-1 and HPIV-3, and the *Rubulavirus* genus is home for HPIV-2, HPIV-4, and mumps virus. The *Paravirinae* subfamily includes two additional genera: *Morbillivirus,* of which measles virus is a member, and *Megamyxovirus,* of which Hendra and Nipah viruses are members. The *Pneumovirinae* subfamily completes the *Paramyxoviridae* family. Within this subfamily are the *Pneumovirus* genus, which includes respiratory syncytial virus (RSV), and the *Metapneumovirus* genus, which includes human metapneumovirus. The *Paramyxoviridae* family of viruses produces significant human and veterinary disease, with its effects noted among virus families as "one of the most costly in terms of disease burden and economic impact to our planet" (18).

DESCRIPTION OF THE AGENTS

Although some of the HPIV types and mumps virus are classified into different genera, they are all pleomorphic, enveloped, medium-sized helical viruses, usually ranging from 150 to 250 nm in diameter. All have single-stranded, nonsegmented RNA with negative polarity. The genome encodes six common structural proteins. The largest, L, is a polymerase. L, along with the phosphoprotein (P) and the nucleocapsid protein (N, or NP), is associated with the viral RNA to make up the viral nucleocapsid. The surface glycoproteins, hemagglutinin neuraminidase (HN) and fusion protein (F), project from the viral envelope and can be seen with the electron microscope. The sixth structural protein is a membrane (M) protein. In viral replication, N protein binds to viral RNA, L and P function in transcription and replication, and the HN and F surface glycoproteins interact with the M protein, which attracts completed nucleocapsids to areas of infected membrane that will become the envelope of the new virions during budding. The HN surface glycoproteins also function in virus-host cell attachment via sialic acid receptors, and the F proteins function in virus-host cell membrane fusion that allows the viral nucleocapsid to enter and infect a host cell.

Four serotypes of HPIV have been identified: HPIV-1, -2, -3, and -4. HPIV-4 can be subdivided further into HPIV-4A and HPIV-4B; because these are so closely related, they are referred to as HPIV-4 for the remainder of this discussion. Only one antigenic type of mumps virus has been identified, although strains show differences in expression of a small hydrophobic (SH) gene; 12 genotypes have been identified and designated A to L. HPIV and mumps virus are inactivated by temperatures above 50°C, organic solvents, UV irradiation, formalin treatment, low pH (3.0 to 3.4), drying, and desiccation. Preservation by freezing at –70°C or colder is effective, and the addition of 0.5% bovine serum albumin, skim milk, 5% dimethyl sulfoxide, or 2% chicken serum prior to freezing prolongs survival.

Although similar in structure and antigenic composition, HPIV and mumps virus currently present very different pictures in disease production in the United States. The HPIVs are common agents of respiratory infections in children and adults in the United States, and virology laboratories routinely test for HPIV with both direct antigen testing and virus isolation. In contrast, mumps virus, which was considered one of the common diseases of childhood prior to the introduction of an effective vaccine in 1968, is now relatively uncommon, and most virology laboratories no longer focus on its isolation and identification. Because of these differences, the HPIV and mumps viruses are discussed separately.

PARAINFLUENZA VIRUSES

Epidemiology and Transmission

HPIV is thought to be transmitted by large-droplet aerosolization and by contact with contaminated surfaces. The viruses have been shown to survive for up to 10 h on porous surfaces; however, HPIV-3 experimentally placed on fingers has been shown to lose more than 90% of its infectivity in the first 10 min (1). Currently HPIV-1, -2, -3, and -4 represent approximately 5% of all viruses isolated in routine hospital diagnostic laboratories (26) and 13% of viruses isolated from respiratory specimens (3). HPIV-1 occurs most often in the autumn and biennially. The incidence of HPIV-2 is generally less than that

* This chapter contains information presented in chapter 88 by Joseph L. Waner and Ella M. Swierkosz in the eighth edition of this Manual.

of HPIV-1 and HPIV-3. HPIV-2 may occur biennially with HPIV-1, in alternate years from HPIV-1, or yearly. HPIV-3 occurs yearly in the spring and summer. HPIV-4 is seldom isolated.

Clinical Significance

HPIV-1, -2, and -3 are associated with upper respiratory infections in infants, children, and adults. These are typically fairly mild and self-limited (30). Reinfection is common. HPIV accounts for the majority of cases of viral croup, which is the most common cause of upper airway obstruction in children 6 months to 6 years of age. Croup is characterized by inspiratory stridor, barking cough, and hoarseness (28). As many as 7% of all hospitalizations for viral acute respiratory illness in children younger than 5 years have been shown to be due to HPIV infection (21). HPIV-1, -2, and -3 have also been found in as many as one-third of lower respiratory infections in children younger than 5 years in the United States and are second only to RSV as a cause of hospitalization for viral lower respiratory infections (16). Although associated with infections in children, HPIVs have the potential for serious pulmonary infections in adults, with HPIV-1 and HPIV-3 among the four most common pathogens detected in adults requiring hospitalization for community-acquired pneumonia (31).

HPIVs also produce lower respiratory infections in the elderly and in those with chronic diseases, such as heart and lung disease and asthma. HPIV is increasingly recognized as a source of severe morbidity and mortality in immunocompromised patients, especially in those with congenital immunodeficiencies, and is capable of infecting tissues in the gastrointestinal and urinary systems in these individuals (30). In immunocompromised children, HPIV causes more than 50% of the respiratory infections in bone marrow transplant recipients, 24% in those with hematologic malignancies, and 19% in solid-organ transplant recipients (19). HPIVs are important causes of nosocomial respiratory infections (20).

HPIV-1 is associated with up to 50% of cases of croup reported in the United States, with the majority of cases occurring in children 7 to 36 months. HPIV-2 causes typical lower respiratory syndromes in otherwise healthy children, with about 60% of infections occurring in children younger than 5 years; peak incidence is in children between 1 and 2 years of age. HPIV-2 is associated with croup in immunocompromised or chronically ill children. HPIV-3 is more frequent in infants younger than 6 months, with 40% of infections occurring during the first year of life. Only RSV causes more lower respiratory infections in neonates and young infants than HPIV-3. HPIV-2 and -3 can cause acute parotitis in children. Although HPIV-4 is rarely isolated, it can cause all of the different respiratory syndromes (16).

There are currently no U.S. Food and Drug Administration (FDA)-approved antivirals for treatment of HPIV infection. Ribavirin has been used to treat HPIV infections in immunocompromised patients, but results have varied. Elizaga et al. (11) reported no efficacy for this therapy. In contrast, Chakrabarti et al. (6) reported effective ribavirin therapy when high doses were used with early intervention. Management of symptoms through administration of corticosteroids has been recommended (28). The diagnosis of HPIV may be based primarily on clinical signs and symptoms, and laboratory diagnostic studies may not be needed in all patients. However, laboratory assays to confirm HPIV infection, thus differentiating it from the many other viral infections that present with respiratory tract signs and symptoms, are widely available, and confirmation of infection may improve patient management and decrease costs (17, 18).

Collection, Transport, and Storage of Specimens

Testing to confirm HPIV infection may include virus isolation, antigen or nucleic acid detection, or antibody detection (Table 1). Specimen collection, transport, and storage guidelines are provided in chapters 5 and 80 of this Manual. Because detection of HPIV often involves immunofluorescence assays performed directly on the clinical material, care should be taken to include cellular material in samples collected from respiratory sites. The nasopharynx and oropharynx are primary locations of initial HPIV replication, and children shed virus from 3 to 4 days prior to the onset of clinical symptoms until approximately 10 days past. Virus recovery in adults is much more difficult than in children, although immunocompromised patients and adults with chronic diseases, especially lung disease, have been shown to persistently shed HPIV for many months (16). Throat swabs, nasopharyngeal swabs, nasal washes, and nasal aspirates have all been used successfully to recover HPIV. The highest rates of virus recovery have been shown for nasal washes or nasal aspirates. Specimens should be collected and placed in viral transport medium and kept at 4°C until cell culture inoculation. Inoculation within 24 h of collection is recommended (16).

