Polymyxin B-pyruvate-egg yolk-mannitol-bromthymol blue agar is an enriched, selective, and differential medium used for the isolation of *B. cereus*. The nutritive agar base includes peptones, agar, and buffers. Egg yolk emulsion allows detection of lecithinase activity, which is unique to *B. cereus*. Sodium pyruvate is added to reduce the size of the colonies, which may be important when performing plate counts. Bromthymol blue and mannitol combine to make the medium differential. *B. cereus* does not produce acid from mannitol and has a distinctive bright blue color. Polymyxin B inhibits contaminating gram-negative organisms from clinical specimens with mixed flora, such as stool specimens. Mannitol-egg yolk-polymyxin B agar and *B. cereus* medium are similarly used for the isolation of *B. cereus*.

■ Polysorbate 80 medium

See Ellinghausen-McCullough/Johnson-Harris medium.

■ PRAS media

Prereduced anaerobically sterilized (PRAS) media are specifically manufactured (Anaerobe Systems) and packaged to eliminate oxygen to enhance growth of anaerobic organisms. Systems come with and without swabs and are available in various collection formats: tubes, widemouthed collection containers for surgical specimens, and prepackaged plates.

■ *Pseudomonas cepacia* (PC) agar

PC agar is a selective medium used for the isolation of *B. cepacia* (formerly *Pseudomonas cepacia*) from respiratory specimens from cystic fibrosis patients. The medium was originally derived from a holding medium containing salts, phenol red, and agar in a phosphate buffer. Selective agents include crystal violet, ticarcillin, and polymyxin B, which inhibit many gram-positive and gram-negative organisms. PC agar may inhibit *B. cepacia* as well (30, 35, 69). See also *Burkholderia cepacia* selective agar and oxidative-fermentative polymyxin B-bacitracin-lactose agar.

■ Rambach agar

See CHROMagar.

■ Rappaport-Vassiliadis enrichment broth

Rappaport-Vassiliadis enrichment broth is a selective and enriched broth used for the isolation and cultivation of *Salmonella* spp. from food and environmental specimens. A modified Rappaport-Vassiliadis broth is a more selective broth used for the isolation and cultivation of *Y. enterocolitica* from foods. Basic Rappaport-Vassiliadis medium contains soybean peptone digest with salts and malachite green. Malachite green suppresses the growth of contaminating bacteria. The modified Rappaport-Vassiliadis broth uses pancreatic digest of casein with salts, malachite green, and carbenicillin.

■ Regan-Lowe medium

Regan-Lowe medium is an enriched and selective medium used for the isolation of *B. pertussis*. Beef extract pancreatic digest, horse blood, and niacin are the nutritional base. Starch and charcoal neutralize substances, such as fatty acids and peroxides, that are toxic to *Bordetella*. Cephalexin is added to inhibit the normal flora in the nasopharynx. Regan-Lowe transport medium contains half-strength charcoal and horse blood, provides better isolation of *Bordetella* than Bordet-Gengou medium, and has a longer shelf life.

■ Salmonella-shigella agar

Salmonella-shigella agar is a selective and differential medium used for the isolation and differentiation of *Salmonella* and *Shigella* from clinical specimens and other sources. The nutritive base contains animal and casein peptones and beef extract. The selective agents are bile salts, citrates, and brilliant green dye, which inhibit gram-positive organisms. The high degree of selectivity of the medium inhibits some strains of *Shigella*, and the medium is not recommended as a primary medium for isolation of this species. The medium contains only lactose and thus differentiates organisms on the basis of lactose fermentation. The formation of acid on fermentation of lactose causes the neutral red indicator to make red colonies. Non-lactose-fermenting organisms are clear on the medium. As with Hektoen enteric agar, sodium thiosulfate and ferric ammonium citrate allow the differentiation of organisms that produce hydrogen sulfide. Lactose fermenters, such as *E. coli*, have colonies which are pink with a precipitate, *Shigella* appears transparent or amber, and *Salmonella* appears transparent or amber with black centers. Some strains of *Shigella dysenteriae* are inhibited.

■ Schaedler's agar

Schaedler's agar is a general-purpose medium used for the isolation and cultivation of anaerobic bacteria. The nutritive base includes vegetable and meat peptones, dextrose, and yeast extract. Sheep blood, vitamin K, and hemin provide other additives that stimulate the growth of fastidious anaerobes. Because of the high carbohydrate content, colonies with beta-hemolytic reactions may have a greenish hue. This medium may be better than other nonselective anaerobic media for the isolation of fastidious anaerobic organisms.

■ Schleifer-Kramer agar

Schleifer-Kramer agar is a selective medium used for the isolation of *Staphylococcus* from heavily contaminated specimens such as feces. The nutritional base includes casein

peptones with beef and yeast extracts, glycine, and sodium pyruvate. Sodium azide at 0.45% makes the medium selective for staphylococci and some other gram-positive organisms by inhibiting gram-negative organisms.

■ Selenite broth

Selenite broth is an enrichment broth medium used for the isolation of *Salmonella* and *Shigella* species. Casein and meat peptones provide nutrients. Selenite inhibits enterococci and coliforms that are part of the normal flora if the broth medium is subcultured within 12 to 18 h. However, reduction of selenite produces an alkaline condition that may also inhibit the recovery of *Salmonella*. Lactose and phosphate buffers are added to allow stability of the pH. When fermenting organisms produce acid, the acid neutralizes the effect of the selenite reduction and subsequent alkalinization. Cystine added to selenite broth enhances the recovery of *Salmonella*.

■ Sensitest agar

Sensitest agar is a medium used in susceptibility testing outside of the United States. The base is pancreatic digest of casein, peptones, and glucose with other additives. The medium is available as a premixed powder from Oxoid Unipath. See chapter 70 for specific uses.

■ Septic-Chek biphasic mycobacterial media

The Septic-Chek system (Becton Dickinson Microbiology Systems) is a mycobacterial culture system which contains modified 7H9 broth and three types of solid media, modified Lowenstein-Jensen, Middlebrook 7H11, and chocolate agars, with various supplements.

■ Skirrow medium

Skirrow medium is an enriched selective blood agar medium used for the isolation of *Campylobacter* spp. from specimens with mixed flora. The nutritive base is a blood-based agar. Hematin is provided by sheep blood. The selective agents are trimethoprim, vancomycin, and polymyxin B, which inhibit the normal flora found in fecal specimens.

■ STGG

STGG medium (skim milk, tryptone, glucose, and glycerin) is a transport medium that has been used for collection of nasopharyngeal swabs for the purposes of isolation and preservation of *S. pneumoniae*. Collection and storage of nasopharyngeal swabs on STGG at −70 or −20°C were shown to be equal to direct plating of nasopharyngeal swabs onto selective medium (57).

■ Storage media

See chapter 6.

■ StrepB carrot broth kit (Hardy Diagnostics) and GBS broth (Northeast Laboratory Services)

Carrot broth and GBS broth are media that allow for the detection of red, red-orange, or orange pigment production by beta-hemolytic *S. agalactiae* (GBS) due to the hemolytic reaction with substrates such as starch, protease, peptone, and serum. There is a direct genetic linkage identified with the hemolytic activity and pigment production, with about 95% of GBS strains demonstrating hemolysis. The medium is supplemented with growth-promoting components that are added in the form of a disk (antibiotics). Generation of a bright orange or red color occurs within 6 to 24 h. These media have shown to be very specific, with more rapid turnaround time to detection of GBS than subculture to Lim broth (32). Also see Lim broth.

■ Streptococcus selective agar

Streptococcus selective agar is a selective medium for detection of streptococci. The agar base is Columbia agar. Various antibiotic supplements have been used to make the medium selective for streptococci and reduce the numbers of gram-negative organisms. Colistin and oxolinic acid are one combination less detrimental to *Streptococcus* spp. (42).

■ Stuart's transport media with and without charcoal

Stuart's transport medium is an early transport medium first described in 1948. This medium uses glycerol phosphate to maintain the specimen as well as maintain the pH, agar, methylene blue as a redox indicator, and sodium thioglycolate to allow the survival of anaerobes. The glycerol phosphate has also been found to be used as an energy source by certain contaminants which may overgrow the desired pathogen. Charcoal may be added as a detoxifying agent.

■ Sucrose-phosphate-glutamate transport medium

Sucrose-phosphate-glutamate transport medium is used for the maintenance and transport of *Chlamydia* species and viruses. Sucrose and two buffer solutions are the base. Bovine serum and glutamic acid are additives. Glutamic acid is a stabilizing agent that is especially useful for enveloped viruses. The antibiotic combination may be the same as or slightly different from that in 2-sucrose-phosphate. Most commonly the antibiotic combination is vancomycin, streptomycin, and nystatin, which inhibit both gram-positive and gram-negative organisms, as well as yeasts.

■ 2-Sucrose-phosphate transport media

2-Sucrose-phosphate medium is used for transport of specimens for the purpose of culturing *Chlamydia trachomatis* and *Mycoplasma* spp. Sucrose (0.2 M) and two potassium phosphate buffers are the base. Fetal bovine serum allows *Chlamydia* to maintain infectivity, and nystatin and gentamicin are added to inhibit yeasts and bacteria. 4-Sucrose-phosphate agar and broth (Remel) with a higher concentration of sucrose are also used for the isolation of *Mycoplasma* spp.

■ Tetrathionate broth base

Tetrathionate broth base is an enriched liquid medium used for the isolation of *Salmonella* species in contaminated clinical specimens and other products. The nutritive base includes pancreatic digest of casein and peptic digest of animal tissue with sodium thiosulfate. Bile salts inhibit gram-positive organisms and tetrathionate, which is formed when an iodine-potassium iodide solution is added and which is inhibitory to other normal intestinal flora. Addition of brilliant green inhibits gram-positive and gram-negative organisms, including some *Salmonella* spp.

■ Thayer-Martin agar

Thayer-Martin agar is an enriched and selective medium used for the isolation of *Neisseria* from clinical specimens with mixed flora. The nutritive base is chocolate agar, which is a GC agar base with casein and meat peptones, cornstarch for the neutralization of fatty acids, and phosphate buffer for control of the pH. The chocolate agar occurs with the addition of hemoglobin, which provides hemin or X factor, and IsoVitaleX enrichment, which provides NAD, vitamins, and other nutrients, to improve the growth of pathogenic *Neisseria*. The medium is made selective by the addition of vancomycin, colistin, and nystatin, which inhibit the normal flora of gram-positive bacteria, gram-negative bacteria, and fungi, respectively. Some strains of pathogenic *Neisseria* have been reported to be inhibited by vancomycin and trimethoprim. See also Modified Thayer-Martin agar and Martin-Lewis agar.

■ Thioglycolate with hemin and vitamin K

Thioglycolate broth with hemin and vitamin K is an enriched liquid medium used to support the growth of microaerophilic and anaerobic organisms, including fastidious organisms. Casein and soy peptones supply the basic nutrients. Sodium thioglycolate and L-cystine are the reducing agents in the medium, while hemin and vitamin K are additional additives that allow more fastidious anaerobes to thrive. A small amount of agar helps to slow the diffusion of oxygen and is more suitable for anaerobic organisms.

■ Thiosulfate citrate bile salt sucrose (TCBS)

TCBS is a highly selective and differential medium for the recovery of *Vibrio* spp. except *Vibrio hollisae* and *Vibrio cincinnatiensis.* The medium is inhibitory to gram-positive organisms by incorporation of oxgall, a naturally occurring substance containing a mixture of bile salts and sodium cholate, a pure bile salt. Peptic and casein digests are the nutritive base, and sucrose is a fermentable carbohydrate for the metabolism of *Vibrio*. Sodium thiosulfate provides a sulfur source, and ferric citrate detects hydrogen sulfide production. Bromthymol blue and thymol blue are the pH indicators. Alkaline pH enhances the recovery of *Vibrio cholerae*. Color appearance on the agar is dependent on the species. See chapter 47.

■ Tinsdale agar

See Cystine-tellurite blood agar.

■ Todd-Hewitt broth with gentamicin and nalidixic acid

Todd-Hewitt broth is used for the isolation of beta-hemolytic streptococci from mixed flora, especially vaginal specimens for GBS. Beef heart infusion and peptone are the nutritive base, with dextrose as the energy source and sodium-based buffers to protect the hemolysin from inactivation. The antibiotics make the medium selective by inhibiting gram-negative rods.

■ Tryptic or Trypticase soy agar base with 5% sheep blood

Tryptic or Trypticase soy agar base with 5% sheep blood is a general-purpose medium used for the isolation of a wide variety of organisms. The medium contains soybean and casein peptones as the nutritive base. The addition of sheep blood enriches the medium, and the sheep blood allows the growth of more fastidious organisms by providing hemin (X factor). V factor (NAD) is inactivated by enzymes in the sheep blood and thus does not allow the growth of organisms that require the NAD additive, such as *H. influenzae*. The use of sheep blood provides an excellent means of interpretation of hemolytic reactions, especially those of *Streptococcus* spp.

■ Tryptic or Trypticase soy broth

Tryptic or Trypticase soy broth is a general-purpose clear liquid medium used for the cultivation of a wide variety of organisms. It is also recommended by the CLSI for preparation of an inoculum for Kirby-Bauer disk diffusion susceptibility testing and is the CLSI's choice as a sterility testing medium. The base includes digests of casein and soybean, with additional additives of glucose, sodium chloride to maintain osmotic equilibrium, and buffers. For the purpose of a blood culture medium, additional additives include carbon dioxide to enhance the growth of microorganisms and SPS, an anticoagulant, to inactivate blood components and aminoglycosides. Formulations with 6.5% NaCl exist for the purposes of differentiating enterococcal species or salt-tolerant streptococci. Fildes enrichment is added to cultivate fastidious organisms such as *Haemophilus* spp.

■ Trypticase soy agar with horse or rabbit blood

Trypticase soy agar with horse or rabbit blood medium is used for the isolation of *Haemophilus* species. The nutritive base is a combination of soy and casein peptones. The medium provides smaller but adequate amounts of X (hemin) and V (NAD) factors compared to the amounts in sheep blood and is used for the isolation of *Haemophilus* species. In addition, the medium with horse or rabbit blood allows determination of hemolytic reactions.

■ University of Vermont modified listeria enrichment broth

University of Vermont modified listeria enrichment broth is an enriched and selective liquid medium used for the isolation of *L. monocytogenes*. The nutritive base contains pancreatic digest of casein and animal tissue and beef and yeast extract and is supplemented with esculin, acriflavine, and nalidixic acid.

■ V agar

V agar is an enriched and selective medium used for the isolation of *G. vaginalis* from clinical specimens. The nutritive base is GC agar. The addition of 2% hemoglobin, 5% fetal bovine serum, and a supplement containing NAD enhances the recovery of the organism. Vancomycin (3 μg/ml) is added to the medium to inhibit contaminating bacteria. Many formulations with the GC agar base, the enrichments, and vancomycin exist.

■ VMGA III medium

VMGA III (viability medium, Göteborg, anaerobic) is a transport and collection medium specifically designed to maintain viability of mixed anaerobes from peridontal and endodontal sites. The medium is particularly useful for transport of paper

points that are placed in gingival crevices to soak up secretions. A total of 0.5 to 2.0 ml of prereduced, buffered salt suspension is placed into a tube of similar total volume (2 ml) with or without six to eight glass beads (0.1 to 1.5 mm in diameter). The beads aid in dispersing polysaccharide matrices that occur within gingival plaques and granular aggregates (39).

■ Wadowsky-Yee medium

See Buffered charcoal yeast extract (BCYE).

■ Wilkins-Chalgren broth and agar

Wilkins-Chalgren medium is recommended for susceptibility testing with anaerobic organisms. The medium contains specific nutrients that support the growth of anaerobes such as yeast extract, vitamin K, hemin, and arginine. The use of peptones allows a more standardized medium.

■ Xylose-lysine-desoxycholate agar

Xylose-lysine-desoxycholate agar is a selective and differential medium used for the isolation and differentiation of enteric pathogens from clinical specimens. The nutritive base includes carbohydrates and yeast extract. This medium is more supportive of fastidious enteric organisms such as *Shigella*. The selective agent is desoxycholate, which inhibits gram-positive organisms. Phenol red is the color indicator. As with Hektoen enteric and salmonella-shigella agars, ferric ammonium citrate (indicator) and sodium thiosulfate (sulfur source) allow identification of organisms that produce H_2S with the appearance of colonies with a black center. The medium contains xylose, which most enteric organisms ferment. The most important exception is *Shigella*, the colonies of which appear to be transparent or the color of the red media. The enteric organisms that contain the lysine decarboxylase enzyme utilize the lysine in the medium. For *Salmonella*, which contains the lysine enzyme, this reaction reverts the pH to an alkaline state and the colony appears to be transparent or red with a black center. The lactose and sucrose in the medium help to differentiate other enteric organisms. When other enteric organisms ferment these sugars, they maintain the pH at an acidic condition and the colonies appear yellow or yellow-red. A number of other similar media for isolation of enteric pathogens exist, including xylose-galactosidase medium, which is more specific for *Aeromonas* spp. See chapters 43 and 46, which give specific references for performance of the various xylose-containing media.

■ Yersinia selective agar

See Cefsulodin-Irgasan-novobiocin medium.

APPENDIX 1
Medium Additives

N-(2-Acetamido)-2-aminoethanesulfonic acid (ACES): allows optimal pH buffering capacity without inhibition of bacteria as seen with other inorganic buffers

Acriflavine: selective agent; suppresses gram-positive organisms

ADC enrichment: a supplement added to mycobacteriology media that includes albumin, dextrose, catalase, and sodium chloride; catalase destroys peroxides that may be in the medium

Agar used in broth medium (0.05 to 0.1%): used to reduce O_2 tension

Albumin: protects against toxic by-products in medium; binds free fatty acids

Antibiotics: one or many may be added to make a medium selective; inhibitory capacity may vary depending on the concentration used

Bicarbonate-citric acid pellet: used to generate CO_2 gas within closed environment after exposure to moistures; used in transport devices for isolating *Neisseria gonorrhoeae*

Bismuth sulfite: heavy metal that is inhibitory to commensal organisms

Carbohydrates: energy source; used to make medium differential when combined with an indicator

Cetrimide: acts as a quaternary ammonium cationic detergent that causes nitrogen and phosphorus to be released from bacterial cells other than *Pseudomonas aeruginosa*

Charcoal: detoxifying agent, surface tension modifier, scavenger of radicals and peroxides

Cornstarch: works as a detoxifying agent; may provide additional nutrients as an energy source

Dent's supplement (Oxoid): vancomycin, trimethoprim, cefsulodin, and amphotericin B added to Columbia blood agar and laked horse blood for isolation of *Helicobacter*

Dextrose: makes the medium hypertonic; energy source

Egg yolk: used to demonstrate lecithinase, lipase, and proteolytic activities and fatty acids

Ferric ammonium citrate: iron salt used in combination with other agents (esculin, sodium thiosulfate) to make medium differential by producing a black precipitate

Fildes enrichment: peptic digest of sheep blood that provides a rich source of nutrients, including X (hemin) and V (NAD) factors; X originally stood for unknown and V originally stood for vitamin

Glycerol: a purified alcohol and an abundant source of carbon; used in culture, transport, and storage medium and reagent preparation

Glycine: a selective agent that is inhibitory to organisms

Horse serum: an enrichment used in growth media for such organisms as *Mycoplasma* and *Ureaplasma*

IsoVitaleX (BBL): provides V factor (NAD) and additional nutritive ingredients, such as vitamins, amino acids, ferric ion, and dextrose, to stimulate growth of fastidious organisms

Laked blood or laked horse blood: created by freeze-thaw cycles of blood; enhances pigment production of anaerobes and used in susceptibility testing of fastidious organisms

Lithium chloride: a selective agent that inhibits organisms

Malachite green: a dye that partially inhibits bacteria

NAD (V factor): necessary for growth of some fastidious organisms

OADC enrichment: a supplement added to mycobacteriology media that includes oleic acid, albumin, dextrose, catalase, and sodium chloride; the oleic acid provides fatty acids utilized by mycobacteria, and the catalase destroys peroxides that may be in the medium

Oxgall (bile): inhibits specific organisms; allows medium to be selective

Peptones: carbohydrate-free source of nutrients

Phenylethyl alcohol: reversibly inhibits DNA synthesis; results in inhibition of facultative anaerobic gram-negative organisms

Pyridoxal: liquid supplement added to media for isolation of fastidious organisms; also comes in the form of a disk to be used in satelliting tests

Rabbit blood: enhances pigment production of anaerobes; hemolytic reactions of streptococci are "correct"; additive to heart infusion agar for isolation of *Bartonella* spp.

Serum: albumin, fatty acids

Sheep blood and human blood: provide hemin and other nutrients; allow true hemolytic reactions of streptococci; NADase enzyme inactivates the NAD in the sheep blood and is not available for organisms

Skirrow's supplement: vancomycin, trimethoprim, and polymyxin B added to Columbia agar and laked horse blood for isolation of *Helicobacter*

Sodium azide: a selective agent that inhibits gram-negative organisms

Sodium bicarbonate: neutralization agent used with gastric wash or lavage specimens for recovery of acid-fast organisms
Sodium bisulfite: disinfectant, antioxidant, or reducing agent
Sodium chloride: maintains osmotic equilibrium; when added at a high concentration it may be a selective agent
Sodium citrate: a selective agent inhibitory to organisms
Sodium desoxycholate: a salt of bile acid and a selective agent that inhibits gram-positive and spore-forming organisms
Sodium polyanetholesulfonate (SPS): a polyanionic anticoagulant that inactivates aminoglycosides and interferes with the complement cascade, lysozyme activity, and phagocytic activity inherent in blood. May be inhibitory to *Neisseria, Gardnerella, Streptobacillus, Peptostreptococcus, Francisella,* and *Moraxella* spp.
Sodium pyruvate: growth stimulant
Sodium selenite: a selective agent that inhibits coliforms
Sodium thioglycolate: a reducing agent
Starch: a polysaccharide and detoxifying agent incorporated into some media as a differential agent
Tellurite: is toxic to egg-clearing strains of bacteria; imparts black color to colony
Tween 80 (polysorbate 80): an oleic acid ester that stimulates growth and provides fatty acids as well as acts as a dispersal agent
Vitamin K: ingredient required for optimal growth of certain obligate anaerobes, such as the *Bacteroides* group
Vitox (Oxoid): provides V factor (NAD) and other essential growth factors to stimulate growth of fastidious organisms; see IsoVitaleX.
Yeast extract: water-soluble product that provides B vitamins and protein

Algorithm for Identification of Aerobic Gram-Positive Cocci

KATHRYN L. RUOFF

22

Most gram-positive cocci recovered from aerobic cultures can be differentiated with the tests shown in Tables 1 and 2. These organisms include "aerotolerant anaerobes," facultative anaerobes, microaerophiles, and obligate aerobes. The genera display various colony morphologies and hemolytic and catalase reactions (Tables 1 and 2). Their cellular morphologies as revealed by Gram staining of broth cultures are generally either streptococcal, in which gram-positive cocci or coccobacilli are arranged in pairs and/or chains, or staphylococcal, in which cells appear as cocci arranged in pairs, tetrads, clusters, and irregular groups. No taxonomic kinship is implied by division of these bacteria into two groups based on cellular morphology. As new genera and species are described and characterized, it becomes increasingly difficult to identify some of the less frequently isolated organisms solely on the basis of phenotypic traits. The reader is referred to the chapters noted in the tables for more detailed descriptions of these organisms.

TABLE 1 Characteristics of catalase-negative gram-positive cocci that grow aerobically and form cells arranged in pairs and chains[a]

PYR	LAP	6.5% NaCl	BE	Motility	45°C	Probe	HIP	Satellitism	10°C	Vancomycin resistance	Organism(s) (chapter)
+	+	+	+	+	+						*Enterococcus* (30)
					−						*Vagococcus* (31)
				−		+					*Enterococcus* (30)
						−					*Lactococcus* (31)
			−				+	−			*Facklamia* spp.[b] (31)
							−	V			*Ignavigranum* (31)
		−	+	+							*Vagococcus* (31)
				−							*Lactococcus* (31)
			−					+			*Abiotrophia, Granulicatella* (31)
								−			*Gemella* spp.[c] (31)
	−	+									*Globicatella* (31)
		−									*Dolosicoccus* (31)
−	−									+	*Leuconostoc*[d] (31)
										−	*Globicatella* (31)
	+								+		*Lactococcus* (31)
									−		*Streptococcus*[e] (29)

[a] See chapters 21 and 29 to 31 for descriptions of the methods for performing the tests referred to in this table. Reactions shown are typical, but exceptions may occur. Abbreviations, terms, and symbols: PYR, production of pyrrolidonyl arylamidase; LAP, production of leucine aminopeptidase; 6.5% NaCl, growth in 6.5% NaCl; BE, hydrolysis of esculin in the presence of 40% bile; 45°C, growth at 45°C; probe, reaction with commercially available nucleic acid probe for the genus *Enterococcus;* HIP, hydrolysis of hippurate; satellitism, satelliting growth behavior; 10°C, growth at 10°C; +, most strains positive; −, most strains negative; V, variable reactions are observed.

[b] The reactions listed in this table are typical for *F. hominis, F. sourekii,* and *F. ignava. F. languida* cells tend to be arranged in clusters, and isolates are hippurate hydrolysis negative (Table 2).

[c] G. *morbillorum,* G. *bergeri,* and G. *sanguinis* cells tend to be arranged in pairs and chains, in contrast to the cells of G. *haemolysans,* which are arranged in pairs, tetrads, and clusters (Table 2).

[d] *Leuconostoc* is distinguished from the other catalase-negative organisms in Table 1 by its ability to produce gas as an end product of glucose metabolism and by its intrinsic resistance to vancomycin. The phenotypically similar genus *Weissella* contains organisms formerly classified as leuconostocs and the species formerly named *Lactobacillus confusus* (see chapter 31).

[e] Most streptococci are PYR negative, with the exception of *S. pyogenes* isolates and some strains of *S. pneumoniae,* which are PYR positive.

TABLE 2 Differentiating features of gram-positive cocci that grow aerobically and form cells arranged in clusters or irregular groups[a]

Catalase	Obligate aerobe	Oxidase	PYR	LAP	NaCl	ESC	Hemolysis	Vancomycin resistance	BGUR	Organism (chapter)
+	+	+			+[b]					*Micrococcus* (28)
		−			+[c]					*Alloiococcus* (28)
	−	−			+[b]					*Staphylococcus* (28)
					−[b]					*Rothia mucilaginosa*[d] (28, 34)
−	−		+	+	+[c]	+			−	*Dolosigranulum* (31)
									+	*Aerococcus sanguinicola* (31)
						−			−	*Facklamia languida*[e] (31)
					−[c]	+				*Rothia mucilaginosa*[d] (28, 34)
						−				*Gemella haemolysans*[f] (31)
				−			α			*Aerococcus viridans*[g] (31)
							γ			*Helcococcus kunzii*[g] (31)
			−	+				R		*Pediococcus*[h] (31)
								S	+	*Aerococcus urinae* (31)
				−					+	*Aerococcus urinaehominis* (31)
									−	*Aerococcus christensenii* (31)

[a] See chapters 21, 28, and 31 for descriptions of methods for performing the phenotypic tests referred to in this table. Reactions shown are typical; exceptions may occur. Abbreviations and symbols: PYR, production of pyrrolidonyl arylamidase; LAP, production of leucine aminopeptidase; NaCl, growth in the presence of either 5 or 6.5% NaCl (see footnotes *b* and *c*); ESC, esculin hydrolysis; BGUR, production of β-glucuronidase; +, most strains positive; −, most strains negative; V, variable reactions are observed; α, alpha-hemolysis on sheep blood agar; γ, nonhemolytic reaction on sheep blood agar; S, susceptible; R, resistant.

[b] Growth in the presence of 5% sodium chloride.

[c] Growth in the presence of 6.5% sodium chloride.

[d] *R. mucilaginosa* isolates are usually catalase negative or weakly positive but may be strongly catalase positive.

[e] *Ignavigranum ruoffiae* (Table 1) exhibits reactions identical to those of *F. languida* in the PYR, ESC, and NaCl tests. However, *I. ruoffiae* cells are arranged primarily in chains and *F. languida* cells usually form clusters. Other *Facklamia* species form cells arranged in pairs and chains (Table 1).

[f] *G. haemolysans* cells tend to be arranged in pairs, tetrads, and groups, in contrast to the cells of other *Gemella* species, which usually occur in pairs and short chains (Table 1).

[g] *H. kunzii* strains form tiny, pinpoint, nonhemolytic colonies on blood agar after 24 h of aerobic incubation at 35°C, and *A. viridans* isolates form larger, alpha-hemolytic colonies under similar incubation conditions. In contrast to *H. kunzii, A. viridans* prefers aerobic incubation atmospheres. Two additional species of *Helcococcus* isolated from human sources have been described, each based on a single isolate. In contrast to *H. kunzii,* the new species *H. sueciensis* and the proposed species "*H. pyogenes*" are PYR negative (see chapter 31).

[h] The genera *Pediococcus* and *Tetragenococcus* have similar phenotypic characteristics, except that tetragenococci are vancomycin susceptible. The bile esculin test can differentiate between tetragenococci (positive) and *Aerococcus urinae* (negative); see chapter 31.

Algorithm for Identification of Aerobic Gram-Positive Rods

GUIDO FUNKE

23

The aim of the algorithm for the identification of aerobic gram-positive rods described in this chapter is simply to guide the reader to the appropriate chapter of this Manual for further information. The algorithm emphasizes that Gram stain (performed on 24- to 48-h-old colonies from rich media) and macroscopic morphologies are the initial key features for the differentiation of aerobic gram-positive rods. All strains of aerobic gram-positive rods (except the non-rapidly growing mycobacteria) are initially grown on blood agar plates.

Regular rods are organisms with cells whose longitudinal edges are usually not curved but are parallel. If spore formation is not observed initially, it can be tested for on a nutritionally depleted medium. Catalase activity should be tested with colonies from media lacking heme groups. The type of metabolism can be checked in oxidative-fermentative media or in cystine Trypticase agar medium. Irregular rods are organisms with cells whose longitudinal edges are curved and not parallel. Diagnostic end products of glucose metabolism are detected by chromatographic methods. Slight beta-hemolysis is best observed when cells are incubated in a CO_2-enriched atmosphere. Yellow- or orange-pigmented colonies are always composed of irregular rods. Some genera that stain partially acid-fast (e.g., *Gordonia* and *Rhodococcus*) may also show a yellow-orange pigment. Rods exhibiting vegetative substrate filaments may show branched hyphae, which either form spores or reproduce by fragmentation. It is obvious that vegetative substrate filaments might not be present initially (i.e., within 48 h), and so these organisms are prone to initial misidentification.

For the yellow-orange genera (e.g., *Microbacterium, Curtobacterium,* and *Leifsonia*), as well as the rods exhibiting vegetative substrate filaments, chemotaxonomic methods must very often be used for definitive identification to the genus level; for example, partially acid-fast bacteria can be identified to the genus level by analysis of mycolic acids.

Genera which contain strict anaerobic gram-positive rods may also contain aerobically growing species. This is particularly true for the genus *Actinomyces* (as it is presently defined). *Clostridium tertium* (a strong gas producer) may also grow aerobically. Furthermore, some aerobic gram-positive cocci (e.g., *Leuconostoc* spp. or *Streptococcus mutans*) might initially be misidentified as gram-positive rods because of their initial Gram stain appearance. Likewise, but less frequently, some gram-positive rods (e.g., *Rhodococcus* spp.) might be initially misidentified as gram-positive cocci because of their initial Gram stain appearance.

This algorithm should serve only as the basis of a preliminary identification of an unknown aerobic gram-positive rod, and the reader is referred to the chapters given in Table 1 for further information.

TABLE 1 Algorithm for identification of aerobic gram-positive rods

Cellular morphology	Yellow-orange pigment	Vegetative substrate filaments	Spore formation	Catalase	Metabolism[a]	H_2S in TSI	Other unusual Gram stain feature	Diagnostic end product of glucose metabolism[b]	Slight beta-hemolysis	Slow acid production	Acid-fast stain	Partially acid-fast stain	Aerial vegetative filaments	Motility	Growth at 50°C	Organism (chapter)
Regular			+													*Bacillus,* including *Paeni-*, *Brevi-*, *Aneurini-*, and *Virgibacillus* (32)
			−	+	O											*Kurthia*
					F											*Listeria* (33)
				−		+										*Erysipelothrix* (33)

Algorithms for Identification of Aerobic Gram-Negative Bacteria*

PAUL C. SCHRECKENBERGER AND DAVID LINDQUIST

24

These algorithms are meant to assist in the identification of organisms that are not readily identified by methods in place in most clinical laboratories. Microbiologists planning to identify an unknown gram-negative rod begin with colonies on an agar plate. Our definition of "good growth on blood agar plate (BAP)" is the presence of distinct colonies (approximately 1 mm) on Trypticase soy agar with 5% sheep blood after 24 h of incubation at 35°C in room atmosphere. Poor growth indicates that more than 24 h of incubation is necessary for the development of distinct colonies. If an organism fails to grow on BAP after 72 h, it is considered to show "no growth." Morphological and phenotypic criteria were chosen not only for their discriminatory value but also because the methods are available in most laboratories. Cellular morphology is determined by using a Gram stain from a young colony on a BAP. The description of "tiny coccobacilli" used for *Brucella* and *Francisella* in Table 2 implies almost indiscernible cells resembling grains of sand. For many organisms with pleomorphic morphologies, we chose to represent the dominant shape.

The urea test refers to conventional Christensen's urea reaction after 24 h of incubation, whereas the rapid urea result is read after 4 h. Glucose fermentation refers to an acid reaction in the butt of a Kligler iron agar (KIA) or triple sugar iron agar (TSI) tube. "Glucose oxidized" refers to acid production in the upper portion of oxidative-fermentative (OF) media. "BHI+serum" refers to brain heart infusion agar with 10% (vol/vol) serum added. The oxidase test refers to results obtained with the *N,N,N,N*-tetramethyl-*p*-phenylenediamine dihydrochloride reagent. Motility is best observed by preparing a wet preparation from a young colony on a BAP. Decarboxylase reactions are determined by using an extremely turbid inoculum in Moeller's media (heavier than usual inoculum). Polymyxin B sensitivity is indicated by any zone of inhibition surrounding a 300-U disk on a BAP. For glucose-nonfermenting rods and other fastidious organisms, the indole test is performed using the Ehrlich's extraction method (see chapter 50). "Esculin" refers to hydrolysis of esculin in media without bile.

These algorithms are dichotomous, since many organisms may fall into more than one group due to phenotypic variability of a given trait. The presence of two or more atypical traits or a major variation from the ideal phenotype depicted in an algorithm, due to antibiotic use, auxotrophy, or other reasons, may limit the algorithm's utility. These algorithms are intended as a guide to presumptive identification of an unknown isolate. The reference chapter describing the organism should be consulted to determine the definitive identification. To use the algorithms, start with Table 1 for gram-negative bacteria that grow well on blood agar in 24 h at room atmosphere and Table 2 for fastidious gram-negative bacteria. Note that Table 1 consists of three parts, which we have designated Table 1a, Table 1b, and Table 1c. In each case begin in the upper left-hand column of the table; if the test organism matches the given characteristic, then continue horizontally to the right to the next reaction. If the reaction in the box matches your test organism, continue moving horizontally until you reach the organisms listed in the right-hand column. When the reaction in the box does not match your test organism, then move down the column vertically to find the reaction that matches. Repeat the process until you reach the right-hand column. Be sure to check all your reactions with the organism characteristics given in the referenced chapter.

*This chapter contains information presented in chapter 23 by Paul C. Schreckenberger and Jane D. Wong in the eighth edition of this Manual.

Algorithm for Identification of Anaerobic Bacteria

DIANE M. CITRON

25

Anaerobic bacteria are defined for the purposes of this algorithm as organisms displaying better growth when incubated in an anaerobic environment than in the presence of oxygen. The use of selective and differential agars for the primary setup of clinical specimens and prompt incubation in an anaerobic environment can provide rapid presumptive identification of important groups of anaerobes based on distinctive characteristics, such as bile resistance, pigmented colonies, a double zone of beta-hemolysis, or the presence of fusiform cells on Gram stain. Examples of such agars include Bacteroides-bile-esculin (BBE) for isolation and presumptive identification of the *Bacteroides fragilis* group and *Bilophila wadsworthia*. Brucella agar supplemented with laked blood, kanamycin, and vancomycin inhibits enteric and gram-positive organisms and is thus useful for isolation and characterization of *Bacteroides, Prevotella,* and some strains of fusobacteria. Pigmented *Prevotella* spp. produce pigment more rapidly and intensely on laked blood agar. Phenylethyl alcohol blood agar (PEA) and colistin nalidixic acid blood agar inhibit enteric organisms and swarming *Proteus* spp. but allow for growth and isolation of many gram-positive and gram-negative anaerobes. PEA also inhibits the swarming by *Clostridium septicum,* which can completely overgrow and contaminate other anaerobic organisms in a mixed culture. All media for culture of anaerobes should be supplemented with vitamin K_1 and hemin.

Simple tests, such as tests for susceptibility (inhibition zone diameters, $\geq$10 mm) to the special potency disks with 1,000 μg of kanamycin, 5 μg of vancomycin, and 10 μg of colistin; tests for growth in the presence of 20% bile; the spot indole test; and tests for nitrate reduction, catalase and urease production, and lecithinase and lipase production on egg yolk medium are rapid and useful for initial grouping of many anaerobes (1).

The gram-positive non-spore-forming rods are difficult to group by simple tests. Nitrate-reducing strains include *Actinomyces, Propionibacterium,* and some of the *Eubacterium*-like group members. Most *Propionibacterium* spp. and some species of *Actinomyces* are catalase positive. Lactobacilli and bifidobacteria do not reduce nitrate and are catalase, urease, and indole negative.

The genus *Clostridium* includes the gram-positive spore-forming rods; however, many members of this group appear to be gram negative, and spores can be difficult to see under routine conditions. While many species require extensive testing for complete identification, some very clinically important species can be recognized by easily observable characteristics.

Anaerobic bacteria are a diverse group of organisms and include members that often exhibit seemingly contradictory characteristics, such as gram-negative rods sensitive to vancomycin (certain clostridia, *Porphyromonas* spp.), gram-positive rods resistant to vancomycin (some lactobacilli), or rods that appear as cocci (some *Prevotella* and *Porphyromonas* spp.). The algorithm in Table 1 includes characteristics that should be helpful for suggesting the correct category for anaerobes encountered in clinical specimens.

Algorithms for Identification of Curved and Spiral-Shaped Gram-Negative Rods*

IRVING NACHAMKIN

26

Curved and spiral-shaped bacteria have a common microscopic morphology but represent diverse bacterial pathogens (Table 1). These organisms are curved, helical, or spiral-shaped gram-negative rods. Specific detection of these organisms may require a combination of tests including microscopy, histologic staining of tissue, biochemical tests, antigen tests, serologic tests, bacteriologic culture, and molecular approaches (Fig. 1).

Most bacteria in this group of organisms are isolated from patients with gastrointestinal and related infections. *Campylobacter jejuni* subsp. *jejuni* is the most frequently isolated curved gram-negative rod associated with diarrheal illness, but under proper culture conditions, other *Campylobacter* spp., *Helicobacter* spp., and *Vibrio* species may be detected in routine stool cultures. *Helicobacter pylori* is the most common curved gram-negative rod isolated from gastric tissue, but other *Helicobacter* species have also been reported in this site.

Other less commonly isolated curved gram-negative rods include the anaerobes *Desulfovibrio* spp., *Sutterella wadsworthensis, Wolinella succinogenes,* and *Anaerobiospirillum succiniciproducens,* which may be isolated from blood, abscess material, or other clinical samples. Several oxidase-positive nonfermenters may also have a curved appearance, including *Laribacter hongkongensis, Herbaspirillum* species 3, and CDC O-3 (see chapter 50).

The spirochetes *Borrelia* spp. and *Leptospira* spp. cause systemic infections and are infrequently isolated in clinical laboratories, usually only with specialized media. These bacteria are strictly aerobic and have optimal growth temperatures at 28 to 30°C (*Leptospira* spp.) and 30 to 33°C (*Borrelia* spp.). *Treponema* spp. of clinical importance are identified based on clinical and epidemiologic findings, as well as microscopic, serologic, and molecular test procedures.

* This chapter contains information presented in chapter 25 by James Versalovic in the eighth edition of this Manual.

TABLE 1 Curved gram-negative bacilli that may be encountered in clinical specimens[a]

Clinical finding	Specimen type(s)	Curved gram-negative organisms encountered		Microscopic appearance in specimen	Culture conditions and media	Chapter
		Genus or group	Species			
Gastroenteritis	Stool; intestinal biopsy specimen	*Arcobacter*	*A. butzleri*, *A. cryaerophilus*, *A. skirrowii*	Slightly curved, curved, S-shaped, or helical	Microaerobic, may grow aerobically or anaerobically, nonhemolytic, grows on nonselective blood agar (with filtration method), may grow on Campy-CVA	59
		Brachyspira	*B. aalborgi*, *B. pilosicoli*	Spirochete	Anaerobic, prolonged incubation (1–2 weeks) on anaerobic media, selective media may be required	58
		Campylobacter	*C. jejuni* subsp. *jejuni*, *C. jejuni* subsp. *doylei*, *C. coli*, *C. upsaliensis*, *C. fetus* subsp. *fetus*, *C. lari*, *C. curvus*, *C. rectus*, *C. hominis*, *C. lanienae*, *C. hyointestinalis*, *C. sputorum*	Curved, spiral, gull, S-shaped GNR	Microaerobic, 37 or 42°C, increased H_2 required for some non-*C. jejuni*/*C. coli* species, selective media required such as Campy-CVA, charcoal-based media such as CCDA; filtration method for less common species and H_2-requiring species	59
		Helicobacter (Gastric) (Intestinal)	*H. pylori*, *H. bizzozeronii*, *H. canis*, *H. canadensis*, *H. cinaedi*, *H. fennelliae*, *H. pullorum*, *Helicobacter* spp. and flexispira taxon 8	Curved, spiral, gull, S-shaped GNR	Microaerobic, 37°C, increased H_2 required for intestinal species, nonselective blood agar for *H. pylori*, selective supplements (Skirrows, Dents) may be needed for contaminated gastric samples	60
		Laribacter	*L. hongkongensis*	Gull or spiral-shaped	Asaccharolytic nonfermenter, aerobic growth on blood agar, MacConkey agar	50
		Vibrio	*V. cholerae*, *V. parahaemolyticus*, *V. fluvialis*, *V. alginolyticus*, *V. cincinnatiensis*, *V. damsela*, *V. furnissii*, *V. hollisae*, *V. metschnikovii*, *V. mimicus*	Comma-shaped or plain rods, larger than *Campylobacter*	Aerobic conditions, 37°C, grows on routine laboratory media, blood agar, MacConkey agar; use selective medium such as TCBS for primary isolation from stool samples	47
Bacteremia	Blood	*Borrelia* Lyme group	*B. afzelii*, *B. burgdorferi*, *B. garinii*	Not seen in routine BC bottles	Difficult to isolate, special media required for isolation; BSK, MKP	62
		Relapsing fever group	*B. recurrentis*, *B. miyamotoi*, *B. lonestari*, *B. hermsii*			

(Continued on next page)

TABLE 1 *(Continued)*

Clinical finding	Specimen type(s)	Curved gram-negative organisms encountered		Microscopic appearance in specimen	Culture conditions and media	Chapter
		Genus or group	Species			
		Campylobacter	*C. jejuni* subsp. *jejuni*, *C. fetus* subsp. *fetus*, *C. upsaliensis*, *C. lari*, *C. concisus*	Curved, spiral, gull, S-shaped GNR	Microaerobic, incubate subcultures at 37°C, increased H_2 required for some non-*C. jejuni*/*C. coli* species	59
		Herbaspirillum	*Herbaspirillum* species 3 (formerly EF-1)	Curved or helical GNR	Growth properties not described	50
		Helicobacter	*H. cinaedi*, *H. fennelliae*	Curved, spiral, gull, S-shaped GNR	Microaerobic, incubate subcultures at 37°C, increased H_2 required	60
		Leptospira	*L. biflexa*, *L. interrogans*	Not seen in routine BC bottles but may be seen in direct wet preparations of anticoagulated blood	Aerobic growth, 28–30°C, specialized media required for isolation such as EMJH, PLM-5	61
		Vibrio	*V. vulnificus*, *V. damsela*, *V. metschnikovii*, *V. cincinnatiensis*	Comma-shaped or straight rods	Aerobic growth, 37°C, grows on routine blood agar, MacConkey agar	47
		CDC O-3		Thin, medium to slightly long curved rods with tapered ends	Saccharolytic nonfermenter, no growth or poor growth on MacConkey agar, grows on Campy-CVA medium	50
		Spirillum	"Spirillum minus"	Not seen in routine BC bottles	Cannot be cultured in vitro	
Tissue infection, oral	Tissue biopsy specimen, abscess fluid	*Campylobacter*	*C. concisus*, *C. curvus*, *C. rectus*, *C. gracilis*, *C. showae*	Curved, spiral, gull, S-shaped GNR	Microaerobic, incubate cultures at 37°C, increased H_2 required for oral species, use nonselective blood agar or CCDA with filtration method	59
Tissue infection, skin, wound, other	Skin biopsy specimen, lesion fluid	*Borrelia*	Lyme group spp.	Histologic stains required	Difficult to isolate, special media required for isolation; BSK, MKP	62
		Treponema	*T. pallidum* subsp. *pallidum* (syphilis), *T. carateum* (pinta), *T. pallidum* subsp. *pertenue* (yaws), *T. pallidum* subsp. *endemicum* (endemic)	Spirochetes; silver stain; dark-field; DFA	Has not been isolated in vitro	63
		Vibrio	*V. vulnificus*, *V. damsela*, *V. alginolyticus*, *V. harveyi*	Comma-shaped or straight rods, larger than *Campylobacter* spp.	Aerobic, grows on routine laboratory media, blood agar, MacConkey agar	47

Algorithms for Identification of *Mycoplasma, Ureaplasma,* and Obligate Intracellular Bacteria

J. STEPHEN DUMLER

27

The bacteria discussed in chapters 64 to 69 differ from bacteria described in other parts of this Manual by several characteristics, including lack of efficient characterization with the Gram stain method and except for *Mycoplasma* and *Ureaplasma* species, the requirement for intracellular growth. Thus, the most frequently used tests in clinical microbiology laboratories, the Gram stain and culture on artificial media, are unable to detect these organisms in clinical samples. Diagnosis of infections caused by these bacteria has traditionally been accomplished by Romanowsky staining (Giemsa and Wright stains) of clinical samples, by detection of antibody responses to infection using a variety of serological tests, or by histopathologic analysis of biopsy samples. Molecular diagnostic tools and better culture methods have significantly improved the ability to detect these agents and to diagnose the diseases that they cause. For some of these infections, molecular tools are becoming standard practice. The following tables summarize the epidemiology of these infections (Table 1) and the diagnostic tests most often used for the detection of the causative bacteria (Table 2).

TABLE 1 Epidemiology and clinical disease associated with *Anaplasma, Chlamydia, Chlamydophila, Coxiella, Ehrlichia, Mycoplasma, Rickettsia, Tropheryma,* and *Ureaplasma* infections

Organism	Disease	Reservoir	Vector and mode of transmission
Anaplasma phagocytophilum	Human granulocytotropic anaplasmosis (HGA); fever, headache, myalgia, systemic involvement except for central nervous system	White-footed mouse, other small mammals, ruminants, deer	*Ixodes scapularis* (deer or black-legged tick), *I. pacificus* (western black-legged tick), *I. ricinus* (rabbit tick), and *I. persulcatus* tick bites
Chlamydia trachomatis	Endemic trachoma, inclusion keratoconjunctivitis, urethritis, epididymitis, endometritis, salpingitis, perihepatitis, pneumonia, lymphogranuloma venereum	Humans	Sexual contact, hand-eye contact, insect fomites, infected birth canal
Chlamydophila pneumoniae	Pneumonia, bronchitis, sinusitis, pharyngitis	Humans	Inhalation of infected aerosols
Chlamydophila psittaci	Psittacosis (pneumonia), systemic infections	Birds, domestic animals	Inhalation of infected aerosols
Coxiella burnetii	Acute Q fever (self-limited febrile illness ± pneumonia, hepatitis); chronic Q fever (endocarditis, endovascular infections)	Cattle, sheep, goats, cats, rabbits, dogs, ticks	Inhalation of infected aerosols; ingestion of nonpasteurized dairy products
Ehrlichia chaffeensis	Human monocytotropic ehrlichiosis (HME): fever, headache, myalgia, systemic involvement including central nervous system	White-tailed deer, dogs and other canids, raccoons	*Amblyomma americanum* (Lone Star tick) and potentially *Dermacentor variabilis* (American dog tick) tick bites
Ehrlichia ewingii	"Ewingii" ehrlichiosis: fever, headache, myalgia, predominantly in immunocompromised individuals	Dogs and other canids	*Amblyomma americanum* (Lone Star tick) tick bites
Mycoplasma genitalium	Urethritis, cervicitis, endometritis, conjunctivitis	Humans	Sexual contact, vertical transmission in utero or intrapartum
Mycoplasma hominis	Acute pyelonephritis, bacterial vaginosis, pelvic inflammatory disease, postabortion bacteremia	Humans	Sexual contact, vertical transmission in utero or intrapartum
Mycoplasma pneumoniae	Tracheobronchitis, pneumonia, pharyngitis, extrapulmonary complications (meningoencephalitis, arthritis, etc.)	Humans	Contact with infectious aerosols or fomites
Orientia tsutsugamushi	Scrub typhus	Chiggers (larval mites)	*Leptotrombidium* spp. (chigger) bites
Rickettsia africae	African tick-bite fever	Not established	*Amblyomma* spp. tick bites
Rickettsia akari	Rickettsialpox	Mice and other small mammals	*Allodermanyssus sanguineus* (mouse mite) bites
Rickettsia conorii	Boutonneuse fever or Mediterranean spotted fever	Small mammals and ticks	*Rhipicephalus sanguineus* (Brown dog) tick bites
Rickettsia felis	Murine typhus-like illness	Fleas, opossums, cats, dogs	*Ctenocephalides felis* (cat fleas); contamination of infected flea feces into flea bite
Rickettsia prowazekii	Epidemic typhus	Humans, lice, flying squirrels	*Pediculus humanus* subsp. *corporis* (body louse); contamination of infected louse feces into louse bite
Rickettsia rickettsii	Rocky Mountain spotted fever	Ticks, small and medium-size mammals	*Dermacentor variabilis* (American dog tick), *Dermacentor andersoni* (wood tick), *Rhipicephalus sanguineus* (North and Central America), *Amblyomma cajennense* (Central and South America) tick bites
Rickettsia typhi	Murine typhus	Rats and other rodents, opossums	*Xenopsylla cheopis* (rat fleas) and *Ctenocephalides felis* (cat fleas); contamination of flea bite wound with infected flea feces
Tropheryma whipplei	Malabsorption, arthralgias, lymphadenopathy, culture-negative endocarditis, encephalitis	Humans	Environmental contacts (sewage, human stool, saliva); genetic predispositions
Ureaplasma urealyticum	Urethritis, epididymo-orchitis, urinary calculi, abortion, chorioamnionitis	Humans	Sexual contact, in utero or peripartum vertical transmission

TABLE 2 Diagnostic tests for *Anaplasma, Chlamydia, Chlamydophila, Coxiella, Ehrlichia, Mycoplasma, Rickettsia,* and *Ureaplasma*

Organism	Diagnostic test[a]
Anaplasma phagocytophilum	**Microscopy:** Giemsa or Wright stain of peripheral blood or buffy coat smears is positive in approximately 60% of infected persons. **Antigen tests:** None available. **Molecular tests:** EDTA-anticoagulated blood collected during the pretreatment acute phase of illness is used for PCR amplification. Species- and genus-specific tests are available. Current test of choice for diagnosis during active infection. **Culture:** EDTA-anticoagulated peripheral blood is inoculated onto HL-60, THP1, or other myelocytic cell lines. Positive cultures may be obtained between 3 and 30 days from many samples if inoculated within 24 h and if obtained before antimicrobial therapy. Lack of timely results precludes frequent use. **Serologic tests:** IFA is the most frequently used test. A fourfold or greater rise in titer or a single peak titer of ≥80 in a patient with typical clinical features of HGA confirms infection. Test sensitivity is between 90 and 100%; specificity is approximately 95%.
Chlamydia trachomatis	**Microscopy:** Organisms may be detected by Giemsa stain or DFA test. DFA is more sensitive, but neither test should be used alone. **Antigen tests:** Commercial EIAs vary in sensitivity but may cross-react with other bacterial LPS and used alone are not suitable for screening. EIA using blocking antibodies may increase specificity to 99.5%. Point-of-care tests are only 62–72% sensitive compared to culture and less sensitive compared to molecular tests. **Molecular tests:** Commercial NAATs (PCR, transcription-mediated amplification, strand-displacement amplification) are available and are tests of choice for confirmation of *C. trachomatis* infections. **Culture:** Recovered in many different cell cultures commonly including McCoy and HeLa cells. Test sensitivity is dependent on the quality of the submitted specimen. **Serologic tests:** MIF test is most sensitive and specific (test of choice). Diagnosis for acute *C. trachomatis* infection is confirmed by fourfold or greater rise in titer. Rising antibody titers may not be observed with chronic, repeated, or systemic infections. A single IgM titer of ≥32 supports a diagnosis of neonatal pneumonia.
Chlamydophila pneumoniae	**Microscopy:** Organisms may be detected by Giemsa stain or DFA test directed against LPS, but both tests are relatively insensitive. **Antigen tests:** Available EIA tests directed against LPS detect all *Chlamydia* and *Chlamydophila* species but are licensed only for *C. trachomatis.* **Molecular tests:** None commercially available. **Culture:** Recovered best if inoculated onto HL cells or Hep-2 cells. **Serologic tests:** MIF test is the test of choice. Diagnosis is confirmed by fourfold or greater rise in titer or single samples with IgM titer of ≥16 and/or IgG titer of ≥512.
Chlamydophila psittacii	**Microscopy:** Organisms may be detected by Giemsa stain or DFA test directed against LPS, but both tests are relatively insensitive. **Antigen tests:** Available EIA tests directed against LPS detect all *Chlamydia* and *Chlamydophila* species but are licensed only for *C. trachomatis*. **Molecular tests:** None commercially available. **Culture:** Recovered in many different cell cultures commonly including McCoy and HeLa cells. **Serologic tests:** MIF test is most sensitive and specific (test of choice).
Coxiella burnetii	**Microscopy:** DFA or immunohistochemistry tests may be performed but are insensitive and not widely available. **Antigen tests:** None commercially available. **Molecular tests:** PCR available only through reference laboratories; more sensitive than culture from frozen tissue, blood, or for chronic disease; less useful for serum, especially if stored frozen. **Culture:** May be cultivated in a variety of cell lines, especially Vero cells and HEL cells, or by inoculation into embryonated chicken yolk sacs or laboratory animals. **Serologic tests:** Most frequently used diagnostic test. The IFA test is recommended. Acute Q fever is confirmed by a fourfold or greater rise in titer to phase II antigens, or a single IgM titer of ≥50 and IgG titer of ≥200. Chronic Q fever is confirmed in a single serum sample with a ≥800 IgG titer to phase I antigen. A decreasing antibody titer suggests successful therapy.
Ehrlichia chaffeensis	**Microscopy:** Giemsa or Wright stain of peripheral blood or buffy coat smears is positive in up to 29% of infected persons. **Antigen tests:** None available. **Molecular tests:** EDTA-anticoagulated blood collected during the pretreatment acute phase of illness is used for PCR amplification. Species- and genus-specific tests are available. Current test of choice for diagnosis during active infection. Sensitivity ranges from 56 to 100%. **Culture:** EDTA-anticoagulated peripheral blood or CSF is inoculated onto DH82, THP1, HEL-22, Vero, HL-60, or other cell lines. Positive cultures may be obtained between 5 and >30 days from most samples if inoculated within 12 h and if obtained before antimicrobial therapy. Lack of timely results precludes frequent use.

(Continued on next page)

TABLE 2 *(Continued)*

Organism	Diagnostic test[a]
	Serologic tests: IFA is the most frequently used test. A fourfold or greater rise in titer or a single peak titer of ≥64 in a patient with a clinically compatible illness is considered evidence of infection. Test sensitivity is believed to be high.
Ehrlichia ewingii	**Microscopy:** Giemsa or Wright stain of peripheral blood or buffy coat smears occasionally reveals bacterial clusters (morulae) in neutrophils of infected persons.
	Antigen tests: None available.
	Molecular tests: EDTA-anticoagulated blood collected during the pretreatment acute phase of illness is used for PCR amplification. Species- and genus-specific tests are available in some reference and public health laboratories. Current test of choice for diagnosis during active infection. Sensitivity is not currently known but is suspected to be high.
	Culture: No method of in vitro culture has been developed.
	Serologic tests: No specific antibody test is available. Antibody tests are based largely on cross-reactivity with *E. chaffeensis* and alone are not diagnostic.
Mycoplasma genitalium	**Microscopy:** May be detected in genital fluids using DNA fluorochrome stains (Hoechst 33258 or acridine orange), but these are not specific.
	Antigen tests: Not recommended for diagnostic purposes.
	Molecular tests: PCR amplification tests are highly sensitive and have unknown specificity, but clinical studies have yielded variable results when compared with culture and serology. May be the only practical means for detection of the pathogen. Commercial kits are not currently available in the United States.
	Culture: Organisms are isolated from a variety of genital fluids. Wood-shafted cotton swabs should be avoided. Mycoplasmas are extremely labile, and appropriate transport medium should be used. Can be recovered on SP4 glucose broth supplemented with arginine. Growth conditions are not well established. Widely considered insensitive for diagnosis confirmation.
	Serologic tests: MIF and Western immunoblot methods have been described, although none are commercially available.
Mycoplasma hominis	**Microscopy:** May be detected in body fluids using DNA fluorochrome stains (Hoechst 33258 or acridine orange), but these are not specific.
	Antigen tests: None commercially available.
	Molecular tests: PCR tests have been developed but are less useful than culture.
	Culture: Organisms are isolated from a variety of clinical samples. Wood-shafted cotton swabs should be avoided. Mycoplasmas are extremely labile, and appropriate transport medium should be used. Can be recovered on SP4 glucose broth supplemented with arginine, on Shepard's 10B broth, or A8 agar. Growth occurs within 2 to 4 days.
	Serologic tests: Not recommended for routine use.
Mycoplasma pneumoniae	**Microscopy:** May be detected in body fluids by using DNA fluorochrome stains (Hoechst 33258 or acridine orange), but these are not specific.
	Antigen tests: Not recommended for diagnostic purposes.
	Molecular tests: PCR amplification tests are highly sensitive and have unknown specificity, but clinical studies have yielded variable results when compared with culture and serology. Commercial kits are not currently available in the United States.
	Culture: Organisms are isolated from a variety of clinical samples. Wood-shafted cotton swabs should be avoided. Mycoplasmas are extremely labile, and appropriate transport medium should be used. Can be recovered on SP4 glucose broth supplemented with arginine. Growth occurs after 21 days. Widely considered insensitive for diagnosis confirmation.
	Serologic tests: EIA tests are more sensitive and specific than CF and IFA; detection of seroconversion by demonstration of a fourfold increase in antibody titer is preferred, but detection of IgM antibodies in single serum samples may be useful. The cold agglutinin test is not recommended for diagnosis of *M. pneumoniae* infection.
Orientia tsutsugamushi	**Microscopy:** DFA or immunohistochemistry on skin or other tissues may be performed, but tests are not widely available.
	Antigen tests: Not available.
	Molecular tests: PCR amplification performed on EDTA-anticoagulated blood, buffy coat leukocytes, plasma, or tissue samples obtained during the acute phase of illness; available only through reference laboratories.
	Culture: Isolation is performed by intraperitoneal inoculation of mice. Performed only in reference and research laboratories.
	Serologic tests: With the IFA test in a region of endemicity, a titer of ≥400 is 98% specific and 48% sensitive. Lower cutoffs are used for populations in which the infection is not endemic. Indirect immunoperoxidase is also sensitive and specific with diagnostic cutoffs of ≥128 for IgG and ≥32 for IgM. Dot EIA kits are available and have lower sensitivity and specificity than IFA. Weil-Felix (*Proteus*) febrile agglutinins test is insensitive and nonspecific.