Peripheral blood samples for use in HPIV antibody assays should be collected in tubes without anticoagulant, and serum should be separated from the clot as soon as possible to ensure sample integrity. Serum samples may be stored at 4°C if testing will be performed within 24 to 48 h but should be frozen at –20°C or lower if testing is delayed.

Direct Examination

Microscopy

Electron microscopy can easily demonstrate HPIV, but HPIV and the other paramyxoviruses appear the same. Lung, other bronchial tissues, pancreas, kidney, and bladder, when examined with light microscopy, exhibit the typical appearance of giant-cell formation when infected with HPIV (30).

Antigen Detection

HPIV-1, -2, and -3 antigens are routinely detected in clinical specimens through the use of immunofluorescence techniques that employ monoclonal antibodies. Cells from nasopharyngeal washes, aspirates, and swabs are fixed on the microscope slide, usually in several cell spots or dots or by cytocentrifugation (25). At least 20 columnar epithelial cells must be present if the assay is to be valid. Many laboratories use a pool of monoclonal antibodies that includes antibodies against seven common respiratory pathogens; these are adenovirus; influenza A and B viruses; HPIV-1, -2, and -3; and RSV. These antibodies are applied in either a direct (DFA) or an indirect (IFA) fluorescent-antibody assay staining protocol that detects antigens of all seven viruses. When a positive result is seen, individual monoclonals to the seven viruses must be applied to the sample to determine which of the seven is present. Sensitivity of HPIV antigen detection compared to virus isolation in cell culture varies from laboratory to laboratory and with the various DFA and IFA staining methods and reagents but has been reported to range from 70% (26) to 83% (25). Specificity is very high.

Pooled and individual monoclonal antibodies for respiratory viruses, in DFA or IFA formats, are commercially marketed in the United States and approved for use in direct

TABLE 1 Diagnostic methods for parainfluenza and mumps viruses

Virus	Virus isolation	Antigen detection	Molecular methods	Antibody detection
HPIV-1–HPIV-3	Widely available. Replicate in PMK cells in 4–8 days. HAD positive.	IF[a] only. Widely available as single tests or as part of respiratory virus panel. Sensitivity, 80–95% compared to culture.	Available only at larger laboratories. Most sensitive method.	May be available at reference laboratories. Cross-reactivity with other *Paramyxoviridae*
HPIV-4	Replicates in PMK cells in 4–8 days. HAD stronger at room temperature.	IF only. Testing not widely available.	May be available at reference laboratories	Not available at most laboratories
Mumps virus	Widely available. Replicates in PMK cells in 6–8 days. HAD positive.	IF only. Testing not widely available.	May be available at reference laboratories	Immune status (IgG) testing widely available. Seldom used to confirm acute infection due to cross-reactivity with other *Paramyxoviridae.*

[a] IF, immunofluorescence.

specimen testing. Distributors of these reagents include, but are not limited to, Chemicon International, Temecula, Calif.; DakoCytomation USA, Carpinteria, Calif.; Diagnostic Hybrids, Inc., Athens, Ohio; and Trinity Biotech, Carlsbad, Calif. A brief overview of the protocols used for one DFA and one IFA method for respiratory virus screening follows.

DFA (D^3 Respiratory Virus Screening and ID Kit; Diagnostic Hybrids, Inc.)

Detailed instructions provided by the manufacturer should be followed. Briefly, smears from clinical specimens or of cells scraped from an infected cell culture monolayer are prepared on microscope slides. Shell vial monolayers may also be stained. All cells must be acetone fixed (10 min) and dried prior to staining. Fixed smears may be stored for several days at 2 to 8°C or frozen at –20°C for up to a year when stored in an airtight container. For smears on microscope slides, 1 or 2 drops of the fluorescein-labeled monoclonal antibody preparation are added. For shell vial monolayers, 3 or 4 drops of antibodies are added. The preparations are incubated for 15 min at 37°C in a humidified environment. The smears are washed with diluted phosphate-buffered saline (PBS)–detergent solution (supplied in the kit) and then air dried. Mounting fluid and coverslips are added, and the smears are examined microscopically at ×200 or higher magnification using a fluorescein isothiocyanate (FITC) filter system. Infected cells demonstrate bright apple-green fluorescence that is primarily cytoplasmic and often punctate, with irregular inclusions. Uninfected cells appear brick red, due to Evans blue counterstaining, and show no bright green fluorescence. The same protocol is followed both for the seven-virus screening assay and for subsequent staining of positive samples with the individual monoclonal antibodies.

IFA (Bartels VRK Viral Respiratory Kit; Trinity Biotech)

Detailed instructions concerning all aspects of specimen handling, smear preparation, and staining/interpreting results are provided by the manufacturer and should be followed. The IFA is appropriate for the same types of samples as listed above for the DFA, with the same smear preparation and fixation guidelines. In IFA staining, briefly, sufficient unlabeled antiviral antibody reagent is added to each fixed preparation to cover the cells. The samples are incubated in a humidified environment at 35 to 37°C for 30 min. Smears are then washed in PBS for 5 to 10 min and air dried. Sufficient anti-mouse FITC antibodies are added to cover the cells, and the samples are again incubated at 35 to 37°C for 30 min. Following a 5-min wash in PBS and drying, buffered glycerol mounting medium and coverslips are added, and the smears are observed microscopically at ×200 or higher magnification using an FITC filter system. Infected and uninfected cells appear as described above for the DFA procedure. The same protocol is followed both for the seven-virus screening assay and for subsequent staining of positive samples with the individual monoclonal antibodies. Cell culture confirmation is recommended for samples that produce a negative result.

Monoclonal antibody pools that screen for the seven respiratory viruses have also been marketed in a format that allows definitive identification of more than one virus at a time through the use of different fluorescent dyes with overlapping spectra (Light Diagnostics SimulFluor reagents; Chemicon International). The reagents are approved by the FDA for direct specimen testing and for culture confirmation. When stained preparations are examined with a fluorescence microscope with an FITC filter set, one antibody will produce apple-green fluorescence and the second will appear gold or golden orange. SimulFluor reagents that are useful in HPIV antigen detection include a respiratory screen reagent in which RSV appears golden and the other six respiratory viruses, including HPIV-1, -2, and -3, appear green; an RSV/HPIV-3 reagent in which RSV appears green and HPIV-3 appears golden; an HPIV-1, -2, and -3/adenovirus reagent in which HPIV-1, -2, and -3 appear green and adenovirus appears golden; and an HPIV-1 and -2/HPIV-3 reagent in which HPIV-1 and HPIV-2 appear green and HPIV-3 appears golden. The SimulFluor reagents have shown excellent sensitivity and specificity, comparable to those of individual stains for the respiratory viruses (25).

HPIV-4, which is the least frequently encountered of the HPIV types, is not detected by most respiratory virus immunofluorescence screening reagent pools; only HPIV-1, -2, and -3 are detected. Although monoclonal antibodies are available for immunofluorescent staining of HPIV-4 cell culture isolates, these are not approved for use in HPIV-4 antigen detection directly in clinical specimens.

Nucleic Acid Detection Techniques

Several different approaches for detection of HPIV RNAs have been described; all methods, compared to virus isolation in traditional cell cultures, detect more, sometimes double the number (15), of HPIV-positive samples. A reverse transcriptase PCR (RT-PCR) assay involving enzyme hybridization (EH) has been shown to be more sensitive than cell culture in detection of HPIV-1 in nasal wash specimens (12). This RT-PCR–EH technology has been converted into a multiplex assay (Hexaplex; Prodesse, Inc., Milwaukee, Wis.) that rapidly detects RNA of RSV A and B; influenza A and B viruses; and HPIV-1, -2, and -3 in a single test (13). In testing nasal wash samples and other respiratory samples, Hexaplex was 100% sensitive compared to cell culture and detected viral RNA in low copy numbers in several culture-negative samples (13, 22). Hexaplex has been used with various respiratory samples and in detecting HPIV-1 and -3 in the middle ear fluids of children with acute otitis media (7).

Although the Hexaplex assay is not marketed as a "kit," the reagents are commercially available in the United States. The manufacturer's instructions should be followed. Briefly, viral genomic RNA is extracted from 280 μl of specimen, and cDNA is synthesized. The cDNA undergoes PCR amplification in a mixture of DNA polymerase and Supermix (Prodesse, Inc.). AmpliTaq Gold DNA polymerase (Perkin-Elmer Cetus, Foster City, Calif.) may be used (22). The Supermix is the proprietary mixture that contains six and one-half pairs of primers: a pair of primers to the HN genes of HPIV-1, -2, and -3; a pair of primers to the M1 (matrix) gene of influenza A virus; a pair of primers to the nonstructural gene of influenza B virus; and primers to the 1B and nucleocapsid genes of RSV A and B. The PCR mixture also contains Tris-HCl, 2.5 mM $MgCl_2$, a 0.2 mM concentration of each of the four deoxynucleoside triphosphates, and 0.5 μM concentration of the primers. Denaturation is at 95°C for 2 min. Amplification is by two cycles at 95°C for 1 min, 55°C for 45 s, and 72°C for 45 s and 38 cycles at 94°C for 1 min, 60°C for 45 s, and 72°C for 45 s. Reactions are then held at 72°C for 7 min. The PCR product is purified and added to a neutravidin-coated microtiter plate. Proprietary peroxidase-labeled probe solutions 1 to 7 (Prodesse, Inc.), representing highly conserved regions of the previously described genes, are added to each well. After the capture and hybridization reaction is complete, a substrate solution is added, followed after 10 min by addition of a stop solution. The optical density of each well is measured at 450 nm on a spectrophotometer. Cutoff values are established by comparison with negative control values. The assay requires approximately 7 h to complete.

Other molecular methods are being developed to detect respiratory viruses. A rapid real-time multiplex PCR assay using a two-tube multiplex reaction employing molecular beacons to discriminate the pathogens was developed to detect influenza A and B viruses; RSV; and HPIV-1, -2, -3, and -4 in clinical samples. Within 6 h, the PCR assay detected 100% of the respiratory pathogens that were eventually isolated in traditional cell cultures, as well as several additional viruses of each type that failed to grow in traditional cell cultures (39).

Isolation and Identification

Many commonly used cell lines support the growth of HPIV, but the best growth is seen in primary monkey kidney (PMK) cells, including rhesus, cynomolgus, and African green monkey cells (16). LLC-MK2 is also acceptable for primary isolation when 2 to 3 μg of trypsin per ml is added to the cell culture medium (16). Madin-Darby canine kidney (MDCK), HeLa, Vero, and HEp-2 cells may be used for transferring isolates but are not recommended for primary isolation (40). At this writing, commonly used cell lines are available commercially from two suppliers in the United States: Diagnostic Hybrids, Inc., and Viromed Laboratories, Minnetonka, Minn.

In preparation for cell culture inoculation of specimens collected on swabs and transported in a viral transport medium, the transport medium tube is extensively mixed on a vortex mixer, and excess fluid is expressed from the swab by pressing the swab against the side of the tube; the swab is then discarded. The transport medium is then centrifuged at 1,500 × *g* for 10 min. The medium is decanted from cell culture tubes that are to be inoculated, and the supernatant from the centrifuged transport medium, usually 0.2 ml for each tube, is applied to each cell culture monolayer. The inoculated tubes are incubated in a horizontal position in a 35 to 37°C incubator for 1 h before excess inoculum is discarded and fresh cell culture medium is added. Inoculated cell culture tubes are incubated in rotating racks at 35 to 37°C and examined microscopically on alternate days for 14 days.

In PMK cells HPIV may produce some rounding of cells and syncytia in 4 to 8 days. However, many HPIVs will produce little, if any, cytopathogenic effect (CPE) in traditional cell culture tubes. Fortunately, HPIVs produce hemagglutinin proteins that are inserted into the membranes of infected cells. These proteins have an affinity for erythrocytes, a phenomenon called hemadsorption (HAD), and this property can be used as another approach for detection of HPIVs in cell cultures. In HAD testing, culture medium is replaced with a dilute suspension of guinea pig erythrocytes, and the cell culture tubes are refrigerated at 4°C for 30 min; then the tubes are examined microscopically (26). When a hemadsorbing virus is present, erythrocytes adhere to the infected cell monolayer. If hemadsorbing virus is absent, erythrocytes will not adhere and will float free when the tube is tilted or tapped. Uninfected and infected control tubes should be included in HAD testing. HAD testing may be performed at the end of the typical incubation period of 14 days or earlier, after 3 to 7 days of incubation (33). Although an HAD-positive result indicates that the infecting virus has hemagglutinin proteins, this result alone does not identify the virus as HPIV. HPIV-4 hemadsorbs weakly at 4°C and more strongly at room temperature. Other members of the *Paramyxoviridae* family, including mumps viruses, and other viruses such as influenza virus also give positive HAD test results. Whether the presence of HPIV is suspected based on the appearance of typical CPE or by a positive HAD test result, confirmatory testing must be done to definitively identify the virus.

Confirmatory testing is routinely completed by immunofluorescence techniques involving the use of HPIV monoclonal antibodies in DFAs or IFAs as described for HPIV antigen detection in clinical samples. Antibodies against HPIV-1, -2, and -3 are readily available in the various respiratory virus antibody testing kits. However, HPIV-4 antibodies are not included in the testing kits and must be purchased separately. Infected cells are scraped from the cell culture monolayer, applied to a microscope slide, fixed, and stained. The presence of apple-green fluorescence when the smear is viewed with a fluorescence microscope confirms the identification of HPIV. Confirmatory testing may also be accomplished by many other methods, including hemagglutination inhibition, complement fixation, and neutralization.

These techniques are laborious and time-consuming compared to immunofluorescence and are seldom used.

Cell cultures grown on coverslips in shell vials or in microwell plates provide an alternative to traditional tube cell cultures for isolation of HPIVs. Centrifugation of the inoculated vials and plates, usually at 700 × *g* for 1 h, is an important feature of the inoculation process. Inoculated vials or plates are incubated for 24 to 48 h or as long as 5 days. Detection of viral proliferation depends on pre-CPE detection of viral antigens by application of HPIV monoclonal antibodies to the monolayers in a typical DFA or IFA staining procedure. Use of shell vial cultures with centrifugation-enhanced inoculation and pre-CPE detection by immunofluorescence staining has been shown to be very useful in HPIV detection.

Cocultivated mink lung (Mv1Lu) and A549 cells, marketed as R-Mix (Diagnostic Hybrids, Inc.), are used with centrifugation-enhanced inoculation and pre-CPE detection with a DFA staining technique. Staining involves pooled monoclonal antibodies to seven respiratory viruses (adenovirus; influenza A and B viruses; HPIV-1, -2, and -3; and RSV). This system has been shown to effectively detect HPIV-1, -2, and -3 (Fig. 1). In a recent study comparing detection of respiratory viruses in 3,800 clinical samples in R-Mix and in shell vials of PMK, A459, and MRC-5 cells, 33 of 38 (87%) HPIV-positive samples were detected after overnight incubation in the R-Mix cells (10). This included 26 of 30 HPIV-1 samples, 2 of 2 HPIV-2 samples, and 5 of 6 HPIV-3 samples.

An overview of the recommended protocol from the manufacturer of R-Mix (Diagnostic Hybrids, Inc.) is shown here; however, this may be adjusted to meet the needs of the laboratory. Briefly, the processed clinical specimen for respiratory virus detection is inoculated into three vials containing R-Mix cells, and the vials are spun in the centrifuge (700 × *g* for 1 h). At 16 to 24 h, one vial is stained with respiratory virus screening reagent (tests for seven respiratory viruses). If fluorescence is observed, the cells are scraped from one of the remaining shell vials, rinsed in PBS, and spotted onto an eight-well slide; seven of the wells are stained with individual monoclonal antibodies against the seven respiratory viruses, and the eighth well is used as a control well. If no fluorescence is observed when the first vial is stained, the second vial is stained after an additional 16 to 24 h of incubation. If this vial is positive, the cells are scraped from the remaining vial and stained as described above. If the second vial is negative, the culture may be considered negative for the seven respiratory viruses (i.e., the remaining vial is discarded and the culture is terminated), or the third vial may be observed for CPE for up to 7 days.