(Continued on next page)

TABLE 2 Diagnostic tests for *Anaplasma, Chlamydia, Chlamydophila, Coxiella, Ehrlichia, Mycoplasma, Rickettsia,* and *Ureaplasma (Continued)*

Organism	Diagnostic test[a]
Rickettsia africae and Rickettsia conorii	**Microscopy:** DFA or immunohistochemistry on skin biopsy of rash or eschar is sensitive and specific for spotted fever group rickettsiae. Antibodies are not commercially available. **Antigen tests:** Not available. **Molecular tests:** PCR amplification performed on EDTA-anticoagulated blood, buffy coat leukocytes, plasma, skin biopsy, or tissue samples obtained during acute phase of illness; available only through reference laboratories. **Culture:** Heparin-anticoagulated plasma or buffy coat cells or triturated skin biopsy specimens are inoculated into shell vials seeded with cell lines such as Vero, L-929, HEL, or MRC5. Infected cells are detected by immunofluorescence or PCR after 48 to 72 h; sensitivity is up to 59%. **Serologic tests:** IFA is sensitive using *R. africae, R. conorii,* or other spotted fever group rickettsial antigens (e.g., *R. rickettsii*) but is low during the acute phase of illness. A fourfold increase in titer is generally considered most specific, but single titers of ≥128 for IgG and ≥32 for IgM are considered diagnostically significant. A Dot EIA test that is modestly less sensitive and specific is available for *R. conorii*.
Rickettsia akari	**Microscopy:** DFA or immunohistochemistry on skin biopsy of rash or eschar is sensitive and specific for spotted fever group rickettsiae. Antibodies are not commercially available. **Antigen tests:** Not available. **Molecular tests:** PCR amplification performed on skin biopsy specimens of eschars obtained during acute phase of illness; available only through reference laboratories. **Culture:** Heparin-anticoagulated blood plasma or buffy coat cells are inoculated into shell vials seeded with cell lines such as Vero, L-929, HEL, or MRC-5. Infected cells are detected by Giemsa, Gimenez, or fluorescent antibody staining after 48 to 72 h. Sensitivity is not known. **Serologic tests:** IFA is sensitive using either *R. akari* or other spotted fever group rickettsial antigens (e.g., *R. rickettsii*) but is low during the acute phase of illness. A fourfold increase in titer is generally considered most specific, but single titers of ≥128 for IgG and ≥32 for IgM are considered diagnostically significant. *R. akari*-specific testing can be obtained in reference or public health laboratories.
Rickettsia felis	**Microscopy:** Not available. **Antigen tests:** Not available. **Molecular tests:** PCR amplification performed on EDTA-anticoagulated blood, buffy coat leukocytes, plasma, or tissue samples obtained during the acute phase of illness; available only through reference laboratories. **Culture:** Not available except through research laboratories. **Serologic tests:** IFA is sensitive using either *R. felis* or other spotted fever or typhus group rickettsial antigens but is low during the acute phase of illness. A fourfold increase in titer is generally considered most specific; diagnostic titers have not been established. *R. felis*-specific testing can be obtained in reference or public health laboratories.
Rickettsia prowazekii	**Microscopy:** Not available. **Antigen tests:** Not available. **Molecular tests:** PCR amplification performed on EDTA-anticoagulated blood, buffy coat leukocytes, plasma, or tissue samples obtained during the acute phase of illness; available only through reference laboratories. **Culture:** Heparin-anticoagulated blood plasma or buffy coat cells are inoculated into shell vials seeded with cell lines such as Vero, L-929, HEL, or MRC-5. Infected cells are detected by Giemsa, Gimenez, or fluorescent-antibody staining after 48 to 72 h. Sensitivity is not known. **Serologic tests:** IFA is sensitive using either *R. prowazekii* or *R. typhi* as antigen. A fourfold increase in titer is generally considered most specific, but single titers of ≥128 for IgG and ≥32 for IgM are considered diagnostically significant.
Rickettsia rickettsii	**Microscopy:** DFA or immunohistochemistry on skin biopsy of rash is 70% sensitive and 100% specific. Antibodies are not commercially available. **Antigen tests:** Not available. **Molecular tests:** PCR amplification performed on EDTA-anticoagulated blood, buffy coat leukocytes, plasma, or tissue samples obtained during the acute phase of illness; available only through reference laboratories. **Culture:** Heparin-anticoagulated blood plasma or buffy coat cells are inoculated into shell vials seeded with cell lines such as Vero, L-929, HEL, or MRC-5. Infected cells are detected by Giemsa, Gimenez, or fluorescent-antibody staining after 48 to 72 h. Sensitivity is not known. **Serologic tests:** IFA is sensitive using *R. rickettsii* or other spotted fever group rickettsial antigens (for example) but is low during the acute phase of illness. A fourfold increase in titer is generally considered most specific, but single titers of ≥128 for IgG and ≥32 for IgM are considered diagnostically significant.
Rickettsia typhi	**Microscopy:** DFA or immunohistochemistry on skin biopsy of rash is sensitive and specific. Antibodies are not commercially available.

(Continued on next page)

TABLE 2 *(Continued)*

Organism	Diagnostic test[a]
	Antigen tests: Not available. **Molecular tests:** PCR amplification performed on EDTA-anticoagulated blood, buffy coat leukocytes, plasma, or tissue samples obtained during the acute phase of illness; available only through reference laboratories. **Culture:** Heparin-anticoagulated blood plasma or buffy coat cells are inoculated into shell vials seeded with cell lines such as Vero, L-929, HEL, or MRC-5. Infected cells are detected by Giemsa, Gimenez, or fluorescent-antibody staining after 48 to 72 h. Sensitivity is not known. **Serologic tests:** IFA is sensitive using either *R. prowazekii* or *R. typhi* as antigen. A fourfold increase in titer is generally considered most specific, but single titers of ≥128 for IgG and ≥32 for IgM are considered diagnostically significant. A Dot EIA test that is modestly less sensitive and specific is available for *R. typhi*.
Tropheryma whipplei	**Microscopy:** Tissue biopsy with periodic acid-Schiff stain or immunohistochemistry. **Antigen tests:** None available. **Molecular tests:** PCR tests are currently the preferred method for specific diagnosis; performed with small intestinal biopsy specimens, blood, cardiac valve tissues; available through reference laboratories. **Culture:** Blood, small intestine tissue, cardiac valves, CSF, aqueous humor, and synovial fluid can be inoculated onto human fibroblast cell culture. Sensitivity of culture is not known, and at least 30 days are required before detection. **Serologic tests:** Not currently available.
Ureaplasma urealyticum	**Microscopy:** May be detected in body fluids using DNA fluorochrome stains (Hoechst 33258 or acridine orange), but these are not specific. **Antigen tests:** None commercially available. **Molecular tests:** PCR tests have been developed but are less useful than culture. **Culture:** Organisms are isolated from a variety of clinical samples. Wood-shafted cotton swabs should be avoided. Ureaplasmas are extremely labile, and appropriate transport medium should be used. Can be recovered on Shepard's 10B urea broth and A8 urea agar. Growth occurs within 2 to 4 days. **Serologic tests:** Not recommended for routine use.

[a]Abbreviations: CF, complement fixation; CIE, counterimmunoelectrophoresis; CSF, cerebrospinal fluid; DFA, direct fluorescent antibody; EIA, enzyme immunoassay; IFA, indirect fluorescent antibody; Ig, immunoglobulin; MIF, microimmunofluorescence; NAAT, nucleic acid amplification tests.

Staphylococcus, Micrococcus, and Other Catalase-Positive Cocci

TAMMY L. BANNERMAN AND SHARON J. PEACOCK

28

TAXONOMY

Members of the genera *Staphylococcus* and *Micrococcus* are gram-positive, catalase-positive cocci that were placed together with *Stomatococcus* and *Planococcus* in the family *Micrococcaceae* (162). However, the results of DNA base composition testing (155a), DNA-rRNA hybridization (86), and comparative oligonucleotide cataloguing of 16S rRNA (117, 179) indicate that the genera *Staphylococcus* and *Micrococcus* are not closely related. The genus *Staphylococcus* is most closely related to the newly described genus *Macrococcus* (100), but it also has a relatively close relationship to the genera *Bacillus, Brochothrix, Gemella, Listeria,* and *Planococcus*. These genera have been tentatively arranged together with staphylococci and several other genera in the family *Bacillaceae* (22) of the broad *Bacillus-Lactobacillus-Streptococcus* cluster (118, 178) or the order *Bacillales* (22). The genus *Micrococcus* is most closely related to the genus *Arthrobacter* of the coryneform or actinomycete group (177, 179). The genus *Micrococcus* has been dissected into the six genera, *Micrococcus* (comprising the species *Micrococcus luteus*, *Micrococcus lylae,* and *Micrococcus antarcticus*), *Kocuria* (comprising the species formerly known as *Micrococcus roseus, Micrococcus varians,* and *Micrococcus kristinae*), *Kytococcus* (formerly *Micrococcus sedentarius*), *Nesterenkonia* (formerly *Micrococcus halobius*), *Dermacoccus* (formerly *Micrococcus nishinomiyaensis*), and *Arthrobacter* (formerly *Micrococcus agilis,* a member of the "*Arthrobacter globiformis-Arthrobacter citreus* group") (95, 110, 176). The genus *Kocuria* is more closely related to the genus *Rothia* than to other actinomycetes and the genus *Kytococcus* is most closely related to the genus *Dermacoccus* (176). Additional gram-positive, catalase-positive cocci include *Alloiococcus otitis* (1, 49), *Rothia mucilaginosa* (formerly *Stomatococcus mucilaginosus*) (8, 37), and on occasion *Aerococcus* species. *Aerococcus* will be discussed in chapter 31.

DESCRIPTION OF THE GENERA

Members of the genus *Staphylococcus* are gram-positive cocci (0.5 to 1.5 μm in diameter) that occur in irregular grape-like clusters and, less often, singly and in pairs, tetrads, and short chains (three or four cells). They are nonmotile, non-spore forming, and usually catalase positive and are typically unencapsulated or have limited capsule formation under laboratory conditions. The species do not form gas from carbohydrates and are facultative anaerobes with the exception of *Staphylococcus saccharolyticus* and *S. aureus* subsp. *anaerobius,* which initially grow anaerobically but may become more aerotolerant on subculture (Table 1). The genus *Staphylococcus* is currently composed of 37 species (readers are referred to http://www.bacterio.cict.fr/, which provides a list of validly published names of species). Some uncommon strains of staphylococci require the presence of CO_2 or factors such as hemin or menadione for growth. Small-colony variants (SCVs) of *S. aureus* have been described which grow as small, nonpigmented, and nonhemolytic colonies on routine media such as blood agar. SCVs are often auxotrophic for menadione or hemin, have a reduced range of carbohydrate utilization, may fail to express several putative virulence factors, and are resistant to gentamicin owing to poor drug uptake. SCVs are proposed to have a defect in the electron transport chain.

The genome of *S. aureus* has a guanine-plus-cytosine (G+C) content of approximately 32% and is composed of a single chromosome of around 2.8 Mb predicted to carry approximately 2,500 genes. Several sequenced strains also contain a plasmid. Whole genome sequencing is in progress or has been completed for eight *S. aureus* isolates. Published sequences are available for strains N315, Mu50, MW2, COL, MRSA252, and MSSA476 (6, 59, 76, 99); sequencing of strains NCTC 8325 and Michigan vancomycin-resistant *S. aureus* (VRSA) is ongoing. Whole genome sequences have been published for *S. epidermidis* ATCC 12228 and RP62A (59, 206). The whole genome sequence of *S. epidermidis* consists of a single chromosome plus various numbers of plasmids (*S. epidermidis* ATCC 12228 contains six plasmids and strain RP62A contains one) totalling approximately 2.5 Mb. This species has a G+C content of 32% and contains around 2,400 to 2,500 coding sequences. Both *S. epidermidis* genomes contain fewer putative virulence determinants than that of *S. aureus*.

Members of the genus *Micrococcus* are gram-positive cocci (1 to 1.8 μm in diameter) occurring mostly in irregular clusters, tetrads, and pairs. Micrococci and staphylococci have been confused with one another for more than a century on the basis of similar cellular morphologies and Gram-stained appearances and positive catalase activities. Both genera are commonly found on mammalian skin and may be present in various human and veterinary clinical specimens, although micrococci are found less frequently

TABLE 1 Differentiation of members of the genus *Staphylococcus* from other gram-positive cocci[a]

Genus and exceptional species	G+C content (molecular %) of DNA	Strict aerobe	Facultative anaerobe or microaerophile	Strict anaerobe	Tetrad cell arrangement	Strong adherence on agar	Motility	Growth on:					Catalase reaction result[d]	Benzidine test result[e]	Modified oxidase test result[f]	Anaerobic acid production from glucose[g]	Aerobic acid production from glycerol	Resistance to:

[a] Symbols and abbreviations: +, 90% or more species or strains positive; ±, 90% or more species or strains weakly positive; − , 90% or more species or strains negative; *d*, 11 to 89% of species or strains positive; ND, not determined. Parentheses indicate a delayed reaction.

[b] Growth on P agar is under aerobic conditions at 35 to 37°C. Positive growth is indicated for detectable formation of colonies of at least 1 mm in diameter; ± indicates detectable formation of colonies of between 0.5 and 1 mm in diameter. Growth on sheep or bovine blood agar is slightly greater but less discriminative between staphylococci and other genera.

[c] Growth is under aerobic conditions at 35 to 37°C for 24 to 48 h. Positive growth is indicated for a number of CFU on selective medium comparable to that on plate count agar and a colony of 0.5 mm in diameter; ± indicates a significant reduction in the number of CFU on the selective medium compared to that on plate count agar, and parentheses indicate a colony of pinpoint size to 0.5 mm in diameter.

[d] Sometimes a weak catalase or pseudocatalase reaction can be observed with certain strains of species designated as catalase negative. In some species, catalase activity may be activated by hemin supplementation.

[e] Detects the presence of cytochromes. Some strains of benzidine test-negative species can synthesize cytochromes on aerobic media supplemented with hemin (50).

[f] See reference 163.

[g] Standard oxidation/fermentation test (163).

[h] A disk is used. Positive indicates resistance and no zone of inhibition. *Micrococcus*, *Kocuria*, *Kytococcus*, *Stomatococcus*, and *Aerococcus* spp. are susceptible and have an inhibition zone of 10 to 25 mm in diameter.

[i] A disk is used. Positive indicates resistance and no zone of inhibition or a zone of up to 9 mm in diameter. Susceptible species have an inhibition zone of 15 to 35 mm in diameter.

[j] Some strains of *S. epidermidis* adhere tenaciously to the surface of agar, and this property is correlated with heavy slime production.

[k] *S. hominis* does not demonstrate growth in the anaerobic portion of a thioglycolate medium within 24 h and may produce only very poor growth in this portion following 3 to 5 days of incubation. However, it will grow and ferment glucose anaerobically (standard oxidation-fermentation test). Failure to grow anaerobically in thioglycolate may be due in part to inhibition by the ingredients.

[l] *Macrococcus* species can also be differentiated from *Staphylococcus* species on the basis of their generally larger Gram-stained cell size (≥2 μm) and larger number of chromosome fragments produced by digestion with NotI (12 to 36 fragments).

[m] A few *Micrococcus* strains demonstrate high-level (MIC, ≥50 μg/ml) erythromycin resistance.

than staphylococci and are generally regarded as saprophytic rather than as opportunistic pathogens. By the mid-1960s, a clear distinction could be made between staphylococci and micrococci on the basis of DNA base composition (155a). Members of the genus *Staphylococcus* have a G+C content of 30 to 39%, whereas members of the *Micrococcus* and related genera have G+C contents within the range of 66 to 75%. The genus *Micrococcus* is currently composed of three species (110, 176). *Micrococcus luteus* is the most common micrococcal species found in nature and in clinical specimens. In the diagnostic laboratory, staphylococci can be distinguished from micrococci on the basis of the former's resistance to bacitracin and susceptibility to furazolidone. Micrococci are oxidase positive, and staphylococci are oxidase negative, with the exception of *S. lentus*, *S. sciuri*, *S. vitulus,* and *S. fleurettii*. The more distantly related species *Kocuria varians*, *Kocuria kristinae*, and *Kytococcus sedentarius* are occasionally found in clinical specimens and can be distinguished from micrococci on the basis of their cellular fatty acid compositions and results of several simple tests listed below in the section on the identification of *Micrococcus* species.

Alloiococci are aerobic, gram-positive cocci, weakly catalase positive, occurring mostly in clusters and pairs. The G+C content is 44 to 45%. These organisms can be easily distinguished from the aerobic micrococci by their negative oxidase reaction.

R. mucilaginosa is a gram-positive coccus occurring mostly in clusters, is a facultative anaerobe, and is catalase variable. The G+C content is 56 to 60.4%. *R. mucilaginosa* can easily be distinguished from staphylococci and micrococci by its inability to grow on 5% NaCl agar.

Members of the genus *Macrococcus* (including the species *Macrococcus caseolyticus* [formerly *Staphylococcus caseolyticus*], *Macrococcus equipercicus, Macrococcus bovicus,* and *Macrococcus carouselicus*) can be distinguished from staphylococci on the basis of their higher G+C contents (38 to 45%), absence of cell wall teichoic acid (with the possible exception of *Macrococcus caseolyticus*), smaller genome size of approximately 1.5 to 1.8 Mb, and larger Gram-stained cell size of 1.3 to 2.5 μm in diameter. They can also be distinguished from most species of staphylococci by their oxidase activity. They are susceptible to a wide range of antibiotics and do not exhibit the antibiotic resistance profiles characteristic of many staphylococcal species. However, like staphylococci, macrococci have a cell wall peptidoglycan that has L-lysine as the diamino acid with an interpeptide bridge that is susceptible to the action of lysostaphin. Since the clinical significance of macrococci has yet to be established and the genus has a rather restricted host range including only whales and related aquatic mammals and hoofed animals, they will not be described further in this chapter.

NATURAL HABITATS

Staphylococci are widespread in nature, their major habitat being the skin and mucous membranes of mammals and birds. They may be found in the mouth, mammary glands, and intestinal, genitourinary, and upper respiratory tracts of these hosts. Staphylococci generally have a benign or symbiotic relationship with their hosts but can become pathogenic after gaining entry into the host tissue through trauma of the cutaneous barrier, inoculation by needles, or direct implantation of medical devices. Staphylococci found on humans and other primates include *S. aureus, S. epidermidis, S. capitis, S. caprae, S. saccharolyticus, S. warneri, S. pasteuri, S. haemolyticus, S. hominis, S. lugdunensis, S. schleiferi, S. auricularis, S. saprophyticus, S. cohnii, S. xylosus,* and *S. simulans* (88, 141). Most of these species produce resident populations on humans, although *S. xylosus* and *S. simulans* are usually transient residents on humans and are acquired primarily from domestic animals and their products. Some of the human staphylococcal species are transient or temporary residents on domestic animals. *S. aureus* is a major (resident and transient) species for primates, while specific ecovars or biotypes can be found occasionally living on different domestic animals or birds (41, 87). *S. schleiferi, S. intermedius,* and *S. felis* are commonly found living on carnivora (141). *S. lutrae* has been isolated from the European otter (53). *S. xylosus, S. kloosii,* and *S. sciuri* are common residents on a variety of rodents (141). *S. hyicus, S. chromogenes, S. sciuri, S. lentus,* and *S. vitulus* are common residents of ungulates and, in addition, may be isolated from their food products (42). The last three species are also common residents of whales and related aquatic mammals. Other staphylococci associated with food products include *S. fleurettii, S. condimenti, S. carnosus,* and *S. piscifermentans* (150, 183, 193). *S. nepalensis* has been isolated from goats of the Himalayas (173), and *S. pseudointermedius* has been isolated from a range of mammals (43).

Some *Staphylococcus* species demonstrate habitat or niche preferences on their particular hosts (88). For example, *S. capitis* subsp. *capitis* is found in large populations on the adult human head, especially the scalp and forehead, where sebaceous glands are numerous and well developed. *S. capitis* subsp. *ureolyticus* is also found on the head but may produce relatively large populations in the axillae of some individuals. *S. auricularis* has a strong preference for the external auditory meatus. *S. hominis* and *S. haemolyticus* generally produce larger populations on areas of the skin where apocrine glands are numerous, such as the axillae and pubic areas (88). *S. aureus* prefers the anterior nares as a habitat (93). The novobiocin-resistant staphylococci, particularly *S. cohnii*, are found in large populations on the human feet. *S. saprophyticus* appears in high numbers in the female genitourinary tract (154).

Micrococci are widespread in nature and are commonly found on the skin of humans and other mammals (91). They are generally believed to be temporary residents and are most frequently found on the exposed skin of the face, arms, hands, and legs. Alloiococci have been isolated from human middle ear fluid (1, 49), and *R. mucilaginosa* is probably a normal inhabitant of the mouth and upper respiratory tract (8).

CLINICAL SIGNIFICANCE

Staphylococcus

S. aureus is an important cause of community-acquired sepsis and is a leading nosocomial pathogen. Disease manifestations can be broadly divided into toxin-mediated diseases (such as food poisoning, scalded skin syndrome, and toxic shock syndrome [TSS]), infection of the skin and soft tissues (furuncles or boils, cellulitis, and impetigo), infection of deep sites (such as bone and joints and the heart valve, spleen, and liver [almost any organ can be involved]), and infection of the lung and urinary tract. An important complication of *S. aureus* bacteremia is dissemination of the organism to one or more distant sites. Additional manifestations of hospital-acquired infection include surgical wound infection, ventilator-associated pneumonia, bacteremia associated with intravenous devices, and infection associated with other types of prosthetic

material such as cerebrospinal fluid shunts, prosthetic joints, and vascular grafts.

S. aureus toxin-mediated diseases range in severity from self-limiting to life threatening. TSS is associated with colonization by or infection with a strain of *S. aureus* that is positive for one of the superantigens, most commonly TSS toxin-1 (TSST-1; around 75% of all TSS cases). TSST-1 is a member of a superantigen family that has the ability to stimulate T cells and induce tumor necrosis factor and the cytokine interleukin-1. Gaining notoriety in the 1980s in association with the use of high-absorbancy tampons (45), TSS is now also recognized to occur in nonmenstrual settings including invasive disease and *S. aureus* colonization of sites such as postoperative wounds. Those affected present with severe disease with high fever, hypotension, an erythematous rash that becomes desquamating 1 to 2 weeks later, and involvement of three or more organs (45). Diagnosis is made on clinical grounds. A clinical case definition devised by the Centers for Disease Control and Prevention is useful (26), although not all cases of suspected TSS have sufficient criteria to fulfill this definition. In such cases, circumstantial evidence for the diagnosis includes the isolation of an *S. aureus* strain that is capable of producing TSST-1 or another superantigen (the remainder being positive for staphylococcal enterotoxin B or C). Methods for detecting TSST-1 and enterotoxin production include enzyme-linked immunosorbent assay (128), reverse passive latex agglutination (Oxoid, Ogdensburg, N.Y.), and PCR (7, 125, 129, 164).

Staphylococcal scalded skin syndrome affects primarily neonates and young children and results from the action of *S. aureus* exfoliative toxins on skin epidermidis. Fragile blisters form which rupture and lead to skin loss associated with poor temperature control, fluid loss, and secondary infection (102). Diagnosis is made on the basis of clinical features, including Nikolsky's sign, in which the skin wrinkles on gentle pressure. *S. aureus* may be isolated from a site of localized infection, such as the umbilical stump, but blister fluid is usually culture negative for *S. aureus*.

Staphylococcal food poisoning results from ingestion of preformed staphylococcal enterotoxins (45). Nausea and vomiting occur after an incubation period of 2 and 6 h. Abdominal pain and diarrhea are also common features. Diagnosis is made on clinical grounds; suspected food can be cultured for the presence of *S. aureus*.

S. aureus bacteremia is a major scourge of modern medical care. Around two-thirds of all cases are related to nosocomial infection, much of which is associated with the use of intravenous devices. One of the greatest challenges faced in caring for individuals with *S. aureus* bacteremia is to determine whether the disease is uncomplicated or complicated (that is, associated with bacterial spread to one or more distant sites). A study of clinical identifiers for complicated disease represents significant progress (55). The most common deep-site infections involve bones, joints, and heart valves. Rates of *S. aureus* endocarditis have increased, with the use of intravenous catheters potentially contributing to this rise. A rare but important syndrome of rapidly progressive *S. aureus* necrotizing pneumonia and other invasive diseases affecting previously healthy children and young adults have recently been described (17, 60, 160). The strains responsible were positive for Panton-Valentine leukocidin, and pneumonia was often preceded by influenza-like symptoms. The increase in community-associated methicillin-resistant *S. aureus* (MRSA) infections is further discussed later in "Antimicrobial Susceptibilities."

The role of coagulase-negative staphylococci (CoNS) as nosocomial pathogens has been recognized and well documented over the last 2 decades, especially for the species *S. epidermidis* (147). An increase in the number of infections involving CoNS has paralleled the increasing use of prosthetic and in-dwelling devices and the growing number of immunocompromised patients in hospitals. *S. epidermidis* has been documented as a pathogen in numerous cases of bacteremia; native and prosthetic valve endocarditis; surgical (particularly sternal) wounds, urinary tract, and ophthalmologic infections; and prosthetic joint-, ventricular shunt-, peritoneal dialysis-, and intravascular catheter-related infections (158, 197). *S. saprophyticus* is an important opportunistic pathogen in human urinary tract infections, especially in young, sexually active females. It has been proposed as an agent of nongonococcal urethritis in males and as a cause of other sexually transmitted diseases, prostatitis, wound infections, and septicemia (158). *S. haemolyticus*, the second most frequently encountered CoNS species associated with human infections, has been implicated in native valve endocarditis, septicemia, peritonitis, urinary tract infections, and wound, bone, and joint infections (89, 158). *S. lugdunensis* has been reported as a cause of endocarditis (189). The aggressive nature of *S. lugdunensis* endocarditis, as reflected by the frequent need for valve replacement and the high mortality rate, indicates that rapid recognition of *S. lugdunensis* is needed. *S. lugdunensis* has also been implicated in arthritis, bacteremia, urinary tract infection, and prosthetic material-associated infection (89).

Other CoNS have been implicated in a variety of infections. For example, *S. capitis, S. caprae, S. saccharolyticus, S. simulans,* and *S. warneri* have been implicated in endocarditis; *S. capitis, S. cohnii, S. hominis, S. schleiferi, S. simulans,* and *S. warneri* have been implicated in bacteremia; *S. epidermidis* and *S. haemolyticus* have been implicated in meningitis (79); *S. warneri* and *S. simulans* have been implicated in osteomyelitis; *S. cohnii* has been implicated in native valve endocarditis and pneumonia; *S. cohnii, S. xylosus, S. schleiferi, S. hominis,* and *S. caprae* have been implicated in urinary tract infections; *S. caprae* and *S. cohnii* have been implicated in arthritis; *S. schleiferi* and *S. caprae* have been implicated in wound and joint infections and osteomyelitis (20); *S. warneri* has been implicated in multifocal discitis; and *S. capitis, S. schleiferi,* and *S. warneri* have been implicated in catheter-related infections (89, 158). *S. schleiferi* may cause wound infections in humans and has been implicated in infections related to pacemaker insertion (25, 75). *S. hominis* subsp. *novobiosepticus* has been isolated from human blood cultures and has been associated with clinically significant septicemia (90). *S. sciuri* has been isolated from wounds and from individuals with skin and soft tissue infections (123).

The coagulase-positive species *S. intermedius* and the coagulase-variable species *S. hyicus* are of particular importance in veterinary infections. *S. aureus* and these two coagulase-positive species are serious opportunistic pathogens of animals. *S. intermedius* has been associated with a variety of canine infections including cellulitis, otitis externa, pyoderma, abscesses, reproductive tract infections, mastitis, and wound infections (61). *S. intermedius* infections in humans are usually associated with animal bites. This species has been implicated in a food-poisoning outbreak involving butter blend products (85). *S. hyicus* has been implicated in infectious exudative epidermitis and septic polyarthritis in pigs and mastitis in cows. *S. schleiferi* subsp. *schleiferi* and *S. schleiferi* subsp. *coagulans* have been isolated

from dogs with pyoderma, and *S. schleiferi* subsp. *coagulans* has been isolated from dogs with external otitis (81).

Micrococcus, Alloiococcus, and *R. mucilaginosa*

Members of the genus *Micrococcus* and the related coccal genera *Kocuria* and *Kytococcus* are generally harmless saprophytes that inhabit or contaminate the skin, mucosa, and perhaps also the oropharynx; however, they can be opportunistic pathogens for the immunocompromised. *Micrococcus luteus* has been implicated as the causative agent in cases of intracranial abscesses, pneumonia, septic arthritis, endocarditis, and meningitis (165). *Kytococcus sedentarius* has been associated with prosthetic valve endocarditis. Other infections associated with micrococci and their relatives include bacteremia, continuous ambulatory peritoneal dialysis peritonitis, and infection associated with ventricular shunts and central venous catheters (3, 139).

Significant levels of inflammatory cells along with the observation of intracellular *Alloiococcus* led Faden and Dryja to suggest that this organism plays a pathogenic role in persistent otitis media (49). Additional studies employing either culture (65) or PCR (11, 74) support the role of alloiococci in chronic otitis media, but its pathogenic potential should be the subject of further investigation since it has also been found as an inhabitant of the external outer ear in healthy individuals (57).

R. mucilaginosa has been implicated in numerous reports of infection since the mid to late 1980s. This organism has been isolated in cases of bacteremia, endocarditis, endophthalmitis, intravascular catheter-related and central nervous system infections, pneumonia, peritonitis, and septicemia (64, 66, 103) and from a patient with cervical necrotizing fasciitis arising from an infected parotid cyst (116).

PREVENTION OF STAPHYLOCOCCAL INFECTION

There are no licensed vaccines available for the prevention of staphylococcal disease. Data on the efficacy of passive vaccination using hyperimmune antistaphylococcal immunoglobulin for the prevention of staphylococcal disease in high-risk groups have not been published to date. Hospital infection control measures are central to the prevention of nosocomial infection. Guidelines for the prevention of nosocomial transmission of MRSA are available (132). The recommendations continue to include the use of contact precautions for patients colonized by or infected with MRSA but also suggest that hospitals implement a program of active surveillance cultures to identify possible reservoirs in patients at high risk for carriage of MRSA at the time of hospital admission. A full discourse is outside the scope of this chapter; readers are referred to standard texts. Nasal carriage of *S. aureus* has been suggested as a risk factor for the development of infection (196). Infection rates are higher in carriers than in noncarriers, and patients with *S. aureus* sepsis are often infected with their own strain. Multiple studies have been conducted to determine the effect of temporary eradication of *S. aureus* carriage. This is usually achieved by the topical application of mupirocin to the anterior nose. Most studies have been conducted with the dialysis population. Several studies have shown a reduction in the rate of *S. aureus* infection in those receiving hemodialysis (14, 77, 94). Topical mupirocin applied to the peritoneal dialysis catheter exit site reduces *S. aureus* exit site infection and peritonitis (9, 185, 187). The effect of routine decolonization using mupirocin on the rate at which drug resistance will emerge is unclear. A double-blind, placebo-controlled trial of intranasal mupirocin treatment of patients undergoing surgery did not result in a significantly reduced rate of *S. aureus* surgical site infections overall, but the treatment did decrease the rate of all nosocomial *S. aureus* infections among patients who were *S. aureus* carriers (144). An evidence-based review of intranasal mupirocin treatment concluded that this was highly effective at eradication of nasal carriage in the short term, but this did not convert into clinical benefit overall (104). However, this review also reported that subgroup analyses and several small studies revealed lower rates of *S. aureus* infection among selected populations (such as the dialysis population) (104). A systematic review of the effect of mupirocin on rates of *S. aureus* infection in the peritoneal dialysis and hemodialysis populations provided further support for nasal eradication in these patients (182). A Cochrane review of the effects of topical and systemic antimicrobial agents on nasal and extranasal MRSA carriage, adverse events, and the incidence of subsequent MRSA infections concluded that there is insufficient evidence to support the use of topical or systemic antimicrobial therapy for eradicating nasal or extranasal MRSA (112). In summary, the strongest evidence for the efficacy of interrupting nasal *S. aureus* carriage rests with the renal dialysis population; the optimal use of nasal decolonization in other patient groups is less well defined. Despite the use of mupirocin for several decades, little resistance has been observed to date (16, 24, 111, 204). Rectal carriage may represent a reservoir for *S. aureus* for patients in the intensive care unit and liver transplant recipients (174); it is unclear whether nasal decolonization would interrupt gut or rectal carriage.

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

The general principles of collection, transport, and storage of specimens as described in chapters 5, 6, and 20 of this Manual are applicable to the organisms listed in this chapter. No special methods or precautions are usually required for these organisms because they are easily obtained from clinical material of most infection sites and are relatively resistant to drying and to moderate temperature changes. Some strains of staphylococci may require anaerobic conditions or CO_2 supplementation for satisfactory growth, but these survive transport and limited storage in air.

DIRECT EXAMINATION

The direct microscopic examination of normally sterile fluids such as cerebrospinal fluid and joint aspirates may be useful. Direct examination of certain nonsterile fluids may also be useful if the microscopist evaluates the specimen by noting the presence of inflammatory cells versus epithelial cells. Even if large numbers of gram-positive cocci are present, only a presumptive report of "gram-positive cocci resembling staphylococci (or micrococci)" should be made. Culture and appropriate identification techniques must confirm this report; microscopy alone cannot adequately differentiate various species of staphylococci or micrococci from one another or from planococci, some streptococci, aerococci, various anaerobic cocci, and other cocci related to micrococci.

ISOLATION PROCEDURES

Considering the widespread distribution of staphylococci and micrococci over the body surface, careful procedures should be used to isolate organisms from the focus or foci of

infection without collecting surrounding normal flora (89). Distinguishing contaminants from the infecting staphylococci and micrococci continues to be an important clinical challenge.

The basic procedures for culture and isolation described in chapter 20 of this Manual should be followed. Every specimen should be plated onto blood agar (preferably sheep blood agar) and other media as indicated. On blood agar, abundant growth of most staphylococcal species occurs within 18 to 24 h, and abundant growth of micrococci occurs within 36 to 48 h. Although most CoNS colony morphologies cannot be distinguished from one another, preliminary identification testing should begin after overnight incubation. Further incubation of the primary isolation plate for 2 to 3 days allows the colony morphology to develop and helps to determine if the culture is mixed or pure. Failure to hold plates for 72 h can result in (i) selection of more than one species or strain if two or more colonies are sampled to produce an inoculum, (ii) selection of an organism(s) not producing the infection if the specimen contains two or more different species or strains, and (iii) incorrect labeling of a mixed culture as a pure culture. Colonies should be Gram stained, subcultured, and tested for genus, species, and when applicable, strain properties. The degree to which staphylococci are identified is discussed in more detail below. Most staphylococci of major medical interest produce growth in the upper as well as the lower anaerobic portions of the thioglycolate broth or semisolid agar.

Specimens from heavily contaminated sources such as feces should be streaked onto a selective medium such as mannitol-salt agar, Columbia colistin-nalidixic acid agar, lipase-salt-mannitol agar (Remel, Lenexa, Kans.), or phenylethyl alcohol agar. These media inhibit the growth of gram-negative organisms but allow staphylococci and certain other gram-positive cocci to grow. In addition, two chromogenic agars, CHROMagar Staph aureus (BD, Sparks, Md.) and *S. aureus* ID (bioMérieux, Hazelwood, Mo.), have been evaluated for their ability to isolate *S. aureus* from clinical specimens (46, 52, 58, 127, 146, 161). CHROMagar Staph aureus medium has been shown to inhibit *Pseudomonas* strains from cystic fibrosis patients as well as provide a better means to recover SCVs.

PCR methodology has been described that can detect MRSA directly from clinical samples. Most reports describe the use of a selective preenrichment step in overnight broth prior to PCR (51, 70, 82). One report described PCR using nasal swab material following an enrichment step for *S. aureus* with the use of immunomagnetic separation (56). Direct PCR has also been applied to a small number of nasal swabs without an enrichment step (80) and to clinical blood culture specimens (140). Detection of *S. aureus* directly from blood cultures using peptide nucleic acid fluorescence in situ hybridization (AdvanDx, Woburn, Mass.) has also been described (33).

IDENTIFICATION

Staphylococcus Species

Laboratory tests that differentiate members of the genus *Staphylococcus* from other gram-positive cocci are listed in Table 1. *Staphylococcus* species can be identified on the basis of a variety of conventional phenotypic characteristics, as shown in Table 2. The most clinically significant species can be identified on the basis of several key characteristics; these are shown in Table 3. In more specialized settings, species can be identified on the basis of molecular constituents such as cellular fatty acids (97) and further identified or characterized using genotypic tests such as analysis of macrorestriction patterns, ribotyping (21), amplification of DNA regions (62, 119, 126, 203), gene sequencing of loci including the 16s RNA gene, *hsp, sodA,* and *tuf* (73, 101, 170), and use of a PCR-enzyme-linked immunosorbent assay system (201). Most molecular methods pertaining to species-level identification are confined to the reference or research laboratory. Further discussion of the role of bacterial typing in clinical microbiology and the methods available is provided later in this chapter.

Colony Morphological Appearance

On nonselective blood agar, nutrient agar, tryptic soy agar, or brain heart infusion agar, isolated colonies of most staphylococci are 1 to 3 mm in diameter within 24 h and 3 to 8 mm in diameter after 3 days of incubation in air at 34 to 37°C, depending on the species. Exceptions are *S. aureus* subsp. *anaerobius, S. saccharolyticus, S. auricularis, S. equorum, S. vitulus,* and *S. lentus*, which grow more slowly and usually require 24 to 36 h for detectable colony development. Colony morphology can be a useful supplementary characteristic in the identification of species. In order for morphology differences among species to be observed, isolated colonies need to develop for several days at 34 to 37°C (and should be further augmented by 2 days of growth at room temperature).

The typical 24-h *S. aureus* colony is pigmented (cream yellow to orange), smooth, entire, slightly raised, and hemolytic on routine blood agar. Rare strains that produce abundant capsule material may have a glistening, wet appearance. Colonies reach 6 to 8 mm in diameter by 3 days of incubation. SCVs of *S. aureus* may require at least 48 h of incubation to become visible. Colony size is usually about 1/10 that of the wild type, and the colony lacks pigment. SCVs are often auxotrophic for menadione or hemin, have a reduced range of carbohydrate utilization, and are resistant to gentamicin (152). They may be isolated in purity or mixed with colonies with normal morphotypes, giving the appearance of a mixed culture, and may remain stable upon subculture or may rapidly revert to the wild type. They are most commonly isolated from patient populations with unusually persistent infections such as cystic fibrosis or chronic osteomyelitis and/or from patients who have prolonged exposure to aminoglycosides and trimethoprim-sulfamethoxazole (113, 152). Normal growth may be restored if the isolate is grown in the presence of menadione, hemin, and/or CO_2 supplementation (153).

The typical 24-h CoNS colony is nonpigmented, smooth, entire, glistening, slightly raised to convex, and opaque. Rare strong slime producers develop a mucoid colony morphology. Colony diameter reaches 2.5 to 6 mm by 3 days of incubation. Colonies of *S. haemolyticus* are smooth, butyrous, and opaque and are usually larger than those of *S. epidermidis* and *S. hominis*. *S. haemolyticus* and *S. hominis* may be nonpigmented or cream to yellow-orange. Colonies of *S. lugdunensis* are usually 4 to 7 mm in diameter by 3 days of incubation, smooth and glossy and may be nonpigmented or cream to yellow-orange. The edges are entire and rather flat, and the centers are slightly domed. *S. schleiferi* colonies are usually 3 to 5 mm in diameter by 3 days of incubation and are nonpigmented. They are smooth and glossy and are slightly convex, with entire edges. Colonies of *S. saprophyticus* are large (5 to 8 mm in diameter by day 3), entire, very glossy, opaque, smooth, butyrous, and more convex than the colonies of the aforementioned species. Approximately one-half of the

strains are pigmented, ranging from cream to yellow-orange. Colonies of *S. intermedius* and *S. hyicus* are relatively large, usually 5 to 8 mm in diameter. They are slightly convex, entire, smooth, glossy, and usually nonpigmented. Colonies of *S. intermedius* are translucent. Those of *S. hyicus* are more opaque, becoming translucent with prolonged incubation.

Colonies of the same strain generally exhibit similar features of size, consistency, edge, profile, luster, and color on nonselective media commonly used for the culture of staphylococci or micrococci. Certain strains may exhibit variant morphotypes, and in these situations, chromosomal analyses can be used to clarify the relationship of each morphotype. At least one colony of each morphotype should be selected from the primary isolation plate for subsequent analyses. Members of the same strain usually have the same biotype profile. However, further differentiation may be necessary if the strain has a common biotype profile.

Coagulase Production

The ability to clot plasma continues to be widely used as a criterion for the identification of pathogenic staphylococci associated with acute infections, i.e., *S. aureus* in humans and animals and *S. intermedius* and *S. hyicus* in animals. This activity is due to the action of coagulase which is secreted during bacterial growth. The test is performed by mixing 0.1 ml of an overnight culture in brain heart infusion broth with 0.5 ml of reconstituted plasma, incubating the mixture at 37°C in a water bath or heat block for 4 h, and observing the tube for clot formation by slowly tilting the tube 90° from the vertical. Alternatively, a large, well-isolated colony on a noninhibitory agar can be transferred into 0.5 ml of reconstituted plasma and incubated as described above. Any degree of clotting constitutes a positive test result. A flocculent or fibrous precipitate is not a true clot and should be recorded as negative. If no clot is formed by 4 h, the tube should be reincubated overnight at 35 to 37°C. Some strains of *S. intermedius* and most coagulase-producing strains of *S. hyicus* require more than 4 h for a positive coagulase test. If incubation exceeds 4 h, the following points must be considered: (i) staphylokinase produced by some strains may lyse the clot after prolonged incubation, yielding false-negative results; (ii) false-positive or false-negative results may occur if the plasma used is not sterile; and (iii) an inoculum from an agar-grown colony may not be pure and a contaminant may produce false results after prolonged incubation. For uncommon *S. aureus* strains requiring a longer clotting period, other characteristics (Table 3) should also be tested to confirm identity. Additional characteristics are required to identify rare coagulase-negative *S. aureus* strains.

Slide Agglutination Test

The slide agglutination test detects bacterial aggregation of *S. aureus* in the presence of plasma through the action of a cell wall-associated protein termed clumping factor A, which is an adhesin for fibrinogen. A positive slide test may also aid in the identification of *S. lugdunensis* and *S. schleiferi* (Table 3). It is performed by making a heavy uniform suspension of growth in distilled water, stirring the mixture to a homogeneous composition so as not to confuse clumping with autoagglutination, adding 1 drop of plasma, and observing for clumping within 10 s. Slide tests must be read quickly because false-positive results may appear with reaction times of longer than 10 s. In addition, colonies for testing must not be picked from media containing high concentrations of salt (e.g., mannitol-salt agar) because autoagglutination and false-positive results may occur. Some uncommon strains of *S. intermedius* may give a positive slide test result. Alternative methods include commercial kits that detect one or more of the following: clumping factor, protein A, and other surface antigens. Latex agglutination tests often have a higher specificity and sensitivity than the conventional slide test for the identification of *S. aureus*, although they are generally less reliable for the identification of *S. lugdunensis*. Some members of the *S. saprophyticus* and *S. sciuri* species groups and *Macrococcus* species may produce positive results with latex agglutination tests, but they are usually negative in the slide test. Due to the low levels of bound coagulase and protein A in MRSA strains, the detection of MRSA by rapid agglutination tests requires the incorporation of antibodies against staphylococcal capsular polysaccharide. Latex agglutination tests that detect both serotype 5 and serotype 8 capsular polysaccharides of methicillin-susceptible *S. aureus* and MRSA strains are available (54); however, false-positive reactions can occur (13, 68, 191). When the test organism is suspected to be *S. aureus*, negative slide tests should be confirmed by the coagulase test. Various manufacturers provide commercial latex agglutination kits, including the Slidex Staph (bioMérieux), BBL Staphyloslide (BD), Staphaurex (Murex Diagnostics Inc., Norcross, Ga.), Staphaurex and Staphaurex Plus (Remel), Mastastaph (Mast, Merseyside, United Kingdom), and Staphytect Plus and Dry Spot Staphytect Plus (Oxoid). A variety of plasmas may be used for the coagulase or slide agglutination tests. Dehydrated rabbit plasma containing EDTA is commercially available. Human plasma should not be used unless it has been tested for clotting capability and lack of infectious agents.

Heat-Stable Nuclease Production

A heat-stable staphylococcal nuclease (thermonuclease [TNase]) that has endo- and exonucleolytic properties and can cleave DNA or RNA is produced by most strains of *S. aureus, S. schleiferi, S. intermedius,* and *S. hyicus*. Some strains of *S. epidermidis, S. simulans,* and *S. carnosus* demonstrate weak TNase activity. TNase can be detected by a metachromatic-agar diffusion procedure and DNA-toluidine blue agar. A commercial TNase test with toluidine blue agar is available (Remel), and results can be interpreted in 4 h. Regular DNase agar such as that used for differentiation of *Enterobacteriaceae* should not be used for TNase detection.

Phosphatase Activity

Detection of phosphatase activity is based on the hydrolysis of *p*-nitrophenylphosphate into phosphate and *p*-nitrophenol by alkaline phosphatase. This process has been incorporated into several commercial biochemical test systems for staphylococcal species identification. Phosphatase activity is indicated by the release of yellow *p*-nitrophenol from the colorless substrate. Strains of *S. aureus, S. schleiferi, S. intermedius,* and *S. hyicus* and most strains of *S. epidermidis* are alkaline phosphatase positive. Phosphatase-negative strains of *S. epidermidis* can be distinguished from the related species *S. hominis* on the basis of their strong anaerobic growth in thioglycolate within 18 to 24 h or resistance to polymyxin B on a 300-U disk (BD).

Pyrrolidonyl Arylamidase Activity

Pyrrolidonyl arylamidase (pyrrolidonase) activity can be determined by the hydrolysis of pyroglutamyl-ß-naphthylamide (L-pyrrolidonyl-ß-naphthylamide [PYR]) into L-pyrrolidone and ß-naphthylamine, which combines with a PYR reagent (*p*-dimethylaminocinnamaldehyde) to produce a red color.

TABLE 2 Differentiation of *Staphylococcus* species

| Species | Characteristic[a] | | |

S. vitulinus	−	+	−	(+)	−	−	−	+	+	−	ND	−	−	*d*	−	−	−	−	*d*	+	ND	(*d*)	+	−	−	*d*	*d*	−	−	−	+	−	−

[a] Symbols and abbreviations (unless otherwise indicated): +, 90% or more strains positive; ±, 90% or more strains weakly positive; −, 90% or more strains negative; *d*, 11 to 89% of strains positive; ND, not determined. Parentheses indicate a delayed reaction.

[b] Positive is defined as a colony diameter of ≥ 6 mm after incubation on P agar at 34 to 35°C for 3 days and at room temperature (ca. 25°C) for an additional 2 days; exceptions are *S. succinus* (4 to 6 mm on tryptic soy agar) and *S. fleuretti* (8 to 12 mm on tryptic soy agar).

[c] Positive is defined by the visual detection of carotenoid pigments (e.g., yellow, yellow-orange, or orange) during colony development at normal incubation or room temperatures. Pigments may be enhanced by the addition of milk, fat, glycerol monoacetate, or soaps to P agar.

[d] Growth is in a semisolid thioglycolate medium. Symbols: +, moderate or heavy growth down the tube within 18 to 24 h; ±, heavier growth in the upper portion of the tube and weaker growth in the lower, anaerobic portion of tube; −, no visible growth within 48 h but very weak diffuse growth or a few scattered, small colonies may be observed in the lower portion of the tube by 72 to 96 h. Parentheses indicate delayed growth appearing within 24 to 72 h, sometimes noted as large, discrete colonies in the lower portion of the tube.

[e] Growth is on P agar or bovine, sheep, or human blood agar at 34 to 37°C. *S. equorum* grows slowly at 35 to 37°C; its optimum growth temperature is 30°C. Anaerobic species *S. saccharolyticus* and *S. aureus* subsp. *anaerobius* grow very slowly in the presence of air. *S. aureus* subsp. *anaerobius* requires the addition of blood, serum, or egg yolk for growth on primary isolation medium. *S. auricularis, S. lentus,* and *S. vitulus* produce just-detectable colonies on P agar in 24 to 36 h, and these colonies remain very small (1 to 2 mm in diameter).

[f] The slide agglutination test using rabbit or human plasma detects the expression of clumping factor. Use human plasma for *S. lugdunensis* and *S. schleiferi*. Latex agglutination is less reliable for the detection of clumping factor in *S. lugdunensis*.

[g] Hemolysis on bovine blood agar. Symbols and abbreviations: +, wide zone of hemolysis within 24 to 36 h; (+), delayed moderate to wide zone of hemolysis within 48 to 72 h; (*d*), no or delayed hemolysis; −, no or only very narrow (1 mm) zone of hemolysis within 72 h. Some strains designated as negative may produce a slight greening or browning of blood agar.

[h] Catalase and cytochrome synthesis cannot be induced in *S. aureus* subsp. *anaerobius* by the addition of H_2O_2 or hemin to the culture medium. Catalase activity can be induced in *S. saccharolyticus* by hemin supplementation. In this species, cytochromes *a* and *b* are present in small quantities.

[i] Determined by the modified oxidase test to detect the presence of cytochrome *c* (50).

[j] Determined primarily by commercial rapid identification tests (see the text).

[k] Positive (resistant) is defined by an MIC of ≥ 1.6 μg/ml or a growth inhibition zone diameter of ≤ 16 mm with a 5-μg novobiocin disk.

[l] Positive is defined by a growth inhibition zone diameter of < 10 mm with a 300-U polymyxin B disk.

[m] Approximately 6 to 15% of strains of *S. epidermidis* are negative for alkaline phosphatase activity, depending on the population sampled. A low but significant number of clinical isolates are phosphatase negative.

[n] rRNA gene restriction site polymorphism using pBA2 as a probe can distinguish this species from other staphylococcal species, including *S. warneri* (34).

[o] All strains tested are also resistant to penicillin G, methicillin, oxacillin, gentamicin, and streptomycin.

[p] Positive reactions are with the Staph latex agglutination test (Remel) that detects clumping factor and/or protein A.

[q] Positive with the STAPH-ZYM tests but negative with the API STAPH tests (43).

A commercial PYR broth and PYR reagent (Remel) recommended for the identification of streptococci are useful for distinguishing certain staphylococcal species. A loopful of a 24-h agar slant culture or several well-isolated colonies are dispersed in the PYR broth (containing 0.01% PYR) to a turbidity of a 2 McFarland standard. The suspension is incubated at 35°C for 2 h. After incubation, 2 drops of PYR reagent are added to each tube without mixing. The development of red within 2 min is indicative of positive activity. Yellow, orange, or pink is considered a negative result. The basic features of the test have been incorporated into several of the commercial biochemical test panels for the identification of staphylococcal species. *S. haemolyticus, S. lugdunensis, S. schleiferi,* and *S. intermedius* are usually pyrrolidonase positive.

Ornithine Decarboxylase Activity

Positive ornithine decarboxylase activity can identify the species *S. lugdunensis* with considerable accuracy. Ornithine decarboxylase activity can be determined as follows. Decarboxylase basal medium (BD) is prepared according to the instructions of the manufacturer, 1% (wt/vol) L-ornithine dihydrochloride is added, and the final medium is adjusted to pH 6 with 1 N sodium hydroxide before sterilization. The medium is dispensed in 3- to 4-ml amounts into small (13 by 100 mm) screw-cap tubes and autoclaved at 121°C for 10 min. A loopful of an overnight agar slant culture or several well-isolated colonies are dispersed in the test broth, followed by overlaying of each tube with 4 to 5 mm of sterile mineral oil. Inoculated tubes should be incubated at 35 to 37°C for up to 24 h. They can be read initially at as early as 8 h for the positive identification of most strains of *S. lugdunensis;* at this time, *S. epidermidis* will produce negative results. A positive reaction is indicated by alkalinization of the medium, with a change in the initial grayish color or slight yellowing (caused by the initial fermentation of glucose) to violet (caused by decarboxylation of L-ornithine). Yellow at 24 h indicates a negative result.

Urease Activity

Conventional urea broth or agar (BD and Oxoid) can be used to detect urease activity in staphylococcal species. Miniaturization of the broth urease test has been incorporated into several of the commercial biochemical test systems for species-level identification of staphylococci. *S. epidermidis, S. intermedius,* and most strains of *S. saprophyticus* are usually urease positive.

ß-Galactosidase Activity

Detection of high levels of ß-galactosidase activity for the differentiation of certain staphylococcal species can be accomplished by commercial biochemical test systems that use 2-naphthol-ß-D-galactopyranoside as a substrate. Fast blue BB salt in 2-methoxyethanol is added to the test well after an appropriate incubation period to detect free ß-naphthol released by ß-galactosidase. Positive activity is indicated by plum purple. By this assay, *S. intermedius* and most strains of *S. saprophyticus* are ß-galactosidase positive; *S. schleiferi* is delayed or weakly positive.

Acetoin Production

Acetoin production from glucose or pyruvate is a useful alternative characteristic to distinguish *S. aureus* (positive) from another coagulase-positive species, *S. intermedius* (negative), and coagulase-positive strains of *S. hyicus*

TABLE 3 Key tests for identification of the most clinically significant *Staphylococcus* species

Species	Result of test for[a]:								
	Colony pigmentation[b]	Staphylocoagulase	Clumping factor[b]	Heat-stable nuclease	Alkaline phosphatase	Pyrrolidonyl arylamidase[b]	Ornithine decarboxylase	Urease[b]	β-Galactosidase[b]
S. aureus subsp. *aureus*	+	+	+	+	+	−	−	*d*	−
S. epidermidis	−	−	−	−	+	−	(*d*)	+	−
S. haemolyticus	*d*	−	−	−	−	+	−	−	−
S. hyicus (veterinary)	−	*d*	−	+	+	−	−	*d*	−
S. intermedius (veterinary)	−	+	*d*	+	+	+	−	+	+
S. lugdunensis	*d*	−	(+)	−	−	+	+	*d*	−
S. schleiferi subsp. *schleiferi*	−	−	+	+	+	+	−	−	(+)
S. saprophyticus subsp. *saprophyticus*	*d*	−	−	−	−	−	−	+	+

[a] Symbols: +, 90% or more species or strains positive; ±, 90% or more species or strains weakly positive; −, 90% or more species or strains negative; *d*, 11 to 89% of species or strains positive. Parentheses indicate a delayed reaction.
[b] Descriptions are the same as those in Table 2.

(negative). The conventional Voges-Proskauer test tube method with an incubation of 72 h may be used. For speed and convenience, acetoin production can be determined by a miniaturized Voges-Proskauer test incorporated into several of the commercial biochemical test systems for staphylococcal species identification.

Novobiocin Resistance

A disk diffusion test for estimating novobiocin susceptibility and distinguishing *S. saprophyticus* from other clinically important species can be performed using a 5-μg novobiocin disk on Mueller-Hinton agar or tryptic soy sheep blood agar. With an inoculum suspension equivalent in turbidity to a 0.5 McFarland opacity standard and incubation at 35 to 37°C for overnight to 24 h, novobiocin resistance is indicated by an inhibition zone diameter of ≤16 mm with any of these media. Rapid disk elution procedures with either manual or automated instrument interpretation have also been reported to predict reliably novobiocin resistance after only 4 to 5 h of incubation (71). Novobiocin resistance is intrinsic to *S. saprophyticus* and several other species (Table 2) but is uncommon in the other clinically important species.

Polymyxin B Resistance

A disk diffusion test to estimate polymyxin B susceptibility using a 300-U polymyxin B disk can be performed on any of the media mentioned above for estimation of novobiocin resistance, although the largest database has been obtained for tryptic soy sheep blood agar. Test conditions are as described above for novobiocin resistance. The 5-μg novobiocin disk and the 300-U polymyxin B disk can be tested on the same inoculated plate. Polymyxin B resistance is indicated by an inhibition zone diameter of <10 mm. *S. aureus, S. epidermidis, S. hyicus*, and *S. chromogenes* are usually resistant. Some strains of *S. lugdunensis* are also resistant.

Acid Production from Carbohydrates

Acid production from carbohydrates can be detected by the agar plate method of Kloos and Schleifer (92). A wide range of individual diagnostic tests can be performed using Diatabs, which are available from Rosco, Taastrup, Denmark. Carbohydrate reactions are also incorporated into several of the commercial biochemical test systems for staphylococcal species identification. These systems use a more acid-sensitive indicator than the bromcresol purple (pH ≤5.2) in the agar plate method. For this and other reasons, results with conventional carbohydrate tests (Tables 2 and 3) may be slightly different from those obtained with rapid commercial biochemical test systems. The production of acid from maltose and sucrose and the absence of acid production from trehalose and mannitol can distinguish *S. epidermidis* from other novobiocin-susceptible species. Some uncommon strains of this species may produce acid from trehalose. These isolates can be distinguished from other species on the basis of phosphatase activity, anaerobic growth in thioglycolate, polymyxin B resistance, colony morphology, and the absence of ornithine decarboxylase and pyrrolidonase activities. Production of acid from trehalose, mannose, maltose, and sucrose and the absence of acid production from mannitol can identify *S. lugdunensis*. *S. schleiferi* produces acid from mannose and sometimes from trehalose but does not produce acid from mannitol, maltose, or sucrose. The production of acid from sucrose and turanose and the absence of acid production from mannose, xylose, cellobiose, arabinose, and raffinose can distinguish *S. saprophyticus* from other novobiocin-resistant species.

Identification of Species by Commercial Biochemical or Nucleic Acid Test Systems

Commercial kit identification systems and automated instruments (see chapter 15) can identify a number of the *Staphylococcus* species with an accuracy of 70 to >90% with relative speed and simplicity. Since their introduction, systems have been improved and expanded to include more species. *S. aureus, S. epidermidis, S. capitis, S. haemolyticus, S. saprophyticus, S. simulans,* and *S. intermedius* are identified reliably by most of the commercial systems now available. For some systems, reliability depends on additional testing as

Result of test for[a]:										
Acetoin production	Novobiocin resistance[b]	Polymyxin B resistance[b]	Acid production (aerobically) from:							
			D-Trehalose	D-Mannitol	D-Mannose	D-Turanose	D-Xylose	D-Cellobiose	Maltose	Sucrose
+	−	+	+	+	+	+	−	−	+	+

−	−	+	+	−	+	−	−	−	−	+
−	−	−	+	(*d*)	+	*d*	−	−	(±)	+
+	−	*d*	+	−	+	(*d*)	−	−	+	+
+	−	−	*d*	−	+	−	−	−	−	−
+	+	−	+	*d*	−	+	−	−	+	+

suggested by the manufacturer. This might include determining coagulase, clumping factor, or ornithine decarboxylase activity, anaerobic growth in thioglycolate, or novobiocin resistance. Identification systems now available include the following: RAPIDEC Staph (identification of *S. aureus, S. epidermidis,* and *S. saprophyticus*), and API STAPH, VITEK, a fully automated microbiology system that uses a gram-positive identification card, and the more recent Vitek 2 (all from bioMérieux); the MicroScan Pos ID panel (read manually or automatically on MicroScan instrumentation) and the MicroScan Rapid Pos ID panel (read by the WalkAway systems; in addition, the ID panels are available with antimicrobial agents for susceptibility testing [Dade MicroScan, Inc., West Sacramento, Calif.]); the Crystal gram-positive identification system, Crystal rapid gram-positive identification system, Pasco MIC/ID gram-positive panel, and BD Phoenix, an automated identification system (BD); the GP MicroPlate test panel (read manually with the Biolog MicroLog system or automatically with the Biolog MicroStation system; Biolog, Hayward, Calif.); the MIDI Sherlock identification system; microbial identification system that automates microbial identification by combining cellular fatty acid analysis with computerized high-resolution gas chromatography (MIDI, Newark, Del.); and the RiboPrinter microbial characterization system (Qualicon, Inc., Wilmington, Del.), based on ribotype pattern analysis. Rapid identification of the species *S. aureus* can be made using the AccuProbe culture identification test for *S. aureus* (Gen-Probe, Inc., San Diego, Calif.). This test is a DNA probe assay directed against rRNA and is reported to be very accurate (≥95% specificity) (2, 172). Coagulase-negative and slide agglutination test-negative strains of *S. aureus* should be identified correctly by the AccuProbe test. Real-time PCR and melt curve analysis based on amplification of a portion of the 16S rRNA gene are reported to give accurate results for nine common staphylococcal species (including *S. aureus* and *S. epidermidis*) (171).

Micrococcus and Related Species, *Alloiococcus,* and *R. mucilaginosa*

Pigment production and colony morphology may be used as simple tests in the presumptive identification of *Micrococcus* species and other related gram-positive cocci. *Micrococcus lylae* can be distinguished from *Micrococcus luteus* by its cream-white or unpigmented colonies, lack of growth on organic nitrogen agar, and lysozyme resistance. However, a small percentage of *Micrococus luteus* strains produce cream-white colonies. *Micrococcus* species can be distinguished from species of the genus *Kocuria* on the basis of their inability to produce acid, aerobically, from D-glucose and β-D-fructose. Furthermore, the species *Kocuria varians* and *Kocuria rosea* can be distinguished from micrococci by the former species' nitrate reduction and negative or only weak oxidase activity, and *Kocuria kristinae* can be distinguished from micrococci by the former's production of acid, aerobically, from glycerol and D-mannose, production of acetoin, and hydrolysis of esculin. The orange-pigmented species *Dermacoccus nishinomiyaensis* can be distinguished from micrococci by the former's small, pale orange colonies, nitrate reduction, and lack of growth on 7.5% NaCl agar. *Kytococcus sedentarius* differs from other micrococci by being resistant to penicillin and methicillin and exhibiting arginine dihydrolase activity. Colonies of this species may produce a brownish water-soluble pigment and grow more slowly than those of micrococci. *Nesterenkonia halobia* can easily be separated from micrococci because it requires at least 5% NaCl for growth.

Alloiococci form small, alpha-hemolytic colonies on blood agar after 48 h of incubation. Isolates can be distinguished from other similar organisms by their inability to utilize carbohydrates, obligate aerobic nature, and negative oxidase activity. On routine blood agar, colonies of *R. mucilaginosa* are mucoid or sticky, transparent to white, and nonhemolytic and often adhere to the agar. This organism is distinguished from other similar organisms by its inability to grow in the presence of 5% NaCl and its ability to hydrolyze gelatin and esculin.

TYPING SYSTEMS

Typing is used in the clinical setting to investigate the relationship between strains of the same bacterial species associated with a cluster of infections (such as during a suspected outbreak of MRSA infections) or to track the spread of strains such as MRSA strains between units or

hospitals. This information is central to the effective functioning of infection control. Typing may also be used for patients with recurrent staphylococcal infections to indicate whether a second episode is due to relapse or recurrence. Identification of the same bacterial species with identical genotype during independent episodes of infection in a given patient has a high probability of representing relapse, although the possibility that a single colonizing strain has caused both infections cannot be excluded.

A wide range of typing techniques have been described, but the most common technique used worldwide is pulsed-field gel electrophoresis (PFGE). This is particularly suitable for the investigation of local outbreaks. It may also be used to compare banding patterns of *S. aureus* between centers, although this has been hampered by a lack of reproducibility both within and between laboratories. Considerable efforts have been made to standardize PFGE methodology for the typing of MRSA (130, 131). Multilocus sequence typing (MLST) is a sequence-based approach that has the advantage of being highly reproducible (48), but it depends on the availability of sequencing facilities, is expensive, and requires highly experienced personnel. Comparison of MLST and PFGE in a microepidemiological setting has demonstrated similar discriminatory abilities (142). Although the use of MLST may become more widespread, it is predominantly a research tool at the present time.

Other typing techniques include ribotyping (186), which can be performed using an automated system such as the RiboPrinter microbial characterization system (Qualicon) (40, 124), and random amplified polymorphic DNA (122, 137, 188). PCR amplification methodology includes analysis of the 16S to 23S rRNA intergenic spacer region (69, 98), restriction digestion or sequencing of *coa* (encoding coagulase) (35, 63, 167), and sequencing of *spa* (encoding protein A) (96, 136). The PCR-based technique termed variable-number tandem repeat analysis has been used to study *S. aureus*. A scheme using five variable-number tandem repeat loci *(sdr, clfA, clfB, ssp,* and *spa)* has been reported to be equivalent to PFGE in terms of discriminatory power and reproducibility (121, 159). GeneChip technology (Affymetrix Inc.) (47) and matrix-assisted laser desorption ionization–time of flight mass spectrometry (10) have been described for the study of *S. aureus* but are currently research tools.

ANTIMICROBIAL SUSCEPTIBILITIES

Staphylococci may be susceptible to a wide range of antimicrobial agents, and testing of a panel of drugs is common. However, the major emphasis in contemporary laboratories is the isolation and identification of MRSA. Methicillin-resistant strains emerged soon after the introduction of methicillin into clinical practice. This was followed from the mid-1970s by outbreaks of MRSA infection in many countries, mostly caused by a single epidemic strain that was transferred between hospitals. The picture of MRSA within the hospital setting is now one of both epidemic and sporadic infection caused by a broader range of strains. In addition to being a nosocomial pathogen, MRSA has become a community pathogen. High-risk groups including intravenous drug users, individuals with a serious underlying disease, those on antimicrobial therapy, and those recently discharged from the hospital accounted for the first reports of MRSA infection in the community (106). Skin and soft tissue infections are the most commonly reported diseases involving community-associated MRSA, particularly in correctional facilities (30), among competitive sports participants (29) and military recruits (207), and in hospital nursery and maternity units (17, 160). Community-associated isolates typically possess the Panton-Valentine leukocidin locus, share a type IV staphylococcal cassette chromosome *mec* (SCC*mec*), and may be categorized into two to three PFGE clonal groups (39, 133, 135, 190). Although the community-associated MRSA isolates typically are susceptible to various antimicrobial classes, sole empiric therapy to treat these infections may prove unsuccessful as resistance to clindamycin and induced resistance to macrolide-lincosamide-streptogramin have been observed (19, 84, 133).

MRSA strains are often heteroresistant to beta-lactam antibiotics in that two subpopulations (one susceptible and the other resistant) coexist within a culture (32). Each cell in the population may carry the genetic information for resistance, but only a small fraction (10^{-8} to 10^{-4}) express the resistant phenotype under in vitro test conditions. The resistant subpopulation usually grows much more slowly than the susceptible subpopulation and may be missed during laboratory testing. The successful detection of heteroresistant strains depends largely on promoting the growth of the resistant subpopulations, which is favored by neutral pH, cooler temperatures (30 to 35°C), the presence of NaCl (2 to 4%), and possibly prolonged incubation (up to 48 h) (18). Cefoxitin disk (30 μg) diffusion is a better indicator of the presence of *mec*A-mediated resistance than the oxacillin disk (149, 192). Detection of oxacillin resistance in staphylococci can be done by the methods recommended by the Clinical and Laboratory Standards Institute (CLSI; formerly the National Committee for Clinical Laboratory Standards [NCCLS]) guidelines (36) and those described in chapters 73 and 74 of this Manual. To increase the accuracy of methicillin susceptibility testing, recent changes in the CLSI guidelines have given *S. lugdunensis* the same MIC breakpoints as *S. aureus* but susceptibility breakpoints separate from those of other CoNS isolates. Difficulties in the differentiation of MRSA isolates from borderline oxacillin-resistant strains of *S. aureus,* which are resistant due to the hyperproduction of beta-lactamase rather than the presence of the *mec*A determinant, may be problematic to many clinical laboratories not routinely utilizing PCR as their standard method of detecting MRSA. However, to date, there have been no reports of treatment failure with penicillinase-resistant penicillins in cases of infection with these organisms.

New chromogenic media, MRSA ID (bioMérieux) and CHROMagar MRSA (BD), have the ability to identify *S. aureus* isolates and differentiate MRSA isolates (44, 72, 145). The application of a cefoxitin disk to CHROMagar Staph aureus and *S. aureus* ID media may be an alternative means to detect MRSA and has the added benefit of preventing growth inhibition of MRSA on the whole agar surface (72).

A signal-amplified, sandwich hybridization kit, EVIGENE MRSA (AdvanDX) (107), is available for the rapid identification of *mec*A from either positive blood cultures or clinical isolates, although it is for research-only use in the United States. Rapid detection of the *mec*A gene product in *S. aureus* is also possible by using a commercial slide latex agglutination test (23, 134, 155). Accurate differentiation of MRSA from borderline oxacillin-resistant *S. aureus* by using a slide latex agglutination test has also been reported (114). Genotypic testing for detecting the presence of *mec*A may be performed using PCR (51, 67, 82, 155, 168, 181). Some

investigators include PCR detection of a second gene such as *femA, femB, orfX,* or *sa442* (80, 155, 168) or the *S. aureus*-specific marker gene *nuc* (thereby providing simultaneous identification) (38), and multiplex PCR may be performed to detect several genes associated with resistance to different antibiotic groups (143). A quadriplex PCR targeting the 16S RNA gene (*Staphylococcus* genus specific), *nuc* (*S. aureus* species specific), *mecA,* and *mupA* (a determinant of mupirocin resistance) (205) demonstrates the potential scope of this rapidly developing technology. The use of real-time PCR is increasing and provides the potential for rapid results. The GenoType MRSA test kit (Hain Lifescience, Nehren, Germany) detects *mecA* plus an *S. aureus*-specific sequence by using PCR and reverse hybridization (138). The probe-based Velogene rapid MRSA identification assay (ID Biomedical Corp., Vancouver, Canada) is based on a chimeric probe to detect the *mecA* gene (115). This test is reported to be accurate and has the advantage that it does not rely on PCR technology.

Antimicrobial susceptibility testing of SCVs of *S. aureus* presents a challenge for the clinical microbiology laboratory. Since SCVs have minimal amounts of ATP available and cannot effectively transport aminoglycosides into the cell, resistance to gentamicin and other aminoglycosides can be expected (152). Resistance to trimethoprim-sulfamethoxazole is observed in thymidine auxotrophs (151). The slow growth of SCVs limits the usefulness of antimicrobials directed against the cell wall. No approved method has been developed to determine the susceptibility profiles of SCVs. Susceptibililty profiles have been determined by using the broth or agar dilution MIC method with low levels of auxotroph supplements, disk diffusion under NCCLS guidelines with MH agar supplemented with blood, and the E test (AB Biodisk, Skolna, Sweden) with Mueller-Hinton (MH) agar supplemented with blood (83, 151).

With the increase in methicillin resistance in *Staphylococcus* species, other antibiotics have been used in the treatment of serious infections caused by this group of bacteria. The glycopeptide vancomycin has been regarded as the drug of choice for the treatment of infections due to methicillin-resistant staphylococci. The appearance of vancomycin-intermediate (MICs, 8 to 16 μg/ml) *S. aureus* (VISA), VRSA (MICs, ⩾32 μg/ml), and resistant CoNS requires the prudent use of vancomycin (12, 28, 31, 184). The Centers for Disease Control and Prevention have developed a recommended algorithm for testing *S. aureus* with vancomycin (see http://www.cdc.gov/ncidod/hip/vanco/vanco.htm). Automated susceptibility systems and disk diffusion are not reliable means to detect VISA or VRSA. A vancomycin-intermediate or -resistant result for a staphylococcal isolate should be verified by repeating a validated MIC method (broth microdilution reference MIC, agar dilution reference MIC, or the E test), and the organism should be identified (36). Detecting vancomycin-heteroresistant populations of staphylococci appears to be a challenge similar to that of detecting methicillin-heteroresistant populations. Heterogeneous VISA poulations include two populations of cells, the majority of which are susceptible to vancomycin (175). The heteroresistant populations are associated with clinical failure of glycopeptide therapy, and the use of other antimicrobials such as linezolid along with surgical intervention may be necessary to effectively treat the infection (78, 109, 156). An evaluation of methods used to detect staphylococcal isolates with reduced susceptibility to glycopeptides suggests that the E test with an inoculum with a 2.0 McFarland standard on brain heart infusion yields the highest sensitivity and specificity, with values of 88 and 88%, respectively (198). Interim guidelines have been established to prevent and control staphylococcal infections associated with reduced susceptibility to vancomycin (27).

Reviews have summarized the antimicrobial susceptibilities of staphylococcal species to various drugs (105, 141). Multidrug resistance is more frequent in *S. haemolyticus, S. epidermidis, S. hominis,* and *S. aureus* than in other staphylococcal species isolated in the clinical laboratory. Increased levels of resistance to antimicrobial agents used for therapy, including aminoglycosides, glycopeptides, quinolones, tetracyclines, macrolides, lincosamides, and trimethoprim-sulfamethoxazole, make the treatment of multidrug-resistant-staphylococcus infections difficult. Recent reviews provide a summary of a variety of new compounds being investigated or utilized for the therapy of MRSA infections, including daptomycin and linezolid (4, 166). Several studies comparing vancomycin and linezolid therapy indicate that linezolid may give a better outcome for patients with complicated skin and soft tissue infections (108, 199), pneumonia (202), and surgical site infections (200) caused by MRSA. It is important to note that clinical failures have occurred with linezolid (148, 157).

Micrococci appear to be susceptible to most antibiotics. Successful treatment has been accomplished using vancomycin, penicillin, gentamicin, clindamycin, or a combination of these antibiotics (120). Strains of alloiococci show resistance to both erythromycin and trimethoprim-sulfamethoxazole and relative resistance to beta-lactams (15). *R. mucilaginosa* appears to be variable in its antimicrobial susceptiblity (194, 195). The observation that *R. mucilaginosa* exhibits poor to no growth on MH agar and MH agar with sheep blood may make susceptibility testing a challenge for clinical microbiology laboratories.

INTERPRETATION AND REPORTING OF RESULTS

The first critical step when interpreting a culture that is positive for staphylococci is to distinguish between *S. aureus* and other species. The laboratory tests required to reach this point are essential in all cases. It is also important to have an appreciation of the quality of the specimen under consideration. A positive culture taken from a sterile site is relatively straightforward to interpret, but one from a contaminated site cannot be interpreted accurately away from the bedside. Clinical features and the results of other investigations should be taken into account during the interpretative process. There is no replacement for good communication between laboratory staff and primary physicians.

Identification of the causative pathogen represents the "gold standard" for the diagnosis of staphylococcal disease; serological testing lacks specificity and predictive accuracy. Isolation of *S. aureus* from a sterile-site culture (such as aspirated pus, blood, or cerebrospinal fluid) should be considered clinically significant unless there is strong evidence to the contrary. Contamination of high-quality samples by *S. aureus* is rare, and further samples should be taken if there is clinical doubt. Interpreting the isolation of *S. aureus* from specimens contaminated with normal flora requires consideration of setting, clinical features, and recent interventions. For example, interpretation of the significance of *S. aureus* in bronchoalveolar lavage fluid from a ventilated patient will require an evaluation of the features of pneumonia such as fever, raised peripheral white blood count, new pulmonary infiltrates upon chest radiography,

increasing oxygen requirements, and increased production of respiratory secretions. Quantitative culture may be helpful, for example, when interpreting a bronchoalveolar lavage or urine sample. Isolation of *S. aureus* from surgical wounds and other sites such as ulcers may represent infection or colonization, and clinical response to the culture should be strongly guided by the presence of features of infection. Colonization alone is an insufficient reason to treat, unless the patient is colonized by MRSA and decolonization is undertaken as part of a specific infection control policy. Susceptibility testing, and in particular the detection of methicillin resistance, should always be carried out following the identification of *S. aureus*.

Interpreting the significance of cultures that are positive for other staphylococcal species is more challenging. It is almost inevitable that samples taken from colonized sites will contain CoNS, and blood samples taken without careful skin cleaning will become contaminated with skin flora. Interpretation of blood cultures positive for CoNS requires knowledge of the presence of prosthetic material in the intravascular compartment, risk factors for true CoNS sepsis such as prematurity or the presence of an immunocompromised immune system, and clinical features of sepsis (the nature of which will vary depending on the clinical scenario). A review of CoNS infections has summarized factors that are helpful in distinguishing between true positive and contaminated cultures taken from a patient with clinical features of infection (89). These include (i) isolation of a strain in pure culture from the infected site or body fluid (most contaminated clinical specimens produce mixed cultures of different strains and/or species; however, some infections may be the consequence of more than one strain or species) and (ii) the repeated isolation of the same strain or combination of strains over the course of the infection. Thus, repeated acquisition of high-quality samples may prove extremely helpful, where clinically possible. If a patient with suspected bacteremia is due to start antibiotics, then independent blood samples may be taken from different sites over a relatively short period of time. The presence of the same CoNS on an intravenous catheter tip and in a blood culture is supportive evidence for intravenous catheter-associated bacteremia. Isolation of CoNS from peritoneal dialysis fluid or cerebrospinal fluid taken from ventricular shunts in a patient suspected of having infection is usually significant. Again, culture of more than one sample may provide helpful confirmation. Cultures of explanted prosthetic material such as pacemakers and joint replacements are often positive for CoNS and may contain mixed flora. When infection is considered likely and treatment is required, each species should be identified and all species should be tested for antimicrobial susceptibilities, after which the choice of therapy may be based on the combined antibiogram. If mixed colony morphology is observed in a potentially significant culture, one or more aged (≥72 h) colonies of a particular morphotype should be isolated from the primary isolation plate for each culture to be identified. The practice of pooling two or more young (24- to 48-h) colonies in the preparation of an inoculum or culture carries the risk of producing a mixed culture, resulting in an erroneous identification and accompanying antibiogram. Selecting only one young colony from a primary isolation plate carries the risk of missing the actual etiologic agent.

Interpretation of other samples will be influenced by sample type. For example, it is recognized that *S. saprophyticus* is a common cause of urinary tract infection, and laboratory tests that distinguish this species are often performed on urine specimens. Colony counts of ≥100,000 CFU/ml in two or more cultures of midstream urine are taken to indicate significant bacteriuria (180), but staphylococci grow relatively slow in urine and lower counts may be significant in the symptomatic patient. Isolation of CoNS from other samples taken from colonized sites rarely represents a clinically significant result. If doubt remains, repeated sampling (if possible, a higher-quality sample) can be performed.

Given the problems of interpreting cultures containing CoNS, it is worthwhile to develop a sampling strategy for complicated patients who probably have a true CoNS infection. This is particularly pertinent when dealing with patients with low-grade infection associated with implanted prosthetic material such as a joint replacement or vascular graft. These patients may require prolonged courses of antibiotics, and optimizing culture techniques may prove crucial to accurate diagnosis, therapy, and cure. As an example, deep-site samples taken by direct visualization from an area of suspected osteomyelitis during an operative procedure, particularly when the lesion communicates with the exterior, should include samples from each anatomical layer or region, and fresh instruments should be used to gather deep-site samples (5).

All CoNS associated with true infection require susceptibility testing. The decision about when to undertake species-level identification of CoNS associated with infection is a matter for debate. It is often helpful to identify to the species level when there are mixed populations (based on colony morphologies) in a clinically significant sample or when samples from different sites or serial samples are positive. The antibiogram is often used as a surrogate marker for the presence of the same or different strains or species, but this is not 100% reliable. It is also prudent to identify organisms from deep-tissue infections and from the bloodstreams of patients with suspected endocarditis, since the identification of *S. lugdunensis* raises the index of suspicion for aggressive disease. However, species-level identification of CoNS rarely leads to an intervention or to changes in therapy, and there is no compelling clinical reason to identify to the species level in many cases. Species-level identification of pathogenic CoNS contributes epidemiological information, but this is probably not sufficient justification to identify all CoNS to the species level in routine diagnostic laboratories. Contaminants do not require susceptibility testing or identification.

BARBARA SPELLERBERG AND CLAUDIA BRANDT

29

TAXONOMY

The taxonomy of streptococci has experienced a number of changes during the last 20 years mostly due to the application of molecular biology techniques such as DNA-DNA reassociation experiments and 16S rRNA gene sequencing. Among the currently established 17 different genera of catalase-negative gram-positive cocci are several genera that were split off from the genus *Streptococcus* some time ago such as *Enterococcus* and *Lactococcus,* or more recently *Abiotrophia, Granulicatella, Facklamia,* and *Globicatella*. For an excellent review on the topic reflecting many of the recent changes, see reference 34. Molecular 16S rRNA analysis of streptococci has shown that species designation based solely on the hemolysis reaction, colony size, and the presence of Lancefield antigens does not correspond well with the molecular analysis in all cases. Taxonomic changes will certainly continue in the future. However, the traditional streptococcal classification system is well established and still of value to the clinical microbiologist. The phenotypic classification system correlates with clinical syndromes caused by different species and enables a first distinction of broad categories of streptococci that is useful for the choice of further tests and guidance of empirical treatments. The information and the identification schemes presented in this chapter therefore adhere in many aspects to this well-known phenotypic classification system.

The classical phenotypic differentation of streptococci separates the group of beta-hemolytic streptococci, which are discussed first in this chapter, from the group of non-beta-hemolytic streptococcal species. Beta-hemolytic streptococci, also referred to as pyogenic streptococci, include the species *S. pyogenes, S. agalactiae, S. dysgalactiae, S. equi,* and *S. canis*. The designation pyogenic streptococci is more precise, since the group includes species that are non-beta-hemolytic like *S. dysgalactiae* subsp. *dysgalactiae,* which is closely related to several beta-hemolytic species, and the term excludes beta-hemolytic strains of the *S. anginosus* group, which are more appropriately placed into the viridans streptococcal group. The small colony size of streptococci from the anginosus group (<0.5 mm) helps to distinguish them from the large-colony-forming (>0.5 mm) streptococci of the pyogenic group. Species from the pyogenic or beta-hemolytic group are further characterized by the presence of Lancefield antigens, which correlates in the case of group A streptococci fairly well but not precisely with the species designation *S. pyogenes*. While the B antigen appears to be limited to *S. agalactiae,* the Lancefield group A antigen has been detected not only in *S. pyogenes* but also in *S. dysgalactiae* subsp. *equisimilis* isolates (16) and in species from the *S. anginosus* group, (Table 1). Correlation with the other Lancefield antigens is even more complicated, which led to the need for novel species designations, presented below and in Table 1.

The group of nonpyogenic streptococci includes mostly α-hemolytic as well as nonhemolytic and even beta-hemolytic streptococcal species from the large category of viridans streptococci. In a study of the genus *Streptococcus* based on sequence comparisons of small-subunit (16S) rRNA genes, five species groups of viridans streptococci were demonstrated (57) in addition to the pyogenic group (beta-hemolytic, large-colony formers). These nonpyogenic groups were designated the *S. mitis* group, the *S. anginosus* group, the *S. mutans* group, the *S. salivarius* group, and the *S. bovis* group. A few streptococcal species were not unequivocally assigned and remain ungrouped. Descriptions of the species in the nonpyogenic groups follow the discussion on *S. pneumoniae*. Among α-hemolytic streptococci, *S. pneumoniae* can be separated from other streptococci of the viridans group through bile solubility and optochin susceptibility. However, phenotypic characterization and taxonomic considerations place *S. pneumoniae* into the *S. mitis* group (57). The relationship of *S. pneumoniae* to other species of the *S. mitis* group is so close that 16S rRNA gene analysis reveals greater than 99% identity to the nucleotide sequences of *S. mitis* and *S. oralis*. A novel, closely related species, *S. pseudopneumoniae,* has recently been split off from *S. pneumoniae,* following DNA-DNA hybridization studies and phenotypic characterization (1). Strains are nonencapsulated and insoluble in bile, and their clinical significance is currently uncertain.

S. mitis, S. sanguinis, S. parasanguinis, S. gordonii, S. cristatus, S. oralis, S. infantis, S. peroris (58), and *S. pneumoniae* are members of the *S. mitis* group. These species form a group whose classification and nomenclature have been a source of considerable confusion in the past. Among the changes that were made is the reclassification of the original *S. mitis* type strain as an *S. gordonii* strain and the subsequent replacement by a new *S. mitis* type strain (NCTC12261^T) (61). Further

* This chapter contains information presented in chapter 29 by Kathryn L. Ruoff, R. A. Whiley, and D. Beighton in the eighth edition of this Manual.

TABLE 1 Phenotypic characteristics of beta-hemolytic streptococci[a]

Species	Lancefield group	Colony size[e]	Hosts	Bacitracin	PYR[f]	CAMP[g]	VP[i]	Hippurate hydrolysis	Trehalose	Sorbitol
S. pyogenes	A	Large	Humans	+	+	–[h]	–	–	+	–
S. agalactiae	B	Large	Humans, cows	–	–	+	–	+	v	–
S. dysgalactiae subsp. *dysgalactiae*[b]	C	Large	Animals	–	–	–	–	–	+	v
S. dysgalactiae subsp. *equisimilis*	A, C, G, L	Large	Humans	–	–	–	–	–	+	–
S. equi subsp. *equi*	C	Large	Animals	–	–	–	–	–	–	–
S. equi subsp. *zooepidemicus*	C	Large	Animals, humans[c]	–	–	–	–	–	–	+
S. canis	G	Large	Dogs, humans[c]	–	–	+	–	–	v	–
S. anginosus group[d]	A, C, G, F, none	Small	Humans	–	–	–	+	–	+	–
S. porcinus	E, P, U, V, none	Large	Swine, humans[c]	–	+	+	+	v	+	+

[a] Symbols and abbreviations: +, positive; –, negative; v, variable.
[b] *S. dysgalactiae* subsp. *dysgalactiae* is α-hemolytic on sheep blood agar plates.
[c] *S. equi* subsp. *zooepidemicus*, *S. canis,* and *S. porcinus* are primarily animal pathogens that are only rarely isolated from humans.
[d] Species included in the *S. anginosus* group can be beta-hemolytic, alpha-hemolytic, or nonhemolytic on sheep blood agar plates.
[e] Large colony size refers to colonies >0.5 mm after 24 h of incubation, whereas small colony size is <0.5 mm.
[f] Presence of the enzyme pyrrolidonyl aminopeptidase.
[g] CAMP factor reaction (synergistic hemolysis in the presence of *S. aureus* β-hemolysin).
[h] *S. pyogenes* may occasionally yield a false-positive CAMP factor reaction.
[i] Voges-Proskauer test (formation of acetoin from glucose fermentation).

confusion is caused by the use of the term "biotype," especially for the species *S. sanguinis*. While the biotypes differ in phenotypic reactions, biotypes are not included in the approved lists of bacterial names and appear to vary between different studies (7, 61), and in most cases, no type strains are available. Based on phenotypic reactions (especially arginine hydrolysis and esculin tests), the *S. mitis* group can be further subdivided into the *S. sanguinis* and the *S. mitis* groups (34), but based on 16S rRNA analysis, these two groups appear to belong together (57). Since correlation of the renamed streptococcal species with human infections is still difficult, we chose to present these species as part of the *S. mitis* group until further information becomes available.

The small-colony-forming *S. anginosus* group consists of the three distinct species *S. anginosus, S. constellatus,* and *S. intermedius* (118). It includes streptococcal species previously referred to as Lancefield group F streptococci, "*S. milleri*" group or "*S. milleri.*" The species "*S. milleri*" has no standing taxonomically. The *S. mutans* group comprises the species *S. mutans, S. sobrinus, S. criceti,* and *S. ratti* and numerous species that have been identified only from animals thus far *(S. downei, S. ferus, S. macacae,* and *S. hyovaginalis)*.

The human species *S. salivarius, S. vestibularis,* and *S. thermophilus,* which is found in dairy products, belong to the *S. salivarius* group. Whether *S. thermophilus* was a subspecies of *S. salivarius* was controversial, although DNA-DNA reassociation experiments determined that they are two separate species (96). The whole *S. salivarius* group is closely related to the *S. bovis* group. Some streptococcal species that are currently part of the *S. bovis* group *(S. infantarius* and *S. alactolyticus)* (94) were formerly part of the *S. salivarius* group (34).

The *S. bovis* group has experienced extensive taxonomic changes (28, 80, 88, 94, 95). Four DNA clusters are currently recognized. DNA cluster I consists of the species formerly known as animal strains of *S. bovis* and *S. equinus*. Molecular analyses of these strains showed that they belong to a single species (41), and the earlier species name *S. equinus* has been formally adopted. DNA cluster II consists of one species, *S. gallolyticus,* with three subspecies: subspecies *gallolyticus* (formerly *S. bovis* biotype I), subspecies *pasteurianus* (formerly *S. bovis* biotype II.2), and subspecies *macedonicus*. DNA cluster III consists of one species, *S. infantarius* (formerly *S. bovis* biotype II.1), with two subspecies: subspecies *infantarius* and subspecies *coli* (formerly called *S. lutetiensis*). DNA cluster IV consists of one species, *S. alactolyticus*. These changes were made because DNA-DNA reassociation studies revealed considerable heterogeneity among the human isolates described as *S. bovis* biotypes.

DESCRIPTION OF THE GENUS

Bacterial species belonging to the genus *Streptococcus* are catalase-negative, gram-positive cocci of less than 2 μm that tend to grow in chains in liquid media. The cell wall composition is typical for gram-positive bacteria and consists mainly of peptidoglycan with glucosamine and muramic acid as amino sugars and galactosamine as a variable component. A variety of carbohydrates, surface protein antigens, and teichoic acid are attached to the cell wall and are, among other characteristics, responsible for species differences and clonal differences among streptococci. Most species of the genus *Streptococcus* have a low G+C content of DNA that lies in the range of 34 to 46%. Streptococci are facultative anaerobic bacteria. Due to a lack of heme compounds, streptococci are incapable of respiratory metabolism. Some species of the viridans streptococcal group and *S. pneumoniae* require 5% CO_2 levels for adequate growth, and the growth of many streptococcal species is enhanced in the presence of 5% CO_2. The temperature optimum for most streptococci is around 37°C, while some species like *S. uberis* also grow at temperatures as low as 10°C. The complex nutritional

requirements of streptococci are usually provided by the addition of blood or serum to the growth medium. Glucose and other carbohydrates are metabolized fermentatively, with lactic acid as the major metabolic end product. The addition of glucose or other carbohydrates to liquid medium enhances growth but lowers the pH, resulting in growth inhibition unless the medium is highly buffered (e.g., Todd-Hewitt broth [THB]). Leucine aminopeptidase (LAP) is produced by all streptococci and enterococci but can also be found in lactococci, pediococci, and other catalase-negative gram-positive cocci. It helps to distinguish these species from the LAP-negative *Aerococcus* species and *Leuconostoc*. All streptococci are catalase negative upon exposure to 3% hydrogen peroxide. False-positive reactions may occur if bacteria are grown on blood-containing media.

EPIDEMIOLOGY AND TRANSMISSION

Streptococci can cause infections in humans and in many different animal species including mammals and fish. Different species of streptococci are frequently found as commensal bacteria on mucous membranes. Occasionally streptococci are present as transient skin microbiota. Several streptococcal species exhibit high virulence potential, but even the highly virulent streptococcal species are frequently found as colonizing strains without any apparent effect on the host. *S. pneumoniae* was responsible for approximately 40,000 invasive infections in the United States in 2003, leading to an estimated 5,500 deaths (http://www.cdc.gov/abcs), and was found as a colonizing bacterial species in many asymptomatic carriers. The asymptomatic carriage rate for *S. pneumoniae* differs considerably between children and adults. Detection rates of 30 to 70% have been reported for young children, depending on the sampling method, while carriage rates among healthy adults are often reported to be below 5% (47, 51, 90). Evidence for household transmission between parents and their children has been found, demonstrating colonization rates for adults living in a household with young children that are significantly higher than in adults with no contact with preschool children (51).

Due to active bacterial surveillance in the emerging infections program network (99), reliable epidemiologic data on invasive infections due to *S. pneumoniae* (described above), *S. pyogenes* (group A), and *S. agalactiae* (group B) have been obtained for a population of 17 to 30 million people in the United States during 2003. *S. pyogenes* caused an estimated 11,300 cases of invasive disease and 1,800 deaths, with the peak of infections in people older than 65 years. Invasive infections due to *S. agalactiae* were second to those due to *S. pneumoniae,* with an estimated 20,400 cases and 2,200 deaths in 2003. Reflecting the ongoing changes in the epidemiology of group B streptococcal disease, the highest attack rates were observed for patients less than 1 year and adults greater than 65 years of age. Apart from causing invasive infections, both of these streptococcal species are frequently encountered as colonizing strains. While asymptomatic colonization of the nasopharynx with *S. pyogenes* occurs in less than 5% of the adult population in most studies, *S. agalactiae* colonization rates of the urogenital and gastrointestinal tracts can be demonstrated in 10 to 30% of the female as well as the male population. No significant differences are observed in the colonization rates of pregnant and nonpregnant women.

Transmission of streptococcal infections can occur by different routes. Pathogenic species like *S. pyogenes* and *S. pneumoniae* are primarily transmitted through droplets or direct contact. Transmission can first lead to colonization with the potential for the development of a subsequent infection. The tooth decay-causing species *S. mutans* is transmitted from mother to child during early infancy, most probably through oral secretions. Transmission from mother to child is also the typical transmission mode for neonatal invasive *S. agalactiae* infections. Newborns acquire the bacteria usually during delivery, although transmissions, shortly after birth, from the mother or health care personnel to infants have been documented, especially in late-onset neonatal infections. Endogenous infections most often occur by viridans streptococci as part of the oral microbiota.

Streptococcal infections do not represent classical zoonoses, although most species have a preferred host. While occasional animal-to-human transmissions do occur, as in the case of *Streptococcus suis* (67), genotypic and phenotypic analyses of animal and human strains demonstrated that the strains causing human infections were distinct from the strains causing animal infections. For beta-hemolytic group C and G streptococci, such an analysis led to an important change in species designations (111). Human group C and group G streptococcal strains were demonstrated to belong to a separate subspecies, designated *S. dysgalactiae* subsp. *equisimilis,* while animal group C, G, and L streptococci are classified as *S. dysgalactiae* subsp. *dysgalactiae, S. canis, S. equi* subsp. *equi,* and *S. equi* subsp. *zooepidemicus* (27, 40). The reservoir for *S. dysgalactiae* subsp. *equisimilis* strains is the human host, and transmission usually occurs among humans.

CLINICAL SIGNIFICANCE

Streptococcus pyogenes (Group A Streptococci)

S. pyogenes colonizes the human throat and skin and has developed complex virulence mechanisms to avoid host defenses (20, 31). The upper respiratory tract and skin lesions serve as primary focal sites of infections and principal reservoirs of transmission. *S. pyogenes* can cause superficial or deep infections due to toxin- and immunologically mediated mechanisms of disease. *S. pyogenes* is the most common cause of bacterial pharyngitis and impetigo. In the past, *S. pyogenes* was a common cause of childbed fever or puerperal sepsis. *S. pyogenes* is responsible for deep or invasive infections, especially bacteremia; sepsis; deep soft tissue infections, such as erysipelas; cellulitis; and necrotizing fasciitis. Less common presentations include myositis, osteomyelitis, septic arthritis, pneumonia, meningitis, endocarditis, pericarditis, and severe neonatal infections following intrapartum transmission. One or more erythrogenic exotoxins produced by *S. pyogenes* may cause a confluent erythematous sandpaper-like rash characteristic of scarlet fever. While systemic toxic effects occur rarely with scarlet fever, severe clinical manifestations in streptococcal toxic shock syndrome (STSS) may result from massive superantigen-induced cytokine and lymphokine production. Nonsuppurative complications include poststreptococcal glomerulonephritis and acute rheumatic fever. While either of these conditions may follow pharyngitis, only glomerulonephritis is linked with skin infections due to *S. pyogenes*. *S. pyogenes* has also been associated with pediatric autoimmune neuropsychiatric disorders (106).

Causes of the emergence of STSS, frequently accompanied by necrotizing fasciitis, and the resurgence of invasive *S. pyogenes* infections since the mid-1980s are mostly unexplained (105). *S. pyogenes* remains exquisitely sensitive to penicillin. Despite the continuous exposure and subsequent type-specific immunity, the most prevalent

M types associated with STSS continue to be M1 and M3, together accounting for approximately 50% of invasive infections. Since identical strains have accounted for less serious infections (78), host factors and comorbid conditions account for different diseases. The incidence of STSS seems highest among young children, particularly those with varicella, and the elderly. Other persons at risk include those with diabetes mellitus, chronic cardiac or pulmonary diseases, human immunodeficiency virus infection, intravenous drug abuse, and alcohol use. The risk for severe invasive infection in contacts has been estimated to be 200 times greater than for the general population, but most contacts are asymptomatically colonized (23).

Streptococcus agalactiae (Group B Streptococci [GBS])

S. agalactiae was first identified as the cause of bovine mastitis at the end of the 19th century. Since the 1970s it has been increasingly reported as the cause of invasive neonatal infections. Neonatal infections present as two different clinical entities: early-onset neonatal disease, characterized by sepsis and pneumonia within the first 7 days of life; and late-onset disease with meningitis and sepsis between 7 days and 3 months of age. The most important risk factor for the development of invasive neonatal disease is the colonization of the maternal urogenital or gastrointestinal tract by *S. agalactiae,* which is found in 10 to 30% of pregnant women. Prevention of early-onset neonatal infections can be achieved in the majority of cases by administration of intrapartum antibiotic prophylaxis starting at least 4 h before delivery. Official CDC recommendations for the prevention of neonatal *S. agalactiae* infections were first issued in 1996 (100), were revised in 2002 (97), and resulted in a substantial decline of early-onset neonatal GBS disease (98). Invasive *S. agalactiae* infections of adult patients may be observed as postpartum infections or in immunocompromised adult patients with alcoholism, diabetes mellitus, cancer, or human immunodeficiency virus infection (39). The spectrum of infections in adult patients includes pneumonia, bacteremia, endocarditis, urinary tract infections, skin and soft tissue infections, and osteomyelitis.

Streptococcus dysgalactiae subsp. *equisimilis* (Human Group C and G Streptococci)

Human isolates of large-colony-forming beta-hemolytic streptococci harboring the Lancefield group C or group G antigens belong to *Streptococcus dysgalactiae* subsp. *equisimilis,* a novel species described in 1996 (111). While most isolates of this species possess either the Lancefield group C or the G antigen, strains harboring the Lancefield group L as well as the group A antigen (16) have been described. The clinical spectrum of disease caused by *S. dysgalactiae* subsp. *equisimilis* resembles infections caused by *S. pyogenes,* consistent with strains harboring genes similar to virulence factor genes of *S. pyogenes,* such as *emm*-like genes. These organisms are associated with upper respiratory tract infections, skin infections, soft tissue infections, and invasive infections such as necrotizing fasciitis, STSS, bacteremia, and endocarditis. Similar to *S. pyogenes* infections, cases of glomerulonephritis and acute rheumatic fever have been reported (5, 49) following *S. equi* subsp. *zooepidemicus* and *S. dysgalactiae* subsp. *equisimilis* infections.

Streptococcus anginosus Group

Species from the *Streptococcus anginosus* group (*S. anginosus, S. constellatus,* and *S. intermedius)* are regarded generally as harmless commensals of the oropharyngeal, urogenital, and gastrointestinal microbiota. However, these organisms are strongly associated with abscess formation in the brain, the oropharynx, or the peritoneal cavity. A subspecies of *S. constellatus, S. constellatus* subsp. *pharyngis,* has also been described and associated with pharyngitis (119). All species of this group are small-colony-forming bacteria (colony size, <0.5 mm) that can display variable patterns of hemolysis (alpha, beta, or gamma). Since they can also harbor the Lancefield group antigens A, C, F, or G (or none at all), it is especially important to reliably distinguish them from large-colony-forming (>0.5 mm) beta-hemolytic streptococci of the pyogenic group. Association of certain species with specific isolation sites has been reported. Whereas *S. anginosus* is frequently found in specimens from the urogenital or gastrointestinal tracts, *S. constellatus* is commonly isolated from the respiratory tract and *S. intermedius* is most often identified in abscesses of the brain or liver.

Streptococcus pneumoniae

S. pneumoniae is described separately in this section due to its clinical features that distinguish it from other species of the *S. mitis* group. *S. pneumoniae* is the most frequently isolated respiratory pathogen in community-acquired pneumonia. In as many as 30% of community-acquired pneumonia cases, *S. pneumoniae* can be found in peripheral blood cultures of patients. *S. pneumoniae* is also a major cause of meningitis, leading to high morbidity and mortality in pediatric and adult patients. The most frequently observed infection due to *S. pneumoniae* is otitis media, with an estimate of one infection for every child up to the age of 6 in the United States. Other infections due to *S. pneumoniae* include sinusitis, endocarditis, and rare cases of peritonitis. *S. pneumoniae* colonizes the upper respiratory tract commonly in individuals, especially children, without evidence of infection. Prevention of pneumococcal infections can be achieved by immunization with a 23-valent capsular polysaccharide vaccine in adults or the 7-valent conjugate vaccine in children. Widespread use of these vaccines has resulted in a reduction of invasive pneumococcal infections during the past several years.

Streptococcus mitis Group

S. mitis, S. sanguinis, S. parasanguinis, S. gordonii, S. cristatus, S. oralis, S. infantis, S. peroris (58), and *S. pneumoniae* are members of the *Streptococcus mitis* group. The *S. mitis* group members are regular commensals of the oral cavity, the gastrointestinal tract, and the female genital tract. Isolation of these species from blood cultures in asymptomatic patients often does not require antibiotic treatment, if it is due to a transient bacteremia. The *S. mitis* group members can also be found as transient microbiota of the normal skin and often represent contaminants when isolated from blood cultures. At the same time these species are the most frequently isolated bacteria in bacterial endocarditis in native valve and, less frequently, in prosthetic valve infections. Careful evaluation of the clinical situation is therefore crucial to correctly interpret the clinical significance of blood culture isolates from the *S. mitis* group. In neutropenic patients, streptococcal species from the *S. mitis* group are often responsible for life-threatening sepsis and pneumonia cases following immunosuppression by chemotherapy (14).

Streptococcus salivarius Group

Streptococcal species that belong to the *Streptococcus salivarius* group and have been isolated from human sources include *S. salivarius* and *S. vestibularis*. Another species of this

group, *S. thermophilus,* has been identified only from dairy products. *S. salivarius* has been repeatedly reported as a cause of bacteremia, endocarditis, and meningitis (sometimes iatrogenic), whereas *S. vestibularis* has not been clearly associated with human infection. Isolation of *S. salivarius* from blood cultures does correlate to some extent with intestinal neoplasia (93).

Streptococcus mutans Group

S. mutans and *S. sobrinus* belong to the *Streptococcus mutans* group. They are the most commonly isolated species of the group that originate from human clinical specimens, usually obtained from the oral cavity. *S. criceti* and *S. ratti* have occasionally been identified from human sources, while the other streptococcal species of the *S. mutans* group *(S. downei, S. ferus, S. macacae,* and *S. hyovaginalis)* have been identified only in animals. *S. mutans* is the primary etiologic agent of dental caries, and infection is transmissible. By 18 years of age, 85% of the population have at least one caries lesion (103). Permanent colonization with *S. mutans* occurs under normal living conditions in the Western world between the second year and the end of the third year of life (103). Molecular analysis of mother and infant isolates reveals that strains are usually acquired from the mother and that the colonization rate of infants depends on the bacterial load of the mother (17). Analyses of streptococcal blood culture isolates show that *S. mutans* is the most frequently isolated species of this group in cases of bacteremia.

Streptococcus bovis Group

The *Streptococcus bovis* group includes *S. equinus, S. gallolyticus, S. infantarius,* and *S. alactolyticus*. Species from this group are frequently encountered in blood cultures of patients with bacteremia, sepsis, and endocarditis. The clinical significance of blood cultures growing streptococci from the *S. bovis* group lies in the association of *S. gallolyticus* subsp. *gallolyticus* with gastrointestinal cancer and of *S. gallolyticus* subsp. *pasteurianus* with meningitis (4, 43, 63, 82). Extensive taxonomic changes have occurred in this group, and strains formerly known as human *S. bovis* isolates are now designated as different species (see "Taxonomy" above).

Other Streptococci Infrequently Isolated from Human Specimens

Streptococcal species that are primarily animal pathogens are sometimes isolated from human hosts, in most cases from humans that are in close contact with animals. *S. suis, S. porcinus,* and *S. iniae* belong to this category. *S. suis* is a swine pathogen that has occasionally been isolated from cases of human meningitis and bacteremia (67). *S. suis* is encapsulated and appears alpha-hemolytic on sheep blood agar plates, although some strains are beta-hemolytic on horse blood agar. *S. suis* strains are positive for the Lancefield group antigens R, S, or T. These antigens help to distinguish them from the phenotypically similar species *S. gordonii, S. sanguinis,* and *S. parasanguinis*. Similar to *S. suis, S. porcinus* (Lancefield groups E, P, U, and V) is primarily a swine pathogen. Beta-hemolytic *S. porcinus* strains have rarely been isolated from human sources such as peripheral blood, wounds, and the female genital tract (35). *S. porcinus* can be misidentified as *S. agalactiae* due to its isolation from the female genital tract, false-positive reactions with commercially available group B antisera, and a positive CAMP test reaction. *S. porcinus* is PYR (pyrrolidonyl aminopeptidase) positive, in contrast to *S. agalactiae*. *S. iniae* is a fish pathogen that is beta-hemolytic but does not possess any Lancefield group antigens. It has been isolated from soft tissue infections, bacteremia, endocarditis, and meningitis in people handling fish (36, 115). *S. iniae* isolates resemble *S. pyogenes* strains due to the fact that they are PYR positive. Beta-hemolysis of the species can be observed only around agar stabs or under anaerobic culture conditions. Commercial identification systems do not correctly identify the species; the failure to react with Lancefield group antisera is important to notice, since it is rare among beta-hemolytic streptococci.

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

Specimens suspected of harboring streptococci should be collected by methods outlined elsewhere in this Manual (chapters 5 and 20). Since many streptococcal species lose viability fairly quickly, it is best to place swabs in an appropriate moist transport medium and process specimens rapidly. If transport time is below 1 to 2 h, a special transport system is not absolutely necessary. *S. pyogenes* can safely be transported on dry swabs; desiccation enhances recovery from mixed cultures by suppression of accompanying microbiota (70). Detailed recommendations for collection and storage of swabs from pregnant women to detect *S. agalactiae* colonization have been issued by the U.S. Centers for Disease Control and Prevention. These recommendations are summarized below under "Special Procedures for *S. agalactiae* (GBS)."

DIRECT EXAMINATION

Microscopy

Microscopic examination shows streptococci as gram-positive bacteria growing in chains of varying length. *S. pneumoniae* organisms most often present as gram-positive diplococci with an elongated appearance. In blood culture specimens, *S. pneumoniae* tends to form chains of varying length, similar to other streptococci. Direct identification of streptococci by microscopic methods is most helpful in the case of clinical specimens from sterile body sites, such as cerebrospinal fluid (CSF). Tiny, irregular cocci in clumps of chains seen in abscess- or peritonitis-associated aspirates are suggestive of the *S. anginosus* group. Interpretation of Gram stain results from nonsterile body sites is difficult, due to the residential microbiota of mucous membranes that frequently include streptococci. Thus, for example, throat swabs should not be examined by Gram stain for diagnosis of "strep" throat. Identification of *S. pneumoniae* by direct microscopic evaluation can be aided by the Neufeld Quellung reaction, which can be performed directly on clinical specimens (for instructions, see below). This procedure is not established in most clinical microbiological laboratories today.

Direct Antigen Detection of *S. pyogenes* from Throat Specimens

S. pyogenes is the most common cause of acute pharyngitis and accounts for 15 to 30% of cases of acute pharyngitis in children and 5 to 10% of cases in adults. If diagnosis can be provided rapidly, antibiotic therapy can be initiated promptly to relieve symptoms, to avoid sequelae, and to reduce transmission. Numerous assays for direct detection of the group A-specific carbohydrate antigen in throat swabs by agglutination methods or immunoassays (enzyme, liposome, or optical), also referred to as "rapid antigen assays," have become commercially available during the past 2 decades.

A list of FDA-cleared tests is accessible via the Internet (http://www.accessdata.fda.gov/scripts/cdrh/cfdocs/cfRL/LSTSimpleSearch.cfdm). Although these tests provide rapid results and allow early treatment decisions, sensitivities and specificities have never equaled those of culture, ranging from 58 to 96% and 63 to 100%, respectively (38, 110). The throat culture remains the "gold standard," and national advisory committees recommend confirmation of negative rapid test results with a conventional throat culture. Currently, the low positive predictive value of rapid group A antigen tests in the adult population frequently results in prescribing unnecessary antimicrobial therapy (83).

Antigen Detection of *S. pneumoniae* in Urine Samples

An immunochromatographic membrane test relying on the detection of the cell wall-associated polysaccharide that is common to all *S. pneumoniae* serotypes (C-polysaccharide antigen) (Binax NOW; Binax Inc., Portland, Maine) has proven helpful for the identification of *S. pneumoniae* infections in adult patients, especially in patients that already received antibiotic treatment. Compared to conventional diagnostic methods, reported sensitivities of antigen detection in urine samples range between 50 and 80% and specificities are approximately 90% (48, 75). Due to the fact that the test is also positive in *S. pneumoniae* carriage without infection, as is often observed among infants (30), it is of limited value for pediatric patients. The test should not be used for children below the age of 6 (30), and comprehensive studies on schoolchildren with lower colonization rates have not been performed. It can currently be recommended only for adults as an addition to conventional diagnostic culture techniques for *S. pneumoniae* (69) and is probably most helpful for patients who received antimicrobial treatment before cultures were obtained.

Antigen Detection of *S. agalactiae* in Urogenital Tract Samples

Several different commercially available antigen detection tests have been developed for the identification of *S. agalactiae* in samples from the urogenital tract. Independent from the technique involved (latex agglutination, enzyme immunoassay, or optical immunoassay), all of the currently available tests lack sufficient sensitivities to detect bacterial colonization with *S. agalactiae* (107). They are not recommended for screening of pregnant women by the CDC. Even though modified protocols with an incubation of the samples in selective broth prior to antigen testing appear to increase assay sensitivities, the current CDC recommendations rely on selective broth culture performed at 35 to 37 weeks of gestation for this purpose (see "Special Procedures for *S. agalactiae* (GBS)."

Streptococcal Antigen Detection in CSF

Commercially available antigen detection tests for the detection of pathogenic microorganisms in CSF samples include reagents for the detection of *S. agalactiae* and *S. pneumoniae*. These tests have also been used on positive blood culture specimens. The tests are not recommended for routine use, as the results should not be used to change decisions about empiric therapy based on clinical and laboratory criteria (108). It has also been shown that the sensitivity of direct antigen detection in CSF is low (<30%) and offers no advantage over a conventional Gram stain (72).

Nucleic Acid Detection Techniques

S. pyogenes

A rapid method for the detection of *S. pyogenes* in pharyngeal specimens is based on a single-stranded chemiluminescent nucleic acid probe assay to identify specific rRNA sequences (Group A Streptococcus Direct Test; Gen-Probe, Inc., San Diego, Calif.). This test has a reported sensitivity and specificity of 89 and 93.5%, respectively, compared with the results of culture (50, 85). Moreover, a real-time PCR assay (LightCycler Strep A assay; Roche Diagnostics, Indianapolis, Ind.) has been recently developed for the detection of *S. pyogenes* in throat swabs (110). Real-time PCR proved to be more sensitive than the standard culture method in one study, and it appears to be unnecessary to perform cultures when results of the real-time PCR are negative. Real-time PCR allows the detection of beta-hemolytic species *S. pyogenes* and *S. dysgalactiae* subsp. *equisimilis*.

S. agalactiae

A rapid method for the detection of *S. agalactiae* colonization in pregnant women at the time of delivery has recently been developed and evaluated (11). The test is based on the detection of the *S. agalactiae cfb* gene (84) by a fluorogenic real-time PCR assay (IDI-Strep B; Becton Dickinson, Sparks, Md.), and results can be obtained in a few hours with a reported sensitivity of 94% and specificity of 95.9% (24). The test has been evaluated and approved by the FDA for combined rectal and vaginal swabs. The IDI-Strep B test is commercially available and performed well in a multicenter evaluation study (24). If real-time PCR is used at the time of delivery, only a vaginal swab (minus the rectal sample) should be tested. A major advantage is that results are available within a short time frame, and the vaginal colonization status can be assessed at the time of delivery. In comparison with the gold standard of selective broth culture, as recommended by the CDC, the test may offer an alternative for the future.

S. pneumoniae

Several different PCR assays have been developed for the identification of *S. pneumoniae* from culture isolates. Tests are based on the detection of the genes for autolysin *lytA*, the pneumococcal surface antigen *psaA*, and the pneumolysin gene *ply*. Comparison of the ability to distinguish difficult-to-identify *S. pneumoniae* strains and closely related atypical streptococci revealed that the *lytA*-based PCR was the most specific method (73). While results based on the detection of *psaA* are also acceptable, the different pneumolysin-targeted methods appear to be relatively nonspecific. Nucleic acid probes for the detection of cultured isolates of *S. pyogenes*, *S. agalactiae*, and *S. pneumoniae* are commercially available (AccuProbe; GenProbe) (21, 25). Detection relies on hybridization of a specific probe to 16S rRNA sequences. These tests are not routinely performed for standard identification procedures but can aid in the identification of atypical streptococcal isolates. Atypical organisms include *S. pneumoniae* isolates with unusual patterns of bile solubility and optochin susceptibility, nonhemolytic *S. agalactiae* strains, or beta-hemolytic streptococci harboring the Lancefield group A antigen with questionable species identification.

ISOLATION PROCEDURES

General Procedures

Streptococci are usually grown on agar media supplemented with blood because the assessment of the hemolytic reaction is important for identification. Growth of streptococci is often enhanced in the presence of an exogenous catalase source. Streptococcal species with low or absent hydrogen peroxide production, such as *S. agalactiae,* can be grown on other commonly used nonselective media without blood.

Agar media selective for gram-positive bacteria (e.g., phenylethyl alcohol-containing agar or Columbia agar with colistin and nalidixic acid) support the growth of streptococci. The optimal incubation temperature range for most streptococcal species lies between 35 and 37°C. Supplemental carbon dioxide (5% CO_2) and anaerobic conditions enhance the growth of many streptococcal species, since streptococci are facultative anaerobes. Although some streptococci grow well in ambient air, incubation in 5% CO_2 is recommended for the culture of *S. pneumoniae* and other streptococcal species of the viridans group.

Special Procedures for *Streptococcus pyogenes* Throat Cultures

A properly performed and interpreted throat culture remains the gold standard for the diagnosis of *S. pyogenes* acute pharyngitis. The recovery of *S. pyogenes* from throat swabs on 5% sheep blood agar with Trypticase soy base and incubated in air is a reliable and well-accepted method (77). Lack of hemolysis, overgrowth and production of toxic bacterial metabolites by normal upper respiratory tract microbiota, or depletion of substrates often leads to false-negative results or delays caused by labor-intensive reisolation steps. More rigorous standards for the isolation of *S. pyogenes* include an additional blood agar plate containing sulfamethoxazole-trimethoprim, which inhibits the normal respiratory microbiota (65). *Streptococcus* selective medium is highly sensitive for isolation of *S. pyogenes,* suppressing the growth of commensal respiratory microbiota including other beta-hemolytic streptococci (116). Incubation in anaerobic or CO_2-enriched atmosphere more frequently leads to the isolation of non-*S. pyogenes* beta-hemolytic streptococci (77). Important details have been summarized (13, 59). The isolation of a few colonies of *S. pyogenes* does not differentiate a carrier from an acutely infected individual and may reflect inadequate specimen collection (12).

After 18 to 24 h of incubation, culture plates should be examined for growth of beta-hemolytic colonies. Negative cultures should be reexamined after an additional 24-h incubation period. Presumptive identification of *S. pyogenes* can be achieved by susceptibility to bacitracin or testing for PYR activity. Other beta-hemolytic streptococci are occasionally positive in one of these tests, but not in both. Definitive diagnosis includes the demonstration of the Lancefield group A antigen by immunoassay. Although other species may rarely possess the group A antigen (Table 1), they lack PYR activity (34).