Serologic Tests

Most children are born with HPIV-neutralizing antibodies, but these diminish by 6 months of age, allowing more than two-thirds of children to be infected by HPIV during the first year of life. Most children have early serologic evidence of HPIV-3 infection, with HPIV-1 and -2 antibodies developing later, at age 2 to 3 years. Antibodies to HPIV-4 peak in school-age children (16). Immunoglobulin M (IgM) is produced in most primary HPIV infections of children, so IgM detection in a single sample supports current infection. Likewise, measurement of a significant increase in IgG antibody level, which is an increase of fourfold or more in assays that test serial twofold dilutions, in serum samples collected 2 weeks apart supports current

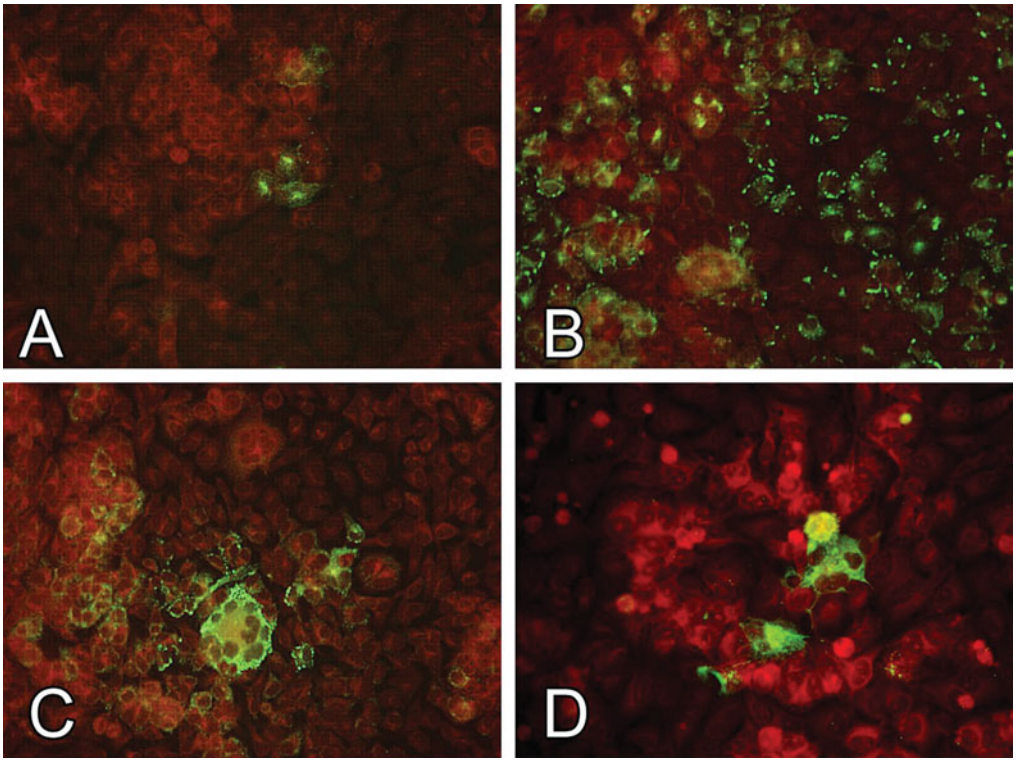

FIGURE 1 Immunofluorescence staining of infected R-Mix cells. (A) HPIV-1; (B) HPIV-2; (C) HPIV-3; (D) mumps virus. Magnification, ×200 (all). Photos courtesy of Diagnostic Hybrids, Inc.

infection. Cross-reactivity among the various HPIV types and other paramyxoviruses such as mumps virus makes serologic diagnoses more difficult. Serologic differentiation of the HPIV types is unreliable by all methods; this determination can be made only through virus isolation and antigen typing with monoclonal antibodies or identification of the viral RNAs.

Antibodies to the HN protein may appear early, but both HN and F protein antibodies must be present for protection. Immune status determinations are not useful for HPIV. Serology, in general, is seldom used as a diagnostic approach for HPIV infection because of the wide availability of virus isolation and viral antigen and nucleic acid detection methods.

Principles of various serologic assays are described in detail in chapter 18 of this Manual. HPIV antibodies can be detected by many types of assays, including hemagglutination inhibition, complement fixation, and neutralization; all of these detect total antibody (IgG and IgM), and most laboratories will not offer these methods due to their cumbersome nature. A detailed procedure for hemagglutination inhibition testing for HPIV antibodies was published previously (40). HPIV antibody detection can be accomplished by enzyme immunoassay (EIA), but commercial kits are not available. Complement fixation is the least sensitive method for antibody detection, and EIA is the most sensitive.

Evaluation, Interpretation, and Reporting of Results

Isolation of HPIV-1, -2, -3, and -4 in traditional or shell vial or microwell cell cultures and detection of HPIV RNA in clinical samples are the best evidence for current or very recent infection because HPIV is seldom present in the absence of infection. These methods are the most sensitive and specific. Rapid reporting of these positive results is important (40). Although the sensitivity of HPIV antigen detection by immunofluorescence is lower than that of virus isolation in cell culture or molecular detection, the rapid availability of results make such testing useful in patient management. Because these tests are widely available and have high specificity, they should be considered an important diagnostic tool. Confirmation of HPIV infection via the serologic route and HPIV immune status determinations are seldom employed due to the difficulties with cross-reactions among the paramyxoviruses.

MUMPS VIRUS

Epidemiology and Transmission

Most mumps cases occur in children. More than 150,000 cases of mumps were expected each year in the United States before the aggressive vaccination programs implemented in the late 1960s. The mumps vaccine was combined with the measles and rubella vaccines to make a trivalent vaccine (MMR). In the United States the initial dose of MMR is administered to children between 12 and 15 months of age. Vaccination produced a dramatic decline in the incidence of mumps, resulting in fewer than 3,000 cases in the United States by 1985. There was a brief resurgence of mumps in 1986 and 1987 that peaked at 8,000 to 12,000 cases. Following the resurgence, a requirement for a second dose of the MMR vaccine was implemented. This dose is administered to children between ages 4 and 6 or 11 and 13 years (4) and should confer lifelong immunity. The number of mumps cases continues to decline in the United States. Only 231 mumps cases were reported in the United States in 2003 (5), although sporadic and imported cases continue to occur. Mumps remains common throughout much of the world.

The virus is transmitted from person to person through respiratory droplets and is highly contagious, with approximately 85% of susceptible contacts becoming infected when first exposed. Humans are the only known host and reservoir for the virus. The virus replicates initially in epithelial cells in the upper respiratory tract and in regional lymph nodes. Initial replication is followed by viremia, which results in infection of salivary glands and other sites. The period of communicability can be from 7 days before salivary gland involvement until 9 days after. The virus is excreted in urine for as long as 14 days after the onset of illness.

Clinical Significance

The average incubation period for mumps is 16 to 18 days. Mumps virus infection is clinically inapparent in 25 to 30% of cases and is associated with nonspecific or respiratory symptoms in 50% of cases. Symptoms are typically mild and characterized by slightly elevated temperature and enlargement of one or both parotid glands in 30 to 40% of cases. Complications of mumps include meningoencephalitis (up to 15% of cases) and, in postpubertal individuals, orchitis in males (20 to 30%) and oophoritis in females (7%). Polyarthritis and pancreatitis have also been associated with mumps.

When mumps was a common disease of childhood, the diagnosis was made largely on clinical grounds alone. With the decrease in incidence of mumps, many physicians no longer readily recognize the symptoms. In addition, typical clinical signs and symptoms may be absent in underimmunized or immunocompromised individuals. Parotitis, the hallmark of clinical diagnosis, is now known to be present in other viral and nonviral diseases or conditions. Mumps-like symptoms in acutely ill children who previously received the MMR vaccine have been associated with Epstein-Barr virus, HPIV, adenovirus, and human herpesvirus type 6 (9). Therefore, laboratory confirmation of mumps virus infection is now more important in making the diagnosis.