Special Procedures for *S. agalactiae* (GBS)

Early-onset neonatal group B streptococcal *(S. agalactiae)* (GBS) infections can be prevented by administration of antibiotic prophylaxis during delivery (97). An essential requirement for efficient prophylaxis is the reliable detection of colonization with *S. agalactiae* in pregnant women before delivery. Screening should be performed between weeks 35 and 37 of pregnancy. A lower vaginal swab and a rectal swab (i.e., insert swab through the anal sphincter) should be obtained with either one or two different swabs and placed in an appropriate transport medium (Amies or Stuart's without charcoal; see chapter 20). While culture counts decline to some extent, viability of *S. agalactiae* is preserved in transport medium kept at room temperature or 4°C for up to 4 days. To reduce costs, vaginal and rectal swabs can be placed in a single transport medium tube and cultured together. Swabs should be cultured in selective broth medium for 18 to 24 h at 35 to 37°C in ambient air or 5% CO_2 and subsequently plated on Trypticase soy blood agar plates. Selective broth medium is commercially available (Trans-Vag broth supplemented with 5% sheep blood [Remel Inc., Lenexa, Kans.] or LIM broth [BBL Microbiology Systems, Cockeysville, Md.]). Selective broth can also be prepared by supplementation of Todd-Hewitt broth (THB) with nalidixic acid (15 μg/ml) and colistin (10 μg/ml) or supplementation of THB with nalidixic acid (15 μg/ml) and gentamicin (8 μg/ml). Trypticase soy blood agar plates should be checked for typical colonies (narrow zone of beta-hemolysis) of *S. agalactiae* after 24 and 48 h of incubation at 35 to 37°C. Identification of *S. agalactiae* is then achieved by standard techniques as described below. Selective media relying on the detection of the *S. agalactiae* pigment (StrepB Carrot broth [Hardy Diagnostics, Santa Maria, Calif.] or GBS broth [Northeast Laboratory Services, Waterville, Maine]) are highly specific and sensitive (91, 113). Subculture is needed to detect nonhemolytic strains with pigment-dependent selective media. Methods to detect *S. agalactiae* by nucleic acid probes (AccuProbe; GenProbe) following overnight enrichment have also been published (15, 121). Commercially available antigen detection tests cannot be recommended for the detection of *S. agalactiae* colonization, due to poor sensitivities in comparison to selective broth isolation procedures (107).

IDENTIFICATION

Description of Colonies

Colonies of streptococci usually appear gray or almost white with moist or glistening features. Dry colonies are rarely encountered. Colony size varies between the different beta-hemolytic species and helps to distinguish groups of streptococci. Beta-hemolytic streptococci of the pyogenic group *(S. pyogenes, S. agalactiae,* and *S. dysgalactiae* subsp. *equisimilis)* form colonies of >0.5 mm after 24 h of incubation, in contrast to beta-hemolytic strains of the *S. anginosus* group (formerly called "*S. milleri*" group), which present with pinpoint colonies of <0.5 mm after the same incubation time (Fig. 1). Members of the *S. anginosus* group emit a distinct odor resembling butterscotch or caramel, presumably due to the production of diacetyl (18) by the species belonging to this group. Among the beta-hemolytic species of the pyogenic group, *S. agalactiae* produces the largest colonies with a relatively small zone of hemolysis. Nonhemolytic *S. agalactiae* strains do occur and look like enterococci.

Within the group of alpha-hemolytic streptococci, *S. pneumoniae* has a distinct colony morphology that helps to distinguish pneumococcal isolates from other streptococci of the viridans group. Due to the production of capsular polysaccharide, colonies glisten and appear moist. Colonies may be large and mucoid if large amounts of capsular

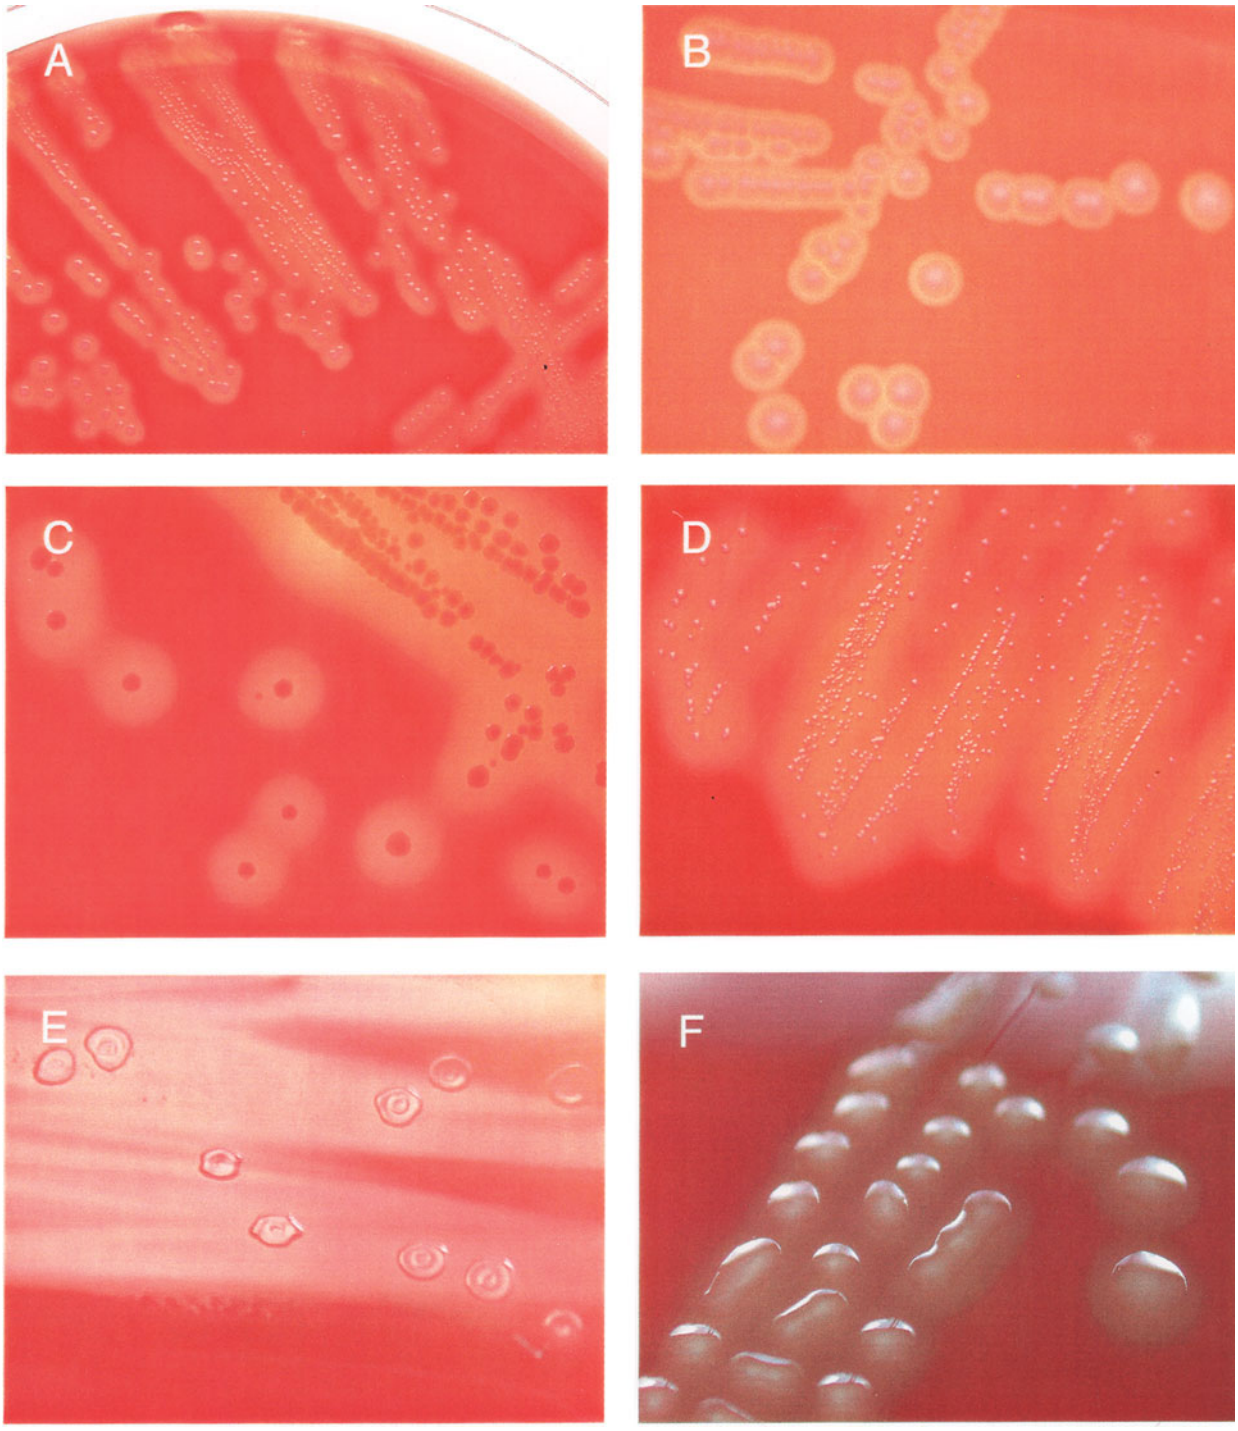

FIGURE 1 Colony morphology of clinical isolates of selected streptococci. (A) *S. pyogenes;* (B) *S. agalactiae;* (C) *S. dysgalactiae* subsp. *equisimilis* (Lancefield group G); (D) *S. anginosus* (note the pinpoint size colonies); (E) *S. pneumoniae* (note the central depression of the colonies); (F) *S. pneumoniae* (note the mucoid appearance of the colonies). (Courtesy of Tim Pietzcker, University of Ulm, Germany.)

polysaccharide are made, a feature often encountered in serotype 3 strains. The mucoid appearance is usually very typical for *S. pneumoniae* but can also occasionally be observed in *S. pyogenes*. Another feature characterizing *S. pneumoniae* isolates is the central navel-like depression of the colonies that is caused by the pneumococcal autolysin. Colonies of other viridans streptococci lack this feature and have a dome-like appearance. Nonhemolytic gray colonies are typical for species of the *S. bovis* and *S. salivarius* groups. Typical streptococcal colony morphologies are presented in Fig. 1.

Identification of Beta-Hemolytic Streptococci by Lancefield Antigen Immunoassays

Commercially available Lancefield antigen grouping sera are primarily used for the differentiation of beta-hemolytic streptococci. Products for rapid antigen extraction and subsequent agglutination can be obtained from many different suppliers. The presence of the Lancefield group B antigen in beta-hemolytic isolates from human clinical specimens correlates with the species *S. agalactiae*. Similarly, the detection of the Lancefield group F antigen in small-colony-forming streptococci from human clinical material allows a fairly reliable identification of a strain as a member of the *S. anginosus* group. The presence of Lancefield group A, C, or G antigens necessitates further testing (Table 1). Beta-hemolytic streptococcal strains not reacting with any of the Lancefield antisera are rare and should be further identified by phenotypic tests or application of nucleic acid probes.

Identification of Beta-Hemolytic Streptococci by Phenotypic Tests

A number of streptococcal identification products incorporating batteries of physiologic tests are commercially available (see chapter 15). In general, these products perform well with commonly isolated streptococci but may lack accuracy for identifying streptococci of the viridans group. For the bulk of pathogenic streptococci isolated in clinical laboratories (e.g., *S. pyogenes, S. agalactiae,* and *S. pneumoniae*), serologic or presumptive physiologic tests (as described below) offer an acceptable alternative to commercially available identification systems.

PYR Test

The presence of the enzyme PYR is often tested to distinguish *S. pyogenes* from other beta-hemolytic streptococci. Hydrolysis of L-pyrrolidonyl-β-naphthylamide by the enzyme to β-naphthylamine produces a red color with the addition of cinnamaldehyde reagent (chapter 21). *S. iniae* and *S. porcinus,* which are also positive with this test, are only rarely identified in human clinical specimens since they are primarily animal-associated species. PYR spot tests are commercially available. It is important to distinguish *Streptococcus* from *Enterococcus* prior to PYR testing, and strains of other related genera may be PYR positive (including the genera *Abiotrophia, Aerococcus, Enterococcus, Gemella,* and *Lactococcus*). However, PYR-positive beta-hemolytic enterococcal isolates typically present with a different colonial morphology, and when combined with other phenotypic characteristics (see chapter 30), may be distinguished from streptococci. To avoid false-positive reactions caused by other PYR-positive bacterial species (for example, staphylococci), the test should be performed only on pure cultures.

Bacitracin Susceptibility

S. pyogenes displays bacitracin susceptibility, in contrast to other beta-hemolytic streptococci found in humans. Together with Lancefield antigen determination, it can be used for the identification of *S. pyogenes* since beta-hemolytic strains of other streptococcal species that may contain the group A antigen are bacitracin-resistant. The test can also be used to distinguish *S. pyogenes* from other PYR-positive beta-hemolytic streptococci *(S. iniae* and *S. porcinus)*. A bacitracin disk (0.04 U) is applied to a sheep blood agar plate that has been heavily inoculated with 3 or 4 colonies of a pure culture of the strain to be tested. After overnight incubation at 35°C in 5% CO_2, any zone of inhibition around the disk is interpreted as indicating susceptibility. Importantly, bacitracin-resistant *S. pyogenes* isolates have been reported and clusters of bacitracin-resistant strains were recently observed in Europe (68, 74).

Voges-Proskauer Test (VP)

The Voges-Proskauer (VP) test detects the formation of acetoin from glucose fermentation. It is performed on streptococci as a modification of the classical VP reaction that is used for the differentiation of enteric bacteria. Small-colony-forming beta-hemolytic streptococci of the *S. anginosus* group that are VP positive may be distinguished from large-colony-forming beta-hemolytic streptococci harboring identical Lancefield antigens (A, C, or G). Streptococci of the *S. mitis* group are VP negative. For the modified VP reaction as described by Facklam in a previous edition of this Manual, the culture growth of an entire agar plate is used to inoculate 2 ml of VP broth and incubated at 35°C for 6 h. Following the addition of 5% α-naphthol and 40% KOH, the tube is shaken vigorously for a few seconds and incubated at room temperature for 30 min. A positive test yields a pink-red color that results from the reaction of diacetyl with guanidine.

β-Glucuronidase Test

Detection of β-glucuronidase (BGUR) activity distinguishes *S. dysgalactiae* subsp. *equisimilis* strains containing Lancefield group antigens C or G from BGUR-negative, small-colony-forming streptococci of the *S. anginosus* group with the same Lancefield group antigens (Table 1). Rapid methods for the BGUR test are commercially available. Alternatively, a rapid fluorogenic assay with methylumbelliferyl-β-D-glucuronide containing MacConkey agar, often used for *Escherichia coli,* has been described (62).

CAMP Test

The CAMP factor reaction was first described in 1944 by Christie, Atkins, and Munch-Petersen and refers to the synergistic lysis of erythrocytes by the beta-hemolysin of *Staphylococcus aureus* and the extracellular CFB protein of *S. agalactiae*. The gene and its expression can be demonstrated in the vast majority (>98%) of *S. agalactiae* isolates, but CAMP-negative mutants do occur. The strain to be tested and an *S. aureus* strain (ATCC 25923) are streaked onto a sheep agar plate at a 90° angle. Plates are incubated in ambient air overnight at 36 ± 1°C. A positive reaction can be detected by the presence of a triangular zone of enhanced beta-hemolysis in the diffusion zone of the beta-hemolysin of *S. aureus* and the CAMP factor (Fig. 2). CAMP factor-positive strains can also be detected by a method using β-lysin-containing disks (Remel Inc.) (120) or by a rapid CAMP factor spot method (89). Despite the fact that close homologs of the CAMP factor gene are present in many *S. pyogenes* strains, beta-hemolytic streptococci other than *S. agalactiae* are usually negative in the above-described CAMP factor test. Several gram-positive rods including corynebacteria and *Listeria monocytogenes* strains may be CAMP factor positive.

Hippurate Hydrolysis Test

The ability to hydrolyze hippurate is an alternative test for the presumptive identification of *S. agalactiae*. A rapid version of the test, as it is used for campylobacters, can be performed by incubating a turbid suspension of bacterial cells in 0.5 ml of 1% aqueous sodium hippurate for 2 h at 35°C. Glycine formed as an end product of hippurate hydrolysis is detected by adding ninhydrin reagent and

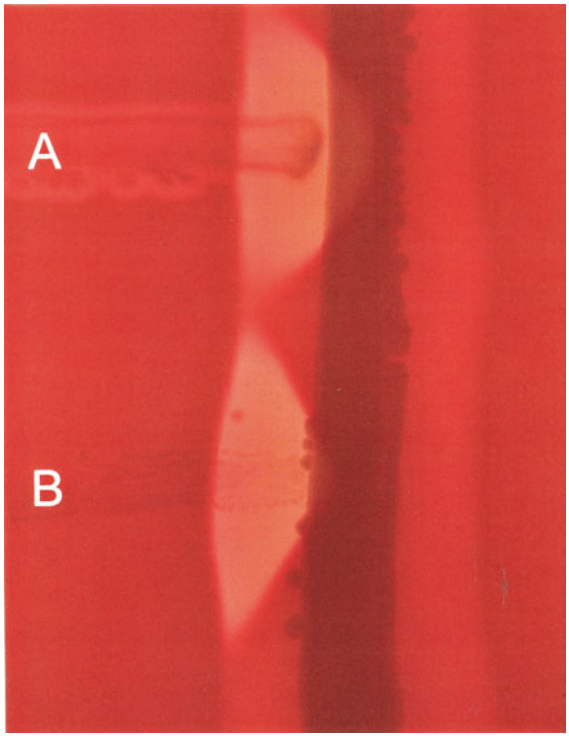

FIGURE 2 CAMP factor test. Arrowhead-shaped zone of hemolysis in the zone of *S. aureus* β-hemolysin. (A) Beta-hemolytic *S. agalactiae* strain O90R; (B) nonhemolytic *S. agalactiae* strain R268.

observing the development of a deep purple color, signifying a positive test (chapter 21) (53). Streptococci other than *S. agalactiae* may also be hippurate hydrolysis positive (114), especially viridans streptococci.

Identification of *S. pneumoniae* and Viridans Group Streptococci

The correct species identification of viridans group streptococci other than *S. pneumoniae* is challenging. Recent taxonomic changes and identification of novel streptococcal species have further complicated matters. The number of recognized species in this group is now greater than 30. The viridans group includes alpha-hemolytic, nonhemolytic (*S. salivarius* group and *S. bovis* group), and beta-hemolytic (*S. anginosus* group) streptococcal strains. All of the viridans streptococci are LAP positive and PYR negative. Conventional microbiologic tests are limited with respect to species identification but are helpful in placing isolates into the correct streptococcal groups (Table 2). Beighton et al. described an identification scheme based on phenotypic tests that allowed the differentiation and correct species identification of the majority of viridans group species (7). The scheme requires the evaluation of enzymatic reactions performed by in-house fluorogenic tests that are not commercially available. Importantly, most clinical laboratories must strive for group, instead of species, classifications with current phenotypic test panels.

The API tests (bioMerieux, Marcy l'Etoile, France) offer species identification of viridans group streptococci. While many species from this group are identified with acceptable accuracy, several species have not been included in the database. Comparisons of molecular species identification by DNA reassociation studies with the results of the API Rapid ID 32 Strep system showed that more than 85% of 156 strains from streptococcal species included in the database were correctly identified (60). However, in the same study, more than 50% of six species not included in the database were incorrectly identified by the test (60). Evaluation studies performed under routine clinical conditions appear to yield less favorable results (46). In conclusion, reliable phenotypic identification of viridans group streptococci can currently be achieved only to the group level.

Molecular methods may offer alternative approaches to conventional phenotypic identification schemes. The most common molecular identification method, 16S rRNA gene sequencing, does not yield reliable species identification for several species including *S. mitis, S. oralis,* and *S. pneumoniae*. The 16S rRNA gene sequences are more than 99% identical (57). Whole-cell protein analyses were unable to yield good correlation with species identification by other methods. Sequence determination of the manganese-dependent superoxide dismutase gene *sodA* appears promising (87, 88). In contrast to 16S rRNA gene sequencing, it allows the differentiation of *S. mitis, S. oralis,* and *S. pneumoniae* and the correct identification of almost 30 different streptococcal species including 16 species from the viridans group.

Descriptions of the species belonging to the nonpyogenic groups are given below, and physiological traits of the groups are shown in Table 2.

TABLE 2 Phenotypic characteristics of viridans streptococcal groups[a]

Streptococcal group	Arginine hydrolysis	Esculin	Mannitol	Sorbitol	Urea hydrolysis	VP
S. mitis	v[b]	v	–	v	–	–
S. anginosus	+	+	–	–	–	+
S. mutans	–	+	+	+	–	+
S. salivarius	–	v	–	–	v[d]	+
S. bovis	–	+	v[c]	–	–	+

[a] Symbols and abbreviations: +, positive; –, negative; v, variable.

[b] The species *S. cristatus, S. gordonii, S. parasanguinis,* and *S. sanguinis* are arginine hydrolysis positive; other species of the *S. mitis* group are arginine hydrolysis negative.

[c] *S. gallolyticus* subsp. *gallolyticus* is positive for the acidification of mannitol, and the other species of the *S. bovis* group are negative for mannitol acidification.

[d] *S. salivarius* is variable for urea hydrolysis, and *S. vestibularis* is positive for urea hydrolysis. All other species of the *S. salivarius* group are negative for urea hydrolysis.

S. mitis Group

Streptococcal species belonging to the *S. mitis* group include *S. mitis, S. sanguinis, S. parasanguinis, S. gordonii, S. cristatus, S. oralis, S. infantis* (58), *S. peroris* (58), and *S. pneumoniae,* which is discussed separately. This group of predominantly alpha-hemolytic streptococci includes several species of known clinical significance together with others for which few or no clinical data have been collected. Among the phenotypic characteristics of the species in this group, extracellular polysaccharide production is negative for *S. mitis* strains but a variable characteristic of *S. oralis* isolates. This feature correlates with the smooth colony surface of many *S. oralis* strains and the rough and dry appearance of *S. mitis* colonies.

S. anginosus Group

The small-colony-forming species *S. anginosus, S. constellatus,* and *S. intermedius* belong to the *S. anginosus* group, which is sometimes referred to as the "*S. milleri*" group. Strains of the *S. anginosus* group may be non-, alpha-, or beta-hemolytic on blood agar plates, with some variations between the species. While *S. constellatus* is frequently beta-hemolytic, most isolates of *S. intermedius* are nonhemolytic. For many strains, growth is enhanced in the presence of CO_2, with some strains requiring anaerobic conditions. *S. anginosus* and *S. constellatus* strains may possess Lancefield group antigens A, C, F, or G. Most *S. constellatus* or *S. intermedius* strains react with antisera against Lancefield group F antigen or are nongroupable.

The species *S. constellatus* has been further subdivided into two subspecies, *S. constellatus* subsp. *constellatus* and *S. constellatus* subsp. *pharyngis* (119). *S. constellatus* subsp. *constellatus* is phenotypically different from *S. constellatus* subsp. *pharyngis,* which usually possesses the Lancefield group antigen C, is beta-hemolytic, and has been associated with pharyngitis. Detailed phenotypic characteristics of the *S. anginosus* group are shown in Table 3.

TABLE 3 Phenotypic characteristics of streptococcal species of the *S. anginosus* group[a]

Test	*S. anginosus*	*S. constellatus*	*S. intermedius*
β-D-Fucosidase	–	–/+[c]	+
β-D-Acetylglucosaminidase	v	–/+[c]	+
β-D-Acetylgalactosaminidase	–	–/+[c]	+
Neuraminidase	–	–	+
α-D-Glucosidase	v	+	+
β-D-Glucosidase	+	–/+[c]	v
α-D-Galactosidase	v	–	–
β-D-Galactosidase	v	v	+
Amygdalin (acidification)	+	v	v
Mannitol (acidification)	v	–	–
Sorbitol (acidification)	–	–	–
Lactose (acidification)	+	v	+
Melibiose (acidification)	v	v	v
Arginine hydrolysis	+	+	+
Esculin hydrolysis	+	v	+
VP[b]	+	+	+
Urease	–	–	–
Hyaluronidase	–	+	+

[a] Symbols and abbreviations: +, positive; –, negative; v, variable.
[b] Voges-Proskauer test (formation of acetoin from glucose fermentation).
[c] The species *S. constellatus* subsp. *pharyngis* is positive for β-D-fucosidase, β-D-acetylglucosaminidase, β-D-acetylgalactosaminidase, and β-D-glucosidase activities. In contrast, *S. constellatus* subsp. *constellatus* is negative for these enzymatic activities.

S. mutans Group

The *S. mutans* group includes *S. mutans, S. sobrinus, S. criceti, S. ratti, S. downei, S. ferus, S. hyovaginalis,* and *S. macacae*. *S. mutans* and *S. sobrinus* are frequently found in human hosts, while the other species are only rarely encountered in humans or represent animal pathogens. The species of the *S. mutans* group are characterized by the production of extracellular polysaccharides from sucrose, which can be tested by culturing the bacteria on sucrose-containing agar and by the ability to produce acid from a relatively wide range of carbohydrates. *S. mutans* strains may present with an atypical morphology for streptococci, forming short rods on solid media or in broth culture under acidic conditions. On blood agar, colonies are often hard, adherent, and usually alpha-hemolytic. On sucrose-containing agar, species from this group form colonies that are rough (frosted glass appearance), heaped, and surrounded by liquid-containing glucan. Under anaerobic growth conditions, some strains are beta-hemolytic. *S. sobrinus* strains are mostly nonhemolytic or occasionally alpha-hemolytic.

S. salivarius Group

Streptococcal species in the *S. salivarius* group are *S. salivarius, S. vestibularis,* and *S. thermophilus*. *S. salivarius* strains are usually non- or alpha-hemolytic on blood agar. On sucrose-containing agar, strains form large mucoid or hard colonies due to the production of extracellular polysaccharides. A high proportion of *S. salivarius* strains react with the Lancefield group K antiserum. Species in this group may also react with the streptococcal group D antiserum. It is unclear if these strains truly possess the group D antigen or yield a nonspecific cross-reaction. *S. vestibularis* is alpha-hemolytic, and the failure of this species to produce extracellular polysaccharides on sucrose-containing agar is helpful in distinguishing *S. vestibularis* from *S. salivarius* strains. *S. thermophilus* is found in dairy products but has not been isolated from clinical specimens.

S. bovis Group

The species belonging to the *S. bovis* group *(S. equinus, S. gallolyticus, S. infantarius,* and *S. alactolyticus)* are non-enterococcal group D streptococci, grow on bile esculin agar, and are unable to grow in 6.5% NaCl. On blood agar, strains are either nonhemolytic or alpha-hemolytic. Strains of the *S. bovis* group share phenotypic characteristics with *S. mutans* strains, such as production of glucan, fermentation of mannitol, and growth on bile esculin agar. However, the *S. bovis* group does not ferment sorbitol, is able to ferment starch or glycogen, and gives a Lancefield group D reaction. Species of the *S. bovis* group may resemble *S. salivarius* strains. Differentiation of these two groups on the basis of the Lancefield group D reaction, ability to grow on bile esculin agar, fermentation of mannitol, and production of inulin, starch, and urease has been suggested (92). Strains from the *S. bovis* group are usually β-galactosidase negative and α-galactosidase positive, in contrast to *S. salivarius*. As described, strains formerly known as *S. bovis* currently belong to several species of the *S. bovis* group.

Physiologic Tests

Optochin Test

Most *S. pneumoniae* isolates are optochin susceptible. Before application of the optochin disk, several colonies of a pure culture are streaked on a sheep blood agar plate. Optochin testing should be performed on plates that are

incubated at 35 to 36°C overnight in 5% CO_2 because up to 8% of strains do not grow under ambient conditions. *S. pneumoniae* isolates show inhibition zones of ≥14 mm with a 6-mm disk (containing 5 μg of optochin) and inhibition zones of ≥16 mm with a 10-mm disk. Incubation in 5% CO_2 yielded increased specificity (1). Optochin-resistant *S. pneumoniae* strains have been reported as well as optochin-susceptible *S. mitis* isolates (especially when tested in ambient conditions). Since optochin testing may miss up to 4% of bile-soluble *S. pneumoniae* isolates (1), strains displaying a smaller zone of inhibition (9 to 13 mm for the 6-mm disk) should be subjected to additional testing for bile solubility to confirm species identification.

Application of an optochin disk onto the primary culture medium may facilitate a rapid presumptive identification but may miss pneumococcal isolates in a mixed culture. The optochin susceptibility test should be repeated with a pure culture in cases of mixed cultures, or additional tests should be performed (e.g., bile solubility).

Bile Solubility Test

Bile solubility can be performed either in a test tube or by direct application of the reagent to an agar plate. For the test tube method, a saline suspension of a pure culture is adjusted to a McFarland standard of 0.5 to 1.0, and 0.5 ml of the suspension is added to a small tube. The bacterial suspension is mixed with 0.5 ml of 10% sodium deoxycholate (bile) and incubated at 35°C. A control containing 0.5 ml of bacterial suspension with 0.5 ml of saline should be prepared for each strain tested. A positive result is characterized by clearing of the bile suspension within 5 to 15 min and allows the identification of a strain as *S. pneumoniae*. For the plate method, one drop of 10% sodium deoxycholate is placed directly on a colony of the strain in question and incubated at 35°C for 15 min in ambient air. It is important to keep the plates in a horizontal position in order to prevent the reagent from washing away the colony. Colonies of *S. pneumoniae* will disappear or demonstrate a flattened colony morphology, while other viridans streptococci will appear unchanged.

Bile Esculin Test

Bile esculin medium (available from commercial sources) in either plates or slants should be inoculated with one to three colonies of the organism to be tested and incubated at 35°C in ambient air for up to 48 h. Optimal results can be achieved by using media supplemented with 4% oxgall (equivalent of 40% bile) (Remel) and a standardized inoculum of 10^6 CFU (19). A definitive blackening of plated media or blackening of at least one-half of an agar slant is considered a positive test, indicative of species belonging to the *S. bovis* group or enterococci. Occasional other viridans streptococci are positive with this test or display weakly positive reactions that are difficult to interpret (92). Isolates from patients with serious infections (e.g., endocarditis) should be more completely characterized.

Arginine Hydrolysis

Arginine hydrolysis is a key reaction for the identification of viridans streptococci. Discrepancies can occur among test methods (117). Two commonly used methods are detailed here. Moeller's decarboxylase broth containing arginine (Becton Dickinson and other sources) should be inoculated with the test organism, overlaid with mineral oil, and incubated at 35 to 37°C for up to 7 days. Degradation of arginine results in elevated pH, indicated by development of a purple color. Negative results are indicated by a yellow color, which is due to acid accumulation from metabolism of glucose only. For the microtiter plate method (8), 3 drops of the arginine-containing reagent are inoculated with 1 drop of an overnight THB culture and incubated for 24 h at 37°C anaerobically. Production of ammonia is detected by the appearance of an orange color following the addition of 1 drop of Nessler's reagent.

Urea Hydrolysis

Christensen urea agar (Becton Dickinson and other sources) is inoculated and incubated aerobically at 35°C for up to 7 days. Development of a pink color indicates a positive reaction. An alternative format is to dispense Christensen's medium without agar into a microtiter tray well and, after inoculation, overlay it with mineral oil prior to incubation.

Voges-Proskauer (VP) Test

The VP test can be performed as described for the identification of beta-hemolytic streptococci. A standard method for performing the VP test, requiring extended incubation, is described in chapter 21.

Esculin Hydrolysis

Esculin agar slants (Becton Dickinson and other sources) are inoculated and incubated for up to 1 week. A positive reaction appears as a blackening of the medium; no change in color indicates a negative esculin hydrolysis test.

Hyaluronidase Production

Hyaluronidase activity can be detected on brain heart infusion agar plates supplemented with 2 mg of sodium hyaluronate per liter (Sigma-Aldrich, St. Louis, Mo.) (104). The strains to be tested are inoculated by stabbing into the agar, and plates are incubated anaerobically at 37°C overnight. After the plate is flooded with 2 M acetic acid, hyaluronidase activity is indicated by the appearance of a clear zone around the stab. A quantitative method for determining hyaluronidase activity can be performed in microtiter trays (52).

Production of Extracellular Polysaccharide

Strains may be isolated as single colonies on sucrose-containing agar. The two most commonly used media are (i) mitis-salivarius agar containing 0.001% (wt/vol) potassium tellurite (Becton Dickinson) and (ii) tryptone-yeast-cystine agar (Lab M, Bury, United Kingdom). Incubation may require up to 5 days at 37°C.

TYPING SYSTEMS

In the majority of cases, typing of streptococci has no immediate clinical or therapeutic consequences. It is most often performed by reference laboratories for the purposes of epidemiologic studies and the evaluation of vaccine efficacy. Although classical antibody-dependent typing systems for capsular serotypes and surface proteins have been used for years, molecular methods have become attractive, since they do not require special techniques or the maintenance of rarely used reagents such as a large antibody panel. Another advantage lies in the fact that the interrogation of DNA sequences is independent of culture conditions and gene expression. For the differentiation of distinct clones, pulsed-field gel electrophoresis (PFGE) and multilocus sequence typing (MLST) systems have been established for many streptococcal species (32).

S. pneumoniae comprises 90 antigenically distinct capsular serotypes that can be detected by the Neufeld test (Quellung reaction), which is still regarded as the gold standard for epidemiologic studies. Pure cultures of pneumococci are grown on a freshly prepared 5% sheep blood agar plate or a 10% horse blood agar plate at 35 to 37°C and 5% CO_2 for 18 to 24 h. A small amount of bacterial growth (less than a 10-μl loop) is resuspended in a droplet of phosphate-buffered or physiological saline (McFarland standard of approximately 0.5). A few microliters of the saline suspension are mixed with an equal amount of specific pneumococcal rabbit antisera on a glass slide. The specimen is subsequently evaluated for capsular swelling (a clear area surrounding the bacterial cells) by phase-contrast microscopy (×1,000 magnification; oil immersion) (2). The reaction is stable for approximately 30 min. The best results are achieved when 10 to 50 bacterial cells are visible per high-power (×1,000) microscopic field. To increase the visibility of the result, it is possible to add 0.3% aqueous methylene blue in the same amount as the antiserum to the mixture. Following the same principle, commercially available kits (Pneumotest; Statens Serum Institut, Copenhagen, Denmark) allow rapid testing of *S. pneumoniae* serotypes with pooled antisera by a checkerboard method. A rapid antigen detection test using pooled antisera coupled to latex beads (Statens Serum Institut) has been developed (102). Due to strain discrepancies, confirmation by the Neufeld Quellung reaction is recommended. For the distinction of single clones, PFGE (66, 71) or MLST typing schemes (32) have been used in pneumococcal investigations.

Nine different antibody-defined capsular polysaccharides have been described for *S. agalactiae* (Ia, Ib, and II through VIII). The percentage of nontypeable strains can be minimized by optimization of capsular expression (10). In addition to antibody detection of capsular serotypes, recently developed PCR- and DNA sequencing-based techniques allow the detection of capsular serotypes (64). Individual clones of *S. agalactiae* have been detected either by MLST (55) or PFGE (9, 45).

Conventional typing of *S. pyogenes* is based upon the antigenic specificity of the surface-expressed T and M proteins (54). The function of the trypsin-resistant T protein is unknown. The T type can be identified by agglutination with commercially available serologic assays utilizing approximately 20 accepted anti-T sera. M proteins are major antiphagocytic virulence factors of *S. pyogenes* (42). N-terminal sequence variation in genes encoding these highly protective antigens is the basis of the *S. pyogenes* precipitation typing system. At present, 83 M serotypes are unequivocally validated and internationally recognized to be serologically unique and are designated M1 to M93 in the Lancefield classification (37). M serotypes that are not included are from non-*S. pyogenes* organisms or correspond to an existing M serotype.

A molecular serotyping system has been established on the basis of nucleotide sequences encoding the amino termini of M proteins. The *emm* gene sequences encode M proteins and have been correlated with Lancefield M serotypes. This methodology allows assignment to a validated M protein gene sequence *(emm1* through *emm124)* and identification of new *emm*-sequence types and subtypes. Molecular serotyping has evolved into the gold standard molecular methodology of *S. pyogenes* typing (37). A large database of approximately 350 *emm* gene sequences from strains originally used for Lancefield serotyping and including *emm* sequences from beta-hemolytic groups C, G, and L streptococci has been developed by the CDC (http://www.cdc.gov/ncidod/biotech/infotech_hp.html). Recently, MLST has been developed for *S. pyogenes*. Population genetic studies demonstrated stable associations between *emm* type and MLST among isolates obtained decades apart and/or from different continents (33).

In outbreak situations that include *S. pyogenes,* restriction enzyme-mediated digestion of *emm* amplicons is a valuable tool for rapid identification of isolates containing similar *emm* genes (6). For clusters of isolates sharing the same *emm* type, PFGE profiles may be helpful for distinguishing similar strains (79).

SEROLOGIC TESTS

Determination of streptococcal antibodies is indicated for the diagnosis of poststreptococcal disease, such as acute rheumatic fever or glomerulonephritis (101). A fourfold rise in antibody titer is regarded as definitive proof of an antecedent streptococcal infection. Multiple variables, including site of infection, time since the onset of infection, age, the background prevalence of streptococcal infections (3), antimicrobial therapy, and other comorbidities, influence antibody levels. The most widely used antibodies are anti-streptolysin O and anti-DNase B.

Antibodies against streptolysin O (ASO) reach a maximum at 3 to 6 weeks after infection. While ASO responses following streptococcal upper respiratory tract infections are usually elevated, pyoderma caused by *S. pyogenes* does not elicit a strong ASO response. *Streptococcus dysgalactiae* subsp. *equisimilis* can also produce streptolysin O, and thus elevated ASO titers are not specific for *S. pyogenes* infections.

Among the four streptococcal DNases produced, the host response is most consistent against DNase B. Anti-DNase B titers may not reach maximum titers for 6 to 8 weeks, but they remain elevated longer than ASO titers and are more reliable than ASO for the confirmation of a preceding streptococcal skin infection. Moreover, since only 80 to 85% of patients with rheumatic fever have elevated ASO titers, additional anti-DNase B titers may be helpful.

Due to frequent exposure to *S. pyogenes,* ASO and anti-DNase B titers are higher in children in the United States from 2 to 12 years of age. Geometric mean values of 89 Todd U (ASO) and 112 U (anti-DNase B) and 240 Todd U and 640 U, respectively, represent the upper limits of normal values (56). Prompt antibiotic therapy of streptococcal infections can reduce the titer but does not abolish antibody production. Streptococcal carriers do not experience a rise in streptococcal antibody titers.

The hemagglutination-based streptozyme test (Streptozyme; Carter-Wallace, Inc., Cranbury, N.J.) was developed to detect antibodies against multiple extracellular streptococcal products. However, variabilities in test standardization and inconsistent specificities have been reported (44).

ANTIMICROBIAL SUSCEPTIBILITIES

Beta-Hemolytic Streptococci

Penicillin remains the drug of choice for the treatment of streptococcal infections due to beta-hemolytic streptococci, because in contrast to *S. pneumoniae* and other alpha-hemolytic streptococci, beta-hemolytic streptococci remain uniformly susceptible to penicillin. Reports of penicillin-resistant strains of beta-hemolytic streptococci have not been

confirmed by reference laboratories. Due to suspected or confirmed penicillin allergies in more than 10% of patients, macrolides are often given as an alternative treatment. Macrolide resistance rates among isolates of *S. pyogenes* and *S. agalactiae* have been increasing in North America as well as in Europe (26). Resistance rates correlate with the use of macrolides in clinical practice, and geographic differences in resistance rates are often due to differences in macrolide use. In the United States, macrolide resistance among *S. agalactiae* isolates rose from 12 to 20% from 1990 to 2000 (76). Two major mechanisms are responsible for macrolide resistance in streptococci. Resistance encoded by the *mefA* gene results in low-level erythromycin but not clindamycin resistance due to increased drug efflux from the bacterial cell. Methylation of the macrolide binding site within 23S rRNA by methylases encoded by *erm* genes mediates resistance to macrolides, lincosamides, and streptogramin group B (MLS_B) agents. The methylation causes high-level macrolide resistance and is either inducible or constitutively expressed. Strains with inducible MLS_B resistance are resistant to erythromycin and susceptible to clindamycin in vitro. In contrast, strains with constitutive MLS_B resistance demonstrate resistance to both erythromycin and clindamycin. The majority of macrolide-resistant *S. pyogenes* isolates from North America harbor the *mefA* gene, and macrolide resistance due to the presence of *erm* genes is less common in *S. pyogenes*. Among *S. agalactiae* isolates from North America, the predominant macrolide resistance mechanism is methylation of 23S rRNA due to the *erm* methylase genes (*ermTR* and *ermB*), and only a few strains harbor the efflux gene *mefA* (26). Beta-hemolytic streptococcal isolates with a reduced susceptibility to vancomycin have not been reported.

S. pneumoniae and Viridans Streptococci

In view of the development of penicillin resistance in *S. pneumoniae* and other alpha-hemolytic streptococci, penicillin can no longer be recommended as the initial treatment of choice in many countries. Penicillin is considered a preferred antimicrobial agent only for *S. pneumoniae* and other alpha-hemolytic streptococci with demonstrated susceptibilities to penicillin. Penicillin resistance in *S. pneumoniae* is caused by altered penicillin-binding proteins.

Approximately 20% or more of *S. pneumoniae* isolates are not fully susceptible to penicillin in many geographic regions (http://www.cdc.gov/abcs). *S. pneumoniae* infections should be treated according to current guidelines (69). Depending on the clinical situation, treatment options include extended-spectrum cephalosporins, macrolides, fluoroquinolones, and vancomycin. In addition, more than one-third of blood culture isolates of the viridans group collected in the late 1990s in the United States were not susceptible to penicillin (29). Especially *S. mitis* and *S. salivarius* isolates show high percentages of penicillin-resistant strains.

S. pneumoniae was uniformly susceptible to macrolides until the late 1980s in the United States, but macrolide resistance is now evident in 25% of *S. pneumoniae* strains (109). Macrolide resistance in *S. pneumoniae* is caused by ErmB-mediated methylation of 23S rRNA, causing a high-level resistance phenotype, or MefA-mediated efflux of macrolides resulting in a low-level resistance phenotype. In contrast to the United States, where two-thirds of macrolide resistance is mediated by MefA, a higher overall prevalence of macrolide resistance is found in some parts of Europe and most European macrolide-resistant *S. pneumoniae* isolates contain the *ermB* gene (81).

The increased use of fluoroquinolones to treat *S. pneumoniae* infections has been accompanied by a rise in fluoroquinolone-resistant *S. pneumoniae* strains. Resistance occurs in a stepwise fashion and is due to mutations in DNA topoisomerase IV or a subunit of DNA gyrase. While the overall prevalence of fluoroquinolone resistance is below 1% according to ABC surveillance data (http://www.cdc.gov/abcs), the increase in resistant strains during recent years emphasizes the need for close monitoring. Clinical failures of levofloxacin therapy due to resistance have been reported (22). Vancomycin-resistant *S. pneumoniae* isolates have not been described. However, the isolation of a vancomycin-resistant *S. bovis* isolate has been reported (86).

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

Streptococci from the pyogenic group and *S. pneumoniae* are important human pathogens. Timely identification of these species in clinical specimens is therefore crucial to treat infections adequately and to reduce transmission. Detection of *S. pyogenes* strains in throat specimens allows adequate therapy and reduces nonsuppurative sequelae. Because *S. dysgalactiae* subsp. *equisimilis* (human group C and G streptococci) has been documented as an agent of pharyngitis including cases complicated by nonsuppurative sequelae, the presence of *S. dysgalactiae* subsp. *equisimilis* in throat cultures should be reported. To avoid unnecessary antibiotic treatment, it is important to correctly differentiate these pathogens from the small-colony-forming beta-hemolytic species of the *S. anginosus* group that constitute part of the oropharyngeal microbiota. However, *S. anginosus* group species isolated from wound specimens or abscesses are likely to represent true pathogens. While invasive neonatal *S. agalactiae* infections are declining due to improved prenatal screening and peripartal antibiotic prophylaxis, increased detection of *S. agalactiae* from adult patients has been reported. Thorough identification and reporting of this organism should therefore not be confined to screening swabs during pregnancy or in newborns.

The correct identification of viridans streptococci to the species or group level is often difficult and should be reserved for strains isolated from serious infections, such as endocarditis, abscesses, and infections in neutropenic patients. While in the normal host, transient bacteremia with viridans streptococci is generally cleared without adverse sequelae, prolonged bacteremia, particularly that caused by *S. mitis* in neutropenic patients, has become recognized as a distinct clinical entity that can be complicated by adult respiratory distress syndrome. Severe bacteremic infections with viridans streptococci have also been reported from low-birth-weight term and preterm neonates. Many *S. mitis* isolates are no longer penicillin-susceptible, and special attention should be paid to susceptibility testing. For *S. pneumoniae*, the elevated prevalence of resistance to penicillins, macrolides, ketolides, and fluoroquinolones varies worldwide. Careful identification of, and interpretation of susceptibility testing for, invasive and noninvasive *S. pneumoniae* isolates is required to guide appropriate antimicrobial therapy and to monitor the further spread of resistant pathogens. Due to the association of *S. gallolyticus* subsp. *gallolyticus* with malignancies of the gastrointestinal tract, and in view of the recent taxonomic changes within the *S. bovis* group, reports of novel species designations should include information about former species names (112).

Enterococcus

LÚCIA MARTINS TEIXEIRA, MARIA DA GLÓRIA SIQUEIRA CARVALHO, AND RICHARD R. FACKLAM

30

TAXONOMY

Microorganisms that are now included in the genus *Enterococcus* were related mainly to the "streptococci of fecal origin" or "enterococci" (26). These microorganisms were considered for a long time to be a major division of the genus *Streptococcus,* differentiated by their higher resistance to chemical and physical agents and accommodating most of the serological group D streptococci. In the last decades, however, the enterococci have undergone considerable changes in taxonomy, which started with the splitting of the genus *Streptococcus,* and the recognition of *Enterococcus* as a separate genus (89). Definite evidence that *Streptococcus faecalis* and *Streptococcus faecium* were sufficiently different from the other members of the genus to merit allocation into a separate genus was provided by studies using molecular approaches (89). The other enterococcal species were then transferred to the new genus, and several new species have been described and proposed for inclusion in the genus *Enterococcus* (25, 26). Some of the proposed new enterococcal species were not validated because they were shown to belong to previously described enterococcal species or did not belong to the genus *Enterococcus* at all (24, 26, 75, 104).

The phylogenetic analysis of genera of catalase-negative gram-positive cocci based on the comparison of the 16S rRNA gene sequences has revealed that *Enterococcus* organisms are more closely related to *Vagococcus, Tetragenococcus*, and *Carnobacterium* than they are to *Streptococcus* and *Lactococcus,* genera to which they have been phenotypically associated (17, 26).

Current criteria for inclusion in the genus *Enterococcus* and for the description of new enterococcal species encompass a polyphasic approach resulting from a combination of different molecular techniques (frequently involving DNA-DNA reassociation experiments, 16S rRNA gene sequencing, and whole-cell protein profiling analysis) and phenotypic tests. Partial or nearly entire sequencing of the 16S rRNA genes is now considered a practical and powerful tool in aiding the identification of enterococccal species, and it has been performed for all recognized species of *Enterococcus*. Figure 1 shows the phylogenetic relationships, based on the analysis of 16S rRNA gene sequences, among the species of *Enterococcus* that have their sequences already available at the GenBank database (as of December 2005). More recently, a variety of other nucleic acid-based methods have been used as additional tools to assess the phylogenetic relationships among enterococcal species and to formulate the descriptions of new species (26, 30, 74, 97, 98), but their use is still limited. The long-chain fatty acid composition of enterococcal cells, as revealed by gas-liquid chromatography analysis, is also of taxonomic value and has been used to discriminate species (30, 42, 89, 109).

DESCRIPTION OF THE GENUS

The members of the genus *Enterococcus* are catalase-negative gram-positive cocci that occur singly or arranged in pairs or as short chains. Cells are sometimes coccobacillary when Gram stains are prepared from growth on solid medium but tend to be ovoid and in chains when grown in thioglycolate broth. After growth on blood agar media for 24 h, colonies are usually between 1 and 2 mm in diameter although some variants may appear smaller. Some (about one-third) cultures of *Enterococcus faecalis* may be β-hemolytic on agar containing rabbit, horse, or human blood but nonhemolytic on agar containing sheep blood. Some cultures of *Enterococcus durans* are β-hemolytic regardless of the type of blood used. All other species are usually α-hemolytic or nonhemolytic. Enterococci are facultative anaerobes with a homofermentative metabolism that follows the Embden-Meyerhof-Parnas pathway resulting in the production of lactic acid as the end product of glucose fermentation. Because of their ability to ferment carbohydrates to lactic acid, the enterococci are referred to as typical lactic acid bacteria. Gas is not produced. These microorganisms are usually able to grow in temperatures ranging from 10 to 45°C, with optimum growth at 35°C. The majority of the species grow in broth containing 6.5% NaCl, and they hydrolyze esculin in the presence of bile salts (bile-esculin [BE] test). They also hydrolyze leucine-β-naphthylamide (LAP) by producing leucine aminopeptidase (LAPase). Most enterococci, apart from *Enterococcus cecorum, Enterococcus columbae* (16), *Enterococcus pallens, Enterococcus saccharolyticus*, and some strains of the recently described species *Enterococcus canintestini*, *Enterococcus devriesei,* and *Enterococcus moraviensis,* hydrolyze L-pyrrolidonyl-β-naphthylamide (PYR) by producing pyrrolidonyl arylamidase (pyrrolidonase [PYRase]). A few species are motile *(Enterococcus casseliflavus* and *Enterococcus gallinarum),* and some are pigmented *(E. casseliflavus, Enterococcus gilvus, Enterococcus mundtii, E. pallens,* and *Enterococcus sulfureus)* (17, 26, 43). Methods used for

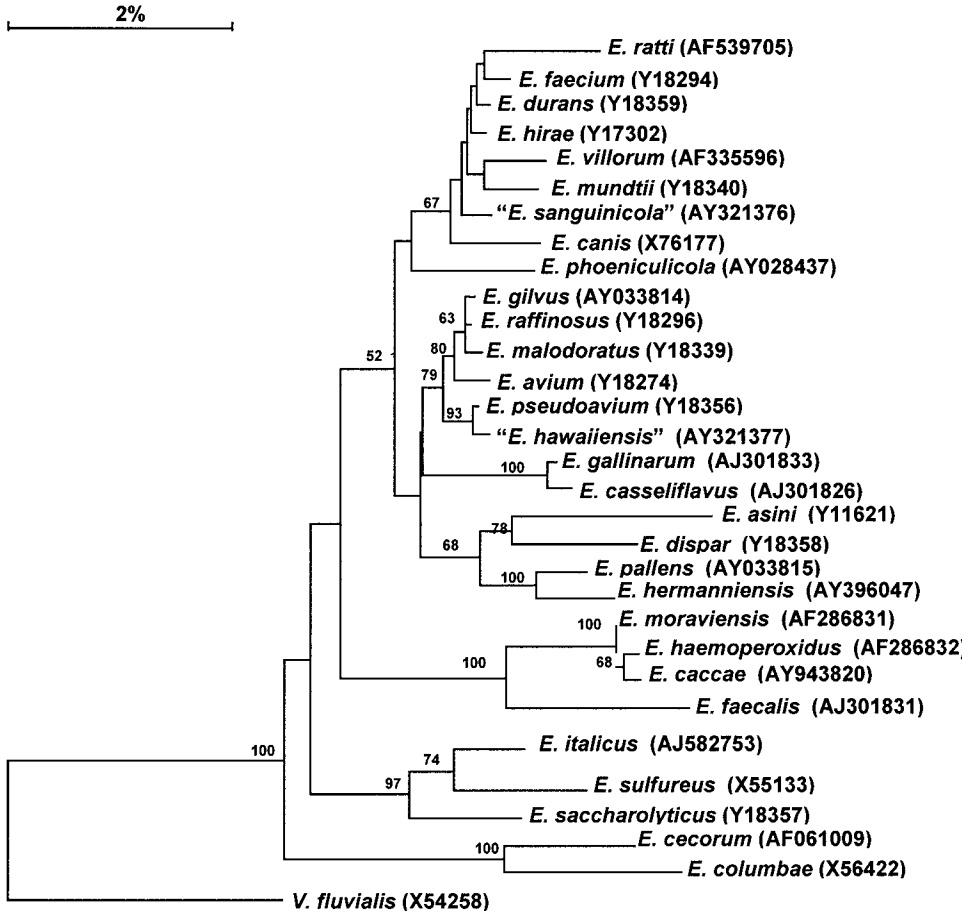

FIGURE 1 Phylogenetic tree based on comparative analysis of 16S rRNA gene sequences, showing the relationships among type strains of species of *Enterococcus*. *Vagococcus fluvialis* was used as an out-group, and bootstrap values at the nodes were displayed as percentages.

detection of enterococcal motility have to be selected carefully, as differences in motility due to the composition of the medium have been demonstrated (111). Enterococci are not able to synthesize porphyrins and, therefore, do not produce cytochrome enzymes (17, 43). However, cytochrome activity is sometimes expressed when strains of *E. faecalis* are grown on blood-containing media, and a weak effervescence is observed in the catalase test. Positive catalase testing has been reported for strains of *Enterococcus haemoperoxidus*, when cultivated on blood-agar media (96). Most enterococcal strains produce a cell wall-associated glycerol teichoic acid that is identified as Lancefield's serological group D antigen. The G+C content of the DNA ranges from 32 to 44 mol%. The genome size is in the range of approximately 2,000 to 3,500 kb (58, 91).

The other genera of catalase-negative gram-positive cocci and the characteristics that distinguish them from the enterococci are discussed in chapters 29 and 31. No phenotypic criteria are available for clearly distinguishing the genus *Enterococcus* unequivocally from other genera, since there are no particular characteristics that are common to all enterococci. However, there are certain characteristics that are usually found in most strains of all the enterococcal species. Accurate presumptive identification of a catalase-negative gram-positive coccus as an *Enterococcus* can be accomplished by demonstrating that the unknown strain is positive for BE, PYR, and LAP tests and grows in the presence of 6.5% NaCl and at 45°C. Because strains of *Lactococcus, Leuconostoc, Pediococcus,* and *Vagococcus* with phenotypic similarities have been isolated from human infections (28, 102), the presumptive identification of enterococci based only on BE reaction and growth in 6.5% NaCl broth can be erroneous. Demonstrating the presence of group D antigen by serological reaction may be helpful in the identification, although antigen is detected in only about 80% of the enterococcal strains. On the other hand, pediococci and leuconostocs (28), as well as some vagococcal strains (102), can also react with anti-group D serum. Reactivity with the AccuProbe *Enterococcus* Culture Identification Test (a genetic probe manufactured by GenProbe, Inc., San Diego, Calif.) can also be used to confirm an unknown strain as an *Enterococcus*. Except for the type strains of *Enterococcus asini*, *Enterococcus canis, E. cecorum, E. columbae, E. haemoperoxidus, E. moraviensis, E. pallens,* and *E. saccharolyticus*, strains of most known species of *Enterococcus* react with this probe. However, *Vagococcus* strains also react with the *Enterococcus* genetic probe (90, 102).

EPIDEMIOLOGY AND TRANSMISSION

Several intrinsic characteristics of the enterococci allow them to grow and survive in harsh environments and to persist almost everywhere. Enterococci are widespread in nature

and can be found in soil, plants, water, food, and in animals, including mammals, birds, insects, and reptiles (1, 16, 17, 100, 101). In humans, as in other animals, they are predominantly inhabitants of the gastrointestinal tract, occurring in high numbers, and are less commonly found in other sites such as the genitourinary tract and the oral cavity (44, 94, 100). The prevalence of the different enterococcal species appears to vary according to the host and is also influenced by age, diet, and other factors that may be related to changes in physiologic conditions, such as underlying diseases and prior antimicrobial therapy. Enterococci are considered to be the most abundant gram-positive coccus colonizing the intestine, with *E. faecalis* being one of the most common bacteria isolated from this site (17, 23, 94, 100). Other species, such as *E. faecium* as well as *E. casseliflavus*, *E. durans,* and *E. gallinarum*, are also found in variable proportions in the gastrointestinal tract of humans. Since the enterococci are opportunistic pathogens, the incidence of each species found in human infections probably reflects the distribution of the different species of *Enterococcus* in the human gastrointestinal tract. This site is believed to represent an important reservoir for strains associated with disease; from this location they may migrate to cause infections and can also disseminate to other hosts and to the environment. Even though the same enterococcal species can be found in several different animal species, the information available on the distribution of distinct enterococcal species in other sources indicates differences from the distribution in humans (1, 17, 100). On the other hand, the occurrence of high numbers of enterococci in the feces, as well as their ability to resist different chemical and physical conditions and to survive in the environment, implies that the enterococci can be used as indicators of fecal contamination and of the hygienic quality of food, milk, and drinking water (31, 33, 93). The occurrence of enterococci in natural nonhuman reservoirs (1), as well as members of the intestinal microbiota of humans (100), and the relationship between the presence of enterococci in foods and human safety (31, 33) have been extensively reviewed recently. Overall, several aspects of the ecology of the enterococci and the real incidence of the different species as members of the microbiota in body sites or in environmental sources merit further evaluation, especially in the light of the changing classification and taxonomic approaches to the genus and of the increasing resistance to antimicrobial agents.

CLINICAL SIGNIFICANCE

The enterococci are commensal microorganisms that act as opportunistic agents of infections, particularly in elderly patients with serious underlying diseases and other immunocompromised patients who have been hospitalized for prolonged periods, have been treated with invasive devices, and/or have received broad-spectrum antimicrobial therapy. From the site of colonization, the microorganism must evade host clearance and produce pathologic changes in the host, either by direct toxic activity or indirectly by inducing an inflammatory response. Several potential virulence factors have been identified in enterococci (13, 22, 39, 44, 47, 66, 84, 94), but none has been established as having a major contribution to virulence in humans. On the other hand, the resistance traits of enterococci may be crucial to allow members of this genus to survive for extended periods of time in the host or environment (44), leading to their persistence and role as prominent nosocomial pathogens. Although the enterococci can cause human infections in the community and in the hospital, these microorganisms began to be recognized with increasing frequency as common causes of hospital-acquired infections in the late 1970s, paralleling the increasing resistance to most currently used antimicrobial agents. As a result, enterococci have emerged as one of the leading therapeutic challenges when associated with serious or life-threatening infections. This trend is likely to continue as the overall population ages and more people become at risk for infection (59). The ubiquitous presence of enterococci, however, requires caution in establishing the clinical significance of a particular isolate. Unnecessary work and potentially misleading laboratory reports should be avoided whenever possible, especially with respect to in vitro susceptibility testing decisions (see "Antimicrobial Susceptibilities" below).