Collection, Transport, and Storage of Specimens

The accepted laboratory criteria for the diagnosis of mumps infection are isolation of the virus from clinical specimens, a significant rise between acute- and convalescent-phase antibody titers in serum, or a positive IgM result for mumps virus. However, collection of samples to allow molecular analysis should be considered (Table 1). Guidelines for specimen collection, transport, and storage of specimens are presented in chapters 5 and 80 of this Manual.

Specimens for mumps virus isolation in cell culture include the following: saliva, blood, urine, and cerebrospinal fluid (CSF). Virus can be isolated from saliva 9 days before and up to 8 days after the onset of parotitis, recovered from urine for up to 2 weeks after onset of symptoms, isolated from CSF during meningitis, and detected rarely in peripheral blood. Throat swabs and urine samples have been shown to be of similar usefulness as sources of mumps virus (38). It is always advisable to collect samples for virus isolation early in the course of the infection, when the viral titer is the highest.

The virus is stable for several days at 4°C, although inoculation of susceptible cell cultures within a few hours of specimen collection is recommended for optimal virus isolation. The virus may survive for months or longer when frozen at –70°C or lower.

Blood samples for use in mumps virus antibody testing should be collected and stored as described in this chapter in the "Parainfluenza Virus" section under "Collection, Transport, and Storage of Specimens." An alternative to serum collected by venipuncture is whole blood obtained by

fingerstick or heel prick and spotted onto filter paper and dried. Venipuncture blood may also be spotted onto filter paper and dried. Following elution and dilution of the dried blood samples, commercial antibody assays may be used to test the sample for mumps virus antibody. Results of EIA for mumps virus IgG and IgM using samples collected as blood spots have shown excellent correlation with those obtained in testing of fresh serum. The dried blood spots may be stored for 6 to 24 months without significant change in antibody testing results (8).

In order to compare IgG or total antibody levels, two samples should be collected, the first (acute) as soon as possible after onset of symptoms and the second (convalescent) within 2 to 3 weeks following collection of the acute sample. A single serum sample collected within 10 days of onset is all that is required for IgM-specific antibody testing. If the purpose of the serologic testing is simply to determine the patient's mumps immune status, a single serum sample collected at random is sufficient.

Direct Examination

Microscopy

Diagnosis of mumps does not typically involve examination of biopsy samples. However, microscopic examination of affected salivary glands reveals edematous interstitium, diffusely infiltrated by macrophages, lymphocytes, and plasma cells, which compress acini and ducts. Neutrophils and necrotic debris may fill the ductal lumen, causing focal damage to the ductal epithelium (32).

Antigen Detection

Mumps virus antigen detection by immunofluorescence in cells from CSF and salivary glands was described in the early 1970s (2, 29). More recent studies of immunofluorescence staining of throat swab specimens for mumps virus antigen have shown sensitivity as high as 98 to 100% compared to mumps virus isolation in cell culture (38). Although mumps virus monoclonal antibodies are available commercially, most are not approved for use in direct detection of mumps virus antigens in tissues and other clinical samples, and most virology laboratories do not offer direct antigen analysis for mumps virus.

Nucleic Acid Detection Techniques

Various molecular approaches have been developed to aid in mumps diagnosis. Mumps RNA has been detected by RT-PCR in oral fluid, CSF, saliva/throat, and urine specimens (36). A nested RT-PCR, targeting a short fragment of the SH gene, was successfully applied directly to CSF and for identification of mumps virus isolates from cell culture (35). A loop-mediated isothermal amplification method has also been used to amplify and detect mumps virus RNA in clinical samples; this method detected more mumps virus-positive samples than cell culture (34). A TaqMan-based one-step real-time RT-PCR that uses oligonucleotides targeting the matrix protein gene was shown to accurately detect and quantify mumps virus strains (24). Although these methods hold great promise in dealing with mumps virus detection and quantification, they are not well standardized, approved reagents are not commercially available at this writing, and testing is available only in specialized laboratories. In routine laboratories, virus isolation remains the standard method for diagnosing mumps virus infection.

Isolation and Identification

Mumps virus proliferates in traditional cell cultures of several cell lines commonly used in viral diagnostic laboratories. These include PMK, human neonatal kidney, HeLa, and Vero. Recently, a marmoset lymphoblastic cell line, B95a, was shown to be equally as sensitive for mumps virus isolation as PMK cells (23). Directions for cell culture inoculation for swab samples in viral transport medium are the same as those described in the "Parainfluenza Virus" section under "Isolation and Identification."

In cells infected with mumps virus, CPE characterized by rounding of cells and multinucleated giant cells is typical, usually appearing after 6 to 8 days of incubation at 35 to 37°C. However, this characteristic CPE may be very subtle, may not appear at all, or may be confused with a similar CPE produced by endogenous contaminant viruses that sometimes infect PMK cells.

Mumps virus, like the HPIVs, inserts hemagglutinin proteins into the membranes of infected cells, so mumps virus-infected cells can be demonstrated through HAD testing. The HAD testing protocol is described in the "Parainfluenza Virus" section under "Isolation and Identification." Whether mumps virus is detected by CPE production or by a positive HAD result, confirmatory testing must be performed. Confirmatory testing for mumps is routinely performed by IFA. The staining protocol for a typical IFA is provided in the "Parainfluenza Viruses" section under "Direct Examination."

Many laboratories currently use centrifugation-enhanced inoculation and pre-CPE detection with monoclonal antibodies to detect mumps virus within 24 to 48 h after inoculation. Various cell lines can be used in either shell vial or microwell plate formats for this purpose. The recommended centrifugation speeds and times may vary for inoculation, ranging from 700 × *g* for 45 min (38) to 3,000 × *g* for 20 min (10). Up to 66% of mumps virus-positive samples were identified within 2 days of inoculation in the shell vial system; after 5 days of incubation, the shell vial system was 96% sensitive compared to mumps virus isolation in traditional cell cultures (14). When various cell lines were compared for efficacy of mumps virus isolation in shell vials, Vero and LLC-MK2 cells were found to be most sensitive (100%), followed by MDCK (78%), MRC-5 (44%), and HEp-2 (22%) (37). Mumps can also be isolated in R-Mix cells (Fig. 1). An overview of the recommended protocol from the manufacturer of R-Mix (Diagnostic Hybrids, Inc.) is discussed in the "Parainfluenza Viruses" section under "Isolation and Identification."

Serologic Tests

In mumps virus infection, IgM is detectable initially within 3 to 4 days of the appearance of clinical symptoms and persists for 8 to 12 weeks. IgG is detectable within 7 to 10 days of the onset of symptoms, is maintained at high levels for years, and remains detectable for life. Traditional serologic diagnosis of mumps virus is based on the detection of virus-specific IgM in a single sample or measurement of a significant increase in titer of IgG or total antibody, equal to or greater than fourfold in methods that use serial twofold dilutions, between two specimens collected 2 weeks apart. Antibodies produced in mumps virus infection often cross-react with related viruses, which complicates interpretation of results. Assays for mumps immune status indicate whether mumps virus IgG is present in detectable levels or is absent or undetectable. With the rarity of mumps cases in the United States at present, most laboratories focus mumps serology on immune status testing.

Basic principles of serologic assays are described in chapter 18 of this Manual. Mumps virus antibodies can be detected by many types of assays, including hemagglutination inhibition, complement fixation, and neutralization; all of these detect total antibody (IgG and IgM). These methods are usually laborious and are available only at reference or specialty laboratories. A detailed procedure for mumps antibody hemagglutination inhibition testing was published previously (27). The complement fixation technique can be used with two different mumps virus antigens, V and S. Antibodies against the S antigen appear earlier and rise quickly, in contrast to antibodies to the V antigen, which appear later. The presence of both V and S antibodies is thought to signal a recent past infection, while V antibodies alone signal a long-past infection (40).

Most diagnostic laboratories use commercially supplied mumps virus antibody EIA kits, in either manual or automated formats, or IFA testing systems for mumps virus antibody determinations. Most of these measure only mumps virus IgG. Antibodies are produced against various mumps virus proteins, but protection is most closely correlated with antibodies to the mumps HN protein. Most assays use whole-virus or viral extract antigens that detect HN antibody effectively. Written protocols, along with the proper reagents and controls, are included with each commercial product, and each manufacturer's guidelines must be followed if assays are to yield high-quality results. The procedural steps for performance of antibody testing are not published here due to the need for strict adherence to manufacturers' guidelines. No specific recommendation on which specific mumps virus antibody test is most useful can be made at this time.