The variety of infections in which enterococci are involved has been thoroughly reviewed and summarized (39, 55, 63, 67, 94). Although the spectrum of infections has remained relatively unchanged since the extensive review by Murray in 1990 (67), trends to increasing prevalence of these organisms as nosocomial pathogens have been frequently observed. Enterococci have become the second or third leading cause of nosocomial urinary tract infections (UTIs), wound infections (mostly surgical, decubitus ulcers, and burn wounds), and bacteremia in the United States (39, 50, 55, 63, 67, 76, 88, 94). UTIs are the most common of the enterococcal infections: enterococci have been implicated in approximately 10% of all UTIs and in up to approximately 16% of nosocomial UTIs (55, 63, 76, 88, 94). Enterococcal bacteruria usually occurs in patients with underlying structural abnormalities and/or in those who have undergone urologic manipulations (63). Intra-abdominal and pelvic infections are the next most commonly encountered infections. However, cultures from patients with peritonitis, intra-abdominal or pelvic abscesses, biliary tract infections, surgical site infections, and endomyometritis are frequently polymicrobial, and the role of enterococci in these settings remains controversial. Enterococci have been considered to be an important cause of endocarditis since early descriptions and are estimated to account for about 20% of cases of native valve bacterial endocarditis and for about 6 to 7% of prosthetic valve endocarditis (59). Whereas endocarditis is a serious enterococcal infection, it is less common than bacteremia. Enterococcal infections of the respiratory tract or the central nervous system, as well as otitis, sinusitis, septic arthritis, and endophthalmitis, may occur but are rare (39, 67, 94). There is evidence for a role of enterococci in dental infections (95). The significance of isolates from some of these sites should be carefully evaluated before any clinical decisions are made.

E. faecalis is the most frequent enterococcal species isolated from human clinical specimens, representing 80 to 90% of the isolates, followed by *E. faecium,* which is found in 5 to 10% of enterococcal infections (6, 27, 35, 64). However, the ratios of isolation of the different enterococcal species can vary according to each setting and can be affected by a number of aspects, including the increasing dissemination of outbreak-related strains such as vancomycin-resistant *E. faecium*. For example, in one recent report, the ratio of *E. faecalis* to *E. faecium* isolates recovered from blood cultures was about 2.5:1.0 (50). Other enterococcal species are identified less frequently, even though clusters of infections associated with *E. casseliflavus* (77) and *E. raffinosus* (113) have been reported. Although less frequently or even rarely, several other enterococcal species, including *E. avium, E. caccae, E. cecorum, E. dispar*, *E. durans, E. gallinarum, E. gilvus,* "*E. hawaiiensis,*" *E. hirae, E. italicus, E. malodoratus, E. mundtii, E. pallens*, *E. pseudoavium*, "*E. sanguinicola*," and *E. faecalis* variant strains, have also been isolated from human sources (12, 27, 35, 42, 62, 64, 109). Isolation of the other species of enterococci has not yet been documented from human sources.

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

The standard methods of collecting blood, urine, wound samples, and other secretions or swab specimens are adequate (see chapters 5 and 20). No special methods or procedures are usually necessary for transporting clinical specimens containing enterococci because these microorganisms are easily recovered and are relatively resistant to environmental changes. Transport can be performed on almost any transport media or on swabs that are kept dry. Like most clinical samples, the material should be cultured as soon as possible, preferably within 1 h.

Enterococcal strains can be stored indefinitely when lyophilized. In our experience, cultures frozen at –70°C or less can be stored for several years as heavy cell suspensions made directly in defibrinated sheep or rabbit blood or in a skim milk (10%) solution containing glycerol (10%). Most strains of enterococci survive several months at 4°C on agar slants prepared with ordinary agar bases, such as brain heart infusion and Trypticase soy agar.

DIRECT EXAMINATION

The direct microscopic examination of Gram-stained smears of normally sterile clinical specimens, such as blood, may be useful for the diagnosis of enterococcal infections. Direct examination of certain nonsterile specimens may also be informative, but should not be overemphasized. In any case only a presumptive report of the "presence of gram-positive cocci" should be made, as microscopy by itself cannot differentiate the enterococci from most of the other gram-positive cocci. Culture and appropriate identification techniques should be performed for confirmation.

As the occurrence of vancomycin-resistant enterococci (VRE) represents an important problem worldwide, hospitals should consider the implementation of surveillance programs for VRE detection. In an attempt to overcome the inherent limitations of culture-based methods of detection (discussed in "Isolation Procedures"), conventional PCR and real-time PCR-based methods have been evaluated for direct detection of these microorganisms in clinical and surveillance specimens (80, 86, 92). The LightCycler *vanA/vanB* detection assay (commercially available from Roche Diagnostics, Indianapolis, Ind.) has shown promise for screening of VRE in rectal or perianal swabs and has been evaluated for identification of VRE in blood cultures (92). Relatively few methods for direct detection of enterococci from blood samples or blood cultures have been reported. Results of a recent report indicate the potential usefulness of the commercially available DNA probe (AccuProbe, Gen-Probe, Inc.) for the direct detection of enterococci in blood cultures (54).

ISOLATION PROCEDURES

Trypticase soy–5% sheep blood agar, brain heart infusion–5% sheep blood agar, or any blood agar base containing 5% animal blood supports the growth of enterococci. Enterococci grow well at 35 to 37°C and do not require an atmosphere containing increased levels of CO_2, although some strains grow better in this atmosphere. If the sample to be cultured is likely to contain gram-negative bacteria, commercially prepared media containing bile, esculin, and azide are excellent options for primary isolation. These media have traditionally been used and are supplied under different designations by the various manufacturers. More recently, media containing chromogenic substrates have been proposed for the isolation and presumptive identification of enterococci and their use in clinical laboratories is gaining acceptance (18, 60). The use of selective media for the isolation of enterococci has been previously reviewed (17). An extensive review of the diversity of media used for the isolation of enterococci from fecal and clinical specimens, as well as water, food, feeds, and environmental sources, was recently presented by Domig et al. (18).

The increasing incidence of vancomycin resistance among the enterococci has raised the importance of selective isolation of VRE. Early identification of infection or colonization by VRE is recommended to prevent the spread of these microorganisms (41, 70). Current recommendations for hospital infection control include VRE fecal surveillance cultures, but the optimal methods for these cultures are still unclear. Several different selective agar and/or broth media and procedures have been employed for the isolation of VRE from sources containing commensal microbiota, such as stool samples and rectal or perianal swab specimens (18, 78, 80, 85, 86). Most of them are variations of selective media differing with regard to the antimicrobial agents or the antimicrobial concentrations used. Depending on the specific purposes, direct plating techniques give some indication of the number of VRE present in the sample, but enrichment procedures are mainly applied to detect VRE present in low numbers. Although there is not a single generally accepted screening method for isolation at this point, the use of a selective-enrichment broth to enhance the recovery of VRE seems to be the most effective procedure. Enterococcosel broth (a bile-esculin azide medium supplied by Becton Dickinson Microbiology Systems, Sparks, Md.) has been used in a number of studies as the base medium supplemented with different concentrations of vancomycin, with 6 μg/ml being the most common concentration. In some of the protocols proposed, vancomycin and other antimicrobial agents, such as aztreonam and clindamycin, have been used in the enrichment broth as well as in the subculture medium. It would be prudent, however, to use a nonselective agar as well for subculturing from a selective-enrichment broth, as some strains may be inhibited to the point of very poor or no growth. In some circumstances, it may be necessary to recover VRE from environmental surfaces for epidemiologic studies. Isolation of the organisms from these surfaces can be accomplished by swabbing the surfaces with premoistened swabs and placing them either into a selective-enrichment broth or onto agar plates. Alternatively, the Rodac imprint method may be employed by applying the agar surface directly to the environmental surface to be cultured (37). Overall, culture-based screening methods for VRE may be especially demanding and can take several days to complete, besides having variable degrees of sensitivity, which affects the timely implementation of infection control procedures. Therefore, some microbiology laboratories have recently considered the introduction of molecular techniques to facilitate the rapid and accurate identification of VRE and to improve the ability for detecting this pathogen. However, most of the approaches described in the literature still require bacterial growth in culture prior to detection, requiring 24 h or more to complete. More rapid detection of VRE directly from patient samples is still an area for which there is an important clinical need and relatively little published literature, as already mentioned (see "Direct Examination" above). Because a laboratory report that indicates the presence of VRE may initiate a cascade of infection control events that are time-consuming and costly (10, 41, 70), laboratories should be confident in the epidemiologic importance of any suspected VRE isolate. Transferable and high-level vancomycin resistance, encoded by the *vanA* or the *vanB* genes and most frequently associated with *E. faecalis* and *E. faecium* isolates, is the major focus of infection

control efforts. In contrast, the intrinsically low-level VanC resistance, which is not transferable and is not associated with dissemination of resistant strains, is less likely to be important to infection control surveillance efforts (10, 44, 85, 86). While the isolation of VRE from clinical and surveillance specimens is important, the need for protocols to rapidly determine the likely underlying mechanism of resistance associated with different genetic determinants (see "Antimicrobial Susceptibilities" below; see also chapters 71 and 78) is equally important (15, 85, 86).

IDENTIFICATION

Identification by Conventional Physiologic Testing

Once it is established that an unknown catalase-negative, gram-positive coccus is an *Enterococcus* or closely related genus (see "Description of the Genus"), the conventional tests (see reference 28 and chapters 14, 15, 29, and 31 for methods) listed in Table 1 can be used to identify the species. Most of the information presented here is related to phenotypic characteristics of strains isolated from humans.

TABLE 1 Phenotypic characteristics used for the identification of *Enterococcus* species and some physiologically related species of other gram-positive cocci

Species	Phenotypic characteristic[a]											
	MAN	SOR	ARG	ARA	SBL	RAF	TEL	MOT	PIG	SUC	PYU	MGP
Group I												
E. avium	+	+	−	+	+	−	−	−	−	+	+	V

Vagococcus fluvialis	+	−	−	−	+	−	−	+	−	+	−	+

[a] Abbreviations and symbols: MAN, mannitol; SOR, sorbose; ARG, arginine; ARA, arabinose; SBL, sorbitol; RAF, raffinose; TEL, 0.04% tellurite; MOT, motility; PIG, pigment; SUC, sucrose; PYU, pyruvate; MGP, methyl-α-D-glucopyranoside; +, 90% or more of the strains are positive; –, 90% or more of the strains are negative; V, variable (11 to 89% of the strains are positive).

[b] Phenotypic characteristics based on data from type strains.

[c] Occasional exceptions occur (<3% of strains show aberrant reactions).

[d] Late positive (3 days of incubation or longer).

[e] Weak reaction.

Enterococcal species can be separated into five physiologic groups of species based on acid formation from mannitol and sorbose, and hydrolysis of arginine (Table 1). Identification of enterococcal species by conventional tests is not rapid and may require up to 10 days of incubation. However, most identifications can be made after 2 days of incubation.

Group I consists of *E. avium, E. gilvus,* "*E. hawaiiensis,*" *E. malodoratus, E. pallens, E. pseudoavium, E. raffinosus,* and *E. saccharolyticus* (Table 1). "*E. hawaiiensis*" is a denomination that has been recently proposed (L. M. Teixeira, M. G. S. Carvalho, A. G. Steigerwalt, R. E. Morey, P. L. Shewmaker, E. Falsen, and R. R Facklam, *Abstr. 2nd Int. ASM-FEMS Conf. Enterococci,* abstr. A15, 2005) for the new species previously designated *Enterococcus* sp. nov. CDC PNS-E3 (7). If the results of conventional tests compare to the results originally reported (98), *E. devriesei,* a recently described species, will be grouped with the enterococcal species in group I.

Group II comprises *E. faecalis, E. faecium, E. casseliflavus, E. gallinarum, E. haemoperoxidus, E. mundtii,* and "*E. sanguinicola.*" These species form acid from mannitol and hydrolyze arginine but fail to form acid from sorbose. The majority of the isolates from human sources belong to species included in this group. Atypical strains that fail to hydrolyze arginine or form acid from mannitol have been documented. *Lactococcus* sp. is also listed in this group because the phenotypic characteristics of some strains can lead to the misidentification as an *Enterococcus*. If nonmotile variants of *E. casseliflavus* and *E. gallinarum* are encountered, production of acid from methyl-α-D-glucopyranoside (MGP) can be used to help in the identification of these species. "*E. sanguinicola*" is the denomination recently proposed (Teixeira et al., *Abstr. 2nd Int. ASM-FEMS Conf. Enterococci*) for the new species previously designated *Enterococcus* sp. nov. CDC PNS-E2 (7).

Group III consists of *E. dispar, E. durans*, *E. hirae*, *E. ratti* (101), and *E. villorum*. Three of these species (*E. durans*, *E. ratti,* and *E. villorum*) have very similar phenotypic profiles in the tests listed in Table 1. They can be differentiated by clotting reactions in litmus milk, hydrolysis of hippurate, and acid formation from trehalose and xylose. *E. durans* forms acid and clot, *E. villorum* forms acid but no clot, and *E. ratti* does not form acid or clot in litmus milk. *E. durans* hydrolyzes hippurate, while *E. villorum* does not. *E. ratti* is variable in the hippurate hydrolysis test. *E. durans* forms acid from trehalose but not from xylose, *E. villorum* forms acid from both trehalose and xylose, and *E. ratti* does not form acid from either trehalose or xylose. The other members of this group are easily identified by the reactions shown in Table 1. Uncommon mannitol-negative variant strains of *E. faecalis* and *E. faecium* resemble species in this group. However, *E. faecalis* strains are positive in the pyruvate test but not for acid formation from arabinose, raffinose, or sucrose, and E. *faecium* variant strains form acid from arabinose. In all likelihood *E. canintestini*, a recently described species (74), will also fall into enterococcal group III.

Group IV is composed by *E. asini, E. caccae, E. cecorum*, *E. phoeniculicola*, and *E. sulfureus* (Table 1). *E. caccae* is a recently proposed new species (8). If the results of conventional tests compare to the results originally reported (97), *E. aquimarinus,* a recently described species, will be grouped with the enterococcal species in group IV. Group V consists of *E. canis*, *E. columbae, E. hermanniensis, E. italicus,* and *E. moraviensis*. Variant strains of *E. casseliflavus*, *E. gallinarum,* and *E. faecalis* that fail to hydrolyze arginine resemble the microorganisms included in this group. However, these variant strains have characteristics similar to those of the strains that hydrolyze arginine and can be differentiated by the same phenotypic tests. *Vagococcus fluvialis* is listed here because the phenotypic characteristics of this species are very similar to those of the genus *Enterococcus* and some strains may be identified as enterococci (102). *E. italicus* corresponds to the new species previously designated *Enterococcus* sp. nov. CDC PNS-E1 (7, 30; Teixeira et al., *Abstr. 2nd Int. ASM-FEMS Conf. Enterococci*).

Identification by Commercial Systems or Molecular Methods

There are several commercially available miniaturized, manual, semiautomated, and automated identification systems for the identification of *Enterococcus* species. Since their introduction, these systems have been updated to improve their performance characteristics and expand their identification capabilities, as investigators have become more aware of inaccuracies (14, 32, 38, 46, 113). In general, these systems are reliable for the identification of *E. faecalis*, and, to a lesser extent, *E. faecium*. Accurate identification of other species, by most systems, depends on additional testing, although improvements have been observed with updated formats and databases. Commercial systems available for the identification of enterococcal species include the API 20S and the API Rapid ID 32 Strep systems (bioMérieux Vitek, Inc., Hazelwood, Mo.), the Crystal Gram-Positive and the Crystal Rapid Gram-Positive identification systems (Becton Dickinson Microbiology Systems), the Gram Positive Identification Card of the Vitek system (bioMérieux), and the Gram-Positive Identification panel of the MicroScan Walkaway system (Dade MicroScan, West Sacramento, Calif.). The accuracy of identification by some of these systems in comparison to identification by molecular techniques has been evaluated (3, 46). In general, a large proportion of enterococcal isolates are accurately identified by any one of these systems; however, the accuracy is dependent on the distribution of species found in each specific setting. Identification of unusual species by a commercial system should be confirmed by a reference method before being reported.

Molecular methods based on the analyses of different target molecules, such as DNA-DNA hybridization and sequencing of the 16S rRNA genes, have been used primarily for taxonomic purposes in special laboratories. In the past 15 years, however, the application of molecular techniques for the identification of *Enterococcus* species has expanded dramatically in an attempt to develop more rapid and accurate identification methods potentially adaptable for use in clinical microbiology laboratories. A variety of molecular procedures have been proposed for the identification of enterococcal species as recently reviewed and summarized (19, 26). These alternate methods include sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) analysis of whole-cell protein (WCP) profiles, vibrational spectroscopic analysis, proton magnetic resonance spectroscopic analysis, randomly amplified polymorphic DNA analysis, sequencing analysis of the 16S rRNA gene, restriction fragment-length polymorphism analysis of the PCR-amplified 16S rRNA gene, broad-range amplification of the 16S rRNA gene or of the *groESL* gene, sequencing of the domain V of the 23S rRNA gene, amplification of the tRNA or the rRNA intergenic spacers, amplification of the D-ala:D-ala ligases *(ddl)* and the vancomycin resistance *(van)* genes, sequencing of the *ddl* genes, amplification and probing of the *Enterococcus* protein A *(efaA)* genes or of the *E. faecalis* adhesin for collagen *(ace)* gene, amplification of the elongation factor EF-Tu *(tuf)* or the pEM1225 genes, sequencing of the manganese-dependent superoxide dismutase (*sodA)* gene, sequencing of the chaperonin 60 *(cpn60)* gene, sequencing of the RNA polymerase β subunit *(rpoB)*

gene (21), sequencing of the RNA polymerase α subunit (*rpoA*) and the phenylalanyl-tRNA synthase (*pheS*) genes (72), and sequencing of the α subunit of the ATP synthase (*atpA*) gene (73). Many of these molecular procedures have been performed in only one or a few laboratories and have not been evaluated for the majority of the species of *Enterococcus*. Most of them are potentially applicable to all enterococcal species, and others are species specific.

Among the molecular techniques proposed to identify the different enterococcal species, SDS-PAGE analysis of WCP profiles and sequencing of the 16S rRNA genes have been evaluated in reference laboratories. SDS-PAGE analysis of WCP profiles appears to be a reliable tool for the differentiation and identification of *Enterococcus* strains, since WCP profiles are species specific (7, 26, 61, 101). Apart from minor differences among strains, each of the known enterococcal species corresponds to a unique WCP profile. WCP profiles of related species of *Lactococcus* and *Vagococcus* are also unique and different from those of the enterococci (90, 102-104). Table 1 depicts the phenotypic characteristics of *Enterococcus* species discussed in this chapter, is based on correlations between the WCP profiles and the phenotypic tests, and may include findings of DNA-DNA reassociation experiments and 16S rRNA gene sequencing. Sequencing of the 16S rRNA gene is a frequently used nucleic acid-based method for identification of enterococcal species (81). The 16S rRNA gene sequences are available for comparison purposes via public databanks of nucleotide sequences such as GenBank. Comparisons can be made by using one of the several sequence-comparing software packages, many of which are available for public access. Figure 1 shows a dendrogram generated by comparison of 16S rRNA gene sequences of the type strains of the species included in the genus *Enterococcus*. Accession numbers of the reference sequences used for comparative analyses are indicated in the figure. Clear-cut identification is not obtained for all enterococcal species, since several species differ by only 1 to 3 bases in the entire 16S rRNA gene (approximately 1,500 bp). Together with phenotypic characterization and other alternative molecular methods such as analyses of WCP profiles, DNA sequencing can be an important tool to establish species identity.

TYPING METHODS

The increasing documentation of *Enterococcus* as a leading nosocomial pathogen frequently exhibiting resistance to several antimicrobial agents and the evidence supporting the concept of exogenous acquisition of enterococcal infections have generated demand for strain typing and epidemiologic studies. Besides outbreak analysis, the methods used for epidemiologic investigation of enterococcal isolates must be able to track enterococcal dissemination in different environments and hosts and the evolution of multidrug-resistant strains. Classic phenotypic methods used to investigate the diversity among isolates of a given enterococcal species have frequently failed to adequately discriminate among strains, and they have limited value in epidemiologic studies. However, phenotypic information in association with molecular data can contribute valuable information (19, 26, 115). Discriminatory molecular typing methods demonstrated that strains can be exogenously acquired by direct and indirect contact among patients. Intrahospital transmission and interhospital spread have also been documented for antimicrobial-resistant enterococci (4, 19, 26, 55, 94, 115, 116).

Improved discrimination among enterococcal strains involved analyses of chromosomal DNA restriction endonuclease profiles by pulsed-field gel electrophoresis (PFGE) (4, 19, 26, 34, 36, 69, 83). Multilocus enzyme electrophoresis (9, 107), ribotyping (23, 35, 52, 116), and PCR-based typing methods, such as randomly amplified polymorphic DNA PCR assay and repetitive element sequence-based PCR, have also been used to investigate genetic relationships among enterococcal strains (45, 56). Sequencing of PCR products and restriction fragment length polymorphism analyses of PCR products have been used to trace and determine differences among antibiotic resistance genes in enterococci (20, 51, 82, 114).

Results from a number of investigations indicate that analysis of SmaI restriction digests of genomic DNA by PFGE is widely useful for studying enterococcal species (26), showing definite advantages in strain discrimination. PFGE is considered to be the "gold standard" for the epidemiologic analyses of enterococcal infections. Several protocols for performing PFGE analyses of enterococcal strains have been published. However, the development of standardized protocols as a result of collaborative studies is needed in order to allow for interlaboratory comparisons. Most of the information accumulated during the past several years is related to *E. faecium* and *E. faecalis*. Although PFGE is quite discriminatory, epidemiologic interpretation of PFGE profiles is not always clear-cut. The occurrence of genetic events can be associated with substantial changes in the PFGE profiles, leading to problems in clonality assessment (51, 65, 87). There is not a single definitive typing technique for enterococci. A strong match among the results of several typing techniques, particularly those based on different genomic polymorphisms, can be used to indicate a high degree of relatedness. The use of PFGE in conjunction with at least one additional typing technique or independent PFGE analyses using different restriction enzymes is highly recommended to help in clarifying epidemiologic interpretations. General principles proposed for the interpretation of molecular typing data based on fragment differences are usually applied to interpret PFGE profiles obtained for enterococcal strains (26, 105). Well-characterized control strains should be evaluated along with unknown isolates. For that purpose, two reference strains, *E. faecalis* OG1RF (ATCC 47077) and *E. faecium* GE1 (ATCC 51558), have been proposed (105).

Two additional powerful molecular techniques, multilocus sequence typing (MLST) and multiple-locus variable-number tandem repeat analysis (MLVA), were developed more recently and have already been used to identify clonal complexes within enterococcal populations and for investigating genetic relatedness between strains. MLST typing schemes have been applied to explore the population structure of *E. faecalis* and *E. faecium* (5, 40, 71). Application of MLST typing has revealed the occurrence of host-specific genogroups of *E. faecium* and a specific genetic lineage that seems to have emerged recently worldwide, associated with nosocomial outbreaks. Two simultaneously published studies described the development of MLVA typing schemes for *E. faecalis* (106) and *E. faecium* (108). The data indicate that this technique can achieve a high degree of discrimination and is suitable for easy interlaboratory data exchange. However, neither MLVA nor MLST is currently feasible for most laboratories.

ANTIMICROBIAL SUSCEPTIBILITIES

Resistance to several commonly used antimicrobial agents is a remarkable characteristic of most enterococcal species. Moreover, most of this information is based on studies with *E. faecalis* and *E. faecium*, the two species most frequently associated with human infections. Antimicrobial resistance can be classified as either intrinsic or acquired. Intrinsic

resistance is related to inherent or natural chromosomally encoded characteristics present in all or most of the enterococci. Furthermore, certain specific mechanisms of intrinsic resistance to some antimicrobial agents are typically associated with a particular enterococcal species or groups of species. In contrast, the occurrence of acquired resistance is more variable, resulting from either mutations in existing DNA or acquisition of new genetic determinants found in plasmids or transposons (44, 48, 67, 68, 94). Intrinsic resistance among enterococci involves two major groups of antimicrobial agents, the aminoglycosides and the β-lactams. Because of the poor activity of several antimicrobial agents against enterococci due to intrinsic resistance, the recommended therapy for serious infections (i.e., endocarditis, meningitis, and other systemic infections, especially in immunocompromised patients) includes a combination of a cell wall-active agent, such as a β-lactam (usually penicillin) or vancomycin, combined with an aminoglycoside (usually gentamicin or streptomycin). These combinations overcome the intrinsic resistance exhibited by enterococci, and a synergistic bactericidal effect is generally achieved since the intracellular penetration of the aminoglycoside is facilitated by the cell wall-active agent.

In addition to the intrinsic resistance traits, enterococci have acquired different genetic determinants that confer resistance to several classes of antimicrobial agents, including chloramphenicol, tetracyclines, macrolides, lincosamides and streptogramins, aminoglycosides, β-lactams, glycopeptides, and, more recently, quinolones. During the past several decades, the occurrence of acquired antimicrobial resistance among enterococci, especially high-level resistance (HLR) to aminoglycosides, β-lactams, and resistance to glycopeptides (especially vancomycin), has been increasingly reported. Isolates that are resistant to the cell wall-active agent or have HLR to aminoglycosides are resistant to the synergistic effects of combination therapy and constitute an even more serious problem. Therefore, the detection of resistance to these groups of antimicrobial agents is important in order to predict the likelihood of synergy by using antimicrobial combinations as a therapeutic strategy. Enterococcal isolates exhibiting HLR to one or more aminoglycosides have been described with increasing frequencies (35, 44, 48, 64, 67, 68, 94) and are now present in large proportions in several geographic areas. Strains expressing acquired HLR to aminoglycosides frequently have MICs of >2,000 μg/ml and cannot be detected by diffusion tests with conventional disks. Special tests using high-content gentamicin and streptomycin disks, as well as a single-dilution method, were developed to screen for this type of resistance (see chapters 73 and 74). Strains exhibiting high-level resistance to penicillin and ampicillin due to altered penicillin-binding proteins have also disseminated widely (44, 48, 67, 68, 94), while strains producing β-lactamase have been rarely identified (35, 67).

The emergence of vancomycin resistance as a therapeutic problem in enterococcal strains was first documented in western Europe and in the United States (49, 53, 110). Thereafter, the isolation of VRE has been continuously reported in diverse geographic locations (10, 44, 48, 66, 94). VRE strains have been classified according to phenotypic and genotypic features. Six types of glycopeptide resistance have already been described among enterococci, including three common phenotypes. The VanA phenotype, with inducible high-level resistance to vancomycin as well as to teicoplanin, encoded by the *vanA* gene; the VanB phenotype, with variable (moderate to high) levels of inducible resistance to vancomycin only, encoded by the *vanB (vanB1* and *vanB2)* genes; and the VanC phenotype, encoded by the *vanC* genes, conferring noninducible low-level resistance to vancomycin. VanA and VanB are considered the most clinically relevant phenotypes and are usually associated with *E. faecium* and *E. faecalis* isolates, while VanC resistance is an intrinsic characteristic of *E. gallinarum* (*vanC1* genotype) and *E. casseliflavus* (*vanC2* and *vanC3* genotypes) strains (10, 11, 44, 68, 82). Three additional types of glycopeptide resistance, encoded by the *vanD* (79), *vanE* (29), and *vanG* (57) genes, seem to occur rarely among enterococci. Furthermore, the isolation of vancomycin-dependent (99) and vancomycin-heteroresistant (2) enterococcal strains from clinically significant infections, although still sporadically reported, may represent additional serious threats for the treatment and control of enterococcal infections.

Although β-lactams other than penicillin or ampicillin (e.g., mezlocillin, piperacillin, azlocillin, amoxicillin-clavulanate, ampicillin-sulbactam, and imipenem) do not offer any significant advantages over ampicillin when they are used against enterococci, they may be useful against polymicrobial infections involving enterococci and gram-negative bacilli. Ampicillin testing, along with a test for β-lactamase production, can be used to predict resistance to other β-lactam antibiotics. Susceptibility testing for the other β-lactams is rarely necessary. A positive test for β-lactamase production (see chapter 74) indicates resistance to ampicillin and the acylureidopenicillins (i.e., azlocillin, mezlocillin, or piperacillin). Resistance to ampicillin revealed by disk diffusion or dilution methods indicates the presence of penicillin-binding protein-mediated resistance to these agents, as well as to β-lactam-β-lactamase inhibitor combinations and imipenem (67, 94, 112).

While in vitro methods for detecting vancomycin resistance are discussed in detail in chapters 73 and 74, some aspects regarding VanC-containing species (i.e., *E. gallinarum* and *E. casseliflavus*) need to be emphasized. Resistance usually associated with *vanC* genotypes is not detected by disk diffusion, but VanC strains usually grow on vancomycin agar screen tests. Because the clinical significance of VanC is still uncertain, the implications of susceptibility testing for patient management may be unclear. However, the need to differentiate VanA or VanB strains from VanC strains is quite evident for therapeutic, infection control, and surveillance reasons. Because growth on the vancomycin agar screen fails to help with this important distinction, species identification is necessary. VanC resistance in *E. faecalis* or *E. faecium* is yet to be described, so growth on the vancomycin agar by either of these species is likely due to VanA or VanB resistance. Although rare, the occurrence of the other kinds of vancomycin resistance may also be considered. Additionally, VanA resistance together with VanC resistance has been described for *E. gallinarum* so that identification of a species that usually harbors only VanC resistance does not completely rule out moderate to high levels of vancomycin resistance. In this regard, determining vancomycin MICs is useful as VanC resistance frequently results in MICs of <16 μg/ml, whereas VanA and VanB usually result in MICs of >32 μg/ml. Resistance to other agents such as ampicillin and aminoglycosides also is uncommon among VanC isolates. Because of limited alternatives, VRE isolates may be tested for susceptibilities to chloramphenicol, erythromycin, tetracycline (or doxycycline or minocycline), and rifampin. Testing of quinupristin-dalfopristin, daptomycin, or linezolid is recommended for reporting of vancomycin-resistant *E. faecium*.

Since enterococci are often discussed in terms of their multidrug resistance phenotypes, two of the most problematic resistance profiles, ampicillin and vancomycin resistance, are most commonly associated with *E. faecium* (44, 48). This

is important in terms of resistance surveillance. Because both ampicillin resistance and vancomycin resistance are less commonly seen in *E. faecalis* than in *E. faecium*, widespread emergence and dissemination of these resistance traits in *E. faecalis* would significantly add to the current problem of multiply resistant enterococci. Therefore, enterococcal species identification is important for the purposes of therapy and meaningful surveillance.

Molecular methods (see reference 26 and chapter 78) have been used to detect specific antimicrobial resistance genes and have substantially contributed to the understanding of the spread of acquired resistance among enterococci, especially resistance to vancomycin. However, because of their high specificity, molecular methods do not detect antimicrobial resistance due to mechanisms, including emerging resistance mechanisms, not targeted by testing.

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

The diversity and, in some cases, species specificity of emerging antimicrobial resistance traits among enterococcal isolates created an additional need for accurate identification at the species level and for in vitro evaluation of susceptibility to antimicrobial agents. The significance of a particular enterococcal isolate is a major factor in determining when antimicrobial testing should be done. Once the need to test a particular isolate has been established, selection of the appropriate antimicrobial agents for testing must be considered on the basis of the site of infection. Testing of antimicrobial agents to which enterococci are intrinsically resistant is contraindicated. The drugs that should not be tested include aminoglycosides at standard concentrations, aztreonam, cephalosporins, clindamycin, methicillin (or oxacillin), and trimethoprim-sulfamethoxazole. These drugs may appear active for enterococci in vitro but are not effective clinically, and isolates should not be reported as susceptible to these agents. Due to difficulties with some phenotypic methods for detection of HLR to aminoglycosides and resistance to vancomycin, updated guidelines for the selection of antimicrobial agents should be followed for routine testing and reporting. The in vitro methods for detecting antimicrobial resistance in enterococcal isolates were reviewed and summarized by Facklam et al. (26) and are also discussed in detail in chapters 73 and 74.

As already mentioned, synergy testing should be done with any enterococcal isolate implicated in infections for which combination therapy is indicated (e.g., for systemic infections). Enterococci are also frequently encountered in polymicrobial infections associated with the gastrointestinal tract or superficial wounds of hospitalized patients. Their pathogenic significance in such settings is uncertain, but susceptibility testing is warranted when predominant or heavy growth is observed (63). Testing of enterococcal isolates from lower UTIs is optional, as these infections usually respond to therapy with ampicillin. However, many hospital infection control programs require routine testing as a means of surveillance for VRE. For those instances when testing a urinary tract isolate is appropriate, ciprofloxacin, levofloxacin, nitrofurantoin, norfloxacin, or tetracycline could be selected, in addition to ampicillin (44, 55, 94). In cases of treatment failure, testing is always warranted.

Aerococcus, Abiotrophia, and Other Aerobic Catalase-Negative, Gram-Positive Cocci

KATHRYN L. RUOFF

31

TAXONOMY

The bacteria included in this chapter are taxonomically diverse catalase-negative, gram-positive cocci. All, however, share the characteristic of being infrequent clinical isolates found as opportunistic agents of infection in hosts who are usually compromised. Most of these organisms resemble other, more well known clinical isolates (e.g., streptococci and enterococci) and consequently may be mistaken for members of those genera. These bacteria may have been misidentified or overlooked in clinical cultures in the past or may represent emerging pathogens in compromised patient populations. Table 1 lists the organisms included here along with some of their basic characteristics.

Most organisms discussed in this chapter exhibit fairly low G+C contents (30 to 45 mol%) and are not currently affiliated with taxa above the genus level. Two additional infrequently isolated gram-positive cocci (*Rothia mucilaginosa* and *Alloiococcus* sp.) can display positive catalase reactions. The catalase-variable *R. mucilaginosa* (29), formerly called *Stomatococcus mucilaginosus* (G+C content, 50 to 60 mol%), was historically included with staphylococci in the family *Micrococcaceae* (101). The sole species of the catalase-positive genus *Alloiococcus* is *Alloiococcus otitis* (1) (see chapter 28).

The genus *Lactococcus* is composed of organisms formerly classified as Lancefield group N streptococci (102). Motile *Lactococcus*-like organisms with the Lancefield group N antigen (a teichoic acid antigen) have been classified in the genus *Vagococcus* (25, 116). The vagococci also resemble the enterococci, and Facklam and Elliott (51) reported that *Vagococcus* isolates examined at the Centers for Disease Control and Prevention, Atlanta, Ga., gave positive reactions in a commercially available nucleic acid probe test (Gen-Probe, San Diego, Calif.) for enterococci.

The genera *Abiotrophia* and *Granulicatella* have been proposed to accommodate organisms previously known as nutritionally variant or satelliting streptococci (34, 72). These bacteria were initially considered to be nutritional mutants of viridans group streptococcal strains, most notably of the species *Streptococcus mitis*. The work of Bouvet and colleagues (15) suggested that these organisms were really members of two novel streptococcal species given the names *Streptococcus defectivus* and *Streptococcus adjacens*. A comparative analysis of 16S rRNA sequences led Kawamura and coworkers to propose the creation of a new genus, *Abiotrophia*, containing two species, *Abiotrophia defectiva* and *Abiotrophia adiacens,* to accommodate these bacteria (72). A third species from human sources, *Abiotrophia elegans,* was described in 1998 (97). Kanamoto et al. noted the heterogeneity among *Abiotrophia* strains and proposed a fourth species, *Abiotrophia para-adiacens* (71). Most recently, Collins and Lawson proposed a new genus, *Granulicatella*, with *Granulicatella adiacens* and *Granulicatella elegans* encompassing strains formerly called *A. adiacens* and *A. elegans*. *A. defectiva* remains as the sole *Abiotrophia* species (34).

Taxonomic changes among the intrinsically vancomycin-resistant, catalase-negative, gram-positive cocci include the formation of the genus *Weissella* to accommodate the species formerly known as *Leuconostoc paramesenteroides* and related species (38). The vancomycin-susceptible species *Pediococcus halophilus*, formerly included in the otherwise intrinsically vancomycin-resistant *Pediococcus* genus, was reclassified in the genus *Tetragenococcus* (39). The organism formerly called *Enterococcus solitarius* has also been transferred to the *Tetragenococcus* genus as *Tetragenococcus solitarius* (48). Little is known about the role of the tetragenococci in human infection.

The organism we now know as *Gemella morbillorum* was noted in 1917 by Tunicliff (111), who was searching for the etiologic agent of measles. The organism she isolated from blood cultures from numerous measles patients was originally named *Diplococcus rubeolae*. This bacterium was also known as *Diplococcus morbillorum, Peptostreptococcus morbillorum,* and *Streptococcus morbillorum* until a proposal to include it in the genus *Gemella* was made in 1988 (74). *Gemella haemolysans* was originally classified as a *Neisseria* species due to its gram-variable or even gram-negative nature and its cellular morphology (diplococci with flattened adjacent sides). Collins and coworkers described two additional *Gemella* species isolated from human sources, *Gemella bergeri* (originally named *Gemella bergeriae*) (31) and *Gemella sanguinis* (32). The genus *Dolosigranulum* shows phenotypic similarities to *Gemella,* although it is not phylogenetically closely related to *Gemella* strains (3, 79).

Aerococcus urinae, described in 1992, is negative for pyrrolidonyl arylamidase production (PYR) and positive for leucine aminopeptidase production (LAP), showing reactions opposite those of *Aerococcus viridans* in these important identification tests (2). In spite of these phenotypic differences, molecular taxonomic studies suggest that *A. urinae*

TABLE 1 Basic phenotypic characteristics of catalase-negative, gram-positive cocci[a]

[a] Abbreviations and symbols: PYR, production of pyrrolidonyl arylamidase; LAP, production of leucine aminopeptidase; NaCl, growth in 6.5% NaCl; BE, hydrolysis of esculin in the presence of 40% bile; ESC, hydrolysis of esculin; MOT, motility; HIP, hydrolysis of hippurate; SAT, satelliting behavior; ARG, hydrolysis of arginine; BGUR, production of β-glucuronidase; MORPH, cellular arrangement; VAN, susceptibility to vancomycin; +, ≥90% of strains positive; −, ≤10% of strains positive; V, variable (60 to 90% of strains positive); ND, no data; chains, cells arranged primarily in pairs and chains; clusters, cells arranged primarily in clusters, tetrads, or irregular groups; S, susceptible; R, resistant.

[b] Although *H. kunzii* shares some phenotypic traits with *A. viridans*, *H. kunzii* is facultative and usually nonhemolytic, in contrast to *A. viridans*, which favors an aerobic growth atmosphere and is alpha-hemolytic. Two additional species of *Helcococcus* (*H. sueciensis* and "*H. pyogenes*") have been proposed (27, 91), both based on the isolation of single strains. These new species display negative reactions in the PYR test, in contrast to *H. kunzii*.

[c] LaClaire and Facklam (79) note that strains of *Dolosigranulum* are esculin hydrolysis positive when tested on conventional media, but the original description of this organism notes a lack of esculin hydrolysis activity (3).

[d] Most enterococcal strains are capable of growth at 45°C, which differentiates them from vagococci, which may be phenotypically similar. Strains of vagococci have been reported as testing positive with a commercially available nucleic acid probe for members of the genus *Enterococcus*.

[e] Phenotypically similar strains of enterococci and lactococci can be differentiated with a commercially available nucleic acid probe for members of the genus *Enterococcus*.

[f] *F. languida* cells are characteristically arranged in clusters, and cells of other *Facklamia* species are arranged in pairs and chains.

[g] *G. haemolysans* cells are arranged in pairs and clusters, and the cells of other *Gemella* species are arranged in pairs and chains.

[h] Formerly classified as a member of the genus *Abiotrophia*.

[i] Most lactococcal strains are capable of growth at 10°C, which differentiates them from streptococci, which may be phenotypically similar.

[j] *Streptococcus pyogenes* and some strains of *S. pneumoniae* are PYR positive.

should remain in the *Aerococcus* genus. Organisms currently included in the *A. urinae* species are fairly heterogeneous and can probably be subdivided into at least two subspecies (23). *Aerococcus christensenii,* isolated from the human genitourinary tract, was described by Collins and coworkers in 1999 (33) and was joined by the species *Aerococcus sanguinicola* (originally named *Aerococcus sanguicola*) (52, 82) and *Aerococcus urinaehominis* (81) in 2001.

The genera *Facklamia*, *Ignavigranum,* and *Dolosicoccus* are related to, but distinct from, *Globicatella sanguinus*, an organism initially named *Globicatella sanguis*, which was described in 1992 (24). The genus *Facklamia* currently contains four species isolated from human sources: *Facklamia hominis* (28), *Facklamia sourekii* (30), *Facklamia ignava* (35), and *Facklamia languida* (80). The genus *Ignavigranum*, currently consisting of a single species, *Ignavigranum ruoffiae*, was described by Collins and coworkers (36), along with the genus *Dolosicoccus* and its single species, *Dolosicoccus paucivorans* (37).

The genus *Helcococcus* was originally composed of the single species *Helcococcus kunzii* (26), which was joined by a new species isolated from humans, *Helcococcus sueciensis,* in 2004 (27). A third human species, "*Helcococcus pyogenes*," has been proposed but to date has not received official taxonomic standing (91).

The examination of gram-positive cocci with molecular taxonomic methods has encouraged the delineation of new groups of organisms and the refinement of a genetically based taxonomy for the catalase-negative, gram-positive cocci.

DESCRIPTION OF THE GENERA

The organisms included in this chapter form gram-positive coccoid cells, but *G. haemolysans* may appear to be gram variable or gram negative due to the ease with which its cells are decolorized. Cell shape and arrangement can aid in dividing these organisms into two broad groups: those with a streptococcal-like Gram stain morphology (coccobacilli in pairs and chains) and those with a staphylococcal-like Gram stain morphology (more spherical cocci in pairs, tetrads, clusters, or irregular groups). Members of the genera *Abiotrophia* and *Granulicatella* (formerly the nutritionally variant streptococci) form coccobacilli arranged in pairs and chains, but these organisms may also appear pleomorphic, especially when grown under less than optimal nutritional conditions (21). *Weissella* strains form coccobacilli or short rods arranged in pairs and chains (89). Dividing these diverse bacteria into two groups based on cellular shape and arrangement serves only as an aid in identification; no relatedness of organisms is implied by this grouping. With the exception of the infrequently isolated vagococci, these organisms are nonmotile.

Members of most of the genera are catalase-negative facultative anaerobes, but *A. viridans* is classified as a microaerophile that grows poorly if at all under anaerobic conditions. Some strains of *Aerococcus* may exhibit weakly positive catalase reactions due to nonheme catalase activity. None of the members of the genera are beta-hemolytic on routinely employed blood agars, but *G. haemolysans* is described as producing beta-hemolysis on agars supplemented with rabbit or horse blood (95), and some strains of *G. bergeri* and *G. sanguinis* may exhibit hemolytic reactions on horse blood agar (31, 32).

NATURAL HABITATS

Some of the genera discussed here are members of normal flora of the oral cavity or upper respiratory tract (*Gemella*, *Abiotrophia,* and *Granulicatella)* or colonize the skin (*Helcococcus*). Foods and vegetation are normal habitats for lactococci, pediococci, and leuconostocs (59, 60); members of the genera *Lactococcus, Pediococcus,* and *Leuconostoc* may also be found as normal flora of the alimentary tract, but thorough data supporting this contention are lacking. Aerococci are environmental isolates that can also be found on human skin. Although the organisms have been isolated from human sources, the natural habitats of many of the organisms mentioned here are not well characterized.

CLINICAL SIGNIFICANCE

Although the organisms included in this chapter may be present as contaminants in clinical cultures, they are also isolated infrequently as opportunistic pathogens. These bacteria appear to be of low virulence and are usually pathogenic only in compromised hosts. Infection often occurs in previously damaged tissues (e.g., heart valves) or may be nosocomial and associated with prolonged hospitalization, antibiotic treatment, invasive procedures, and the presence of foreign bodies. Specimens likely to yield significant numbers of isolates of these bacteria are blood, cerebrospinal fluid, urine, and wound specimens.

Lactococcus

Difficulties in distinguishing lactococci from either streptococci or enterococci have probably led to the misidentification of clinical *Lactococcus* isolates in the past and may have contributed to the paucity of reports concerning the clinical role of these bacteria. Elliott and coworkers (45) studied the phenotypic characteristics of a number of lactococcal strains isolated from blood, specimens from patients with urinary tract infections, and an eye wound specimen culture. The authors observed that three blood culture isolates were obtained from patients diagnosed with prosthetic valve endocarditis. Other reports have noted cases of lactococcal native valve endocarditis (56, 84, 94), septicemia in an immunosuppressed patient (86), osteomyelitis (69), and liver abscess (4).

Vagococcus

To date, only a handful of *Vagococcus* isolates from human sources have been reported in the literature. Teixeira and coworkers (110) described strains isolated from blood, peritoneal fluid, and a wound specimen. Vagococci are motile organisms that, like lactococci, express the Lancefield group N antigen (51). Difficulties encountered in identifying vagococci may partially account for their infrequent recognition in clinical cultures.

Abiotrophia and *Granulicatella*

Organisms formally known as nutritionally variant streptococci are normal residents of the oral cavity but have been identified as agents of endocarditis involving both native and prosthetic valves (68). These organisms have also been isolated in cases of ophthalmic infections (87, 90), a brain abscess following neurosurgery (14), and iatrogenic meningitis following myelography (100).

Leuconostoc, Pediococcus, and *Weissella*

The vancomycin-resistant genera *Leuconostoc* and *Pediococcus* have been recognized in clinical specimens since the mid-1980s. Handwerger and colleagues (66) noted host defense impairment, invasive procedures breaching the integument, gastrointestinal symptoms, and prior antibiotic treatment as common features among adult patients infected with *Leuconostoc*. They also observed a predisposition to *Leuconostoc* bacteremia among neonates, suggesting that infants may become colonized during delivery by leuconostocs inhabiting the maternal genital tract. In addition to causing bacteremia, leuconostocs have been isolated from cerebrospinal fluid, peritoneal dialysate fluid, and wound specimens. Case reports have implicated leuconostocs as agents of infection in osteomyelitis (119), ventriculitis (43), and postsurgical endophthalmitis (76).

Pediococcus strains have been isolated in cases of bacteremia, sepsis, and hepatic abscess in compromised patients (9, 62, 85, 105). Barros and coworkers (9) noted that *Pediococcus acidilactic*i was isolated from clinical specimens more frequently than *Pediococcus pentosaceus* and was also more commonly isolated in cases of bacteremia. Barton and coworkers noted the role of *Pediococcus* in bacteremia in infants with gastrointestinal malformations requiring surgical correction (10).

Weissella confusa, formerly classified as *Lactobacillus confusus*, has been reported infrequently as an agent of bacteremia and endocarditis (57, 89).

Gemella

G. haemolysans has been isolated as a pathogen in cases of endocarditis (20), meningitis (58), brain abscess (83), and total knee arthroplasty (44). *G. morbillorum* has been isolated (when still classified as a streptococcus; see "Taxonomy") from blood cultures and cultures of respiratory, genitourinary,

wound, and abscess specimens (53). This *Gemella* species has been implicated in cases of empyema and lung abscess (41), septic shock (115), endocarditis (55, 61, 118), brain abscess (108), osteomyelitis (114), peritonitis (6), and infection in an arteriovenous shunt (7). The clinical significance of *G. bergeri* and *G. sanguinis* is not well described, but strains of these species have been isolated from blood cultures, and they may also function as agents of endocarditis (31, 32).

Dolosigranulum

Little is known about the clinical significance of *Dolosigranulum*, a genus that is phenotypically similar, but not closely related to, *Gemella* (3). Strains of *Dolosigranulum pigrum,* the sole species in the genus, have been isolated from blood and eye and respiratory specimens (77), and this organism has been cited as a probable agent in a case of synovitis (65).

Aerococcus

Although aerococci appear as contaminants in clinical cultures, occasional reports have noted a clinically significant role for these organisms in cases of endocarditis and bacteremia (40, 73, 92). Until the early 1990s, *A. viridans* was the only species reported from human specimens, but four additional species isolated from humans have been described to date. *A. urinae* (2, 63) has been implicated as a urinary tract pathogen in patients predisposed to infection (22) and also as an agent of endocarditis (75, 107), lymphadenitis (99), and spondylodiscitis (5). Little is currently known about the clinical significance of *A. christensenii* (isolated from vaginal specimens) (33), *A. urinaehominis* (isolated from urine) (81), and *A. sanguinicola* (isolated from blood and urine) (52, 82).

Globicatella

G. sanguinis, the sole *Globicatella* species isolated from humans, has been implicated in cases of bacteremia, urinary tract infection, and meningitis (24). A second species in the genus, *Globicatella sulfidifaciens*, has been isolated in cases of purulent infections in domestic mammals (113).

Facklamia

Members of the *Facklamia* genus are closely related to, but phenotypically and phylogenetically distinct from, members of the *Globicatella* genus (28). Strains of the four *Facklamia* species isolated from humans have been recovered from blood, wound, and genitourinary sites (28, 30, 35, 80), and a patient with chorioamnionitis (67).

Ignavigranum

Only a few strains of *I. ruoffiae,* the sole species of the genus *Ignavigranum,* have been described to date. Sites of isolation include a wound and an ear abscess (36).

Dolosicoccus

Strains of *D. paucivorans*, the only species currently included in the genus *Dolosicoccus,* have been recovered from blood cultures (37, 50).

Helcococcus

H. kunzii has been recovered from intact skin of the lower extremities (64), as well as from wound specimen cultures (notably those from foot ulcers) containing mixtures of bacteria (26). Consequently, the clinical significance of this organism is difficult to interpret, since it may be present merely as a colonizer of the wound site. The ability of this species to function as an opportunist was, however, suggested by its isolation in pure culture from an infected sebaceous cyst (93) and a breast abscess (19). Classification of two additional species isolated from humans, *H. sueciensis* and "*H. pyogenes,*" is based on single isolates from a wound and a prosthetic joint infection specimen, respectively (27, 91).

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

The organisms described in this chapter have all been isolated from routine cultures of clinical specimens, and special requirements for collection and processing of specimens have not been described. Since these bacteria are facultative anaerobes or microaerophiles, aerobic collection, transport, and storage methods as described in chapter 5 of this Manual should allow for their isolation.

ISOLATION PROCEDURES

Generally, there are no special requirements for isolation of the group of bacteria discussed here; general recommendations for the culture of blood, body fluids, and other specimens should be followed (see chapters 5, 6, and 20). These organisms are likely to be isolated on rich, nonselective media (e.g., blood and chocolate agars and thioglycolate broth) since they are nutritionally fastidious. If selective isolation of members of the vancomycin-resistant genera *Leuconostoc* and *Pediococcus* is desired, Thayer-Martin medium may be used to inhibit normal flora or other contaminating microorganisms (98). Members of some of the genera (e.g., *Helcococcus*) grow slowly, forming tiny colonies that may not be visible unless extended incubation (48 to 72 h) is employed. The recovery of members of many of the genera included in this chapter may be enhanced by CO_2 enrichment of the incubation atmosphere.

Members of the genera *Abiotrophia* and *Granulicatella* usually grow on chocolate agar, on brucella agar with 5% horse blood, and in thioglycolate broth but not on Trypticase soy agar with 5% sheep blood. These organisms can be cultured on nonsupportive media that have been appropriately supplemented (see "*Abiotrophia* and *Granulicatella*" under "Additional Procedures for Characterization of Selected Genera with Negative Catalase Reactions" below).

IDENTIFICATION

The phenotypic characteristics detailed here may not always be sufficient for accurate identification of the aerobic catalase-negative, gram-positive cocci encountered infrequently in clinical laboratories. Although Gram stain morphology is prone to subjective interpretation, it has been employed as a major decision point in the identification protocols, with two general categories: Gram stain morphology resembling that of streptococci, meaning cocci or coccobacilli in pairs and chains, and staphylococcal morphology, meaning coccoid cells arranged in pairs, clusters, tetrads, or irregular groups. Broth-grown cells (thioglycolate broth is suitable) should be used for making morphological determinations. The flowcharts in this chapter (Fig. 1 and 2) should not be used for definitive identification. In most cases, additional procedures (Table 1) are recommended before identification to the genus level is made. Identifications of unfamiliar organisms from important specimens should be confirmed by a reference laboratory. Molecular methods such as 16S rRNA

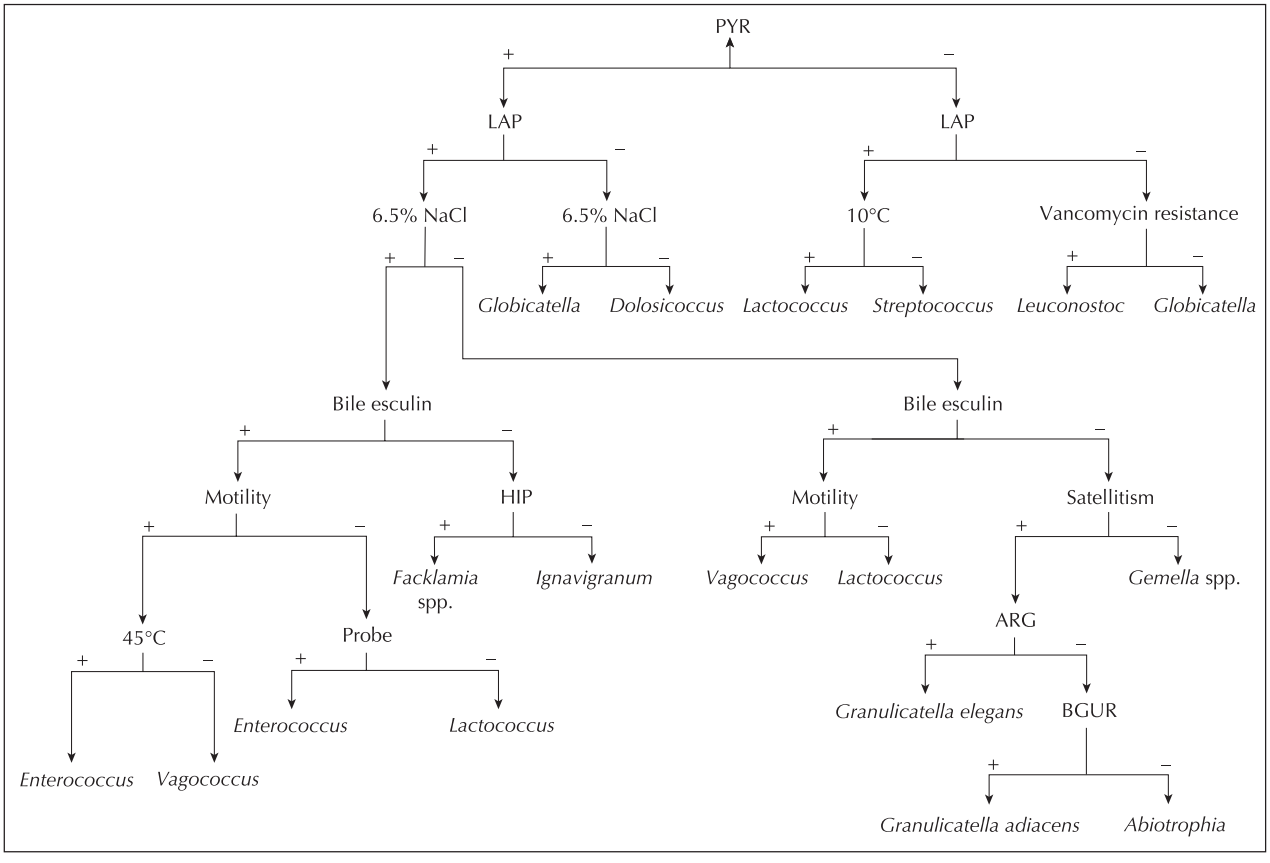

FIGURE 1 Identification of catalase-negative, gram-positive cocci that grow aerobically with cells arranged in pairs or chains. Abbreviations: PYR, pyrrolidonyl arylamidase activity; LAP, leucine aminopeptidase activity; 6.5% NaCl, growth in broth containing 6.5% NaCl; bile esculin, hydrolysis of esculin in the presence of 40% bile; motility, motility in motility test medium; 45°C, growth at 45°C; 10°C, growth at 10°C; probe, reaction with commercially available nucleic acid probe for the genus *Enterococcus;* HIP, hydrolysis of hippurate; satellitism, satelliting growth behavior; ARG, arginine hydrolysis activity; BGUR, β-glucuronidase activity.

gene-based DNA sequencing or the use of alternative genetic targets may be useful for genus- and species-level identification (117).

Procedures for Initial Differentiation of Genera with Negative Catalase Reactions

Initial testing procedures for catalase-negative isolates with streptococcal (Fig. 1) or staphylococcal (Fig. 2) Gram stain morphology are represented in the flowcharts. Note that *Gemella* and *Facklamia* strains may display either type of cellular morphology, depending on the species (see "Additional Procedures for Characterization of Genera with Negative Catalase Reactions" below). Descriptions of tests for these organisms follow.

Catalase Test

If a positive or weakly positive catalase reaction is observed with growth from blood-containing media, growth from a medium devoid of blood (e.g., brain heart infusion agar) should be used to repeat the catalase test. A loopful of growth is transferred onto a microscope slide or empty petri dish and observed for the evolution of bubbles after the addition of a drop of 3% H_2O_2. It may be necessary to use a hand lens to detect weakly positive reactions.

PYR Test

See chapter 21 and reference 51 for a description of the PYR test. Rapid disk tests are commercially available, and an assay for PYR is contained in some commercially available identification kits (e.g., API 20 Strep; bioMerieux, Durham, N.C.).

LAP Test

The LAP test determines the presence of the enzyme leucine aminopeptidase, also called leucine arylamidase. See chapter 21 for a description of this test. An assay for this enzyme is contained in some commercially available identification kits (e.g., API 20 Strep; bioMerieux), and a rapid disk test for LAP is also available commercially (BD Diagnostic Systems, Sparks, Md.; Remel, Lenexa, Kans.). The manufacturer's instructions should be followed when the test is performed (51, 54).

Growth in 6.5% NaCl

Heart infusion broth supplemented with 6.0% NaCl, with or without the acid-base indicator bromcresol purple, may be

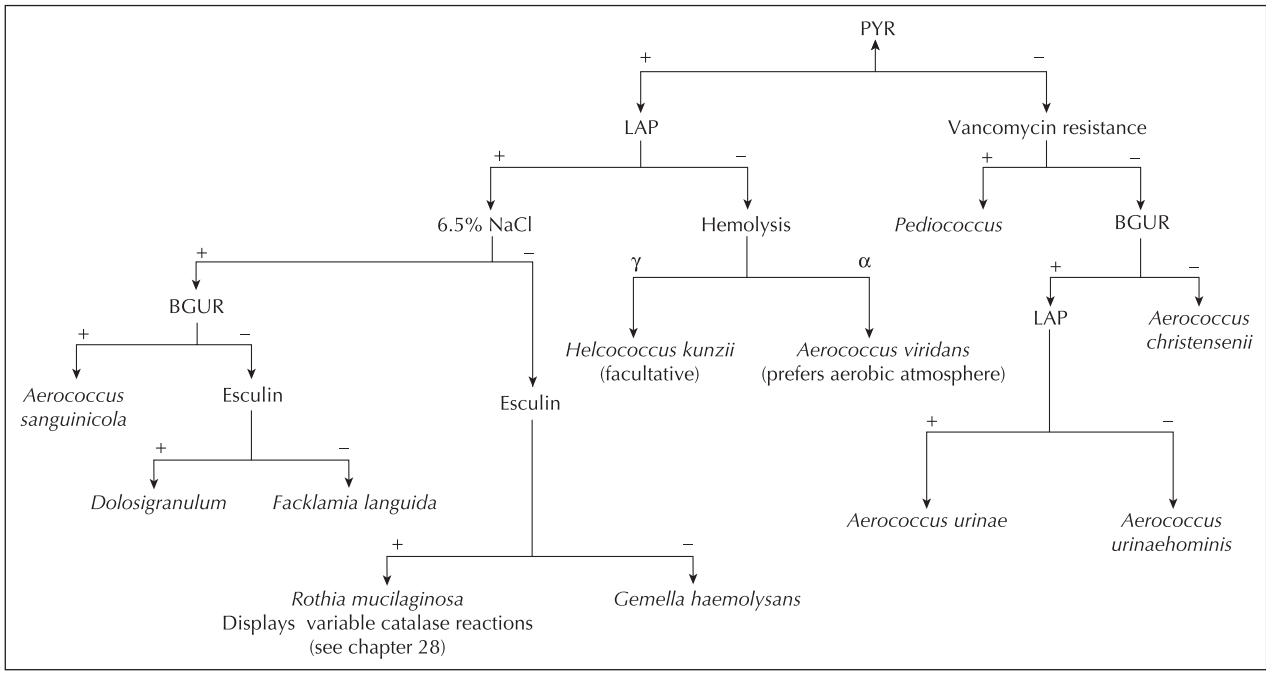

FIGURE 2 Identification of catalase-negative, gram-positive cocci that grow aerobically with cells arranged in pairs, tetrads and clusters, or irregular groups. Abbreviations: PYR, pyrrolidonyl arylamidase activity; LAP, leucine aminopeptidase activity; 6.5% NaCl, growth in broth containing 6.5% NaCl; esculin, hydrolysis of esculin; BGUR, β-glucuronidase activity.

used to test for growth in 6.5% NaCl. The broth is inoculated with two to three colonies of the organism to be tested and incubated at 35°C for up to 72 h. Turbidity with or without a color change from purple to yellow (due to production of acid) indicates growth (51, 54).

Bile Esculin Test

The ability to hydrolyze esculin in the presence of 40% bile is tested by culturing the test organism on bile esculin agar in an ambient-atmosphere incubator at 35°C for up to 48 h. Blackening of the agar indicates a positive reaction (54).

Motility Test

The motility test is performed by stab inoculating modified motility test medium and incubating at 30°C (instead of 35°C) for up to 48 h, according to the method of Facklam and Elliott (51).

Hippurate Hydrolysis Test

Facklam and Elliott recommend a conventional broth medium for determining hippurate hydrolysis (51). This test may also be contained in commercially available identification kits.

Satellitism Test

In a test for satelliting behavior, the strain to be examined is streaked for confluent growth on a medium that fails to support growth or supports only weak growth (e.g., sheep blood agar or brain heart infusion agar). A single cross streak of *Staphylococcus aureus* (ATCC 25923 or another suitable strain) is applied to the inoculated area. After incubation at 35°C in an atmosphere containing an elevated CO_2 level, strains of *Abiotrophia* or *Granulicatella* will grow only in the vicinity of the staphylococcal growth. Alternatively, media can be supplemented with pyridoxal in the form of an aqueous stock solution of filter-sterilized 0.01% pyridoxal hydrochloride. This solution, which can be stored frozen, should be added to media to achieve a final concentration of 0.001%. Disks containing pyridoxal may also be used in the satelliting test and are commercially available (Remel). Some strains of *Ignavigranum* may show satelliting behavior (36).

Arginine Hydrolysis Test

The arginine hydrolysis test can be performed with Moeller's decarboxylase broth containing arginine (51).

β-Glucuronidase Test

A test for β-glucuronidase is included in a number of commercially available identification products or may be performed using commercially prepared disks.

Vancomycin Susceptibility Test

Several colonies are streaked over half of a plate containing Trypticase soy agar with 5% sheep blood. After placing of a 30-μg vancomycin disk in the center of the inoculated area, the plate is incubated overnight in a CO_2-enriched atmosphere at 35°C. Any zone of inhibition indicates susceptibility, and resistant strains exhibit no inhibition zone (51, 54).

Esculin Hydrolysis Test

Esculin agar slants (heart infusion agar containing 0.1% esculin and 0.5% ferric citrate) are employed for the esculin hydrolysis test. After inoculation, slants are incubated at 35°C for up to 7 days. Partial or complete blackening of the agar indicates a positive reaction (51).

Additional Procedures for Characterization of Selected Genera with Negative Catalase Reactions

Lactococcus

Facklam and colleagues (51, 54) recommend growth temperature tests for distinguishing lactococci from streptococci and enterococci. Consult Fig. 1 for growth temperature characteristics of each of the genera. Broths (heart infusion broth containing 1% glucose and bromcresol purple indicator) are inoculated with a single colony or a drop of broth culture of the test strain and incubated at 35°C for up to 7 days. A water bath is recommended for incubation of cultures at 45°C. Turbidity with or without a change in the broth's indicator to yellow indicates a positive test.

If it is important to rule out enterococci, suspicious isolates can be tested with a commercially available nucleic acid probe test for the genus *Enterococcus*. *Lactococcus lactis* and *Lactococcus garvieae* are the *Lactococcus* species most commonly isolated from clinical specimens. Further information on the differentiation of *Lactococcus* isolates to the species level may be found in references 45, 47, and 102.

Abiotrophia and *Granulicatella*

Lists of additional phenotypic traits for *Abiotrophia* and *Granulicatella* species can be found in references 11, 16, 21, and 34. Davis and Peel (42) reported that the API 20 Strep system (bioMerieux) is superior to the Rapid ID 32 Strep system (bioMerieux) for identification of these organisms. They found that accurate results were obtained when a dense inoculum (confluent growth from two blood agar plates) was employed.

Leuconostoc and *Pediococcus*

Members of the genera *Leuconostoc* and *Pediococcus* produce small, alpha- or nonhemolytic colonies on blood agar that can appear similar to those of viridans streptococci. In addition to having differing cellular morphologies (Table 1), members of these vancomycin-resistant genera, along with vancomycin-resistant strains of lactobacilli that form short coccoid cells, may be separated by tests for gas production from glucose and arginine hydrolysis. Leuconostocs produce gas and are always arginine negative. Lactobacilli are variable in both tests, but a positive arginine test for a gas-producing strain would rule out the identification of the organism as a leuconostoc. Pediococci are gas production negative and show variable reactions in the arginine test, although *P. acidilactici* and *P. pentosaceus*, the two species commonly found in clinical material, are arginine positive.

Gas production is measured by inoculating MRS (deMan, Rogosa, Sharpe) broth (BD Diagnostic Systems; Hardy Diagnostics, Santa Maria, Calif.) with the test organism, sealing the culture with melted petrolatum, and incubating for up to 7 days at 35°C. Gas production is evidenced by displacement of the petrolatum plug (51, 54). The arginine hydrolysis test can be performed with Moeller's decarboxylase broth containing arginine (51). The Lancefield group D antigen can be detected in pediococci (54). References 8, 9, 46, 51, 54, and 96 should be consulted for further information on the identification of *Leuconostoc* and *Pediococcus* to the species level.

Tetragenococcus

The organisms formerly known as *P. halophilus* and *E. solitarius* were reclassified in the *Tetragenococcus* genus as *Tetragenococcus halophilus* and *T. solitarius* (39, 48). Although these organisms share some phenotypic characteristics with pediococci, they are vancomycin susceptible. Although little is know about the participation of these organisms in human infection, they should be suspected if vancomycin-susceptible, *Pediococcus*-like strains are encountered.

Weissella

Weissella strains may be misidentified as leuconostocs or lactobacilli. These organisms produce gas from glucose. The few clinical isolates reported in the literature have been described as vancomycin resistant and positive for hydrolysis of arginine. Characteristics useful for the identification of strains of the infrequently isolated *Weissella* genus are found in Table 1 and references 57 and 89.

Gemella

Facklam and Washington (54) state that all *Gemella* species are PYR positive but that *G. morbillorum* displays a weakly positive reaction. Findings of earlier studies (12, 13) generally support these observations, but the previous studies describe some isolates of both *G. haemolysans* and *G. morbillorum* as being negative in the PYR test. Facklam and Washington note that a large inoculum must be used when these bacteria are tested for the pyrrolidonyl arylamidase enzyme. Leucine aminopeptidase is usually absent in isolates of *G. haemolysans* but present in strains of *G. morbillorum* (12, 13). On sheep blood agar media, gemellas form small colonies that are similar in appearance to those of viridans group streptococci. Slow growth of some *Gemella* strains may lead to confusion of these organisms with *Abiotrophia* or *Granulicatella* organisms (formerly called nutritionally variant streptococci). A test for satelliting behavior will separate these two groups of bacteria (54).

Cells of *G. haemolysans* are easily decolorized and resemble those of neisserias, since they occur in pairs with the adjacent sides flattened. *G. haemolysans* favors an aerobic growth atmosphere. *G. morbillorum* cells are gram positive and are arranged in pairs and short chains; individual cells in a given pair may be of unequal sizes. *G. morbillorum* is described as favoring anaerobic growth conditions. Only a small number of strains of *G. bergeri* and *G. sanguinis* have been reported on to date. Information on phenotypic characteristics of these *Gemella* species can be found in references 31 and 32.

Aerococcus

In addition to the traits listed in Table 1, *A. viridans* is characterized by displaying weak or no growth when incubated in an anaerobic atmosphere (49). This trait can be tested by incubating duplicate blood agar plate cultures of the organism in question in an anaerobic and an aerobic atmosphere and comparing growth after 24 to 48 h. When grown aerobically, *A. viridans* forms alpha-hemolytic colonies that may be confused with those of either viridans group streptococci or enterococci. *A. urinae* forms small (0.5 mm in diameter after 24 h of incubation), alpha-hemolytic, convex, shiny, transparent colonies on blood agar media. *A. urinae* is PYR negative and LAP positive, in contrast to *A. viridans* (2). Additional information on the identifying characteristics of *A. urinae* can be found in reference 22, and a second biotype (esculin hydrolysis positive) of this species is described in reference 23. Information on phenotypic traits of the recently described species *A. christensenii*, *A. sanguinicola*, and *A. urinaehominis* can be found in Table 1 and references 33, 52, 81, and 82.

Helcococcus

In addition to the characteristics shown in Table 1, most isolates of *H. kunzii* produce an API 20 Strep (bioMerieux)

profile of 4100413. Colonial morphology (tiny, gray, usually slightly alpha-hemolytic colonies), good growth under anaerobic conditions, and stimulation of growth by the addition of 1% horse serum or 0.1% Tween 80 to the medium differentiate *H. kunzii* from aerococci (26).

ANTIBIOTIC SUSCEPTIBILITIES

The lack of standardized methods and interpretation criteria for antibiotic susceptibility testing results, along with relatively small collections of clinical isolates for some of the genera discussed in this chapter, makes it difficult to accurately assess antimicrobial susceptibility patterns. With the exception of *Leuconostoc*, *Pediococcus,* and *Weissella*, members of all of the genera display susceptibility to vancomycin. Since many of the bacteria presented in this chapter are fairly fastidious, investigators have often employed blood-supplemented Mueller-Hinton medium and, if necessary for good growth, incubation in a CO_2-enriched atmosphere. Pyridoxal hydrochloride (0.001%) should also be added to blood-supplemented media for testing strains of *Abiotrophia* and *Granulicatella*. Most studies have employed streptococcal (other than *Streptococcus pneumoniae*) interpretative criteria for determining susceptibility. Details of susceptibility testing methodology and interpretive criteria can be found in reference 88.

Limited information on the in vitro antimicrobial susceptibilities of *L. lactis* and *L. garvieae* strains isolated from humans suggests that *L. garvieae* isolates are less susceptible to penicillin and cephalothin than are strains of *L. lactis*. The uniform resistance of *L. garvieae* to clindamycin contrasts with the uniform susceptibility of the *L. lactis* strains examined by Elliott and Facklam (47) and led them to propose a test for clindamycin susceptibility as an aid in differentiation of these two species. In clinical practice, patients with lactococcal endocarditis have been successfully treated either with penicillin alone or with penicillin and gentamicin (84, 94).

Teixeira and colleagues examined a small collection of *Vagococcus* isolates and observed that all strains tested were susceptible to ampicillin, cefotaxime, and trimethoprim-sulfamethoxazole. All strains were resistant to clindamycin, lomefloxacin, and ofloxacin. Variable results were observed with other antimicrobial agents (110).

Members of the vancomycin-resistant genera *Leuconostoc* and *Pediococcus* are also resistant to teicoplanin. Although they are usually susceptible to imipenem, minocycline, chloramphenicol, and gentamicin, MICs of penicillin for these strains correspond to the moderately susceptible category (109).

There is a range of MICs of penicillin for *Abiotrophia* and *Granulicatella* isolates, with the majority of strains classified as either susceptible or relatively resistant. There is also variability in susceptibilities to aminoglycosides, but no cases of high-level resistance have been reported. A synergistic effect between beta-lactam agents and aminoglycosides has been demonstrated for isolates of *Abiotrophia* (70). Tuohy and colleagues examined a collection of 27 *G. adiacens* and 12 *A. defectiva* strains, noting susceptibilities of all isolates to clindamycin, rifampin, levofloxacin, ofloxacin, and quinupristin-dalfopristin. These authors noted that the percentage of isolates of *G. adiacens* and *A. defectiva* examined that were susceptible to other agents tested was as follows: penicillin, 55 and 8%; amoxicillin, 81 and 92%; ceftriaxone, 63 and 83%; and meropenem, 96 and 100%, respectively (112). Zheng and coworkers reported high rates of beta-lactam and macrolide resistance in a collection of pediatric *Abiotrophia* and *Granulicatella* isolates (120).

A. viridans and *G. haemolysans* appear to be susceptible to penicillin and display a low level of resistance to aminoglycosides (17, 18). Buu-Hoi and colleagues (17) noted that although *A. viridans* seems to be naturally susceptible to macrolides, tetracyclines, and chloramphenicol, resistance to these agents has been observed. *A. urinae* has been described as susceptible to penicillin, amoxicillin, piperacillin, cefipime, rifampin, and nitrofurantoin but resistant to sulfonamides and netilmicin. Isolates display variable susceptibilities to trimethoprim and cotrimoxazole (22, 103, 106). *A. sanguinicola* isolates display susceptibilities to penicillin, amoxicillin, cefotaxime, cefuroxime, erythromycin, chloramphenicol, quinupristin-dalfopristin, rifampin, linezolid, and tetracycline (52). Buu-Hoi and coworkers (18) demonstrated a synergistic effect of penicillin and gentamicin against *G. haemolysans*.

A collection of 27 clinical isolates of *D. pigrum* studied by LaClaire and Facklam (77) all exhibited susceptibilities to penicillin, amoxicillin, cefotaxime, cefuroxime, clindamycin, levofloxacin, meropenem, quinupristin-dalfopristin, rifampin, and tetracycline. Various susceptibilities to erythromycin were noted, and one of the 27 strains was resistant to trimethoprim-sulfamethoxazole. A small number of *Helcococcus* isolates displayed susceptibilities to penicillin and clindamycin, and most strains were resistant to erythromycin (19, 93). MICs of a variety of antibiotics for strains of *Facklamia* varied (78). A study of 27 strains of *G. sanguinis* reported susceptibilities of all isolates to amoxicillin but various levels of resistance to other antimicrobials tested (104).

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

Since the gram-positive cocci included in this chapter may appear in clinical cultures as contaminants or part of normal microbiota, efforts to identify them should be made only when isolates are considered to be clinically significant (e.g., when isolated repeatedly, when grown in pure culture, or when recovered from normally sterile sites). It should be remembered that these bacteria are opportunists: isolation from an immunocompetent patient may not have the same significance as isolation from a compromised host. Communication with clinicians should guide the microbiology laboratory in evaluating the significance of these infrequently isolated organisms.

Vancomycin susceptibility testing should be performed routinely on significant isolates. Documenting resistance to this antibiotic will not only guide therapy but also aid in identification of the isolates. The method mentioned in this chapter, using a nonstandardized inoculum, seems to be fairly reliable for determining susceptibility to this drug for identification purposes. Since standardized susceptibility testing methods do not exist for these infrequently isolated gram-positive cocci, caution should be observed in interpretation of in vitro susceptibility test results. A reference laboratory should be consulted for identification or confirmation of the identity of unfamiliar organisms.

Bacillus and Other Aerobic Endospore-Forming Bacteria*

NIALL A. LOGAN, TANJA POPOVIC, AND ALEX HOFFMASTER

32

TAXONOMY

Molecular taxonomic methods have had a huge impact on the classification of aerobic endospore-forming bacteria. The 1986 edition of *Bergey's Manual of Systematic Bacteriology* listed 40 valid *Bacillus* species, and since then 218 further species have been newly described or revived among *Bacillus* and the genera derived from it: *Alicyclobacillus* (112), *Paenibacillus* (5), *Brevibacillus* (93), *Aneurinibacillus* (93), *Virgibacillus* (50), *Gracilibacillus* (107), *Salibacillus* (107; subsequently merged with *Virgibacillus* [51]), *Geobacillus* (75), *Marinibacillus* (114), and *Ureibacillus* (37). Three species formerly classified within *Bacillus, B. pasteurii, B. globisporus*, and *B. psychrophilus*, have been transferred (113) to the long-established genus of aerobic endospore-forming cocci, *Sporosarcina,* which now contains six species. Furthermore, 15 new genera containing 33 new species have been proposed to accommodate novel aerobic endospore formers not previously assigned to *Bacillus* (over one-half of these genera have only one species, and over one-half of the species were proposed on the basis of single isolates); they are, in order of validation, *Sulfobacillus*, *Amphibacillus*, *Halobacillus*, *Ammoniphilus*, *Anoxybacillus*, *Thermobacillus*, *Filobacillus*, *Jeotgalibacillus*, *Lentibacillus*, *Oceanobacillus*, *Paraliobacillus*, *Cerasibacillus*, *Pontibacillus*, *Tenuibacillus,* and *Salinibacillus*. Overall, therefore, there have been proposals for 25 new genera containing 234 new or revived species or new combinations, and yet only six proposals for merging species were made in that time. Unfortunately, taxonomic progress has not always revealed readily determinable features characteristic of each genus. They show wide ranges of sporangial morphologies and phenotypic test patterns. Many novel species represent genomic groups disclosed by DNA-DNA pairing experiments or single isolates whose distinction from existing species rests chiefly upon 16S rRNA gene sequence analysis, and routine phenotypic characters for distinguishing some of them are very few and of unproven value.

Bacillus continues to accommodate the best-known species such as *B. subtilis* (the type species), *B. anthracis, B. cereus, B. licheniformis, B. megaterium, B. pumilus, B. sphaericus,* and *B. thuringiensis.* It still remains a large genus, with over 100 species, as losses to other genera have been balanced by new species proposals. Members of the *B. cereus* group, *B. anthracis, B. cereus,* and *B. thuringiensis,* are considered to be pathovars of a single species (104).

DESCRIPTIONS OF THE GENERA

Although the production of resistant endospores in the presence of oxygen remains the defining feature for *Bacillus* and the new genera derived from it, the definition was undermined by the discovery of *Bacillus infernus* and *B. arseniciselenatis,* which are strictly anaerobic, and spores have not been detected in *B. infernus* and *B. subterraneus*.

However, those members likely to be isolated in a clinical laboratory are gram-positive (in young cultures) but sometimes gram-variable or clearly gram-negative, rod-shaped, endospore-forming organisms which may be aerobic or facultatively anaerobic. They are mostly catalase positive and may be motile by means of peritrichous flagella. Most species are mesophilic, but *Bacillus* contains some thermophiles and psychrophiles, and *Paenibacillus* contains one psychrophilic species. *Alicyclobacillus, Gracilibacillus, Marinibacillus,* and *Ureibacillus* strains and members of the 15 new genera not derived from *Bacillus* are unlikely to be encountered in a clinical laboratory, and clinical isolates of *Geobacillus* and *Sporosarcina* have not been reported, so these genera will not be considered further.

NATURAL HABITATS

Most aerobic endospore formers are saprophytes widely distributed in the natural environment, but some species are opportunistic or obligate pathogens of animals, including humans, other mammals, and insects. The main habitats are soils of all kinds, ranging from acid to alkaline, hot to cold, and fertile to desert, and the water columns and bottom deposits of fresh and marine waters. Their spores readily survive distribution in soils, dusts, and aerosols from these natural environments to a wide variety of other habitats; for example, strains of *B. fumarioli* showing similar phenotypic behavior and substantial genotypic similarity have been isolated from volcanic soils in continental Antarctica and from Candlemas Island, which is some 5,600 km distant in the South Sandwich archipelago, and from gelatin production plants in Belgium, France, and the United States (28). Dried foods such as spices, milk powders, and farinaceous products

*This chapter contains information presented in chapter 32 by Niall A. Logan and Peter C. B. Turnbull in the eighth edition of this Manual.

are often quite heavily contaminated with spores. *B. anthracis* is, to all intents and purposes, an obligate pathogen of animals and humans. Its close relative, *B. cereus*, is now well established as an opportunistic pathogen, and other aerobic endospore formers can also be opportunistic pathogens occasionally. Six organisms are important as insect pathogens: *B. thuringiensis* (another close relative of *B. anthracis*), *B. popilliae, B. lentimorbus*, *B. sphaericus*, *P. larvae* subsp. *larvae,* and *P. larvae* subsp. *pulvifaciens*.

CLINICAL SIGNIFICANCE AND INTERPRETATION OF RESULTS

The majority of aerobic endospore-forming species apparently have little or no pathogenic potential and are rarely associated with disease. The principal exceptions to this are *B. anthracis*, the agent of anthrax, and *B. cereus*, but a number of other species, particularly *B. licheniformis*, have been implicated in food poisoning and other human and animal infections. The resistance of the spores to heat, radiation, disinfectants, and desiccation also results in aerobic endospore formers being troublesome contaminants in the operating room, on surgical dressings, in pharmaceutical products, and in foods.

Apart from *B. anthracis*, the majority of species are common environmental contaminants, and isolation from a single clinical specimen is generally not a sufficient basis for incriminating one of these organisms as the etiological agent. Moderate or heavy growth of aerobic endospore formers from wounds is usually significant, however, and *B. cereus* infections of the eye are emergencies which should always be taken seriously and reported to the physician immediately.

In the clinical laboratory, the most important questions to ask about an aerobic spore-forming isolate are as follows. Was it isolated in pure culture or at least apparently dominating the flora? Was it isolated in large numbers? Was it isolated more than once? Low-level contamination of foodstuffs by aerobic endospore formers is common, as is asymptomatic transient fecal carriage. Therefore, in foodborne-illness investigations, qualitative isolation tests are insufficient. The ideal criteria for establishing that an aerobic endospore former is the etiological agent are (i) isolation of significant numbers ($>10^5$ CFU/g) of the organism from the epidemiologically incriminated food (and, in the case of suspected *B. cereus* food poisoning, detection of emetic toxin and/or enterotoxin) and (ii) recovery of the same strain (biovar, serovar, phage type, plasmid type, etc.) in significant numbers from acute phase specimens (feces or vomitus) from the patients, but not from healthy controls.

B. anthracis continues to be generally regarded as an obligate pathogen; its continued existence in the ecosystem appears to depend on a periodic multiplication phase within an animal host, and its environmental presence reflects contamination from an animal source at some time rather than self-maintenance within the environment. In human and animal specimens, it is usually sought only when the case history suggests that it is reasonable to suspect anthrax. Demonstration of capsulating *B. anthracis*, even in low numbers, confirms the clinical suspicion of anthrax, because the bacterium is rapidly destroyed by putrefactive processes after the host's death.

Bacillus anthracis

Anthrax remains the most widely recognized clinical condition caused by a *Bacillus* species. It is primarily a disease of domestic or wild animals, and prior to the availability of an effective veterinary vaccine in the late 1930s, anthrax was one of the foremost causes worldwide of mortality in cattle, sheep, goats, and horses. Humans almost invariably contract anthrax directly or indirectly from animals. The use of veterinary and human vaccines together with improvements in factory hygiene and sterilization procedures for imported animal products and the increased use of man-made alternatives to animal hides or hair have resulted over the past half-century in a marked decline in the incidence of anthrax in both animals and humans. Nevertheless, the disease continues to be endemic in many countries, particularly those that lack efficient vaccination policies (77). Because anthrax spores remain viable in soil for many years and their persistence does not depend on animal reservoirs, *B. anthracis* is exceedingly difficult to eradicate from an area where it is endemic; regions of nonendemicity must be constantly on the alert for the arrival of *B. anthracis* in imported animal products. Anthrax is not contagious, and transmission to humans is usually restricted to direct contact with infected animals or contaminated fomites, including such oddities as communal loofahs and contaminated syringes (84). Direct animal-to-animal transmission within a species (i.e., excluding scavengers feeding on anthrax carcasses) is also very rare.

Circumstantial evidence shows that humans are moderately resistant to anthrax compared with obligate herbivores. Human anthrax has traditionally been classified as either (i) nonindustrial, resulting from close contact with infected animals or their carcasses after death from the disease, or (ii) industrial, i.e., acquired by those employed in processing wool, hair, hides, bones, or other animal products. Dependent on the route of infection, there are three major clinical forms of anthrax: cutaneous, inhalation, and gastrointestinal. Anthrax meningitis can develop as a complication of any of these forms (92). Only a few reports of laboratory-acquired infections exist (18). A major outbreak of anthrax occurred in April 1979 in the city of Sverdlovsk, former USSR (now Yekaterinburg, Russia), in the Urals as a result of the accidental release of spores from a military production facility.

B. anthracis has been subjected to military research, development, and occasional deployment in several countries over many years, following attacks on livestock during the First World War, and it has remained high on the list of agents that could be used in biological warfare or bioterrorism. The natural disease is readily controllable, but the 2001 bioterrorism-related anthrax outbreak in the United States increased public concern about this disease (see chapter 9).

Cutaneous anthrax accounts for about 99% of naturally acquired human anthrax worldwide—an estimated 2,000 cases are reported annually. Infection occurs through a break in the skin. Following the incubation period of usually 2 to 3 days, a small papule appears, progressing over the next 24 h to a ring of vesicles, with subsequent ulceration and formation of a characteristic blackened eschar. Subsequent eschar formation may become thick and surrounded by extensive edema. Fever and pus and pain at the site are normally absent; their presence probably indicates a secondary bacterial infection. Before the availability of antimicrobial agents and vaccines, 10 to 20% of untreated cases of cutaneous anthrax were fatal. Less than 1% of cases are fatal today, and they are due mainly to obstruction of the airways by the edema that accompanies lesions on the face or neck or to the progression of the cutaneous disease into systemic infection.

Gastrointestinal anthrax is not uncommon in regions of endemicity worldwide, where socioeconomic conditions are

poor and people eat raw or undercooked meat of animals that have died suddenly (77, 96); asymptomatic infections and symptomatic infections with recovery may not be uncommon. The symptoms of gastrointestinal anthrax are the result of ulcerations developing primarily in the cecal and terminal ileal mucosae: vomiting, nausea, and abdominal pain, accompanied by fever. This can rapidly progress to bloody diarrhea and systemic infection. Mortality ranges from 4 to 50% (96), greatly due to the nonspecific nature of the early symptoms and late initiation of antimicrobial therapy.

Prior to the bioterrorist attack of 2001, 18 cases of naturally acquired inhalation anthrax had been recorded in the United States since 1900, with 16 (88.9%) of them being fatal (12); figures in the United Kingdom show a similar picture. Among the 22 cases of the bioterrorism-related outbreak in the United States in late 2001, in which spores were delivered in mailed letters and packages, early recognition and treatment of the 11 patients with confirmed inhalation anthrax resulted in 60% survival (9, 58). In inhalation anthrax the inhaled spores are ingested by macrophages and carried from the lungs to the lymphatic system, where the infection progresses. During transit to lymph nodes, spores germinate into vegetative cells, begin to replicate, and produce the capsule and toxins that lead to bacteremia and associated hemorrhage and necrosis. The replacement of the older name for this form of the disease, "pulmonary anthrax," with the newer name, "inhalation anthrax," is a reflection of the fact that active infection occurs in the lymph nodes rather than the lung itself. Analysis of 10 of the cases associated with the bioterrorist events of 2001 (58) revealed a median incubation period of 4 days (range, 4 to 6 days). All 11 patients with inhalation anthrax had severe illness and were hospitalized (6). Their clinical presentation included fever or chills ($n = 11$), fatigue or malaise ($n = 11$), minimal or nonproductive cough ($n = 10$), dyspnea ($n = 9$), nausea or vomiting ($n = 9$), chest pain ($n = 7$), and sweats ($n = 7$). All patients had abnormal chest X-ray images with pleural effusion ($n = 8$), infiltrates ($n = 7$), and mediastinal widening ($n = 7$).

Regardless of the form of the diseases, the generalized symptoms that are usually mild (fatigue, malaise, fever, and/or gastrointestinal symptoms) can rapidly develop into the fulminant state, characterized by dyspnea, cyanosis, severe pyrexia, and disorientation followed by circulatory failure, shock, coma, and death (57, 58). Depending on the host, there is a rapid buildup of the bacteria in the blood over the last few hours to terminal levels of 10^7 to 10^9 organisms/ml in the most susceptible species. Enhancing clinical and laboratory expertise and conducting prospective surveillance are critical components of rapid anthrax diagnosis and of preparedness for bioterrorism (40).

Opportunistic Pathogens

Opportunistic infections with *Bacillus* species other than *B. anthracis* have been reported since the late 19th century. It is important to assess isolates of *Bacillus* in the light of any other species cultured and the clinical context and to be wary of dismissing them as mere contaminants.

Bacillus cereus Group

Bacillus cereus is next in importance to *B. anthracis* as a pathogen of humans (and other animals), causing foodborne illness and opportunistic infections, and its ubiquity ensures that cases are not uncommon.

In relation to foodborne illness, *B. cereus* is the etiological agent of two distinct food poisoning syndromes (31, 62): (i) the diarrheal type, characterized by abdominal pain with diarrhea 8 to 16 h after ingestion of the contaminated food and associated with a diversity of foods from meats and vegetable dishes to pastas, desserts, cakes, sauces, and milk; and (ii) the emetic type, characterized by nausea and vomiting 1 to 5 h after eating the offending food, predominantly oriental rice dishes, although occasionally other foods such as pasteurized cream, milk pudding, pastas, and reconstituted formulas have been implicated. One outbreak followed the mere handling of contaminated rice in a children's craft activity, and fulminant liver failure associated with the emetic toxin has been reported. Both syndromes arise as a direct result of the fact that *B. cereus* spores can survive normal cooking procedures; under conditions of improper storage after cooking, the spores germinate and the vegetative cells multiply. Strains of *B. thuringiensis*, which are close relatives of *B. cereus,* may also produce the diarrheal toxin (24).

The toxigenic basis of *B. cereus* food poisoning and other *B. cereus* infections has begun to be elucidated, and a complex picture is emerging (14). A toxin that is possibly associated with *B. licheniformis* food poisoning has been identified (70), but in general, for species outside the *B. cereus* group, toxins or virulence factors associated with foodborne illness have not been identified.

B. cereus is also a destructive ocular pathogen. Endophthalmitis may follow penetrating trauma of the eye or hematogenous spread and evolve very rapidly. Loss of both vision and the eye is likely if appropriate treatment is instituted too late (26). *B. cereus* keratitis associated with contact lens wear has also been reported (80). Other *B. cereus* infections occur mainly, though not exclusively, in persons predisposed by neoplastic disease, immunosuppression, alcoholism and other drug abuse (including a case associated with contaminated heroin), the presence of catheters (49) or implants such as fluid shunts, or some other underlying condition, and fatalities occasionally result. Reported conditions include bacteremia, septicemia, fulminant sepsis with hemolysis, meningitis, brain hemorrhage, ventricular shunt infections, endocarditis (23), pneumonia, exacerbation of bronchiectasis, empyema, pleurisy, lung abscess, brain abscess (23), liver abscess, osteomyelitis, salpingitis, urinary tract infection, and primary cutaneous infections. Wound infections, mostly in otherwise healthy persons, have been reported following surgery (associated, in one report, with contaminated incontinence pads), road traffic and other accidents, scalds, burns, plaster fixation, drug injection, and close-range gunshot and nail bomb injuries; some became necrotic and gangrenous (25, 66). A fatal inflammation was caused by a blank firearm injury; blank cartridge propellants are commonly contaminated with the organism. Neonates also appear to be particularly susceptible to *B. cereus* (100), especially with umbilical stump infections; respiratory tract infections associated with contaminated ventilation systems have also occurred (105). Recently, a near-fatal *B. cereus* pneumonia in an otherwise normal patient was reported (54). Such severe infection in healthy individuals is more typical of *B. anthracis*. Interestingly, the isolate from this case was found to harbor a plasmid (pBCXO1) that was 99.6% similar to the pXO1 virulence plasmid of *B. anthracis* (54); its role, if any, in the virulence of this isolate is not known. A hospital pseudo-outbreak of *B. cereus* infection was associated with contaminated ethanol used as a skin disinfectant.

There have been reports of wound, burn, and ocular infections with *B. thuringiensis* (24), but there is as yet no evidence of infections associated with the use of this organism as an insecticide. The safety of using *B. thuringiensis* as a biopesticide on crop plants has been reviewed (11). Strains

of this species commonly carry genes for *B. cereus* enterotoxins, but it was found that the main pesticide strains assayed produced low titers of enterotoxin. Occupational exposure to the organism has been connected with the presence of the organism in feces but without gastrointestinal symptoms. Cases of illness caused by *B. thuringiensis* may have been diagnosed as caused by *B. cereus*, as the former may not produce its characteristic insecticidal toxin crystals when incubated at 37°C, owing to the loss of the plasmids carrying the toxin genes (44). Strains of *B. cereus* and *B. thuringiensis* have been isolated in association with periodontitis (47). *B. cereus* also causes infections in domestic animals. It is a well-recognized agent of mastitis and abortion in cattle and can cause these conditions in other livestock.

Other Species

Reports of infections with non-*B. cereus* group species are comparatively rare but very diverse (see reference 66 for the earlier literature), and there have been several hospital pseudoepidemics associated with contaminated blood culture systems. *B. licheniformis* has been reported from ventriculitis following the removal of a meningioma, cerebral abscess after penetrating orbital injury, septicemia following arteriography, bacteremia associated with indwelling central venous catheters, bacteremia during pregnancy with eclampsia and acute fibrinolysis, peritonitis in a chronic ambulatory peritoneal dialysis patient and in a patient with volvulus and small-bowel perforation, ophthalmitis, and corneal ulcer after trauma. Most bizarre, perhaps, are two reports of bacteremia in cases of Munchausen's syndrome: one case followed self-inoculation with organic drain cleaner (46), and in another *B. pumilus* and *Paenibacillus polymyxa* were also isolated (39). There have also been reports of L-form organisms, phenotypically similar to *B. licheniformis,* occurring in human blood and other body fluids (66). *B. licheniformis* can cause foodborne diarrheal illness and has been associated with an infant fatality (70). This organism is frequently associated with bovine abortion and has been shown to have a tropism for the bovine placenta; it has also been associated with abortion in water buffalo and occasionally with bovine mastitis. These types of *B. licheniformis* and *B. cereus* infections are associated with wet and dirty conditions during winter housing, particularly when the animals lie in spilled silage, and in one outbreak a water tank contaminated with *B. licheniformis* was implicated.

The name *B. subtilis* was often used in the past to mean any aerobic, endospore-forming organism, but since 1970 there have been reports of infection in which the identification of this species appears to have been made accurately. They include cases of pneumonia, bacteremia, and septicemia associated with neoplastic disease; breast prosthesis and ventriculoatrial shunt infections; isolations from surgical wound drainage sites; endocarditis in a drug abuser; meningitis following a head injury; bacteremia associated with trauma; cholangitis associated with kidney and liver disease; and isolation from dermatolymphangioadenitis associated with filarial lymphedema. The administration of a probiotic preparation marketed for the treatment or prevention of intestinal disorders and allegedly containing *B. subtilis* led to a fatal septicemia in an immunocompromised patient (76). Subsequently, the organism concerned was identified as *B. clausii* (97). The authors of the latter report reported another *B. clausii* infection, cholangitis in polycystic kidney disease in a 15-year-old French boy who had undergone renal transplant, but the source of the organism was unclear. *B. subtilis* has also been associated with cases of bovine mastitis and ovine abortion (66). *B. subtilis* has been implicated in foodborne illness: vomiting has been the commonest symptom, but with accompanying diarrhea frequently reported; the onset periods have been short (ranging from 10 min to 14 h; median; 2.5 h), the bacterial loads of the organism were high (10^5 to 10^9 CFU/g), and the implicated foods were often prepared dishes in which meat or fish was served with cereal-based components such as bread, pastry, rice, or stuffing (63). *B. amyloliquefaciens*, a close relative of *B. subtilis*, is widely used industrially for enzyme and amino acid production, but human consumption of L-tryptophan manufactured in an organism genetically engineered from a strain of this species was associated with a large epidemic of eosinophilia-myalgia syndrome with 37 deaths (71); the causative agent has not been identified with certainty (71). Environmental strains of this species producing a heat-stable, nonprotein toxin have been isolated in association with building-related health problems (71).

Organisms identified as *B. circulans* have been isolated from cases of meningitis, a cerebrospinal fluid shunt infection, endocarditis, a wound infection in a cancer patient, a bite wound, endophthalmitis, and epidemic endophthalmitis associated with a contaminated product used during cataract surgery (89). It must be noted, however, that many isolates previously identified as *B. circulans* might have been misallocated (see comments on *B. circulans* below). *B. coagulans* has been isolated from corneal infection, bacteremia, and bovine abortion. *B. pumilus* has been found in cases of pustule and rectal fistula infection, bacteremia in an immunosuppressed patient, bacteremia in a patient with Munchausen's syndrome (39) and in association with bovine mastitis. Toxigenic strains of *B. pumilus* have been isolated in association with foodborne illness and from clinical and environmental specimens (98). *B. sphaericus* has been implicated in a fatal lung pseudotumor and in meningitis (66). Among 18 cancer patients with 24 bacteremic episodes, Banerjee et al. (7) isolated *B. cereus* (eight cases), *B. circulans* (three cases), *B. subtilis* (two cases), *B. coagulans* (one case), *B. licheniformis* (one case), *B. pumilus* (one case), *B. sphaericus* (one case), and six unidentified aerobic endospore formers. *B. megaterium* (eight isolates), *B. pumilus* (six isolates), *Brevibacillus brevis* (five isolates), *B. licheniformis* (two isolates), and *B. subtilis* (one isolate), all from chewing tobacco, were found to produce potent exogenous virulence factors that caused plasma exudation and tissue dysfunction in an animal model (90).

Bacillus brevis has been isolated from corneal infection and implicated in several incidents of food poisoning; since the time of these reports, the species has been split (see "Taxonomy" above) and transferred to the new genus *Brevibacillus*. Strains of the new species, *Brevibacillus agri,* have been isolated in association with an outbreak of waterborne illness in Sweden; *Brevibacillus centrosporus* was isolated from bronchoalveolar lavage fluid, *Brevibacillus parabrevis* was found in a breast abscess, and both species have been isolated from human blood (68). *Brevibacillus laterosporus* has been reported in association with a severe case of endophthalmitis (66).

Paenibacillus alvei has been isolated from cases of meningitis and endophthalmitis, from a prosthetic hip infection in a patient with sickle cell anemia, from a wound infection, and, in association with *Clostridium perfringens,* from a case of gas gangrene. *P. macerans* has been isolated from a wound infection following removal of a malignant melanoma, from a brain abscess following penetrating periorbital injury, from a catheter-associated infection in a leukemic patient, and from bovine abortion, and *P. polymyxa* has been isolated from ovine abortion (66) and a bacteremic case of Munchausen's

syndrome (39). *P. popilliae* has been reported from endocarditis, and a new *Paenibacillus* species, *P. hongkongensis*, was discovered in a child with neutropenic fever and pseudobacteremia (99), a case in which the organism was found in only one of four blood cultures and was considered to be an environmental contaminant.

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

Clinical specimens for isolation of *Bacillus* species other than *B. anthracis* can be handled without special precautions. *Bacillus* species will normally survive transport in freshly collected specimens or in a standard transport medium. Local transport of specimens (over a few hours) can be done at room temperature or at 2 to 8°C for most specimens, including serum. Generally, if specimens such as swabs, stool, sputum, pleural fluid, and blood are to be shipped overnight or longer, they should be sent at 2 to 8°C. Fresh tissue and serum samples should be shipped frozen, whereas formalin-fixed tissues can be sent at room temperature primarily for detection using immunohistochemistry and (much less suitable) for PCR. For blood specimens in which PCR will be used to detect *B. anthracis* DNA, collection tubes containing EDTA or citrate as anticoagulants are preferable to those containing heparin.

Safety Aspects in Relation to Anthrax

The infectious doses in human anthrax are considered to be high, with the 50% lethal dose as high as 2,500 to 55,000 (34, 57) but as low as 1 to 3 spores (79) or 2 to 9 spores (34). In general, precautions need to be sensible, not extreme. When collecting specimens for suspected anthrax, personnel should wear disposable gloves, disposable apron or overalls, and boots which can be disinfected after use; for dusty samples that might contain many spores, the use of personal protective equipment such as a face shield and/or a respirator should be considered. It should be noted that although hand washing with soap and water or with chlorhexidine gluconate and the use of hypochlorite-releasing towels may all reduce endospore contamination of the skin, waterless rubs containing ethanol are ineffective at removing spores; the model organism in this study was *B. atrophaeus*, a close relative of *B. subtilis* (110). Disposable items should be discarded into suitable containers for autoclaving. Nonautoclavable items should be immersed overnight in 10% formalin (5% formaldehyde solution), glutaraldehyde (5%), a pH 7-adjusted 1:10 dilution of household bleach, or an aqueous solution of chlorine dioxide (500 mg/liter). Items that cannot be immersed should be bagged and sent for formaldehyde fumigation. Ethylene oxide and hydrogen peroxide vapor are also effective fumigants, but the latter is inappropriate if organic matter is being treated. The best disinfectant for specimen spills is formalin. In cases where this is considered impractical, a 1:10 dilution of household bleach (6,000-mg/liter hypochlorite solution) (http://www.epa.gov/pesticides/factsheets/chemicals/bleachfactsheet.htm) can be used, although its limitations should be appreciated; it is rapidly neutralized by organic matter, and it corrodes metals. Other strong oxidizing agents, such as hydrogen peroxide (5%) and peracetic acid (1%), are also effective but likewise inactivated by organic matter.

When working with pure cultures of *B. anthracis*, direct and indirect contact of broken skin with cultures and contaminated laboratory surfaces, accidental parenteral inoculation, and rarely, exposure to infectious aerosols are the primary hazards to laboratory personnel. Isolation and presumptive identification of *B. anthracis* can be performed safely in the routine clinical microbiology laboratory, provided that the usual good laboratory practice is observed; vaccination is not required for minimal handling of the organism (20).

All of the other species of aerobic endospore-forming bacteria that may be isolated from clinical specimens can be handled safely on the open bench. Efforts should be made to avoid methods that produce aerosols. Any procedures that have the potential to generate aerosols should be done in a biological safety cabinet. In addition, all centrifuging should be done using an aerosol-tight rotor and rotors should be opened within the biological safety cabinet. Centrifuges are the most frequently contaminated pieces of laboratory equipment. Laboratories that frequently centrifuge *B. anthracis* suspensions should use an aerosol-tight rotor that can be repeatedly autoclaved; the rotor and rotor lid should be swabbed regularly to monitor for contamination, and contaminated rotors can be autoclaved before reuse. Biosafety level 2 practices, containment equipment, and facilities are recommended for activities using clinical materials and diagnostic quantities of infectious cultures. Biosafety level 3 practices, containment equipment, and facilities are recommended for work involving production quantities or concentrations of cultures and for activities likely to produce aerosols (20).

Specimens from Suspected Anthrax Patients

In all cases, specimens from possible sources of infection (carcass, hides, hair, bones, etc.) should be sought in addition to patient specimens.

Cutaneous Anthrax

For cutaneous anthrax, collect sufficient vesicular fluid with swabs to allow both culture and a smear for visualizing the capsule. For immunohistochemical analysis of cutaneous lesions, a full-thickness punch biopsy fixed in 10% buffered formalin from a papule or vesicle lesion and including adjacent skin should be taken. Biopsy specimens should also be taken from both vesicle and eschar if present (94).

Intestinal Anthrax

Intestinal anthrax will be suspected only if an adequate history of the patient is known. If the patient is not severely ill, a fecal specimen may be collected, but isolation may not be successful. If the patient is severely ill, blood should also be cultured, although isolation may not be possible after antimicrobial treatment; treatment should not await laboratory results. A blood smear may reveal the capsulated rods or, if treatment has started, capsule "ghosts."

Postmortem blood collected by venipuncture (a characteristic of anthrax is nonclotting blood at death [103]) should be examined by smear (for capsule) and culture. Any hemorrhagic fluid from the nose, mouth, or anus should be cultured. If these are positive, no further specimens are needed. If they are negative, specimens of peritoneal fluid, spleen, and/or mesenteric lymph nodes, aspirated by techniques avoiding spillage of fluids, may be collected for smear and culture.

Inhalation (Pulmonary) Anthrax

As with the intestinal form, inhalational anthrax will be suspected only if the patient's history suggests it. If the patient is severely ill, blood smear and culture should be done. Following the bioterrorist attacks of 2001 in the United States, PCR on pleural fluid specimens was very useful, even when the specimens were collected after antimicrobial therapy had begun;

specimens from three patients were negative by culture but still had positive PCR results even when taken ≥24 h after treatment had begun (53), but results depend somewhat on previous treatment. Serology is also useful for the diagnosis of cases when culture fails due to previous treatment. Sera should be taken <7 days after symptoms appear (or after exposure, if known) and again at >14 days. Postmortem, the approach given above for intestinal anthrax should be followed. If the patient is not severely ill, immediate specimen collection is likely to be unfruitful and the person should be treated and simply observed; paired sera (when first seen and >10 days later) may be useful for confirmation of diagnosis.

Specimens from Animals with Suspected Anthrax

Anthrax should be considered as the possible cause of death in herbivorous animals which have died suddenly and unexpectedly, particularly if hemorrhage from the nose, mouth, or anus has occurred and if death has taken place at a site with a history of anthrax (even several decades previously).

Carcasses 1 to 2 Days Old

Due to the nonclotting nature of blood in anthrax victims, in the case of 1- or 2-day-old carcasses it is usually possible to aspirate a few drops of blood from a vein for (i) M'Fadyean-stained smear and (ii) direct plate culture on blood agar.

Pigs frequently do not develop the enormous terminal bacteremia seen in herbivores, and the capsulated rods may not be visible in blood smears. When cervical edema is present, smears and cultures should be made of fluid aspirated from the enlarged mandibular and suprapharyngeal lymph nodes. In porcine intestinal anthrax, possibly obvious only at necropsy, rods are usually visible in stained smears made from mesenteric lymph nodes.

Older Putrefying Carcasses

B. anthracis competes poorly with putrefactive organisms and may not be seen in smears after 2 to 3 days, so culture is necessary for diagnostic confirmation for older putrefying carcasses. Sections of tissue or any blood-stained material should be collected. If the animal has been opened, spleen or lymph node specimens should be taken. With putrefied and very old carcasses, swabs of the nostrils and eye sockets are likely to yield *B. anthracis*, but the best specimens may be samples of contaminated soil beneath the nose and anus.

Other Specimens

Tests for the presence of *B. anthracis* may be requested on a variety of other specimens, such as animal products (e.g., wool, hides, hair, or bonemeal) from regions of endemicity, soil or other materials from old burial sites or tannery or laboratory sites due for redevelopment, or other environmental materials associated with outbreaks (e.g., sewage sludge). At present, culture by the selective agar techniques described below is the only approach. Suitably equipped laboratories are beginning to use PCR techniques for rapid detection of *B. anthracis* in such samples, but at present it is advisable to confirm positives by conventional methods.

Potential Bioterrorism-Related Specimens

In 1999, a Laboratory Response Network (LRN) was established in the United States by the Centers for Disease Control and Prevention (CDC) in partnership with the Association of Public Health Laboratories, the Federal Bureau of Investigation, and the United States Army Medical Research Institute of Infectious Diseases (USAMRIID) to provide the public health laboratory response to acts of bioterrorism (74). This network links local laboratories (sentinel) to laboratories with more specialized testing and increased biosafety level at the state (reference) and federal (national) level. There are reference level laboratories in all 50 states able to detect agents, including *B. anthracis*, rapidly. State public health laboratories are part of the LRN and will be able to provide guidance, or the LRN can be accessed using the Internet (http://www.bt.cdc.gov/lrn/). State and territorial public health laboratory contact information and sentinel laboratory guidelines are also available on the American Society for Microbiology website at http://www.asm.org. Emergency response guidelines for state, local, and tribal public health personnel can be found at http://www.bt.cdc.gov/ under "Additional Topics and Resources" and a 24-h hotline number for urgent advice is 770-488-7100. Although initially limited to the United States, there are now 152 national and international laboratories within the LRN, including Canada, Great Britain, Australia, Germany (U.S. military base), and South Korea (U.S. military base), which are capable of providing a rapid response to acts of biological terrorism, emerging infectious diseases, and other public health threats and emergencies.

ISOLATION PROCEDURES

Specimens with Mixed Microbiota

In specimens submitted for food-poisoning investigations or for isolation of *B. anthracis* from old carcasses, animal products, or environmental specimens, the organisms will be present mostly as spores. Heating (62.5 to 80°C for 10 to 30 min) will both heat shock the spores and effectively destroy nonspore-forming contaminants. A variety of approaches are used to process solid samples prior to heat treatment. Direct plate cultures are made on blood, nutrient, or, selective agars, as appropriate, by spreading up to 100-μl volumes from undiluted and 10- and 100-fold dilutions of the treated sample.

Enrichment procedures are generally inappropriate for isolations from clinical specimens, but when searching for *B. cereus* in stools ≥3 days after a food-poisoning episode, nutrient or tryptic soy broth with polymyxin (100,000 U/liter) may be added to the heat-treated specimen. There is no effective enrichment method for *B. anthracis* in old animal specimens or environmental samples; isolation from these is best done with polymyxin-lysozyme EDTA-thallous acetate (PLET) agar (61; see also chapter 21). A differential/selective chromogenic medium has recently been introduced by R&F Laboratories, Downers Grove, Il. (R&F Anthracis Chromogenic Medium), but it has yet to be thoroughly evaluated. Aliquots (100 μl) of the undiluted and 1:10 and 1:100 dilutions of heat-treated suspension of the specimen are spread across PLET plates, which are read after incubation for 36 to 40 h at 37°C. Roughly circular, creamy white colonies, 1 to 3 mm in diameter, with a ground-glass texture are subcultured on (i) blood agar plates to test for gamma phage and for hemolysis and (ii) directly or subsequently in blood to look for capsule production by using M'Fadyean's stain or, less reliably, India ink negative stain (the ink coagulates the blood and makes interpretation difficult); 2.5 ml of blood (defibrinated horse blood seems best; horse or fetal calf serum is quite good) is inoculated with a pinhead quantity of growth from the suspect colony, incubated statically for 6 to 18 h at 37°C, and then stained. PCR-based methods are being used increasingly for the direct detection of *B. anthracis* in clinical specimens and environmental samples (53).

Several media have been designed for isolation, identification, and enumeration of *B. cereus*. They exploit the organism's egg yolk reaction positivity and acid-from-mannitol negativity;

pyruvate and polymyxin may be included for selectivity. Three satisfactory formulations are MEYP or MYP (mannitol, egg yolk, polymyxin B agar [MEYP]; Oxoid, Basingstoke, United Kingdom; MYP; Difco, BD, Franklin Lakes, N.J.), PEMBA (polymyxin B, egg yolk, mannitol, bromthymol blue agar; Oxoid), and BCM (*Bacillus cereus* Medium; LabM, Bury, United Kingdom) (106) (see chapter 21). There are no selective media for other *Bacillus* species, but spores can be selected for by heat treating part of the specimen, as described above; the vegetative cells of both spore formers and non-spore-formers will be killed, but the heat-resistant spores not only will survive but also may be heat shocked into subsequent germination. The other part of the specimen is cultivated without heat treatment in case spores are very heat sensitive or absent. Heat treatment is not appropriate for fresh clinical specimens, in which spores are usually sparse or absent.

IDENTIFICATION OF *B. ANTHRACIS*

Gram Stain

Inevitably the first examination of smears and cultures will be with the Gram stain. In the past, it has been regarded as being of limited value in anthrax diagnosis because it does not reveal the capsule. In recent bioterrorism cases such preparations were clearly considered to be of great value (Fig. 1a), but caution is still necessary. In a well-developed country, it is unlikely that large numbers of gram-positive bacteria in the blood at death are going to be anything but *B. anthracis*, particularly when supported by the recent events. In other circumstances, and in animals in particular, the blood or other specimen may not be collected soon after death and before putrefactive organisms appear; *B. anthracis* may then be indistinguishable without the use of the proper capsule stain.

The M'Fadyean polychrome methylene blue staining test dates from 1903 and has proved to be a remarkably successful rapid diagnostic test over the decades. However, reliable stain and adequate quality control of its performance are becoming hard to guarantee. A rapid immunochromatographic on-site test has been developed (13) but is not commercially available.

It is generally easy to distinguish virulent *B. anthracis* from other members of the *B. cereus* group. *B. anthracis* isolates are characterized by a typical microscopic appearance (Fig. 1c and 2a) and colonial morphology (Fig. 3a): colonies are white or gray, nonhemolytic or only weakly hemolytic, susceptible to the diagnostic "gamma phage" (inquiries

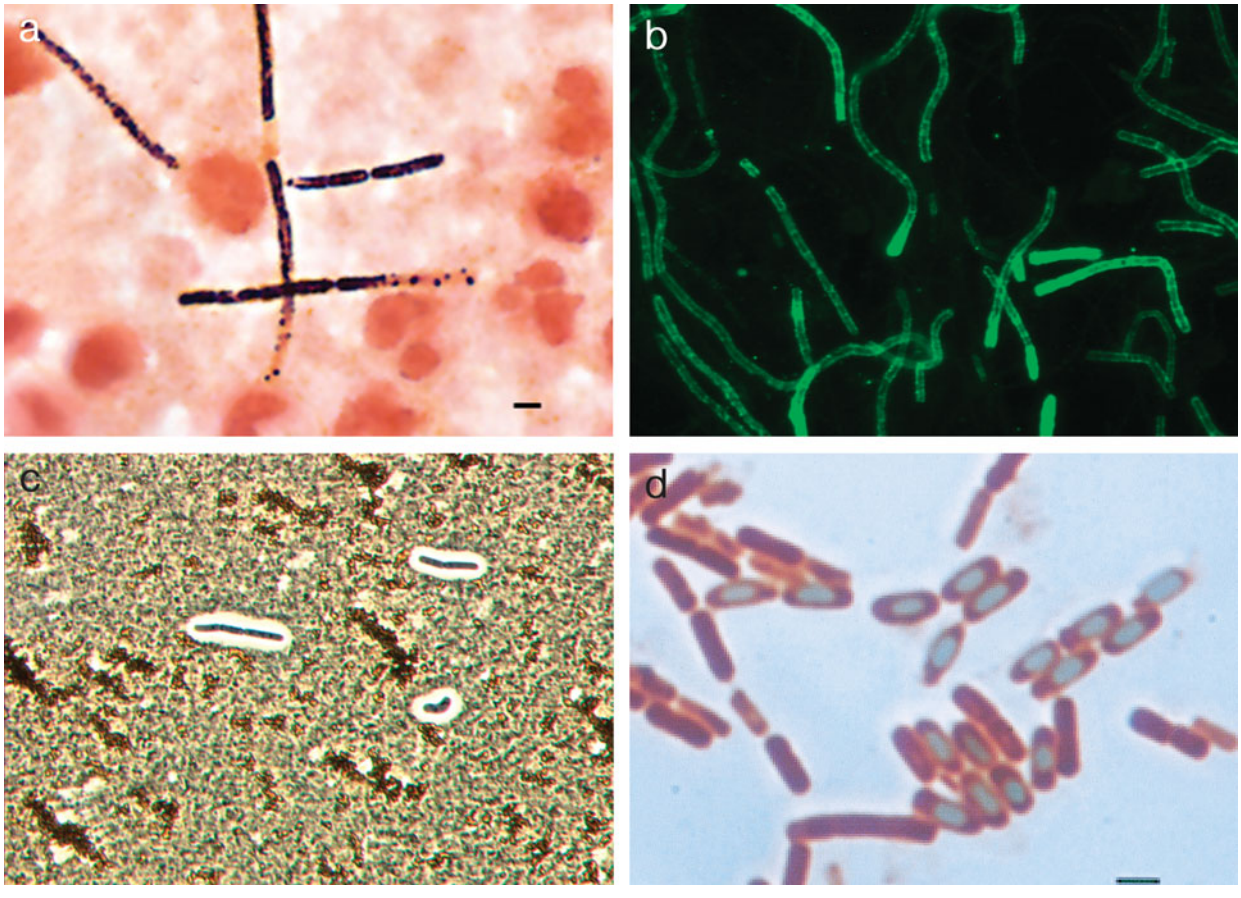

FIGURE 1 (a) Gram stain of *B. anthracis*, associated with a bioterrorism attack, showing gram-positive rods in peripheral blood buffy coat following admission of patient; bar, 3 μm. Courtesy of H. Masur. (b) DFA-stained preparation of *B. anthracis* using an antibody specific for the poly-γ-D-glutamic acid capsule. (c) India ink stain of *B. anthracis* incubated in horse blood. Clear zones surrounding the rods are due to the exclusion of the India ink by the capsule. (d) Spore-stained preparation of *B. cereus* sporangia, viewed by bright-field microscopy. Spores are stained green and vegetative cells are counterstained red. Bar, 2 μm. (Photograph kindly provided by M. Rodriguez-Diaz.)