Evaluation, Interpretation, and Reporting of Results

Isolation of mumps virus in traditional or shell vial or microwell cell cultures is evidence for current or very recent infection. The same can be said for the detection of mumps virus RNA in clinical samples. Rapid antigen detection may also confirm the presence of mumps virus. However, neither molecular methods nor rapid antigen assays are routinely available in U.S. laboratories, so mumps virus isolation in culture remains the most sensitive approach. Confirmation of mumps virus infection via the serologic route is less straightforward. Mumps virus IgM may be detected, along with significant increases in IgG, in patients infected with related viruses, including the other paramyxoviruses, such as HPIV-1, -2, -3, and -4. In general, cross-reactivity with related viruses can be ruled out by testing for antibodies to the related viruses in parallel with mumps virus antibody testing. The greatest increase in antibody level should identify the true infection. Virus isolation in culture and detection of mumps virus RNA in clinical samples are the most effective ways to confirm true infection.

Respiratory Syncytial Virus and Human Metapneumovirus*

YI-WEI TANG AND JAMES E. CROWE, JR.

87

Respiratory syncytial virus (RSV) and human metapneumovirus (hMPV) are two cousins with a 50-year difference in their discovery "age" in the list of viral pathogens causing respiratory tract infections. RSV was first identified as the agent that caused chimpanzee coryza in 1956 (14). After its subsequent isolation from children with pulmonary disease in Baltimore (25), RSV has been described as the single most important virus causing acute respiratory-tract infections in children. hMPV was not recognized until the year 2001 in The Netherlands (135). While diagnostic procedures for detecting and identifying hMPV are emerging, diagnostic procedures for RSV have improved significantly over the past decade thanks to technological revolutions in the field. Improvements include the introduction of more-sensitive mixed cell lines for virus culture and an early detection by shell vials, the application of monoclonal antibodies for rapid detection of viral antigens directly in clinical specimens, and the detection of viral RNA in clinical specimens by nucleic acid amplification techniques.

RESPIRATORY SYNCYTIAL VIRUS

Taxonomy

RSV belongs to the *Pneumovirus* genus of the *Paramyxoviridae* family. Within this same genus are the morphologically and biologically similar pneumonia virus of mice, bovine RSV, ovine RSV, and caprine RSV. Distinctive features of RSV include the number and order of genes and lack of hemagglutinin and neuraminidase activity. This virus derives its name from the characteristic formation of multinucleated giant cells (syncytia) in monolayer cell cultures of nonpolarized epithelial cells (28).

Description of the Agent

RSV is an enveloped virus that contains a single-stranded, negative-sense, nonsegmented RNA genome with 10 genes that are transcribed into 11 monocistronic polyadenylated mRNAs, each of which encodes a major polypeptide chain (Fig. 1). Three of the proteins are associated with the nucleocapsid: the N (nucleoprotein) protein serves as the major structural protein for the nucleocapsid, while P (phosphoprotein) and L (polymerase or large) are involved in transcription and replication (28). The envelope contains five viral proteins: nonglycosylated M (matrix), M2, and the surface glycoproteins F (fusion), G (glycosylated), and SH (short hydrophobic). The SH protein accumulates within lipid raft structures of the Golgi complex during RSV infection (113), the M protein is present in detergent-solubilized cores, and M2 is expressed on the surfaces of infected cells. Between the two glycosylated surface proteins, the F protein initiates viral penetration by fusing viral and cellular membranes and promotes viral spread by melding infected to adjacent uninfected cells; and the G protein mediates attachment of the virus to the host cells (28). Two subgroups of RSV (A and B) are recognized primarily based on variations in the structure of their G protein (22, 128). Comparisons of the G ectodomains showed a 94% homology within subgroup A and a 47% divergence between subgroups A and B RSV viruses. In contrast, the F protein is highly conserved, and antibodies against it cross-react with both subgroups A and B (28). The other two proteins, NS1 and NS2, are nonstructural proteins of the virion that inhibit the induction of alpha and beta interferon in A549 cells and human macrophages (124).

RSV is one of the most vulnerable pathogens to environmental changes. Only 10% of RSV remained alive after exposure to 55°C for 5 min. At room temperature, 10% infectivity was present after 48 h, and at 4°C, 1% of the infectivity remained after 7 days. The RSV infectivity titer fell by approximately 90% after each freeze-thaw cycle. RSV also withstands an acid medium poorly, and the optimal pH is 7.5 (64). The virus is inactivated quickly by ether, chloroform, and a variety of detergents such as 0.1% sodium deoxycholate, sodium dodecyl sulfate, and Triton X-100. Storage of RSV can be enhanced by flash freezing in an alcohol and dry ice bath and by adding stabilizing agents such as glycerin or sucrose. At room temperature, RSV in the secretions of patients may survive on nonporous surfaces such as countertops for 3 to 30 h, depending on the humidity. The survival of RSV in the environment depends in part on drying time as well as humidity (28, 62).

Epidemiology and Transmission

RSV is the most common cause of bronchiolitis and pneumonia among infants and young children worldwide. In the United States, early reports estimated that 100,000 hospitalizations and 4,500 deaths are related to RSV infection annually with expenses in excess of 300 million dollars

* This chapter contains information presented in chapter 89 by Debra A. Tristram in the eighth edition of this Manual.

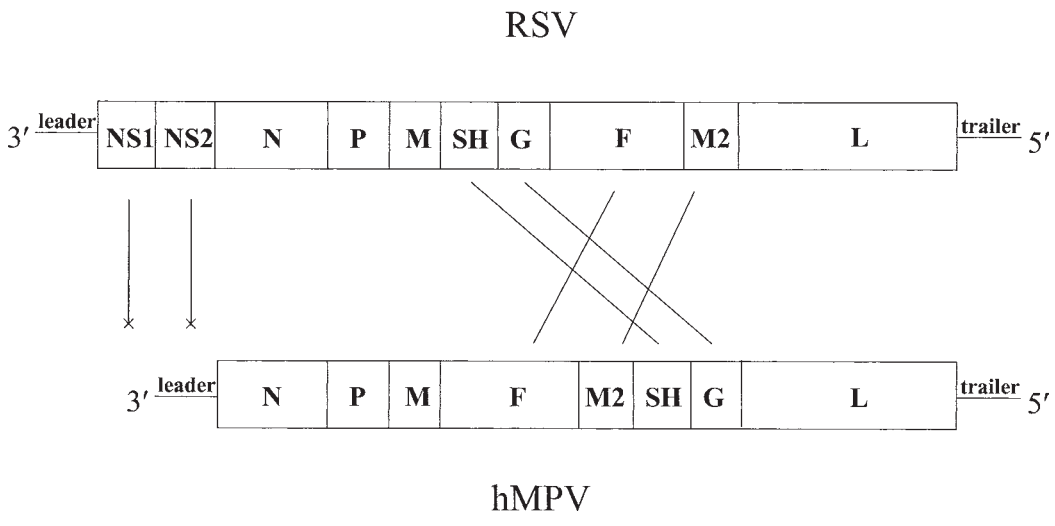

FIGURE 1 A schematic of RSV and hMPV genomic RNAs. The order of the genes from 3′ to 5′ is depicted. The virus-specific proteins encoded by these genes are shown.

per year (33, 62). A recent study revealed that high altitude, above 2,500 m, is a modest predictor for RSV-associated hospitalization (26). A large-scale epidemiology study suggested that medical care has reduced the mortality in children to about 100 cases a year, while over 17,000 deaths a year occur among the elderly (133). Virtually all children are infected by the time they reach 3 years of age. Repeated infections with RSV are common, and no age group appears protected. In older children and immunocompetent adults, RSV infections are seldom severe and are usually manifested as upper respiratory infection or tracheobronchitis. Individuals at high risk for severe RSV infection include premature infants, young infants, immunocompromised individuals, and the elderly (62, 121). RSV activity follows a seasonal pattern in temperate zones of the world. In urban centers, annual outbreaks occur during the fall, winter, and early spring. In the northern hemisphere most outbreaks peak in February or March. In tropical or subtropical areas, epidemics peak during the rainy season (121). Climate change may be shortening the RSV season (34).