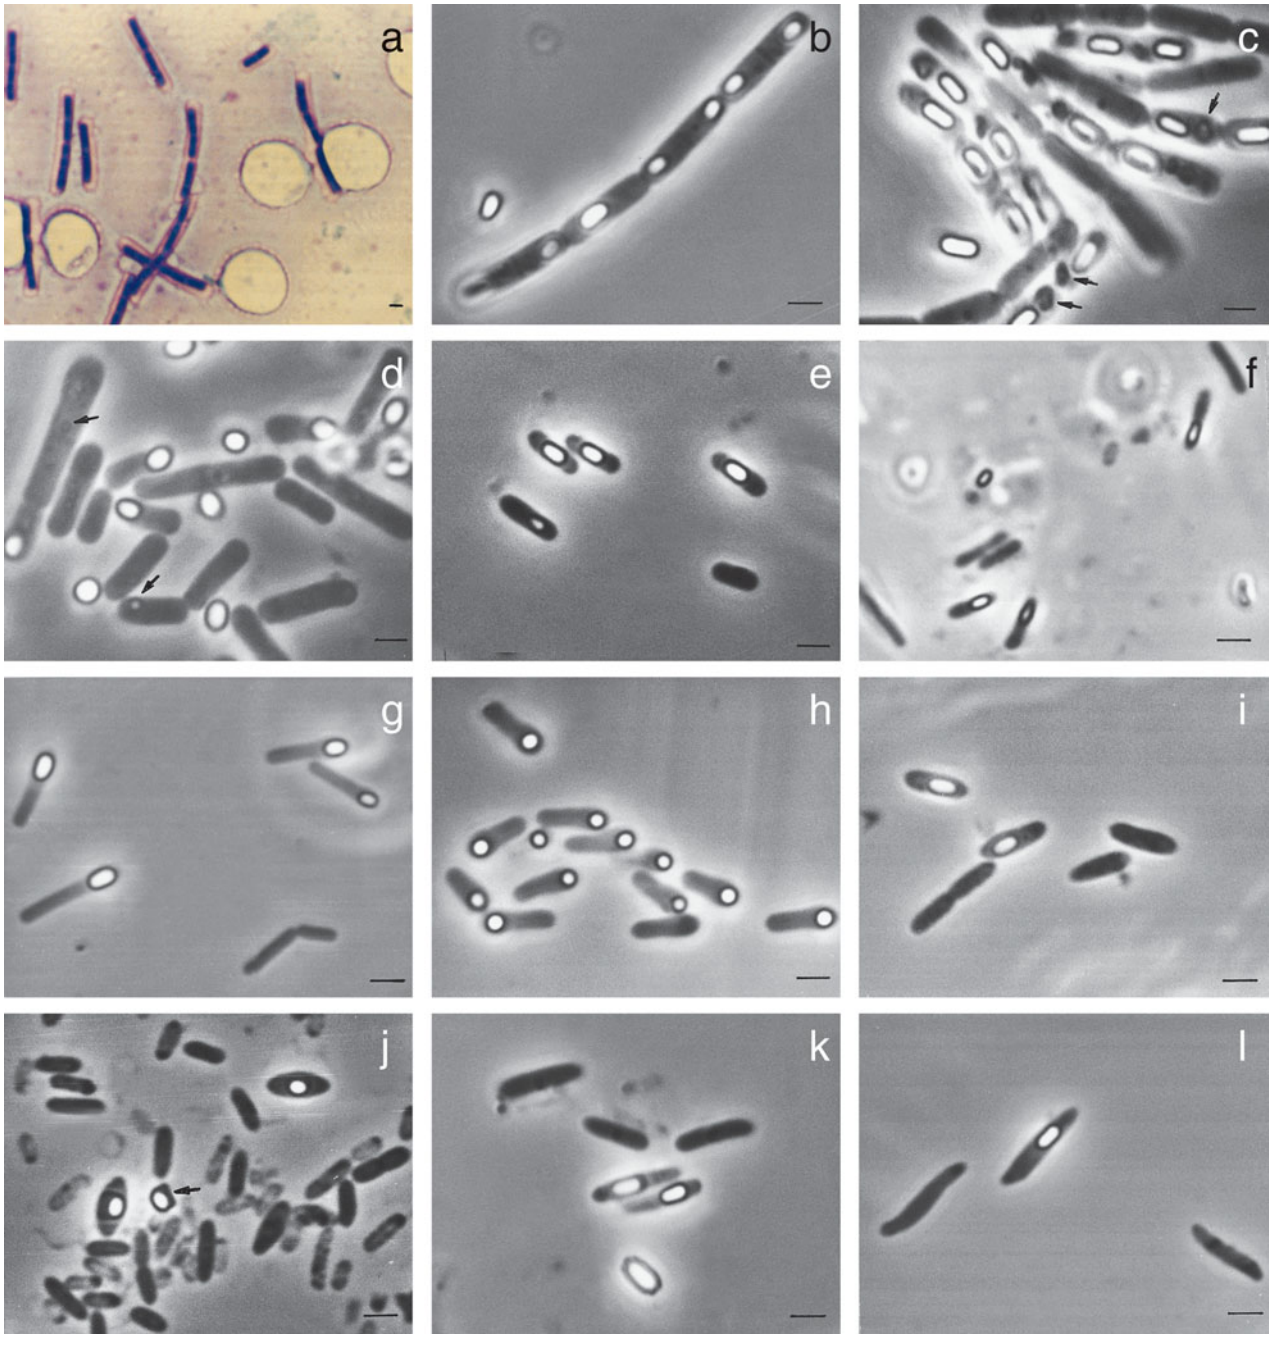

FIGURE 2 Photomicrographs of endospore-forming bacteria viewed by bright-field (a) and phase-contrast (b to l) microscopy. Bars, 2 μm. (a) *B. anthracis,* M'Fadyean stain showing capsulate rods in guinea pig blood smear; (b) *B. cereus,* broad cells with ellipsoidal, subterminal spores, not swelling the sporangia; (c) *B. thuringiensis,* broad cells with ellipsoidal, subterminal spores, not swelling the sporangia, and showing parasporal crystals of insecticidal toxin (arrowed); (d) *B. megaterium,* broad cells with ellipsoidal and spherical, subterminal and terminal spores, not swelling the sporangia, and showing poly-β-hydroxybutyrate inclusions (arrowed); (e) *B. subtilis,* ellipsoidal, central and subterminal spores, not swelling the sporangia; (f) *B. pumilus,* slender cells with cylindrical, subterminal spores, not swelling the sporangia; (g) *B. circulans,* ellipsoidal, subterminal spores, swelling the sporangia; (h) *B. sphaericus,* spherical, terminal spores, swelling the sporangia; (i) *Brevibacillus brevis,* ellipsoidal, subterminal spores, one swelling its sporangium slightly; (j) *Brevibacillus laterosporus,* ellipsoidal, central spores with thickened rims on one side (arrowed), swelling the sporangia; (k) *Paenibacillus polymyxa,* ellipsoidal, paracentral to subterminal spores, swelling the sporangia slightly; (l) *Paenibacillus alvei,* cells with tapered ends, ellipsoidal, paracentral to subterminal spores, not swelling the sporangium.

about gamma phage should be addressed to the Diagnostics Systems Division, USAMRIID, Fort Detrick, Frederick, MD 21702-5011), generally susceptible to penicillin, nonmotile, and able to produce the characteristic capsule, as shown by M'Fadyean staining (Fig. 2a) or India ink staining (103) (Fig. 1c). As an alternative to culture in blood, the capsule of virulent *B. anthracis* can be demonstrated on nutrient agar containing 0.7% sodium bicarbonate, incubated overnight under 5 to 7% CO_2 (candle jars perform well). Colonies of the capsulated organism appear mucoid, and the capsule can be visualized by M'Fadyean or India ink staining of smears or by direct fluorescent antibody (DFA) staining (Fig. 1b; see below) or indirect antibody staining (inquiries about indirect fluorescent antibody capsule staining should be addressed as above to the Diagnostics Systems Division, USAMRIID).

In addition to phenotypic analysis, molecular and antigenic detection assays are available for the rapid identification of *B. anthracis*. The LRN PCR (restricted to LRN laboratories; see "Potential Bioterrorism-Related Specimens" above) targets three distinct loci on the *B. anthracis* chromosome, pXO1

virulence plasmid, and pXO2 virulence plasmid (54). Using several loci increases specificity and allows for the detection of avirulent strains (lacking pXO1 or pXO2). The anthrax toxin genes (*pagA*, *lef*, and *cya*) are located on pXO1, whereas the genes required for capsule biosynthesis (*capBCA*) are located on pXO2. Isolates lacking pXO2 or both plasmids are found mostly in the environment and are frequently mistaken for *B. cereus,* due to the lack of a capsule, and discarded (102). A commercial kit is also available for the detection of the *B. anthracis* toxin gene, *pagA*, and the capsule gene, *capB* (Roche, Mannheim, Germany) (8). These genes have been widely used as *B. anthracis* specific gene targets; however, there have been recent reports of these genes being found in species other than *B. anthracis* (41, 54). Recently, several laboratories have developed specific PCR assays for *B. anthracis* that target chromosomal genes such as *rpoB*, *gyrA*, and *plcR* (30, 56, 82).

A two-component DFA assay has been used to identify encapsulated vegetative cells of *B. anthracis* (27, 33). This assay uses two different monoclonal antibodies specific for a *B. anthracis* cell wall antigen and the *B. anthracis* capsule (Fig. 1b). Neither antigen is 100% specific for *B. anthracis;* however, only *B. anthracis* has been found to be positive for both antigens, and thus the assay is 100% specific when both cell wall and capsule components are used together; it was heavily used at the CDC during the 2001 bioterrorism-associated outbreak for the rapid (<4-h) identification of isolates (27).

Tetracore, Inc. (Gaithersburg, Md.) has produced a rapid (within 15 min) immunochromatographic test (RedLine Alert) utilizing an antibody specific for one of the *B. anthracis* S-layer proteins. This assay has been approved by the Food and Drug Administration (FDA) for use on nonhemolytic *Bacillus* species colonies cultured on sheep blood agar plates. Manufacturer's data suggest that the test was 98.6% sensitive when tested on 145 *B. anthracis* isolates and 45 nonhemolytic, non-*B. anthracis* isolates; however, such identification of *B. anthracis* is considered presumptive and it should not be used as a stand-alone test.

Molecular Characterization of *B. anthracis*

Although *B. anthracis* is a genetically monomorphic species, the development of a multiple-locus variable-number tandem repeat analysis (MLVA) has allowed for effective strain differentiation (59). This method was relied on during the 2001 bioterrorism-associated outbreak in the United States, and MLVA of the attack strain implicated the Ames laboratory strain (52). Recently, Keim et al. proposed adding canonical single nucleotide polymorphisms, expanding MLVA from 8 to 15 loci, and analyzing four single nucleotide repeats to increase genotyping accuracy and resolution (60). In addition, although not in widespread use, the availability of genome data has led to the use of microarray technology to detect differences between strains of *B. anthracis* and other *Bacillus* species (86, 116) (see also "Molecular Typing" below).

Direct Detection of *B. anthracis* in Clinical Specimens

In addition to culturing *B. anthracis,* there are molecular and antigen-based detection methods available for direct detection in clinical and environmental samples. These are essential when cultures fail, as they particularly do after the initiation of antimicrobial therapy. Several methods, including a *B. anthracis*-specific LRN PCR assay, immunohistochemical (IHC) assays, and serology, were useful for confirmation of cases during the 2001 bioterrorism-associated outbreak, particularly when culture failed (45, 53, 83, 85, 94). At least two such tests need to be positive for a case to be considered laboratory confirmed.

The most widely used and available detection method in the U.S. public health system is the LRN PCR as previously described (53). Following the 2001 anthrax attacks in the United States, this assay was negative on all specimens (n = 142) from patients in whom anthrax was excluded (100% specific). In addition, testing of specimens from inhalation anthrax patients produced a positive result in 33% (29/87) of the specimens which were culture negative, with pleural fluid appearing to be the best specimen even after the initiation of antimicrobial therapy. The IHC assay, as performed at the CDC, uses the same antibodies as the DFA assay (specific to cell wall antigen or the capsule) to detect *B. anthracis* in formalin-fixed, paraffin-embedded tissues. This method was particularly useful in the diagnosis of cutaneous cases during the 2001 bioterrorism-associated outbreak. Skin biopsy specimens from cutaneous lesions from 8 of 10 patients were positive for both the capsule and cell wall antigens (94).

The many reports on the use of different PCR assays to detect or identify *B. anthracis* cannot be summarized here. Although PCR is currently the most widely used detection technology (29), there are increasing reports on novel technologies or improvements to existing ones such as mass spectrometry, flow cytometry, time-resolved fluorescent assays, high-performance liquid chromatography, and even the use of engineered B-cells to detect *B. anthracis* (2, 55, 87, 111, 115). With further improvements and validations, these assays may increasingly be used to detect *B. anthracis* in the future.

Serological Detection of Anthrax

Serological assays for the detection of antibody response against the anthrax toxin protein, protective antigen (PA), were used in combination with PCR or IHC assay results to confirm anthrax cases when culture failed. A quantitative human anti-PA immunoglobulin G (IgG) enzyme-linked immunosorbent assay was performed at the CDC during the 2001 outbreak and was positive only on sera from individuals with anthrax or vaccinated with Anthrax Vaccine Adsorbed (BioThrax; BioPort, Lansing, Mich.) (85). More recently, a commercially available, FDA-approved, qualitative kit (QuickELISA Anthrax-PA Kit) from Immunetics (Boston, Mass.) has become available for the detection of anti-PA IgG and IgM antibodies in human serum. Serological assays aided in the effort to confirm cases in the 2001 attack, particularly cutaneous ones; however, the time to seroconversion after infection limits its usefulness in terms of the rapid diagnosis necessary for treatment and a public health response.

IDENTIFICATION OF SPECIES OTHER THAN *B. ANTHRACIS*

Remember that these organisms do not always stain gram positive. Before attempting to identify to the species level, it is important to establish that the isolate really is an aerobic endospore former and that other inclusions are not being mistaken for spores. A Gram-stained smear showing cells with unstained areas suggestive of spores can be stripped of oil with acetone or alcohol, washed, and then stained for spores. Spores are stained in heat-fixed smears by flooding with 10% aqueous malachite green for up to 45 min (without heating), followed by washing and counterstaining with 0.5% aqueous safranin for 30 s; spores are green within pink/red cells at a magnification of ×1,000 (Fig. 1d). Phase-contrast microscopy (at a magnification of ×1,000) should be used if

available, as it is superior to spore staining and more convenient. Spores are larger, more phase bright, and more regular in shape, size, and position than other kinds of inclusion such as polyhydroxybutyrate (PHB) granules (Fig. 2d), and sporangial appearance is valuable in identification (Fig. 2).

Members of the *B. cereus* group and *B. megaterium* produce large amounts of storage material when grown on carbohydrate media, but on routine media this vacuolate or foamy appearance is rarely sufficiently pronounced to cause confusion. Isolates of other organisms have often been submitted to reference laboratories as *Bacillus* species because they were large, aerobic gram-positive rods, even though sporulation had not been observed, or because PHB granules or other storage inclusions had been mistaken for spores.

Bacillus contains facultative anaerobes as well as strict aerobes, which can be a valuable characteristic in identification. For example, *B. licheniformis* and *B. subtilis,* which have very similar colonial (Fig. 3j) and microscopic morphologies (Fig. 2e), are facultatively anaerobic and strictly aerobic, respectively; likewise, the two large-celled species *B. cereus* and *B. megaterium* (Fig. 2b and d) are facultatively anaerobic and strictly aerobic, respectively.

The most widely used diagnostic schemes use traditional phenotypic tests (42) or miniaturized tests of the API 20E and 50CHB kits used together (67) (bioMérieux, Marcy l'Etoile, France). The API 20E and 50CHB kits can be used for the presumptive distinction of *B. anthracis* from other members of the *B. cereus* group within 48 h. bioMérieux also offers identification cards for *Bacillus* and related genera for the Vitek and Vitek Compact automated identification systems. As many new species have been proposed since these schemes were established, updated API and Vitek databases have been prepared. Biolog Inc. (Hayward, Calif.) also offers a *Bacillus* database. The effectiveness of such kits can vary with the genera and species of aerobic endospore formers concerned, but they are improving with continuing development and enlarged databases (67). The many proposals for new species, often on the basis of single isolates, make the satisfactory expansion of such databases problematic; for a database to be effective in identifying a particular species, its entry for that species needs to reflect the characterization of at least 10 authentic strains from a range of sources, but these requirements can be very difficult or impossible to fulfill. It is stressed that the use of these kits should always be preceded by the basic characterization tests described below.

Other approaches include chemotaxonomic fingerprinting by fatty acid methyl ester profiling, polyacrylamide gel electrophoresis analysis, pyrolysis mass spectrometry, and Fourier-transform infrared spectroscopy. All these approaches have been successfully applied either across the genera or to small groups. As with genotypic profiling methods, large databases of authentic strains are necessary; some of these are commercially available, such as the Microbial Identification System software (Microbial ID Inc., Newark, Del.) database for fatty acid methyl ester analysis.

For diagnostic purposes, the aerobic endospore formers comprise two groups: the reactive ones, which give positive results in various routine biochemical tests and which are therefore easier to identify, and the nonreactive ones, which give few if any positive results in such tests. Nonreactive isolates tend to dominate the identification requests sent to reference laboratories. Table 1 shows reactions for some species belonging to the former group, and the phenotypic test scheme outlined above may be used in conjunction with it. Guidance on identifying members of the nonreactive group is found in reference 68.

Identification of *B. cereus* and *B. thuringiensis*

Colonies of *B. cereus* and relatives are very variable but readily recognized (Fig. 3a, b, and c): they are characteristically large (2 to 7 mm in diameter) and vary in shape from circular to irregular, with entire to undulate, crenate, or fimbriate edges; they have matte or granular textures. Smooth and moist colonies are not uncommon, however. The optimum growth temperature is about 37°C with minima and maxima of 15 to 20°C and 40 to 45°C, respectively. Although colonies of *B. anthracis* and *B. cereus* can be similar in appearance, those of the former are generally smaller and nonhemolytic, may show more spiking or tailing along the lines of inoculation streaks, and are very tenacious compared with the usually more butyrous consistency of *B. cereus* and *B. thuringiensis* colonies, so that they may be pulled into standing peaks with a loop. *Bacillus mycoides* produces characteristic rhizoid or hairy-looking, adherent colonies which readily cover the whole agar surface.

There are key characteristics for recognizing and distinguishing the *B. cereus* group organisms. They display a typical colonial morphology (Fig. 3a, b, and c); large cells are observed, often in chains, producing ellipsoidal spores not swelling the sporangia (Fig. 2b and c), usually within 48 h and often apparent after 24 h; they are facultative anaerobes and positive for the egg yolk reaction (i.e., lecithinase positive). Negative or very weak hemolysis and lack of motility distinguish *B. anthracis* and *B. mycoides* from *B. cereus* and *B. thuringiensis*. *B. cereus, B. mycoides, B. thuringiensis,* and, to a lesser extent, *B. anthracis* synthesize lecithinases, forming opaque zones of precipitation around colonies on egg yolk agar as the colonies grow (i.e., usually after overnight or perhaps 24 h of incubation). Recognition of *B. thuringiensis* is largely dependent on observation of its cuboid or diamond-shaped parasporal crystals in sporulated cultures (after 2 to 5 days) by phase-contrast microscopy (Fig. 2c) or by staining with malachite green counterstained with carbol fuchsin or safranin.

Other Species

Other species show a very wide range of colonial morphologies, both within and between species after 24 to 48 h (Fig. 3). They vary from moist and glossy (Fig. 3f to i) through granular to wrinkled (Fig. 3e); shapes vary from round to irregular (Fig. 3d to i), sometimes spreading (Fig. 3k and l), with entire through undulate or crenate to fimbriate edges (Fig. 3d to j); sizes range from 1 to 5 mm; color commonly ranges from buff or creamy gray to off-white, but some strains may produce an orange pigment; hemolysis may be absent, slight or marked, partial or complete (Fig. 3h); elevations range from effuse through raised to convex; the consistency is usually butyrous, but mucoid and dry, adherent colonies are not uncommon. Despite this diversity, *Bacillus* colonies are not generally difficult to recognize, and some species have characteristic yet seemingly infinitely variable colonial morphologies, as does the *B. cereus* group (Fig. 3a to c).

B. subtilis and *B. licheniformis* produce similar colonies, which are exceptionally variable in appearance and often appear to be mixed cultures (Fig. 3j); colonies are irregular in shape and of moderate diameter (2 to 4 mm), and they range from moist and butyrous or mucoid, with margins varying from undulate to fimbriate through membranous with an underlying mucoid matrix, with or without mucoid beading at the surface, to rough and crusty as they dry. The "licheniform" colonies of *B. licheniformis* tend to be quite adherent.

Rotating and migrating microcolonies, which may show spreading growth (Fig. 3k), have been observed macroscopically

in about 13% of strains received as *B. circulans*, but this very heterogeneous species continues to undergo radical taxonomic revision, and such spreading strains are now assigned to *Paenibacillus* species (Fig. 3l).

Other species that have been encountered in the clinical laboratory include *B. coagulans, B. megaterium, B. pumilus,* and *B. sphaericus; B. brevis* and *B. laterosporus* (now both in *Brevibacillus*); and *B. macerans* and *B. polymyxa* (now both in *Paenibacillus*), and they do not produce a particularly distinctive growth (Fig. 3d to i).

Microscopic morphologies, particularly of sporangia (Fig. 2), are much more helpful for distinguishing between species. Vegetative cells are usually round-ended, but those of *P. alvei* may be tapered (Fig. 2l). The large cells of *B. megaterium* may accumulate PHB (Fig. 2d) and appear vacuolate or foamy when grown on glucose nutrient agar. Overall, cell widths vary from about 0.5 to 1.5 μm, and cell lengths vary from 1.5 to 8 μm. Most strains of these species are motile. Spore shapes vary from cylindrical (Fig. 2f) through ellipsoidal (Fig. 2b, c to e, g, and i to l) to spherical (Fig. 2d and h); bean- or kidney-shaped, curved-cylindrical, and pear-shaped spores are also seen occasionally. Spores may be terminally (Fig. 2h), subterminally (Fig. 2b, c, f, g, and i), or centrally (Fig. 2e and j) positioned within sporangia and may distend them (Fig. 2g to k). Despite within-species and within-strain variation, sporangial morphologies tend to be characteristic of species and may allow tentative identification by the experienced worker. One species, *Brevibacillus laterosporus,* produces very distinctive ellipsoidal spores that have thickened rims on one side, so that they appear to be laterally displaced in the sporangia (Fig. 2j).

All these species are mesophilic and grow well between 30 and 37°C. Minimum growth temperatures lie mostly between 5 and 20°C, and maxima are mostly between 35 and 50°C. Strains of *B. coagulans* may show slight thermophily and grow up to 55 to 60°C.

GENE SEQUENCING AND SPECIES IDENTIFICATION

Although the sequencing of several genes, such as *rpoB* and *gyrA,* has been used to aid in the identification of bacterial species, the16S rRNA gene remains the one most commonly used, and it provides an abundance of data for comparison

[c] Reactions shown in brackets are for the biotype isolated particularly in connection with outbreaks of emetic-type food poisoning and for strains of serovars 1, 3, 5, and 8, which are commonly associated with such outbreaks.

[d] Spore shape: C, cylindrical; E, ellipsoidal; S, spherical. Spore position: C, central or paracentral; S, subterminal; T, terminal. The commonest shapes and positions are listed first, and those shown in parentheses are infrequently observed.

(4, 73, 108). Many species, however, including species within the *B. cereus* group, can be extremely difficult to differentiate on the basis of a single gene sequence. Sacchi et al. reported that while *B. anthracis* and *B. cereus* could be differentiated by 16S rRNA gene sequencing, some strains of *B. cereus* and *B. anthracis* differed at only a single nucleotide position; furthermore, a more recent report identified a *B. anthracis* strain with a sequence identical to that of some *B. cereus* strains (3, 91). With differences so small, the quality of the sequence and its analysis are becoming more critically important. Nonetheless, even if sequencing of a gene, such as the 16S rRNA gene, does not always provide identification to the species level with 100% confidence, it is a very helpful component of the identification process and of phylogenetic analyses.

TYPING AND STRAIN DIFFERENTIATION OF SPECIES OTHER THAN *B. ANTHRACIS*

A strain differentiation system for *B. cereus* based on flagellar (H) antigens is available at the Food Safety Microbiology Laboratory, Health Protection Agency Centre for Infections, Colindale, London, United Kingdom, for investigations of food-poisoning outbreaks or other *B. cereus*-associated clinical problems. *B. thuringiensis* strains are classified on the basis of their flagellar antigens; 82 serovars have been recognized. This classification is done at the Institut Pasteur, Paris, France.

Toxin and Antitoxin Detection

The three protein components of anthrax toxin (protective antigen [PA], lethal factor, and edema factor) and antibodies to them can be used in enzyme immunoassay systems. For routine confirmation of anthrax infection, or for monitoring response to anthrax vaccines, antibodies against PA alone appear to be satisfactory; they have proved useful for epidemiological investigations in humans and animals. In human anthrax, however, early treatment sometimes prevents antibody development. PA is available commercially from List Biological Laboratories, Inc., Campbell, Calif. (http://www.listlabs.com). The current human vaccine in the United States is an aluminum hydroxide-adsorbed vaccine strain culture filtrate containing a relatively high proportion of PA and relatively low amounts of lethal factor and edema factor (101).

In countries of the former USSR, a skin test utilizing Anthraxin (trade mark), a heat-stable extract from a noncapsulate strain of *B. anthracis,* which has been licensed for human and animal use since 1962, is widely acclaimed for the retrospective diagnosis of anthrax (95). The delayed-type hypersensitivity is interpreted as indicating cell-mediated immunity to anthrax and can be used to diagnose anthrax retrospectively or to evaluate the vaccine-induced immune status after periods of several years. Anthraxin does not contain highly specific anthrax antigens and depends on the nature of anthrax rather than the specificity of the antigens involved. This is also true of the Ascoli test, which, dating from 1911, must be one of the oldest antigen detection tests in microbiology. It is a precipitin test using hyperimmune serum raised to *B. anthracis* whole-cell antigen to provide rapid retrospective evidence of anthrax infection in an animal from which the material being tested was derived. The test is still in use in Eastern Europe and Central Asia.

The enterotoxin complex responsible for the diarrheal type of *B. cereus* food poisoning has been increasingly well characterized. Two commercial kits are available for its detection in foods and feces, the Oxoid BCET-RPLA (Oxoid Ltd.) and the TECRA VIA (TECRA Diagnostics, Roseville, NSW, Australia). However, these kits detect different antigens, and there is some controversy about their reliabilities. Other assays, based on tissue culture, have also been developed (36). The emetic toxin of *B. cereus* has been identified as a dodecadepsipeptide, and it may be assayed in food extracts or culture filtrates using HEp-2 cells (35) or boar semen (1).

Molecular Typing

Pulsed-field gel electrophoresis has been applied to differentiate between strains of *Bacillus sphaericus* and between very closely related species such as *Bacillus anthracis*, *Bacillus cereus, Bacillus mycoides,* and *Bacillus thuringiensis*, and two studies dealt with infrequently reported clinical infections by *B. cereus* (47, 65).

Amplified fragment length polymorphism is based upon a specific combination of PCR and restriction methodologies, and although it is much more complex than random amplified polymorphic DNA and repetitive extragenic palindromic-PCR methods, it is also much more reproducible. It has been used in epidemiological studies of *B. cereus* (88) and for the genetic comparison of *B. anthracis* and its closest relatives (104). For other members of the *B. cereus* group, which are not as monomorphic as *B. anthracis*, several multilocus sequence typing (MLST) schemes have recently been reported (48, 81), and a *B. cereus* MLST website that allows for viewing of data and submission of new data is available at http://pubmlst.org/bcereus/. These methods include the partial sequencing and comparison of seven housekeeping genes to differentiate strains.

MAINTENANCE OF STRAINS

All the clinically significant isolates reported to date are of species that grow, and often sporulate, on routine laboratory media at 37°C. It seems unlikely that many clinically important, but more fastidious, strains are being missed for the want of special media or growth conditions. Maintenance is simple if spores can be obtained, but it is a mistake to assume that a primary culture or subculture on blood agar will automatically yield spores if stored on the bench or in the incubator. It is best to grow the organism on nutrient agar containing 5 mg of manganese sulfate per liter for a few days and refrigerate the culture when microscopy shows that most cells have sporulated. For most species, sporulated cultures on slants of this medium, sealed after incubation, can survive in a refrigerator for years. Alternatively, cultures (preferably sporulated) can be frozen or lyophilized.

B. anthracis is defined as a select agent and an "overlap" agent on the HHS/CDC and USDA/APHIS select agent lists. Thus, possession of the agent in the United States requires registration of the laboratory with either CDC or APHIS. When *B. anthracis* is identified in an unregistered clinical or diagnostic laboratory, the identification of this agent must be reported to CDC or APHIS within 7 days and to other authorities as required by federal, state, or local laws. When *B. anthracis* is isolated in an unregistered laboratory, the organism must either be destroyed on-site by a recognized sterilization or inactivation process or be transferred to a registered laboratory within 7 days. Shipping of this agent requires completion of the APHIS/CDC Form 2 and prior approval from either CDC or APHIS.

ANTIMICROBIAL SUSCEPTIBILITIES

B. anthracis

Most strains of *B. anthracis* remain susceptible to penicillin (22, 72). Of 25 genetically diverse isolates from around the world, 3 strains were resistant to penicillin but were negative for β-lactamase production. Most strains give variable susceptibility results for cephalosporins; in vitro results, even if susceptible, may not predict clinical efficacy, particularly for expanded- and broad-spectrum cephalosporins (22). In a study of 50 historical isolates from humans and animals and 15 clinical isolates from the 2001 bioterrorist attack in the United States, the majority of strains could be regarded as not susceptible to the broad-spectrum cephalosporin ceftriaxone, and three strains were resistant to penicillin (72). Tetracyclines, fluoroquinolones, and chloramphenicol are suitable for the treatment of patients allergic to penicillin (but these are not good choices clinically, regardless of in vitro results); most strains in the previously mentioned study showed only intermediate susceptibility to erythromycin (72). Ciprofloxacin and the newer quinolone gatifloxacin had good in vitro activities against 40 Turkish isolates, but for another new quinolone, levofloxacin, it was observed that MICs were high for 10 strains (32). Other in vitro studies have shown novel fluoroquinolones and a ketolide to be of potential therapeutic value (38). Standards for antimicrobial susceptibility testing of *B. anthracis* have been recently adopted (21).

Postexposure prophylaxis is needed for the prevention of inhalation anthrax following a bioterrorist attack; the recommended regimen is 60 days of antibiotic therapy and three doses of anthrax vaccine (19), and recommended antimicrobial agents include ciprofloxacin, doxycycline, and levofloxacin. Amoxicillin is recommended as an option in cases where the *B. anthracis* strain has been demonstrated to be susceptible to penicillins and when other antimicrobial agents are not considered safe, as in the treatment of children and pregnant or lactating women (16, 17). The use of penicillins for postexposure prophylaxis or for treatment of inhalation anthrax following the use of *B. anthracis* as a bioweapon gives cause for concern, owing to the presence of β-lactamases in *B. anthracis* isolates, and the poor penetration of β-lactams into macrophages, the site of spore germination (9). Combination intravenous antibiotic therapy with two or more antibiotics, begun early, such as with ciprofloxacin and one or more other antibiotics to which the organism is sensitive, appeared to improve survival during

the treatment of cases during the 2001 outbreak in the United States (58). Following that outbreak, the recommendation for initial treatment of inhalation anthrax is ciprofloxacin or doxycycline along with one or more agents to which the organism is normally susceptible (15).

B. cereus

There have been rather few studies of the antibiotic sensitivity of *B. cereus*, and most information has to be gleaned from the reports of individual cases or outbreaks. *B. cereus* and *B. thuringiensis* produce a broad-spectrum β-lactamase and are thus resistant to penicillin, ampicillin, and cephalosporins; they are also resistant to trimethoprim. An in vitro study of 54 isolates from blood cultures by disk diffusion assay found that all strains were susceptible to imipenem and vancomycin and that most were sensitive to chloramphenicol, ciprofloxacin, erythromycin, and gentamicin (but a small number of strains showed moderate or intermediate sensitivity), while 22 and 37% of strains showed only moderate or intermediate susceptibilities to clindamycin and tetracycline, respectively (109). Although strains are almost always susceptible to clindamycin, erythromycin, chloramphenicol, vancomycin, and the aminoglycosides and are usually sensitive to tetracycline and sulfonamides, there have been several reports of treatment failures with some of these drugs: a fulminant meningitis which did not respond to chloramphenicol (69); a fulminant infection in a neonate which was refractory to treatment that included vancomycin, gentamicin, imipenem, clindamycin, and ciprofloxacin (100); failure of vancomycin to eliminate the organism from cerebrospinal fluid in association with a fluid shunt infection (10); and persistent bacteremias with strains showing resistance to vancomycin in two hemodialysis patients (A. von Gottberg and W. van Nierop, personal communication). Oral ciprofloxacin has been used successfully in the treatment of *B. cereus* wound infections, bacteremia, and pulmonary infection. Clindamycin with gentamicin, given early, appears to be the best treatment for ophthalmic infections caused by *B. cereus,* and experiments with rabbits suggest that intravitreal corticosteroids and antibiotics may be effective in such cases.

Other Species

Information on treatment of infections with other species is sparse. Gentamicin was effective in treating a case of *B. licheniformis* ophthalmitis, and cephalosporin was effective against *B. licheniformis* bacteremia/septicemia. Resistance to macrolides appears to occur naturally in *B. licheniformis*. *B. subtilis* endocarditis in a drug abuser was successfully treated with cephalosporin, and gentamicin was successful against a *B. subtilis* septicemia. Penicillin, or its derivatives, or cephalosporins probably form the best first choices for treatment of infections attributed to other *Bacillus* species. In the study by Weber et al. (109), over 95% of isolates of *B. megaterium*, *B. pumilus*, *B. subtilis*, *B. circulans*, *B. amyloliquefaciens,* and *B. licheniformis*, along with strains of *B.* (now *Paenibacillus*) *polymyxa* and three unidentified strains from blood cultures, were susceptible to imipenem, ciprofloxacin, and vancomycin; between 75 and 90% were susceptible to penicillins, cephalosporins, and chloramphenicol. Isolates of "*B. polymyxa*" and *B. circulans* were more likely to be resistant to the penicillins and cephalosporins than strains of the other species—it is probable that some or all of the strains identified as *B. circulans* might now be accommodated in *Paenibacillus*, along with "*B. polymyxa.*" An infection of a human bite wound with an organism identified as *B. circulans* did not respond to treatment with amoxicillin and flucloxacillin but was resolved with clindamycin (43).

A strain of *B. circulans* showing vancomycin resistance has been isolated from an Italian clinical specimen (64). Vancomycin resistance has been reported for *Paenibacillus popilliae*, a biopesticide, and isolates of this species have been shown to carry genes resembling those responsible for high-level vancomycin resistance in enterococci (78). Of two South African vancomycin-resistant clinical isolates, one was identified as *P. thiaminolyticus* and the other was unidentified but considered to be related to *B. lentus;* the latter was isolated from a case of neonatal sepsis and has been shown to have inducible resistance to vancomycin and teicoplanin; this is in contrast to the *B. circulans* and *P. thiaminolyticus* isolates mentioned above, in which expression of resistance was found to be constitutive (von Gottberg and van Nierop, personal communication).

Listeria and *Erysipelothrix**

JACQUES BILLE

33

LISTERIA

Taxonomy

Listeria and *Brochothrix* form one of several sublines within the *Clostridium* subdivision. The *Listeria-Brochothrix* subline is approximately equidistant from the *Bacillus* and *Enterococcus-Carnobacterium* sublines. On the basis of 23S rRNA gene sequences, *Listeria* is most similar to *Bacillus* and *Staphylococcus*. Phylogenetically, *Listeria* is sufficiently remote from *Lactobacillus* to justify its exclusion from the family *Lactobacillaceae* and formation of a separate *Listeria-Brochothrix* family (20). The phylogenetic position of *Listeria* is consistent with the low G+C content of its DNA (36 to 42 mol%) (20, 49, 82).

Listeria monocytogenes is the type species and one of six species in the genus *Listeria*. The other species are *L. ivanovii*, *L. innocua*, *L. seeligeri*, *L. welshimeri*, and *L. grayi* (73). Two subspecies of *L. ivanovii* have been described: *L. ivanovii* subsp. *ivanovii* and *L. ivanovii* subsp. *londoniensis*. Based on the results of DNA-DNA hybridization, multilocus enzyme analysis, and 16S rRNA gene sequencing, the six species in the genus *Listeria* are divided into two lines of descent: (i) *L. monocytogenes* and its closely related species, namely, *L. innocua*, *L. ivanovii* (subspecies *ivanovii* and *londoniensis*), *L. welshimeri*, and *L. seeligeri*, and (ii) *L. grayi* (12, 13, 20, 71, 73, 74). Within the genus *Listeria*, only *L. monocytogenes* and *L. ivanovii* are considered to be pathogenic, as evidenced by their 50% lethal doses in mice and their ability to grow in mouse spleen and liver. *L. monocytogenes* is a human pathogen of high public health concern; *L. ivanovii* is primarily an animal pathogen.

Description of the Genus

Members of the genus *Listeria* are asporogenous, nonbranching, regular, short (0.5 to 2 by 0.4 to 0.5 μm), gram-positive rods that occur singly or in short chains. Filaments of 6 to 20 μm long may occur in older or rough cultures. The organisms are motile at 28°C by means of one to five peritrichous flagella but are much less motile at 37°C. Colonies are small (1 to 2 mm in diameter after 1 or 2 days of incubation at 37°C), smooth, and blue-gray on nutrient agar when examined with obliquely transmitted light. The optimum growth temperature is between 30 and 37°C, but growth occurs at 4°C within a few days. *Listeria* spp. are facultatively anaerobic. Catalase is produced except in a few strains (24), and the oxidase test is negative. Acid is produced from D-glucose and other sugars. The Voges-Proskauer and methyl red tests are positive. Esculin is hydrolyzed in a few hours. Urea and gelatin are not hydrolyzed. Neither indole nor H_2S is produced. The cell wall contains a directly cross-linked peptidoglycan based on *meso*-diaminopimelic acid, as well as lipoteichoic acid, but no mycolic acid; the major menaquinone contains seven isoprene units (MK-7). The two predominant cellular fatty acids are $C_{ai15:0}$ and $C_{ai17:0}$ (branched-chain type) (5).

Natural Habitats

Listeria species are widely distributed in the environment. They have been isolated from soil, decaying vegetable matter, silage, sewage, water, animal feed, fresh and frozen poultry, fresh and processed meats, raw milk, cheese, slaughterhouse waste, and asymptomatic human and animal carriers (26). *L. monocytogenes* has been isolated from numerous species of mammals, birds, fish, crustaceans, and insects (25). Nevertheless, the primary habitats of *L. monocytogenes* are considered to be the soil and decaying vegetable matter, in which it survives and grows saprophytically. Because of its widespread occurrence, *L. monocytogenes* has many opportunities to enter food production and processing environments and, because of its ability to grow at 4°C, to cause human disease in persons ingesting colonized food (25, 74).

Clinical Significance

In nonpregnant human adults, *L. monocytogenes* causes primarily meningitis, encephalitis, and/or septicemia (55, 80). Elderly patients or persons with predisposing conditions that lower cell-mediated immunity, such as transplants, lymphomas, and human immunodeficiency virus infection, are especially susceptible. On rare occasions, patients have no known predisposing conditions. The tropism of *L. monocytogenes* for the central nervous system leads to severe disease, often with high mortality (20 to 50%) or with neurologic sequelae among survivors (17). In pregnant women, *L. monocytogenes* often causes an influenza-like bacteremic illness that, if untreated, may lead to placentitis and/or amnionitis and infection of the fetus, resulting in abortion, stillbirth, or premature birth, because the pathogen is able to cross the placenta (46) Early diagnosis can be made in some

* This chapter contains information presented in chapter 33 by Jacques Bille, Jocelyne Rocourt, and Bala Swaminathan in the eighth edition of this Manual.

cases by detecting *L. monocytogenes* in maternal blood cultures; at birth, the diagnosis is made by detecting the organism in cerebrospinal fluid (CSF), blood, amniotic fluid, respiratory secretions, placental or cutaneous swabs, gastric aspirate, or meconium of the neonate. Direct microscopic visualization of gram-positive rods in these specimens may be invaluable in early diagnosis of the disease.

Focal infections rarely occur after an episode of bacteremia. However, primary cutaneous listeriosis with or without bacteremia has been reported among veterinarians and abattoir workers, who acquire the illness through contact with infected animal tissues (53). Endocarditis, arthritis, osteomyelitis, intraabdominal abscesses, endophthalmitis, and pleuropulmonary infections have been described infrequently (48).

The incubation period and infective dose have not been firmly established. Reported incubation times vary from a few days to 2 to 3 months. Gastrointestinal symptoms such as diarrhea have been observed in some individuals with systemic listeriosis. A transient healthy carrier state exists in 2 to 20% of animals and humans (25, 35). In the past decade, several outbreaks of febrile gastroenteritis caused by *L. monocytogenes* have been documented (38). Implicated foods were chocolate milk, rice salad, corn-and-tuna salad, cold smoked trout, corned beef and ham, delicatessen meat, and cheese. These gastroenteritis outbreaks differ from the invasive outbreaks in several respects. They affect persons with no known predisposing risk factors for listeriosis. Illness typically occurs 24 h after ingestion of a large inoculum of bacteria (1.9×10^5 to 1×10^9 CFU/g or ml) and usually lasts 2 days. Common symptoms include fever, watery diarrhea, nausea, headache, and pain in joints and muscles (63). Therefore, the possibility of infection with *L. monocytogenes* should be considered in investigations of gastroenteritis in which routine enteric pathogens have been ruled out. Cervicovaginal carriage in women (including pregnant ones) seems to be nonexistent.

Listeriosis is observed mainly in industrialized countries. It can occur sporadically or epidemically; in both cases, contaminated foods are the primary mode of transmission. A few limited, non-food-related nosocomial outbreaks, mainly in nurseries, have been described (51) due to cross-infection and on one occasion caused by contaminated mineral oil for bathing (79). The number of sporadic cases of listeriosis in countries that report the illness is typically in the range of 0.5 to 0.8 cases per 100,000 persons (75); during foodborne-disease outbreaks, the incidence may rise to 5 cases per 100,000 persons (8). Foods implicated as vehicles of infection are ready-to-eat food stored at refrigeration temperatures and able to sustain *Listeria* growth, including coleslaw (cabbage), soft cheeses, paté, poultry, turkey frankfurters, mushrooms, milk, pork tongue in jelly, and smoked fish. Large numbers of organisms ($>10^3$ CFU/g) were detected in foods quantitatively assayed for the organism (25).

Major progress has been made recently in the understanding of *Listeria* pathogenesis. After contaminated food has been ingested, the development of an invasive infection in some individuals depends on several factors: host susceptibility, gastric acidity, inoculum size, virulence factors of the organism, and the type of food. After penetrating the epithelial barrier of the intestinal tract, *L. monocytogenes* can grow within hepatic and splenic macrophages, due to a number of virulence factors (21), and then spread to the central nervous system or pregnant uterus, due to the interaction between internalin, a major *Listeria* virulence factor, and E-cadherin, a placental receptor (46). Immunity to listeriosis relies mainly on T-cell-mediated activation of macrophages by lymphokines; the role of humoral defenses is not fully understood (74).

Determination of Pathogenicity

Methods using laboratory animals for evaluation of the virulence potential of *Listeria* isolates are available but are not used routinely. Such tests include intraperitoneal inoculation of mice, inoculation of the chorioallantoic membranes of embryonated eggs, and inoculation of the conjunctivas of rabbits (Anton test). Also, cell culture cytotoxicity assays using the human intestinal epithelial cell line Caco-2 have been developed to determine the virulence potential of *Listeria* isolates in vitro (74). Although the results generally agree with those of animal tests, cytotoxicity assays do not provide as quantitative a measure of virulence (50% lethal dose) as the animal tests do. Also, some outbreak-associated *L. monocytogenes* isolates show very little cytotoxicity in the Caco-2 cell assays (66, 83).

Collection, Transportation, and Storage of Specimens

Laboratory Safety

The infectious dose for listeriosis has not been determined, and it may depend, in part, on the susceptibility of the host. Therefore, laboratorians working with *L. monocytogenes* should be made aware of this potential risk and advised to be particularly cautious when working with this organism. Because *L. monocytogenes* takes advantage of the localized immunosuppression at the maternal-fetal interface and attacks the fetus with devastating consequences (stillbirths and abortions) while causing only mild, flu-like symptoms in the mother, pregnant women should be particularly careful working in a laboratory where *L. monocytogenes* is propagated or handled (18).

Specimens

Clinical

L. monocytogenes is readily isolated from clinical specimens obtained from normally sterile sites (blood, CSF, amniotic fluid, placenta, or fetal tissue). These specimens should be immediately cultured at 35°C or stored at 4°C for up to 48 h. Stool specimens are more productive than rectal swabs when epidemiologic studies of carriage rates are undertaken. One gram of stool can be inoculated into 100 ml of a selective University of Vermont (UVM) enrichment broth or polymyxin-acriflavin-lithium chloride-ceftazidime esculin-mannitol (PALCAM) (87) (see chapter 21) and then shipped at room temperature by overnight mail. If this is not possible, stools should be shipped frozen on dry ice by overnight mail. Other nonsterile-site specimens may be stored at 4°C for 24 to 48 h. To avoid overgrowth of *L. monocytogenes* by contaminating microflora during longer periods of storage, freezing of specimens at −20°C is recommended. Routine stool cultures performed in clinical laboratories should not include *Listeria* detection.

Foods

Food samples must be collected aseptically in sterile containers. Whenever possible, foods packaged in original containers must be collected. Attempts should be made to collect at least 100 g of a sample. Samples may be placed in sterile bags and shipped on ice by overnight mail. Ice cream and other frozen products are best transported in the frozen state in the original container and must be thawed immediately before analysis. Although *L. monocytogenes* is relatively resistant to freezing, repeated freezing and thawing may adversely affect the viability of the bacteria.

Isolates

Cultures of *Listeria* spp. may be shipped to a distant laboratory on a non-glucose-containing agar slant (such as heart infusion agar or tryptic soy agar) packaged to conform with the requirements for interstate shipment of etiologic agents (e.g., U.S. Code of Federal Regulations, 42CFR, part 72).

Isolation Procedures

Culture

Clinical specimens from normally sterile sites can be plated directly onto tryptic soy agar containing 5% sheep, horse, or rabbit blood. Samples for blood culture can be inoculated into conventional blood culture broth. Clinical specimens obtained from nonsterile sites and foods and environmental specimens should be selectively enriched for *Listeria* spp. before being plated.

The U.S. Department of Agriculture method and The Netherlands Government Food Inspection Service method are used together at the Centers for Disease Control and Prevention to isolate *L. monocytogenes* from nonsterile-site clinical specimens and foods (37). Individually, the two methods are approximately 75% sensitive; in conjunction with each other, they are 90% sensitive. The U.S. Department of Agriculture method involves enrichment of the specimen in UVM primary selective enrichment broth (1 part sample plus 9 parts of broth) at 30°C. After 24 h, 0.1 ml of the enrichment culture is plated onto lithium chloride-phenylethanol-moxalactam (LPM) (47) agar and Oxford or modified Oxford agar (see chapter 21). Another 0.1 ml of the enrichment culture is added to 10 ml of UVM secondary selective enrichment broth, which is then incubated for an additional 24 h. The secondary enrichment culture is plated as described above. The plates are incubated at 35°C and examined after 24 and 48 h. All of the media named above are described in the compendium by Atlas and Parks (2) and in chapter 21 of this Manual.

The Netherlands Government Food Inspection Service method involves enrichment of the specimen in liquid PALCAM-egg yolk broth (see chapter 21) (87) at 30°C and plating of the enrichment culture onto PALCAM agar at 24 and 48 h. PALCAM agar is incubated at 30°C for 48 h under microaerobic conditions (5% oxygen, 7.5% carbon dioxide, 7.5% hydrogen, and 80% nitrogen).

LPM agar (47) was developed as a highly selective but nondifferential medium for the isolation of *Listeria* species. Colonies on LPM agar are examined under a stereozoom microscope (magnification, ×15 to ×25), with oblique lighting directed to the microscope stage by a concave mirror positioned at a 45° angle to the incident light (Henry illumination). *Listeria* colonies appear blue, and colonies of other bacteria appear yellowish or orange.

Oxford and PALCAM agars contain selective differential chemicals that eliminate the need for examination under oblique lighting (87). On Oxford and modified Oxford agars, *Listeria* colonies appear black, are 1 to 3 mm in diameter, and are surrounded by a black halo after 24 to 48 h of incubation at 37°C. Color formation is due to the hydrolysis of esculin by *Listeria* spp. and the formation of black iron-phenol compounds in the medium. On PALCAM agar, *Listeria* colonies appear gray-green, are approximately 2 mm in diameter, and have black sunken centers; esculin, ferric iron, D-mannitol, and phenol red contribute to this color formation. New chromogenic media improve the isolation of *L. monocytogenes* (6, 68). They rely on the production by *L. monocytogenes* —but not by other species of *Listeria*—of a phosphatidylinositol-specific phospholipase C which produces an opaque halo around the colonies. Several formulations are available: ALOAgar (Biolife, Milano, Italy) (89), BCM *L. monocytogenes* (Biosynth, Staad, Switzerland) (69), and CHROMagar (BD, Sparks, Md.) (28). To rule out *Listeria* gastroenteritis in an outbreak situation, at least one selective agar plate medium specific for *Listeria* spp. (Oxford or PALCAM) and/or for *L. monocytogenes* (ALOAgar or CHROMagar) should be added to conventional media used for bacterial stool culture.

Rapid Detection

Many rapid and/or automated methods have been developed to speed up the recovery and identification of *L. monocytogenes* from food. They rely on genus- or species-specific immunoassays, as well as on DNA or RNA (indicating cell viability) amplification methods (6). These kits are for use with food products only; they are not designed for the analysis of clinical specimens or for diagnosis and/or treatment.

L. monocytogenes DNA in CSF and tissue (fresh or in paraffin blocks) can be specifically detected by PCR-based tests (42, 79). The PCR assay is highly sensitive and specific and may be particularly useful when prior administration of antimicrobial agents compromises culture.

Identification

Genus Identification

A simplified identification is based on the following tests: Gram staining, observation of tumbling motility in a wet mount, and tests for a positive catalase reaction and esculin hydrolysis. Acid production from D-glucose and positive Voges-Proskauer and methyl red reactions are confirmatory test results.

Differentiation of the Genus *Listeria* from Other Genera

Because they share some characteristics, *Listeria* spp. and some other gram-positive bacteria may be confused. *Streptococcus* and *Enterococcus* spp. may be differentiated from *Listeria* spp. on the basis of Gram stain morphology, motility, and catalase activity. *Erysipelothrix* spp. differ from *Listeria* spp. in motility, catalase reaction, and ability to grow at 4°C (*Erysipelothrix* spp. do not grow at that temperature). Among background microflora of foods, *Lactobacillus* spp. are usually nonmotile and catalase negative, *Brochothrix* spp. are unable to grow at 37°C, and *Kurthia* spp. are strictly aerobic and esculin negative.

Species Identification

The scheme for identification of *Listeria* species is shown in Table 1. Identification of *Listeria* isolates to the species level is crucial, because all species can contaminate foods but only *L. monocytogenes* is of public health concern. Identification is based on a limited number of biochemical markers, among which hemolysis is essential to differentiating between *L. monocytogenes* and the most frequently isolated nonpathogenic *Listeria* species, *L. innocua*.

Hemolysis

Only three species, *L. monocytogenes*, *L. seeligeri,* and *L. ivanovii*, are hemolytic on sheep blood agar plates. Recent studies indicated hemolysin to be the major virulence factor of *L. monocytogenes;* however, hemolysis alone cannot be used as an indicator of the presence of a virulent species because *L. seeligeri* is hemolytic but nonpathogenic. *L. monocytogenes*

TABLE 1 Biochemical differentiation of species in the genus *Listeria*[a]

and *L. seeligeri* produce narrow zones of hemolysis that frequently do not extend much beyond the edges of the colonies, whereas *L. ivanovii* exhibits a wide zone of hemolysis (Fig. 1).

The CAMP (Christie, Atkins, Munch-Peterson) test uses a β-lysin-producing *Staphylococcus aureus* or *Rhodococcus equi* strain streaked in one direction on a sheep blood agar plate and test cultures of *Listeria* spp. streaked at right angles to (but not touching) the *S. aureus* and *R. equi* lines. According to *Bergey's Manual of Systematic Bacteriology* (82), hemolysis of *L. monocytogenes* and *L. seeligeri* is enhanced in the vicinity of the *S. aureus* streak, and *L. ivanovii* hemolysis is enhanced in the vicinity of *R. equi* (resulting in a shovel shape) (Fig. 2). However, because many investigators have reported observing a synergistic hemolysis reaction between *L. monocytogenes* and *R. equi,* this CAMP reaction must be interpreted with caution. A β-lysin disk (Remel, Lenexa,

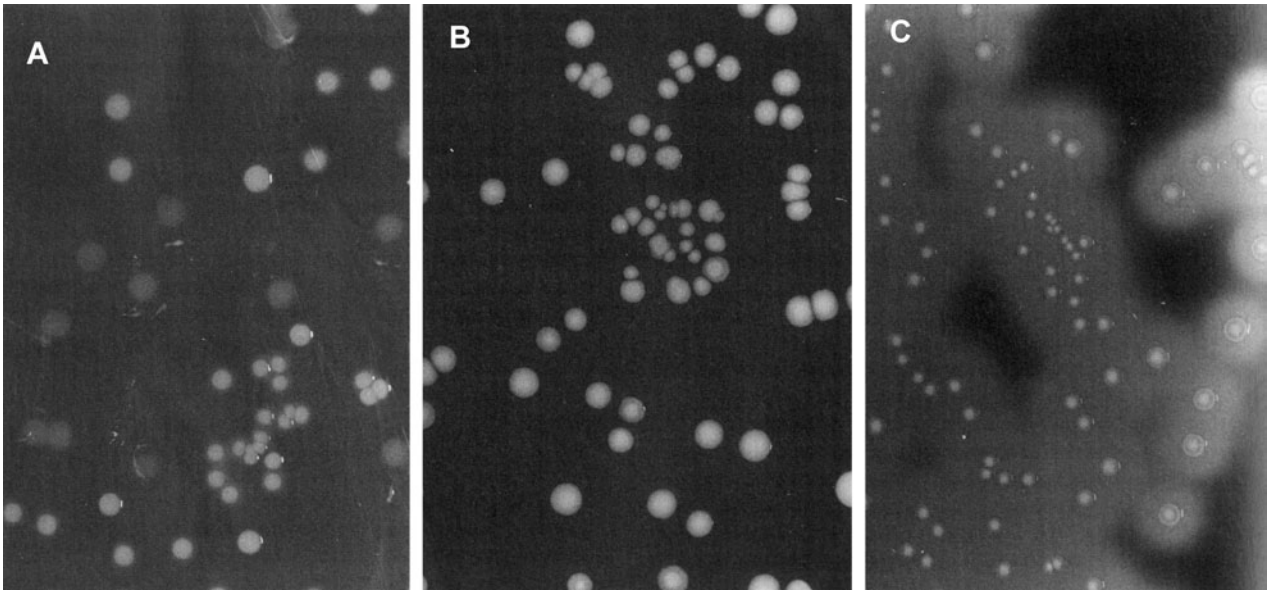

FIGURE 1 Macroscopic view of colonies on 5% human blood agar plates after 24 h of incubation. (A) *L. monocytogenes:* discrete zone of beta-hemolysis under the removed colonies. (B) *L. innocua*: no hemolysis. (C) *L. ivanovii:* wide zone of beta-hemolysis around the colonies.

Kans.) may be used to observe enhancement of *L. monocytogenes* with β-lysin from *S. aureus*.

Acid Production from Carbohydrates

L. monocytogenes is always D-xylose negative and α-methyl-D-mannoside positive. Rare atypical strains may be L-rhamnose negative. Test tubes are incubated for 7 days at 37°C in an aerobic incubator.

Miniaturized Biochemical Tests

The API-Listeria test (bioMérieux Vitek, Inc., Hazelwood, Mo.) was specifically designed for *Listeria* and includes 10 biochemical differentiation tests in a microtube format. It includes a patented DIM test, based on the absence or presence of arylamidase, which distinguishes between *L. monocytogenes* (negative) and *L. innocua* (positive) without further tests for hemolytic activity (9). The API Coryne System (bioMérieux) correctly identifies *Listeria* isolates to the genus level (29).

Automated Identification Systems

Both Vitek 2 (bioMérieux) and Phoenix (BD) automated systems have *Listeria* spp. on the list of organisms for their gram-positive identification cards; Vitek 2 (with the new colorimetric gram-positive card) but not Phoenix is able to differentiate *Listeria* colonies to the species level. No independent evaluation is currently available on their performance in identifying *Listeria* spp. at the species or genus level.

DNA Probe Assay for Colony Confirmation

A 30-min chemiluminescence DNA probe assay is available (Gen-Probe, San Diego, Calif.) for the rapid confirmation of *L. monocytogenes* from colonies on primary isolation plates. This assay was highly specific for *L. monocytogenes* in two independent evaluations (56, 62).

Typing Systems

Serotyping

Strains of *Listeria* species are divided into serotypes on the basis of somatic ("O") and flagellar (H) antigens (81). Thirteen serotypes (1/2a, 1/2b, 1/2c, 3a, 3b, 3c, 4a, 4ab, 4b, 4c, 4d, 4e, and 7) of *L. monocytogenes* are known; 4bX, a variant of serotype 4b, was implicated in a listeriosis outbreak traced to contaminated paté in England (52). Serotyping antigens are shared among *L. monocytogenes*, *L. innocua*, *L. seeligeri*, and *L. welshimeri*. Most human disease is caused by serotypes 1/2a, 1/2b, and 4b; therefore, serotyping alone is not sufficiently discriminating for subtyping purposes. Nevertheless, serotyping is useful as a first-level discriminator. Also, unlike those of other subtyping methods, serotype designations are universal. Determination of the serotype also facilitates selection of appropriate controls for molecular subtyping methods. A commercial kit (Denka Seiken, Tokyo, Japan) which relies on the slide agglutination method (78) has been adapted to an enzyme-linked immunosorbent assay format (64). Recently, a multiplex PCR assay has been designed to separate the four major *L. monocytogenes* serovars (1/2a, 1/2b, 1/2c, and 4b) into distinct groups (23).

Phage Typing

Because of the poor discriminating ability of serotyping, phage typing was the only means of distinguishing strains of the same serotype before the introduction of molecular methods (72) which have largely replaced it today. In addition, phage typing is hampered by the nontypeability of some strains.

MLEE

Multilocus enzyme electrophoresis (MLEE) has been extremely useful for taxonomic studies and for characterization of the evolution of strains within the species (7, 11, 12, 65, 79); however, it does not have adequate discriminatory power for use as the sole subtyping method for epidemiologic investigations.