Crowding increases the attack rate of RSV. Schools or day care centers provide ideal settings for the spread of RSV to susceptible individuals. Passive exposure to tobacco and cigarette smoke is associated with the development of more severe illness (19). Infants who have not been breast-fed appear to be at greater risk for developing severe RSV infections in some studies, but a strong effect has not always been noted (84). Children with underlying heart disease, in particular those conditions complicated by pulmonary hypertension, or chronic lung disease (i.e., bronchopulmonary dysplasia), as well as prematurity, are at increased risk for acquiring more severe RSV infections, as evidenced by their increased rates of intensive care unit admissions and need for mechanical ventilation. RSV infection is an important illness in elderly and high-risk adults, with a disease burden similar to that of nonpandemic influenza A in a population in which the prevalence of vaccination for influenza is high (45, 133). The mean hospital length of stay was 11 days for RSV-infected children with congenital heart disease or chronic lung disease, second only to the group with immunodeficiencies (74). Both subgroups A and B can cocirculate each year, and the predominating subgroup may shift with the season (80, 117).

Clinical Significance

Primary infections with RSV may be manifested as lower respiratory tract diseases, pneumonia, bronchiolitis, tracheobronchitis, or upper respiratory tract illness, often accompanied by a low-grade fever. Otitis media has also been associated with RSV infection (62, 121). The incubation period ranges from 2 to 8 days. Illness begins most frequently with rhinorrhea, sneezing, and cough. Most children experience recovery from illness after 8 to 15 days. During their first RSV infection, 25 to 40% of infected infants and young children have signs or symptoms of bronchiolitis or pneumonia and 0.5 to 2% require hospitalization. In contrast, hospitalization is required in up to 25% of high-risk children such as those with a history of prematurity or chronic lung disease. RSV bronchiolitis or pneumonia should be suspected when an infant or young child presents with progressive cough, wheezing, and dyspnea during an RSV season. Among immunocompetent adults, RSV infection usually manifests with rhinorrhea, pharyngitis, cough, bronchitis, headache, fatigue, and fever (62, 121). In older persons, particularly the institutionalized elderly and those with chronic cardiopulmonary illnesses, severe pneumonia may occur, leading to respiratory failure (33, 45, 121). Among immunocompromised individuals, RSV infection typically begins as an upper respiratory tract infection and may evolve into lower respiratory tract disease in up to 50% of cases (62, 121). The clinical significance of subgroup differentiation has been suggested by some studies. Subgroup A RSV may be more virulent than subgroup B, and its infection may result in greater disease severity among hospitalized infants (89, 92, 141). Subgroup B viruses grow less efficiently in conventional cell culture, so in some studies a detection bias may have occurred.

RSV causes hazardous nosocomial infection and produces outbreaks each year with widespread infection in both children and adults, including medical personnel, who may have a mild enough illness as to not cause absences from work. Furthermore, the spread of the virus is facilitated by

the number of young infants admitted during an outbreak who tend to shed high titers of virus for prolonged periods (62). Outbreaks producing lower respiratory tract disease in nursing homes and institutions have been reported (48). In a classical experiment, volunteers in close physical contact with RSV-infected infants were more readily infected than those who remained 6 feet away, suggesting that small-particle aerosol is less important in the spread of RSV than direct contact with infectious secretions via fomites or large-particle aerosols (61). A targeted infection control intervention has been demonstrated to be cost-effective in reducing the rate of RSV nosocomial infections (84). A contact isolation procedure is recommended for RSV-infected patients when they are hospitalized.

For the majority of infants with mild disease, no specific treatment is necessary other than supportive care. Children with severe disease may require hospitalization. Aerosolized ribavirin (Virasole) was approved in 1986 for the treatment of infants and children with severe RSV disease (97); however, a meta-analysis of clinical trials in infants with RSV lower respiratory tract infection showed that there was no evidence of a significant benefit and that studies lacked the power to detect reductions in mortality (111). In most hospitals, the use of ribavirin is now infrequent and restricted to immunocompromised patients or to those who are severely ill. Palivizumab (Synagis) is a humanized monoclonal antibody directed to the fusion (F) protein that was licensed in the United States for prophylaxis against RSV disease in high-risk infants. Administration of palivizumab to infants with chronic lung disease and/or extremely premature birth reduced the rate of hospitalization by 40 to 50%; however, the intramuscular treatment must be delivered monthly and its impact on mortality remains controversial (72). Most children admitted to the hospital with severe RSV are otherwise healthy infants and thus were not candidates for prophylaxis. Palivizumab has not shown convincing evidence of therapeutic efficacy after infection is established. An experimental combination treatment of ribavirin and palivizumab has been reported to be well tolerated and to improve the outcome of severe RSV infection among bone marrow transplant recipients (146). Delay of immunosuppressive chemotherapy should be considered when severely immunosuppressed individuals develop acute RSV infection (33, 121).

Collection, Transport, and Storage of Specimens

To detect the presence of RSV in clinical specimens, it is important to select the appropriate specimen. Appropriate respiratory specimens include nasal secretions, nasal swabs, nasopharyngeal swabs, and nasopharyngeal aspirates. Among them, secretions obtained by either wash or suction contain the infectious virus necessary for identification by culture and exfoliated nasopharyngeal cells if viral antigen detection methods are used (2, 90). Endotracheal tube aspirate or bronchoalveolar lavage (BAL) fluid collection is more sensitive than the above-mentioned sample types for rapid antigen testing for immunocompromised adults who are being mechanically ventilated (38). The use of nasal or nasopharyngeal swabs is an alternative method for sample collection; cotton-tipped swabs without calcium alginate are recommended (52). However, it has been shown that the use of nasopharyngeal swabs yields the worst results (62). After specimen collection, the swab should be introduced into a vial containing the viral transport medium, with the shaft cut to close the top of the vial, and transported to the laboratory promptly.

While limited studies indicate that there is no significant difference in the RSV antigen detection rates obtained by the nasal wash and by the nasopharyngeal wash/aspiration methods (20), nasal washing should be the recommended method for specimen collection, being the least traumatic for infants and young children (62, 85). A recent study demonstrated that the quantity of virus in the upper respiratory tract (nasal secretions) is nearly equivalent to that found in the lower respiratory tract by using both quantitative culture and real-time PCR (21, 107). To correctly collect nasal washes, the patient should be held from behind in an upright position and the head should be stabilized. A tapered bulb syringe containing 5 to 7 ml of sterile, prewarmed saline solution is introduced into one nostril, and the nasal wash is collected immediately into a medicine cup as it runs out of the other nostril. Residual mucus from both nares is suctioned into the bulb syringe and mixed with nasal wash. The nasal wash specimen is poured into viral transport medium, labeled, and placed on ice for proper transport to the laboratory. The prompt collection of a mucus sample for diagnosis of RSV infection is critical and enhances the rapid detection by viral cultures (62).

All general viral specimen collection rules, such as collecting during the acute phase of infection, keeping intact cells, delivering the specimen promptly, refrigerating specimens if stored temporarily, and sealing well in an O-ring-sealed cryovial if stored on dry ice, apply to specimen collection for RSV detection and culture. In addition, RSV is an extremely labile virus and does not tolerate changes in temperature or prolonged storage during transit to the laboratory (62, 64). Heating or freezing the specimen results in a decreased number of infectious virions in the sample. To effectively isolate RSV, specimen containers should be transported to the laboratory in wet ice as quickly and expeditiously as possible. If specimens cannot be processed rapidly and inoculated into cell culture within 2 h of sample collection, they should be kept refrigerated. Samples should never be frozen without first consulting the virology laboratory.

Direct Detection

Microscopy

Although RSV can be visualized by electron microscopy, its application has been limited to research laboratories. Conventional bright-field microscopy has been used for identifying RSV by visualizing the characteristic syncytial formation cytopathic effect (CPE), which is usually observed 4 to 6 days after inoculation on HEp-2 cell monolayer cultures (Fig. 2).

Antigen

The development of rapid diagnostic techniques for viral detection has received much attention over the last 2 decades. The use of rapid tests in diagnosis of RSV infection allows implementation of appropriate infection control measures, thus reducing nosocomial spread (74, 78, 84), and may be useful for consideration of timely treatment with aerosolized ribavirin in severe cases. It was reported that a reduction in the duration of hospitalization and use of additional laboratory investigations for patients with respiratory infections was achieved after rapid viral diagnosis became available at a hospital (149). The clinical and financial benefits of rapid detection of RSV in respiratory specimens have been demonstrated in several studies (7, 74, 78, 84, 149), indicating a direct correlation between rapid turnaround time and decreased mortality, length of stay, overall costs, and better antibiotic stewardship. There are several rapid RSV antigen tests currently available utilizing four major

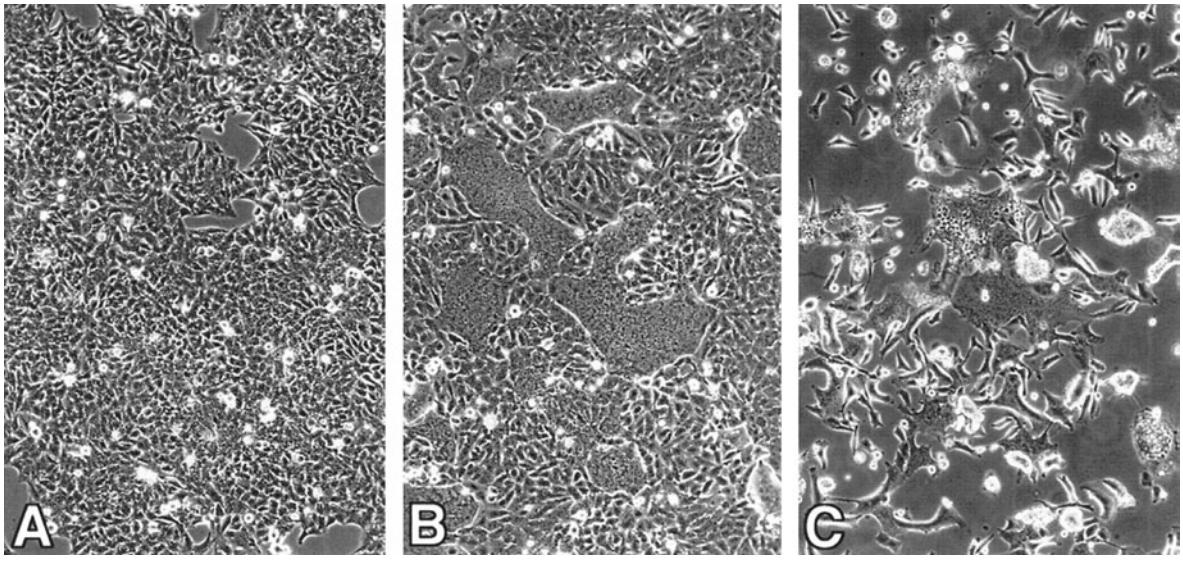

FIGURE 2 RSV-infected respiratory epithelial cells. Respiratory epithelial cells (HEp-2, laryngeal carcinoma cell line) on day 1 (A), day 3 (B), and day 5 (C) following infection with RSV. Magnification, ×400. After 1 day, the cells continue to appear healthy. After 3 days, many of the cells have fused, forming large syncytia. After 5 days, most of the syncytia have detached from the surface and the majority of the cells are dead. Adapted from reference 33.

platforms, i.e., immunofluorescent-antibody assay (IFA), optical immunoassay, enzyme immunoassay (EIA), and chromatographic immunoassay (CIA). Each platform offers a wide range of performance, specimen choices, and limitations for drug interference. Key factors that influence choice include test accuracy, turnaround time, interference with commonly used medications, choice of specimen type, choice of transport products, and reliable supply.

IFA tests have been used widely for rapid diagnosis of RSV infection including the detection of RSV from clinical specimens and confirmation and subgroup differentiation on isolates. Reagents needed for performing the IFA RSV assay are commercially available from a number of companies (Table 1). According to its basic procedure, IFA can be divided into direct and indirect formats. Direct IFA (D-IFA), which uses a fluorophore-conjugated RSV-specific antibody to minimize the test background and enhance the whole test turnaround time, has demonstrated its comparability with culture (81, 110). Indirect IFA (I-IFA), on the other hand, involves two antibodies: one RSV-specific antibody and one species-specific antibody that is preconjugated with a fluorophore. The two-step procedure consumes more time but generally enhances test sensitivity. The use of monoclonal antibodies in these assays has greatly improved the sensitivity and specificity of the test, both of which are more than 85% in most studies (76). An early review discussed several studies in which either D-IFA or I-IFA was used for the detection of RSV infection. With either technique, the sensitivity of the IFA in comparison to culture was usually above 80% and could be as high as 97%. The specificity was generally greater than 90% (76). In general, when an IFA is correctly performed, the sensitivity is higher than that of other rapid antigen tests (81, 110). "Multiplex" D-IFA reagents are available commercially to detect a panel of common respiratory viruses simultaneously (81).

However, IFA testing requires an adequate number of respiratory epithelial cells and a skilled technologist for accurate interpretation (91). Results are usually subjective; background fluorescence and nonspecific staining create difficulties in distinguishing infected cells. The specimen type and collection technique are important factors for the detection of RSV (96). Among respiratory specimens submitted for IFA, approximately 5% were inadequate for IFA interpretation, which requires a sufficient number and quality of cells (146). The high specificity of the IFA and availability of results in 45 min to 3 h have made the IFA a useful diagnostic technique. However, test turnaround time could be significantly longer if larger numbers of specimens are tested in one run, in comparison to the EIA procedure run in a microtiter format (60, 63).

In addition to IFA, other rapid antigen detection immunoassays, with or without enzyme involved, are commercially available (Table 2). These assays offer the advantages of ease of performance, objective reading of results, and very rapid results (15 to 30 min). Another advantage is that they do not require the presence of viable virus to detect an infection, and specimens obtained later in the course of the illness or those with suboptimal handling may yield a positive result. Several membrane flowthrough EIAs are commercially available for the rapid diagnosis of RSV infection. One membrane flowthrough EIA, the TestPack RSV (Abbott Laboratories, Chicago, Ill.), was well received by clinical laboratories until it was recalled by the U.S. Food and Drug Administration (FDA) recently due to its false-positive results (1, 16, 115). Currently available EIA kits include the Directigen RSV EIA (Becton Dickinson). The sensitivity and specificity relative to culture isolation for the second-version Directigen EIA ranged from 61 to 86.1% and from 69 to 95%, respectively (24, 100, 112, 115). Sensitivity and specificity of the rapid RSV EIA assays vary among different kits in different reports.

Another testing format, lateral-flow CIA, has recently been introduced and has been well received for the rapid detection of RSV-specific antigens (Table 2). Since late 2002,

TABLE 1 Commercial RSV IFA reagents and their performances

Format and product(s) (company)	Performance claimed by manufacturer[a]	Application	Remarks (reference[s])
Direct			
Bartels RSV DFA (Bartels, a Trinity Biotech Company, Carlsbad, Calif.)	Sensitivity, 88–100%; specificity, 100%	Direct specimen detection and culture confirmation	Single- or dual-reagent D-IFA available. Acquired recently by Trinity Biotech (63, 110).
Light Diagnostics RSV and Respiratory Virus Panel Screen and/or ID (Chemicon International, Temecula, Calif.)	Sensitivity, 100%; specificity, 86%	Direct specimen detection and culture confirmation	In either single RSV or panel format. The panel covers RSV, influenza A/B virus, adenovirus, and parainfluenza virus 1, 2, and 3 (80).
SimulFluor Respiratory Screen, RSV/flu A or RSV/Para 3 (Chemicon International, Temecula, Calif.)	Sensitivity, 83.3–100%; specificity, 83.8–100%	For screening clinical specimens and culture	Three formats available. Covers RSV, influenza A/B virus, adenovirus, and parainfluenza virus 1, 2, and 3 (81).