DNA Microrestriction Pattern Analysis

Characterization of chromosomal DNA by restriction endonuclease analysis or ribosomal DNA gene restriction

patterns (ribotyping) has been used to differentiate *L. monocytogenes* strains of different serotypes and those within a given serotype, in particular serotype 4b, which is most frequently involved in outbreaks. Microrestriction patterns generated by high-frequency-cutting restriction enzymes (e.g., EcoR1) have proved useful in epidemiologic investigations (3, 57), although the complexity of patterns makes it difficult to compare the patterns of several strains. Ribotyping simplifies the microrestriction patterns by rendering visible only the DNA fragments containing part or all of the ribosomal genes, but its discriminating ability, particularly for serotype 4b, may not be adequate (3, 33, 40, 41, 58). A completely automated RiboPrinter system (Qualicon, Wilmington, Del.) facilitates rapid and easy subtyping of *L. monocytogenes* within 8 h. Although ribotyping alone does not have adequate discriminating power for epidemiologic investigations of outbreaks, the automated RiboPrinter is invaluable for preliminary recognition of disease clusters and for identification of transient and long-term-resident strains of *L. monocytogenes* in food processing plants and their environments (22, 59).

DNA Macrorestriction PFGE Pattern Analysis

Brosch et al. (16) evaluated the pulsed-field gel eletrophoresis (PFGE) method for the World Health Organization multicenter international typing study of *L. monocytogenes*. Four laboratories participated in using PFGE to analyze 80 coded strains. Two restriction endonucleases (ApaI and SmaI) were used by all laboratories; one laboratory used an additional restriction endonuclease (AscI). Agreement of typing data among the four laboratories ranged from 79 to 90%. Sixty-nine percent of the strains were placed in exactly the same genomic groups by all four laboratories; most of the epidemiologically related strains were correctly identified by all four laboratories. This study validated the previous claims that PFGE is a highly discriminating and reproducible method for subtyping *L. monocytogenes* and is particularly useful for subtyping serotype 4b isolates, which are not typed satisfactorily by most other typing methods.

In the United States, the Centers for Disease Control and Prevention has established a network (PulseNet) of public health and food regulatory laboratories that routinely subtype foodborne pathogenic bacteria to rapidly detect foodborne disease clusters that may have a common source. PulseNet laboratories use highly standardized protocols for subtyping of bacteria by PFGE and are able to quickly compare PFGE patterns of foodborne pathogens from different locations within the country via the Internet (84) (PFGE@cdc.gov). A 1-day standardized protocol for PFGE subtyping of *L. monocytogenes* was added to PulseNet in 1998 (34). Routine and timely subtyping of *L. monocytogenes* by participating PulseNet laboratories has significantly enhanced the ability to recognize and investigate outbreaks. For several years now, PFGE has been the standard subtyping method to detect listeriosis outbreaks.

RAPD

Random amplification of polymorphic DNA (RAPD) analysis is a rapid and relatively simple technique for epidemiological typing of *L. monocytogenes* isolates by using several short (10-mer) primers (14, 91). Despite its simplicity and high discriminating ability, RAPD suffers from inconsistent reproducibility of patterns.

MLST

Multilocus sequence typing (MLST) is currently being established for *L. monocytogenes* typing. It is based on the comparative sequencing of housekeeping genes or genes coding for virulence factors. The discriminatory power of MLST is very high, and sequence data comparisons are easily done (70, 76, 93).

Present Status of Subtyping

The vast majority of *L. monocytogenes* strains causing sporadic infections or outbreaks belong to serotypes 1/2a, 1/2b, and 4b. Strains of serotype 1/2a are highly heterogeneous and thus are easily differentiated by any of the molecular methods. In contrast, strains of serotype 4b are more closely related and probably necessitate the combined use of several methods to be optimally differentiated (10). PFGE is considered to be the most effective typing method; it is time and cost efficient and highly discriminative (30).

Serodiagnosis

Serologic responses to whole-cell antigens cannot be used for diagnosis because of antigenic cross-reactivity between *L. monocytogenes* and other gram-positive bacteria such as staphylococci, enterococci, and *Bacillus* species. Furthermore, patients with culture-confirmed listeriosis have had undetectable antibody levels (79). Determination of levels of antibody to listeriolysin O may be of value both for invasive listeriosis and for febrile gastroenteritis (4). Although a serologic method based on the detection of antibodies against recombinant truncated forms of listeriolysin O may be more specific (31), serological tests are not recommended at the present time.

Antimicrobial Susceptibilities

The pattern of antimicrobial susceptibility and resistance of *L. monocytogenes* has been relatively stable for many years (86). In vitro, the organism is susceptible to penicillin, ampicillin, gentamicin, erythromycin, tetracycline, rifampin, and chloramphenicol (77, 92) but only moderately susceptible to quinolones (39). However, many of these antimicrobial agents are only bacteriostatic. Penicillin or ampicillin with or without an aminoglycoside is usually recommended for the treatment of listeriosis. Studies in vitro and in animal models have shown that an aminoglycoside enhances the activity of penicillin against *L. monocytogenes* (54). Trimethoprim-sulfamethoxazole and aminoglycosides are among the few anti-infective agents that are bactericidal to *L. monocytogenes;* only trimethoprim-sulfamethoxazole has been used occasionally with success. Resistance plasmids conferring resistance to chloramphenicol, macrolides, and tetracyclines have been found in several clinical isolates of *L. monocytogenes* and have raised concern for the future (36). *L. monocytogenes* appears to be susceptible in vitro to newly released antibiotics such as linezolid, daptomycin, and tigecyclin, but few strains have been tested. Cephalosporins are ineffective in vivo, although in vitro tests may indicate susceptibility, and should never be administered when listeriosis is suspected.

Evalutation, Interpretation, and Reporting of Results

Colonies from blood, CSF, or other normally sterile-site specimens that show subdued beta-hemolysis on blood agar should be subjected to motility tests, Gram staining, catalase testing, and esculin hydrolysis to confirm identification. They may resemble group B streptococcal colonies on blood agar plates. The CAMP test is not necessary on a routine basis, and the β-lysin test may be substituted for it. Use of the API-Listeria test may eliminate the need for enhanced hemolysis testing altogether. If *L. monocytogenes* is present in low numbers in

CSF, the direct examination of Gram-stained clinical specimens may be of little or no value. Also, Gram-stained *Listeria* cells closely resemble other gram-positive bacteria, such as streptococci, enterococci, and corynebacteria. If antimicrobial therapy was initiated before a CSF specimen was obtained, culture results may be negative. In these instances, Gram staining may be useful, as well as molecular detection of DNA by PCR. Although numerous PCR-based detection methods have been developed and tested with food products, a very limited number of applications to clinical samples have been described, using either a single PCR or multiplex PCR (30).

ERYSIPELOTHRIX

Taxonomy

Included at one time in the coryneform group, *Erysipelothrix* is now classified with the regular non-spore-forming gram-positive rods, a group that comprises the genera *Listeria* and *Lactobacillus*. The genus *Erysipelothrix* has two validated species, *E. rhusiopathiae* and *E. tonsillarum* (85). A third species, *E. inopinata*, has been recently proposed (88). *E. rhusiopathiae*, which is widely distributed in nature and can be carried by a variety of animals, has been recognized for more than 100 years as the agent of swine erysipelas and occasionally causes erysipeloid, a human cutaneous infection usually localized to the hands and fingers (67).

Description of the Genus

Erysipelothrix organisms are mesophilic, facultatively anaerobic, non-spore-forming, non-acid-fast, gram-positive bacteria that appear microscopically as short rods (0.2 to 0.5 μm by 0.8 to 2.5 μm) with rounded ends and occur singly, in short chains, or in long, nonbranching filaments (60 μm or more in length). They are nonmotile and grow in complex media at a wide range of temperatures (5 to 42°C; optimum, 30 to 37°C) and at alkaline pHs (pH 6.7 to 9.2; optimum, pH 7.2 to 7.6). Like *Listeria* organisms, they can grow in the presence of high concentrations of sodium chloride (up to 8.5%). Metabolically, *Erysipelothrix* organisms are catalase negative and oxidase negative, do not hydrolyze esculin, and weakly ferment glucose without the production of gas. They are methyl red and Voges-Proskauer negative and do not produce indole or hydrolyze urea but distinctively produce H_2S in triple sugar iron agar. Key fatty acids are $C_{16:0}$ and $C_{18:cis9}$ (5).

Natural Habitats

E. rhusiopathiae is widespread in nature and is remarkably persistent under environmental conditions such as low temperature and alkaline pH and within organic matter favoring survival. The organism is parasitic on mammals, birds, and fish but is most frequently associated with pigs. Contamination of water and soil from the feces and urine of sick and asymptomatic animals often occurs.

E. tonsillarum has been recovered from water and from the tonsils of healthy swine.

Clinical Significance

Infection with *E. rhusiopathiae* is a zoonosis. Many animal species, especially turkeys and swine, carry the organism in their digestive tracts or tonsils. *E. rhusiopathiae* causes chronic or acute swine erysipelas. Erysipelas can present in several clinical manifestations: skin infection, arthritis, septicemia, and endocarditis. Other domestic and wild animals and birds also can be affected, in particular sheep, rabbits, cattle, and turkeys. Infection is most likely acquired by ingestion of contaminated matter (67).

In humans, *E. rhusiopathiae* causes mostly erysipeloid, a localized cellulitis developing within 2 to 7 days around the inoculation site. The disease is contracted through skin abrasion, injury, or a bite on the hands or arms of individuals handling animals or animal products. Erysipeloid is an occupational disease, occurring most frequently among veterinarians, butchers, and particularly fish handlers. The lesion usually is violaceous and painful, indurated with edema and inflammation but without suppuration, and clearly delineated at the border. Regional lymphangitis may be present, as well as an adjacent arthritis. Dissemination and endocarditis can occur, especially in immunocompromised patients; their prognosis is generally poor (32). Healing of erysipeloids usually takes 2 to 4 weeks, sometimes months, and relapses are common. No apparent immunity develops after an episode of erysipeloid.

E. tonsillarum has not yet been recovered from humans.

Collection, Transport, and Storage of Specimens

Biopsy specimens from erysipeloid lesions are the best source of *E. rhusiopathiae*. Care should be taken to cleanse and disinfect the skin before sampling. The organisms typically are located deep in the subcutaneous layer of the leading edge of the lesion; hence, a biopsy of the entire thickness of the dermis at the periphery of the lesion should be taken for Gram staining and culture. Swabs from the surface of the skin are not useful. In disseminated disease, the organism can be cultured from blood without special procedures.

Isolation Procedures

Microscopic Examination

Generally, direct examination of Gram-stained biopsy specimens is of little value. However, the presence of long, slender, gram-positive rods in tissue from an individual with a consonant history is suggestive of erysipeloid.

Culture

Biopsy specimens should be plated onto blood agar or chocolate blood agar, placed in tryptic soy or Schaedler broth, and incubated at 35°C aerobically or in 5% CO_2 for 7 days. Blood from patients with septicemia or endocarditis can be plated directly onto blood agar plates for primary isolation or inoculated into commercial blood culture systems. *E. rhusiopathiae* colonies generally develop in 1 to 3 days, appearing as pinpoints (<0.1 to 0.5 mm in diameter) on blood agar plates after 24 h of incubation; at 48 h, two distinct colony types can be observed. The smaller, smooth colonies are 0.3 to 1.5 mm in diameter, transparent, convex, and circular with entire edges. Larger, rough colonies are flatter and more opaque and have a matte surface and an irregular, fimbriated edge. A zone of greenish discoloration frequently develops underneath the colonies on blood agar plates after 2 days of incubation (43).

Rapid Detection

PCR initially developed for rapid diagnosis in swine (50) has been used with human samples (15). The target is the 16S rRNA or the 23S rRNA gene.

Identification

Gram Staining of Colonies from a 24-h Blood Agar Plate

Cells stain gram positive but can decolorize and appear gram negative, with gram-positive granules giving a beaded effect. Cells from smooth colonies appear as rods or coccobacilli,

sometimes in short chains. Cells from rough colonies appear as long filaments, often more than 60 μm.

Biochemical Identification of *E. rhusiopathiae*

E. rhusiopathiae is catalase negative; glucose, lactose, and H_2S positive; and nitrate, urease, esculin, gelatin, xylose, mannose, maltose, and sucrose negative. *E. tonsillarum* differs biochemically from *E. rhusiopathiae* by being sucrose positive. Vitek automated systems, as well as API Coryne, usually identify *E. rhusiopathiae* correctly.

Differentiation of *Erysipelothix* from Related Genera

Genera that have morphological and physiological characteristics in common with *Erysipelothrix* include *Lactobacillus*, *Listeria*, *Brochothrix*, and *Kurthia*. All are regular nonpigmented, non-spore-forming, gram-positive rods (44). A major discriminatory characteristic is that *E. rhusiopathiae* produces H_2S in triple sugar iron whereas species of the other genera do not. Furthermore, *Listeria*, *Brochothrix*, and *Kurthia* species are catalase positive. In addition, *Listeria* isolates are motile, are esculin positive, and are not alpha-hemolytic. *Brochothrix* isolates strongly ferment carbohydrates, are Voges-Proskauer positive, and do not grow at above 30°C. *Kurthia* species are strict aerobes and are motile and nonhemolytic (45). Corynebacteria and streptococci also can be confused with *E. rhusiopathiae*, but careful examination of cell morphology should facilitate the distinction. The production of H_2S in triple sugar iron by a gram-positive bacterium is usually indicative of *E. rhusiopathiae* because very few gram-positive bacteria of clinical origin produce H_2S. Exceptions include some *Bacillus* strains, but they are easily differentiated from *E. rhusiopathiae* by cellular morphology, spore formation, and catalase reaction. An additional trait highly characteristic of *E. rhusiopathiae* is its "pipe cleaner" pattern of growth in gelatin stab cultures incubated at 22°C (43, 90).

Typing Systems

Twenty-two serovars of *E. rhusiopathiae* have been identified on the basis of heat-stable somatic antigens. Although most isolates are serovar 1 or 2, no serotyping schemes are available for routine use in clinical laboratories. Both MLEE and ribotyping methods have been applied to *Erysipelothrix* strains and have shown an enormous genetic diversity (1, 19, 61). PFGE with SmaI seems to be the best method for epidemiological studies of *E. rhusiopathiae* isolates (60). In these studies, serotyping was unreliable for use as an epidemiologic tool.

Pathogenicity Testing

Most strains of *E. rhusiopathiae* are virulent for mice in a mouse protection test (43).

Serological Tests

Since humans apparently do not develop immunity after an episode of erysipeloid, there are no serological tests for routine use to demonstrate antibodies to *E. rhusiopathiae*. Active immunization of animals with a live attenuated vaccine protects against erysipelas (67); however, a natural erysipeloid infection in humans does not prevent relapses or reinfection from occurring.

Antibiotic Susceptibility

E. rhusiopathiae isolates are generally susceptible to penicillin, cephalosporins, clindamycin, imipenem, tetracycline, chloramphenicol, erythromycin, and the fluoroquinolones; they are usually resistant to aminoglycosides, sulfonamides, and vancomycin (27). Penicillin is the treatment of choice for both localized and systemic infections (32).

Coryneform Gram-Positive Rods

GUIDO FUNKE AND KATHRYN A. BERNARD

34

This chapter deals with aerobically growing, asporogenous, irregularly shaped, non-partially acid-fast, gram-positive rods generally called "coryneforms." The term "coryneform" is actually somewhat misleading, since only true *Corynebacterium* spp. exhibit a typical club-shaped ("*coryne,*" meaning "club" in ancient Greek) morphology, whereas all the other bacteria discussed in this chapter show an irregular morphology. However, in our experience, the term "coryneforms" is a common and convenient expression used by many clinical microbiologists, and therefore, the term will be used in this chapter.

The coryneform bacteria which were, for didactical reasons, not included in this chapter comprise *Actinomyces* spp. (in particular, the most frequently encountered species on aerobic plates, *A. europaeus, A. neuii, A. radingae,* and *A. turicensis*), *Actinobaculum* spp., *Propionibacterium* spp., and *Propioniferax innocua* (see chapter 56), whereas *Arcanobacterium* spp. are included. *Gardnerella vaginalis* is included in this chapter but is discussed separately. Regularly shaped aerobically growing gram-positive rods (*Bacillus, Listeria* and *Erysipelothrix, Lactobacillus,* and *Clostridium tertium)* are covered in chapters 32, 33, 56, and 57, respectively. Taxa which might be initially misidentified as coryneform bacteria also include partially acid-fast bacteria and other actinomycetes (see chapter 35) as well as rapidly growing mycobacteria (see chapter 38).

GENERAL TAXONOMY

The bacteria discussed in this chapter all belong to the class *Actinobacteria*, the genera of which are characterized by specific 16S rRNA gene signature nucleotides (134). All the genera described in this chapter except *Exiguobacterium* and *Gardnerella* belong to the lineage of the gram-positive bacteria with high guanine-plus-cytosine (G+C) content. The coryneform bacteria are most diverse and are differentiated by chemotaxonomic features (Table 1). Phylogenetic investigations, in particular 16S rRNA gene sequencing, have, in general, confirmed the framework set by chemotaxonomic investigations. The 16S rRNA gene sequencing data demonstrate that the genera *Corynebacterium* and *Turicella* are more closely related to the partially acid-fast bacteria and to the genus *Mycobacterium* than to the other coryneform organisms covered in this chapter (62, 104, 123). The genus *Arthrobacter*, which contains rods, is phylogenetically intermixed with the genus *Micrococcus* (and genera formerly called *Micrococcus*), which contains cocci (44, 79). The genus *Rothia* contains both rod-forming organisms, represented by *Rothia dentocariosa*, and a coccus-forming species, *Rothia mucilaginosa,* the former *Stomatococcus mucilaginosus* (19). Other genera which are phylogenetically closely related include *Oerskovia, Cellulosimicrobium,* and *Cellulomonas* (8, 55, 125, 133), as well as *Arcanobacterium* and *Actinomyces* (105).

DESCRIPTIONS OF THE GENERA

Genus *Corynebacterium*

The genus *Corynebacterium* is presently composed of 67 species (and two taxon groups), 40 (and the two taxon groups) of which are medically relevant. Five of the *Corynebacterium* species have been defined since the last edition of this Manual (Table 2).

The cell wall of corynebacteria contains *meso*-diaminopimelic acid (*m*-DAP) as the diamino acid as well as short-chain mycolic acids with 22 to 36 carbon atoms (17). *C. amycolatum, C. atypicum,* and *C. kroppenstedtii* are the only genuine *Corynebacterium* species which do not possess mycolic acids (16, 18, 69). The corynebacterial cell wall also contains arabinose and galactose (17). Palmitic ($C_{16:0}$), oleic ($C_{18:1\omega9c}$), and stearic ($C_{18:0}$) acids are the main cellular fatty acids (CFAs) in all corynebacteria, and tuberculostearic acid (TBSA) can also be found in some species like *C. urealyticum, C. confusum,* and *C. appendicis* (3, 52, 151). The G+C content of *Corynebacterium* spp. varies from 46 to 74 mol%, indicating the enormous diversity within this genus. The phylogenetic relationships within the genus *Corynebacterium* have been outlined (104, 123), creating an extensive and reliable database for future comparative 16S rRNA gene studies, e.g., for the delineation of new species.

Gram staining of corynebacteria shows slightly curved, gram-positive rods with sides not parallel and sometimes slightly wider ends, giving some of the bacteria a typical club shape (Fig. 1a). Corynebacteria whose morphologies differ from this morphology include *C. durum, C. matruchotii,* and *C. sundsvallense* (see below under each species). Cells infrequently stain unevenly. If *Corynebacterium* cells are taken from fluid media, they are arranged as single cells, in pairs, in V forms, in palisades, or in clusters with a so-called Chinese letter appearance. It is again emphasized that the club-shaped form of the rods is observed only for true

TABLE 1 Some chemotaxonomic features of the bacteria covered in this chapter

Genus	Major CFAs	Mycolic acids	Peptidoglycan diamino acid[a]	Acyl type
Corynebacterium	18:1ω9*c*, 16:0, 18:0	+[b]	*m*-DAP	Acetyl
Turicella	18:1ω9*c*, 16:0, 18:0	−	*m*-DAP	Glycolyl
Arthrobacter	15:0*ai*, 17:0*ai*, 15:0*i*	−	LYS	Acetyl
Brevibacterium	15:0*ai*, 17:0*ai*, 15:0*i*	−	*m*-DAP	Acetyl
Dermabacter	17:0*ai*, 15:0*ai*, 16:0*i*	−	*m*-DAP	ND[c]
Rothia	15:0*ai*, 17:0*ai*, 16:0*i*	−	LYS	ND
Exiguobacterium	17:0*ai*, 15:0*ai*, 16:0, 13:0*i*	−	LYS	ND
Oerskovia	15:0*ai*, 15:0*i*, 17:0*ai*	−	LYS	Acetyl
Cellulomonas	15:0*ai*, 16:0, 17:0*ai*	−	ORN	Acetyl
Cellulosimicrobium	15:0*ai*, 15:0*i*, 17:0*ai*	−	LYS	Acetyl
Microbacterium	15:0*ai*, 17:0*ai*, 16:0*i*	−	LYS, ORN	Glycolyl
Curtobacterium	15:0*ai*, 17:0*ai*, 16:0*i*	−	ORN	Acetyl
Leifsonia	17:0*ai*, 15:0*ai*, 16:0*i*	−	DAB	ND
Janibacter	17:1, 16:0*i*, 17:0	−	*m*-DAP	Acetyl
Pseudoclavibacter	15:0*ai*, 17:0*ai*, 16:0*i*, 16:0	−	DAB	Acetyl
Brachybacterium	15:0*ai*, 16:0*i*, 17:0*ai*	−	*m*-DAP	Acetyl
Knoellia	17:1*i*, 15:0*i*, 16:0*i*, 17:0*i*	−	*m*-DAP	Acetyl
Arcanobacterium	18:1ω9*c*, 16:0, 18:0	−	LYS	ND
Gardnerella	16:0, 18:1ω9*c*, 14:0	−	LYS	ND

[a] *m*-DAP, *meso*-diaminopimelic acid; LYS, lysine; ORN, ornithine; DAB, diaminobutyric acid.
[b] Exceptions: *C. amycolatum*, *C. atypicum*, and *C. kroppenstedtii*.
[c] ND, no data.

Corynebacterium spp. Corynebacteria are always catalase positive, and the medically relevant species are all nonmotile. The genus *Corynebacterium* includes both fermenting and nonfermenting species.

Genus *Turicella*

The genus *Turicella* is phylogenetically closely related to *Corynebacterium* but contains *T. otitidis* as the only species. The cell wall contains *m*-DAP, but mycolic acids are not present (62). The main CFAs for *T. otitidis* are the same as those for *Corynebacterium* spp., but all *T. otitidis* strains also contain significant amounts of TBSA (2 to 10% of all CFAs) (62). *T. otitidis* is the only coryneform bacterium that has a polar lipid profile without glycolipids. The G+C content varies between 65 and 72 mol% (62).

Gram staining shows relatively long gram-positive rods (Fig. 1b). *T. otitidis* is catalase positive, nonmotile, and an oxidizer.

Genus *Arthrobacter*

The genera *Arthrobacter* and *Micrococcus* are so closely related phylogenetically that it has been stated that micrococci are, in fact, arthrobacters which are unable to express rod forms (79). Presently, the genus *Arthrobacter* contains over 50 species, of which only a few have been recovered from human clinical specimens. Lysine is the diamino acid of the cell wall, and $C_{15:0ai}$ is the overall dominating CFA, which represents more than 50% of all CFAs in most *Arthrobacter* species. The G+C content varies between 59 and 70 mol%, indicating the diversity within this genus.

Gram staining may demonstrate a rod-coccus cycle (i.e., rod forms in younger cultures and cocci in older colonies) when cells are grown on rich media (e.g., Columbia base agar). Jointed rods (i.e., rods in a rectangular form, which contributed to the designation of this genus, as "*arthros*" means "joint" in ancient Greek) may also be observed in younger cultures (i.e., after 24 h) but may not be demonstrable for every species. Arthrobacters are catalase positive, motility is variable, and they are always oxidizers.

Genus *Brevibacterium*

The genus *Brevibacterium* presently comprises 17 species, of which 7 species are medically relevant. *m*-DAP is the

TABLE 2 Chronology of recently proposed or reclassified medically relevant coryneform bacteria since publication of the previous edition of this Manual

Yr of definition	Taxon (reference[s])
2002	*Corynebacterium appendicis* (151)
2003	*Brevibacterium luteolum*[a] (146), *Corynebacterium atypicum* (69), *Microbacterium paraoxydans* (82)
2004	*Pseudoclavibacter/Zimmermannella* (87, 90), black-pigmented CDC fermentative group 4 bacteria as *Corynebacterium aurimucosum* and *Rothia dentocariosa* (21), *Corynebacterium tuberculostearicum* (35), *Brevibacterium sanguinis* (147)
2005	*Curtobacterium* spp. (38), *Arthrobacter scleromae* (75), *Janibacter* spp. (31, 88), *Brachybacterium* spp. (K. A. Bernard, unpublished observation), *Knoellia* sp. (K. A. Bernard, unpublished observation), *Corynebacterium resistens* (103), *Cellulomonas denverensis* (7)
2006	*Corynebacterium tuscaniae* (114), *Cellulosimicrobium funkei* (8)

[a] This species had originally been designated *Brevibacterium lutescens*.

diamino acid of the cell wall. $C_{15:0ai}$ and $C_{17:0ai}$ usually represent more than 75% of all CFAs (40). The G+C content varies between 60 and 70 mol%.

Gram staining demonstrates relatively short rods which may develop into cocci when cultures are getting older (after 3 days). Brevibacteria are catalase positive, nonmotile, and oxidizers.

Genus *Dermabacter*

The genus *Dermabacter* presently comprises only one species, *D. hominis*. *m*-DAP is the diamino acid of the cell wall, and $C_{15:0ai}$ and $C_{17:0ai}$ usually account for 40 to 60% of all CFAs. The G+C content range is between 60 and 62 mol% (76).

Gram staining shows very short rods (Fig. 1c), which are often initially misinterpreted as cocci. *D. hominis* strains are catalase positive, nonmotile, and glucose fermenters.

Genus *Rothia*

For didactical reasons, the genus *Rothia* is also included in this chapter because some species are rod-like. The genus *Rothia* belongs to the family *Micrococcaceae*. Collins and colleagues reclassified *Stomatococcus mucilaginosus* as *Rothia mucilaginosa* (19). Since *Rothia mucilaginosa* exhibits coccoid forms in the Gram stain, the genus *Rothia* is also covered in chapter 31 (on the catalase-positive, gram-positive cocci). However, the species *R. dentocariosa* clearly exhibits mainly rod forms and is therefore covered in this chapter on coryneform bacteria.

Lysine is the diamino acid of the cell wall, and $C_{15:0ai}$ and $C_{17:0ai}$ usually represent 40 to 60% of all CFAs. The G+C content ranges between 47 and 56 mol%. *Rothia* strains can be quite pleomorphic by Gram staining, but filamentous forms are normally not observed. They have a variable catalase reaction, are nonmotile, and exhibit a fermentative metabolism.

Genus *Exiguobacterium*

The genus *Exiguobacterium* is phylogenetically related to the so-called group 2 bacilli. Seven species are included in this genus, of which only *E. acetylicum* has been mentioned in any publication as being isolated from human clinical material. Lysine is the diamino acid of the cell wall, and $C_{15:0ai}$ and $C_{17:0ai}$ represent only about 30 to 40% of the total CFAs. *E. acetylicum* contains significant amounts of $C_{13:0}$ and $C_{13:0ai}$, which are not found in any other coryneform taxon (3). The G+C content is about 47 mol%.

Exiguobacteria present as relatively short rods in young cultures. Strains are catalase positive and motile and have a fermentative metabolism.

Genus *Oerskovia*

In older textbooks, oerskoviae were assigned to the nocardioform group of organisms due to their morphological features. This includes branching vegetative substrate hyphae and penetration into agar, but they have no aerial hyphae. However, there is now phylogenetic evidence that *Oerskovia*, including the reclassified *Promicromonospora* (133), is more closely related to genera like *Cellulomonas* than to the mycolic acid-containing genera like *Nocardia*. Representatives of the type species, *O. turbata*, were recovered from soil, but human pathogens originally identified as *O. turbata* have now been placed in *Cellulosimicrobium funkei* (8). Lysine is the diamino acid of the cell wall, and $C_{15:0ai}$ is the main CFA in oerskoviae. The G+C content is 70 to 75 mol%.

Gram staining shows coccoid to rod-shaped bacteria which originate from the breaking up of mycelia. Oerskoviae strains are catalase positive, motility is variable, and they are fermentative.

Genus *Cellulomonas*

The genus *Cellulomonas* presently comprises 13 species, of which only *C. hominis* and *C. denverensis* have been described as being isolated from humans (7, 55). Ornithine is the diamino acid of the cell wall, and $C_{15:0ai}$ and $C_{16:0}$ are the main CFAs. The G+C content is 71 to 76 mol%.

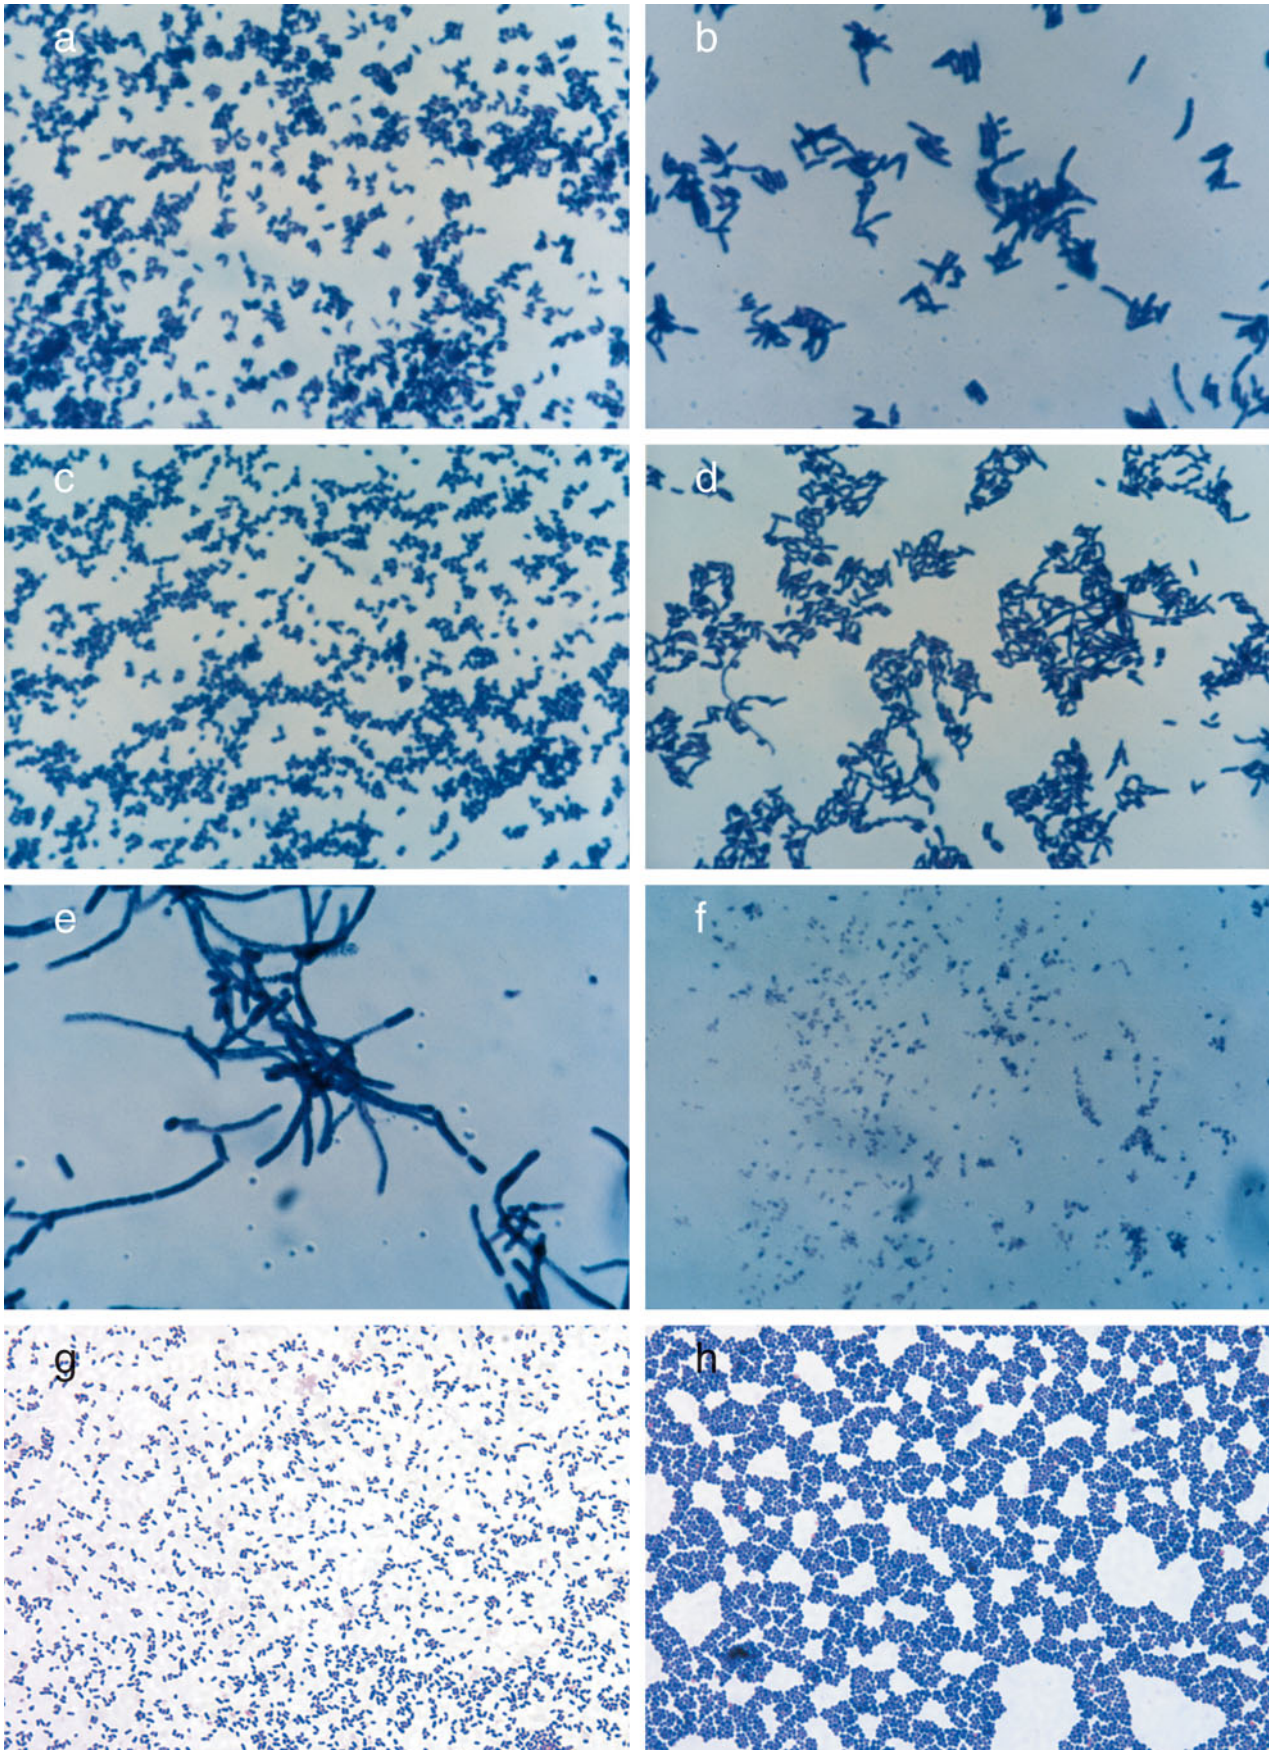
Gram staining shows small, thin rods. All *Cellulomonas* spp., except *C. fermentans* and *C. humilata,* are catalase positive, their motility is variable, the environmental *Cellulomonas* strains are cellulolytic (whereas *C. hominis* did not hydrolyze cellulose in the test system used [55]), and they have a fermentative metabolism.

Genus *Cellulosimicrobium*

The genus *Cellulosimicrobium* presently comprises three species. The medically relevant species are *C. funkei* and *C. cellulans*, which had been designated *Cellulomonas cellulans* or *Oerskovia xanthineolytica* in the past (125). The reason for removing *C. cellulans* from the genus *Cellulomonas* was that the topology of the 16S rRNA gene dendrogram indicated that the branching point of this taxon was outside *Cellulomonas* proper. In addition, the chemotaxonomic characteristic of lysine as diamino acid supported the reclassification. Predominant CFAs include $C_{15:0ai}$, $C_{15:0i}$, $C_{16:0i}$, and $C_{16:0}$. The major menaquinone (MK) is MK-9(H_4), and the G+C content is 74 mol%. It should be noted that the genus *Cellulosimicrobium* is related to the genus *Oerskovia* but nevertheless distinct.

In young cultures, a mycelium is produced that fragments later into irregular, curved, and club-shaped rods. Catalase activity is detected, and strains are nonmotile. All strains have a fermentative metabolism.

Genus *Microbacterium*



It had been known since the mid-1990s that the genera *Microbacterium* and *Aureobacterium* are phylogenetically intermixed (109). The diamino acid in the third position of the tetrapeptide of the peptidoglycan was considered one of the most important chemotaxonomical markers. L-Lysine is present in microbacteria, and D-ornithine is present in the former aureobacteria. Because in some genera (e.g., *Propionibacterium* and *Bifidobacterium*) there is not a good correlation between the type of the diamino acid in their peptidoglycan and their phylogenetic trees and because a set of signature nucleotides within the 16S rRNA gene of both microbacteria and aureobacteria was demonstrated, it has been proposed to unify the two genera in a redefined genus, *Microbacterium* (135).

To date, over 35 *Microbacterium* species have been validated, but only a minority of them have been demonstrated to be of clinical importance. Microbacteria are frequently encountered in environmental specimens (e.g., soil). $C_{15:0ai}$ and $C_{17:0ai}$ are the two main CFAs, often representing up to 75% of the total CFAs (42, 65, 135). The G+C content of *Microbacterium* spp. is 65 to 76 mol%, indicating the diversity within the genus.

Gram staining often shows thin or short rods with no branching. Catalase activity and motility are variable. Microbacteria can be either fermenters or oxidizers.

Genus *Curtobacterium*

Curtobacterium spp., like microbacteria, belong to the peptidoglycan type B actinomycetes (i.e., cross-linkage between positions 2 and 4 of the two peptide subunits). Ornithine is the diamino acid and the only amino acid composing the interpeptide bridge. Curtobacteria have an acetyl peptidoglycan acyl-type and menaquinone MK-9 as major MK, whereas

a
b
c
d
e
f
g
h

microbacteria possess a glycolyl type and MK-11,12 (Table 1). For most curtobacteria, $C_{15:0ai}$ and $C_{17:0ai}$ represent more than 75% of all CFAs (38). The G+C contents range from 68 to 75 mol%. Six *Curtobacterium* species are validly described.

Gram staining shows small and short rods with no branching. Catalase activity is positive, motility is observed in most strains, and all strains show a respiratory metabolism which proceeds slowly in oxidizing carbohydrates.

Genus *Leifsonia*

The former "*Corynebacterium aquaticum*" has been transferred into the new genus *Leifsonia* as *L. aquatica* (34). This species is the only medically relevant species in this genus. *L. aquatica* strains belong to the peptidoglycan B type actinomycetes and therefore cannot be true corynebacteria, which actually possess an A type of peptidoglycan (i.e., cross-linkage between positions 3 and 4 of the two peptide subunits). Diaminobutyric acid is the diamino acid of the cell wall peptidoglycan, and $C_{15:0ai}$ and $C_{17:0ai}$, as in microbacteria, are the main CFAs but represent <75% of all CFAs (65). The G+C content is about 70 mol%.

Gram staining shows thin rods. The strains are catalase and oxidase positive (the latter is an untypical feature for coryneform bacteria), always motile, and oxidizers.

Genus *Janibacter* and Other Unusual Coryneforms

Recent examinations of coryneform bacteria by using primarily sequence-based identification approaches have shown that additional genera could be recovered from human clinical materials.

Genus *Janibacter*

Strains of the genus *Janibacter* (91) were found to be associated with bacteremia and recovered from blood cultures (31, 88; Bernard, unpublished) and are the first medically relevant coryneforms reported from the family *Intrasporangiaceae*. *Janibacter* strains can have gram-variable or gram-positive coccoidal to rod forms in singles, pairs, or irregular clumps. The DNA base composition is 69 to 73 mol% G+C, with an unusual CFA profile consisting of significant volumes of CFAs $C_{16:0i}$, $C_{17:1}$, and $C_{17:0}$. These bacteria are described as oxidizers, with white, creamy, or yellowish pigments. They are nonmotile, and optimal growth may occur at 25 to 30°C.

Genus *Pseudoclavibacter*

The genus *Pseudoclavibacter* was described in 2004 for a previous "*Brevibacterium helvolum*" strain (90). The novel genus *Zimmermannella,* described shortly afterwards, is a later synonym of *Pseudoclavibacter* (87). *Z. alba* strains were recovered from urine, and *Z. bifida* strains were recovered from blood cultures and wounds. By Gram staining, these species were found to be short or medium gram-positive rods, with *Z. bifida* demonstrating some rudimentary branching. The DNA base composition is 62 to 68 mol% G+C. Major CFAs are $C_{15:0ai}$, $C_{16:0}$, $C_{16:0i}$, and $C_{17:0ai}$. These strains are oxidizers, with white or yellowish colonies. Optimal growth occurs at 30°C.

Genera *Brachybacterium* and *Knoellia*

Two isolates from the genus *Brachybacterium* and one strain from the genus *Knoellia*, all recovered from blood cultures, have been characterized (K. A. Bernard, unpublished observations). *Brachybacterium* spp. (15) are members of the familiy *Dermabacteraceae* and so are most closely related to the genus *Dermabacter*. Members of this genus grow at 37°C, exhibit gram-positive coccoidal and rodlike forms, and have a G+C content of 68 to 73 mol%. The *Brachybacterium* blood culture isolates were metabolically fermentative and had branched-chained-type CFAs. The genus *Knoellia* (68), like the genus *Janibacter,* is a member of the family *Intrasporangiaceae*. Cells are irregular gram-positive rods or cocci, with major CFAs of the branched-chain type, and the G+C content is 68 to 69 mol%. The single *Knoellia* blood culture isolate was capnophilic, growing best in 5% CO_2 at 37°C.

Genus *Arcanobacterium*

The genus *Arcanobacterium* presently contains six species, of which *A. haemolyticum, A. bernardiae,* and *A. pyogenes* have been recovered from human clinical specimens. Lysine is the diamino acid of the cell wall, whereas in the phylogenetically closely related *Actinomyces* spp. lysine or ornithine is found. Arcanobacteria contain menaquinones of the MK-9(H_4) type, whereas the *Actinomyces* spp. examined so far have MK-10(H_4). The main CFAs of arcanobacteria are $C_{16:0}$, $C_{18:1\omega9c}$, and $C_{18:0}$ (as in *Corynebacterium* spp. and *T. otitidis*), but in contrast to corynebacteria significant amounts of $C_{10:0}$, $C_{12:0}$, and $C_{14:0}$ may also be detected (3). The G+C content is 48 to 52 mol%.

Gram staining of arcanobacteria shows irregular gram-positive rods. All clinically relevant arcanobacteria are catalase negative, nonmotile, and fermenters.

NATURAL HABITAT

Many species of the corynebacteria are part of the normal flora of the skin and mucous membranes in humans and mammals. The habitat for some medically irrelevant corynebacteria (e.g., *C. terpenotabidum* and *C. halotolerans*) is the environment. It is noteworthy that not all corynebacteria are equally distributed over skin and mucous membranes but many of them occupy a specific niche. *C. diphtheriae* can be isolated from the nasopharynx as well as from skin lesions, which actually represent a reservoir for the spread of diphtheria. Important opportunistic pathogens like *C. amycolatum, C. striatum,* and *D. hominis* are part of the normal human skin flora but have thus far not been recovered from throat swabs from healthy individuals (144). Coryneform bacteria prominent in the oropharynx include *C. durum* and *R. dentocariosa* (144). *C. auris* and *T. otitidis* seem to have an almost exclusive preference for the external auditory canal (73). In nearly every instance that *C. macginleyi* has been isolated, it has been recovered from eye specimens (53). Another *Corynebacterium* species with a distinctive niche is *C. glucuronolyticum,* which is almost exclusively isolated from genitourinary specimens from humans (39) and also from animals (24). *C. urealyticum,* another genitourinary pathogen, has, like *C. jeikeium,* also been cultured from the inanimate hospital environment.

The natural habitat of arcanobacteria is not fully understood, but *A. haemolyticum* is recovered from throat as well as from wound swabs, whereas *A. bernardiae* has been found mainly in abscesses adjacent to skin (G. Funke, unpublished

FIGURE 1 Gram stain morphologies of *Corynebacterium diphtheriae* ATCC 14779 after 48 h of incubation (a), *Turicella otitidis* DSM 8821 (48 h) (b), *Dermabacter hominis* ATCC 51325 (48 h) (c), *Corynebacterium durum* DMMZ 2544 (72 h) (d), *Corynebacterium matruchotii* ATCC 14266 (24 h) (e), *Gardnerella vaginalis* ATCC 14018 (48 h) (f), *Corynebacterium aurimucosum* HC-NML 91-0032 (24 h) (g), and a black-pigmented *Rothia dentocariosa* HC-NML 77-0298 (24 h) (h).

observation). It is unclear whether the two species are part of the normal skin and/or the gastrointestinal flora. *A. pyogenes* is found on mucous membranes of cattle, sheep, and swine. Brevibacteria can be found on dairy products (e.g., cheese) but are also inhabitants of the human skin (40). Arthrobacters are some of the most frequently isolated bacteria when soil samples are cultured, but at least *Arthrobacter cumminsii* also seems to be present on human skin (54). Members of the genera *Exiguobacterium, Oerskovia, Cellulomonas, Cellulosimicrobium,* and *Microbacterium* have their habitats in the inanimate environment (e.g., soil and activated sludge). *Microbacterium* spp. have also been recovered from hospital environments (42). Curtobacteria are primarily plant pathogens (38).

CLINICAL SIGNIFICANCE

Estimating the clinical significance of coryneform bacteria isolated from clinical specimens is often confusing for clinical microbiologists. This is in part due to the natural habitat of coryneform bacteria, which may lead to their recovery if specimens were not taken correctly. The reader is referred to the guidelines on minimal microbiological requirements in publications on disease associations of coryneform bacteria (64).

Coryneform bacteria should be identified to the species level if they are isolated (i) from normally sterile body sites, e.g., blood (except if only one of multiple specimens became positive); (ii) from adequately collected clinical material if they are the predominant organisms; and (iii) from urine specimens if they are the only bacteria encountered and the bacterial count is $>10^4$/ml or if they are the predominant organisms and the total bacterial count is $>10^5$/ml.

The clinical significance of coryneform bacteria is strengthened by the following findings: (i) multiple specimens are positive for the same coryneform bacteria; (ii) coryneform bacteria are seen in the direct Gram stain, and a strong leukocyte reaction is also observed; and (iii) other organisms recovered from the same material are of low pathogenicity.

For a comprehensive summary of case reports on individual coryneform bacteria, the reader is referred to review articles (2, 64). The most frequently reported coryneforms, as well as their established disease associations, are listed in Table 3.

Historically, diphtheria caused by *C. diphtheriae* (or *C. ulcerans*) is the most prominent infectious disease for which coryneform bacteria are responsible. Therefore, special attention is given to that disease in this chapter. Due to immunization programs, the disease has nearly disappeared in countries with high socioeconomic standards. However, the disease is still endemic in some subtropical and tropical countries as well as among individuals of certain ethnic groups (e.g., indigenous peoples in the Americas and Australia). In the 1990s, diphtheria reemerged in the states of the former Soviet Union. However, despite increased global travel activities, only a few imported cases have been reported by countries with well-developed health care systems.

TABLE 3 Most frequently reported disease associations of coryneform bacteria in humans

Taxon	Disease or disease association	Reference(s)[a]
C. amycolatum	Wound infections, foreign body infections, bacteremia, sepsis, urinary tract infections, respiratory tract infections	46, 83
C. aurimucosum	Genitourinary tract infections (mainly females)	126, 127
CDC group F-1	Urinary tract infections	
CDC group G/*C. tuberculostearicum*	Catheter infections, bacteremia, endocarditis, wound infections, eye infections	
C. diphtheriae (toxigenic)	Throat diphtheria, cutaneous diphtheria	30
C. diphtheriae (nontoxigenic)	Endocarditis, foreign body infections, pharyngitis	25, 37, 111
C. glucuronolyticum	Genitourinary tract infections (mainly males)	39
C. jeikeium	Endocarditis, bacteremia, foreign body infections, wound infections	115
C. kroppenstedtii	Granulomatous lobular mastitis	106
C. macginleyi	Eye infections	53
C. minutissimum	Wound infections, urinary tract infections, respiratory tract infections	154
C. pseudodiphtheriticum	Respiratory tract infections, endocarditis	
C. pseudotuberculosis	Lymphadenitis (occupational)	
C. resistens	Bacteremia	103
C. riegelii	Urinary tract infections (females)	49
C. striatum	Wound infections, respiratory tract infections, foreign body infections	
C. ulcerans (toxigenic)	Respiratory diphtheria	
C. urealyticum	Urinary tract infections, bacteremia, wound infections	130
Arthrobacter spp.	Bacteremia, foreign body infections, urinary tract infections	44, 54
Brevibacterium spp.	Bacteremia, foreign body infections, malodorous feet	40
D. hominis	Wound infections, bacteremia	61
Rothia spp.	Endocarditis, bacteremia, respiratory tract infections	
Cellulomonas spp.	Bacteremia, wound infections	7, 55
Cellulosimicrobium sp.	Foreign body infections, bacteremia	8, 93
Microbacterium spp.	Bacteremia, foreign body infections, wound infections	42, 82, 85
A. bernardiae	Abscess formation (together with mixed anaerobic flora)	57
A. haemolyticum	Pharyngitis in older children, wound and tissue infections	89
A. pyogenes	Abscess formation, wound and soft tissue infections	
G. vaginalis	Bacterial vaginosis, endometritis, postpartum sepsis	10

[a] References for taxa without references are our observations. For further information, see references 2 and 64.

The main manifestation of diphtheria is an upper respiratory tract illness with a sore throat, dysphagia, lymphadenitis, low-grade fever, malaise, and headache. A nasopharyngeal adherent membrane which may occasionally lead to obstruction is characteristic. The severe systemic effects of diphtheria include myocarditis, neuritis, and kidney damage caused by the *C. diphtheriae* exotoxin, which is encoded by a bacteriophage carrying the *tox* gene. *C. diphtheriae* may also cause cutaneous diphtheria or endocarditis (with either toxin-positive or toxin-negative strains). Some people with poor hygienic standards (e.g., drug and alcohol abusers) are prone to colonization (on the skin more often than in the pharynx) by *C. diphtheriae* strains, which are often nontoxigenic.

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

In general, coryneform bacteria do not need special handling when samples are collected.

C. diphtheriae

The diagnosis of diphtheria is primarily a clinical one. The physician should notify the receiving laboratory immediately of suspected diphtheria. In case of respiratory diphtheria, material for culture should be obtained on a swab (either a cotton- or a polyester-tipped swab) from the inflamed areas in the nasopharynx. Multisite sampling (nasopharynx) is thought to increase sensitivity. If membranes are present and can be removed (swabs from beneath the membrane are most valuable), they should also be sent to the microbiology laboratory (although *C. diphtheriae* might not be culturable from those in every instance). Nasopharyngeal swabs should be obtained from suspected carriers. It is preferable that the swabs be immediately transferred to the microbiology laboratory for culturing. If the swabs must be sent to the laboratory, semisolid transport media (e.g., Amies) ensure the maintenance of the bacteria. All coryneform bacteria are relatively resistant to drying and moderate temperature changes. Material from patients with suspected cases of wound diphtheria can be obtained by swab or aspiration.

After the appropriate isolation media have been inoculated (see "Isolation Procedures and Incubation" below), the swabs taken from diphtheritic membranes may be subjected to Neisser or Loeffler methylene blue staining (positive if metachromatic granules [polar bodies] are seen). However, it is noteworthy that the sensitivity of the microscopic examination is limited.

A PCR-based direct detection system for diphtheria toxin has been described by the Centers for Disease Control and Prevention (CDC) (98). Their system had the highest sensitivity when Dacron polyester-tipped swabs were used and when silica gel packages were stored at 4°C rather than at room temperature. The approach of a PCR-based direct detection system was successfully used in a retrospective study for which only formalin-fixed clinical specimens were available (80). However, direct detection for diphtheria toxin as the sole, primary test for clinical specimens has not been recommended, and microbiological culture is essential for confirming diphtheria (29).

Long-term preservation in skim milk at −70°C is applicable to all coryneform bacteria. The same skim milk tube except for those containing lipophilic corynebacteria can be thawed and put into the freezer again, and this can be done several times (Funke, unpublished). For nonlipophilic coryneforms, good results were also observed with Microbank tubes (Pro Lab Diagnostics, Austin, Tex.) (Funke, unpublished). The advantage of using these tubes is that individual beads can be taken out of the tube. Coryneform bacteria can also be stored for decades when they are kept lyophilized in an appropriate medium (e.g., 0.9% NaCl containing 2% bovine serum albumin).

ISOLATION PROCEDURES AND INCUBATION

Coryneform bacteria including *C. diphtheriae* can be readily isolated from a 5% sheep blood agar (SBA)-based selective medium containing 100 μg of fosfomycin per ml (plus 12.5 μg of glucose-6-phosphate per ml), since nearly all coryneforms (except *Actinomyces* spp. and *D. hominis*) are highly resistant to this compound (139, 144). It is also possible to put disks containing 50 μg of fosfomycin (plus 50 μg of glucose-6-phosphate [already incorporated in the disk]) (BD Diagnostics, Sparks, Md.) on a SBA plate and then examine the colonies which grow around the disk. Selective media for coryneform bacteria containing 50 to 100 μg of furazolidone/ml (Sigma, St. Louis, Mo.) have also been described. If lipophilic corynebacteria like *C. jeikeium* or *C. urealyticum* are sought, then 0.1 to 1.0% Tween 80 (Merck, Darmstadt, Germany) should be added to a SBA plate (add Tween 80 before pouring the medium). It is also possible to streak sterile filtered Tween 80 with a cotton swab onto SBA plates. Coryneform bacteria do not grow on MacConkey agar. However, if "coryneform" bacteria are recovered from this medium, they should be examined carefully to rule out rapidly growing mycobacteria.

With very few exceptions (some arthrobacters, microbacteria, and curtobacteria, which have optimal growth temperatures of between 30 and 35°C), the medically relevant coryneform bacteria all grow at 37°C. It is desirable to culture specimens for coryneform bacteria in a CO_2-enriched atmosphere, since some taxa, e.g., *Rothia* and *Arcanobacterium* spp., grow much better under those conditions. Nearly all medically relevant coryneform bacteria grow within 48 h, so that primary culture plates should not be incubated longer than that. However, if liquid media are used (e.g., for specimens from normally sterile body sites), these should be checked after 5 days by Gram staining for the presence of coryneform bacteria (only if growth is observed with the naked eye) before they are discarded.

It is recommended that urine specimens be incubated for longer than 24 h to check for the presence of *C. urealyticum* but only when patients are symptomatic or have alkaline urine or struvite crystals in their urine sediment.

C. diphtheriae

The primary plating media for the cultivation of *C. diphtheriae* should be SBA plus one selective medium (e.g., Cystine-Tellurite blood agar [CTBA] or freshly prepared Tinsdale medium) (29, 30). If silica gel is used as a transport medium, the desiccated swabs need to be additionally incubated overnight in broth (supplemented with either plasma or blood), which should then be streaked onto the primary plating medium. The plates are read after 18 to 24 h of incubation at 37°C, preferably in a 5% CO_2-enriched atmosphere. Tellurite inhibits the growth of many noncoryneform bacteria, but even a few *C. diphtheriae* strains are sensitive to potassium tellurite and will therefore not grow on CTBA but may grow on SBA. It is noteworthy that growth on CTBA and tellurite reduction are not specific for *C. diphtheriae,* since many other coryneforms may also produce black (albeit smaller) colonies. The best medium for direct culturing of *C. diphtheriae* is probably Tinsdale medium (30).

However, the limitations of Tinsdale medium are its relatively short shelf life (<4 weeks) and the necessity to add horse serum to it. On Tinsdale plates, both tellurite reductase activity (as shown by black colonies) and cystinase activity (as shown by a brown halo around the colonies) can be observed (see Fig. 3i). If neither CTBA nor Tinsdale medium is available, colistin-nalidixic acid blood agar plates are recommended for the isolation of C. *diphtheriae* or any other coryneform bacterium. It is necessary to pick multiple colonies from CNA plates to rule out C. *diphtheriae* (first Gram staining, then subculturing, and then subsequent biochemical testing). Nonselective Loeffler serum slants are no longer recommended for the primary isolation of C. *diphtheriae* because of overgrowth by other bacteria (but C. *diphtheriae* cells with polar bodies are produced on Loeffler or Pai slants only).

IDENTIFICATION AND TYPING SYSTEMS

Basic tests available in every microbiology laboratory are of great value for the identification of coryneform bacteria. The Gram staining morphology of the cells can exclude the assignment to many genera and may even lead to the assignment to the correct genus (e.g., to the genus *Corynebacterium, Turicella*, or *Dermabacter*) (Fig. 1). Morphology, size, pigment, odor, and hemolysis of colonies are also valuable criteria in the differential diagnosis of coryneform bacteria.

von Graevenitz and Funke (143) had outlined a biochemical identification system for coryneform bacteria which was based on previous results from the CDC Special Bacteriology Reference Laboratory (71). This system includes the following reactions: catalase, test for fermentation or oxidation (in our experience, this is best observed in semisolid cystine Trypticase agar medium [rather than on triple sugar iron or oxidation-fermentation media], with fermentation indicated by acid or alkali production in the entire tube and oxidation found at the surface of the tube); motility; nitrate reduction (24-h incubation); urea hydrolysis (24-h incubation); esculin hydrolysis (up to 48 h of incubation); acid production from glucose, maltose, sucrose, mannitol, and xylose (48-h incubation); CAMP reaction (24-h incubation) with a β-hemolysin-producing strain of *Staphylococcus aureus* (e.g., strain ATCC 25923), i.e., positive reaction indicated by an augmentation of the effect of *S. aureus* β-hemolysin on erythrocytes, resulting in a complete hemolysis in an arrowhead configuration (Fig. 2); and a test for lipophilia (24-h incubation), which is performed only for catalase-positive colonies <0.5 mm in diameter. For the test for lipophilia, colonies are subcultured onto ordinary SBA and onto a 0.1 to 1% Tween 80-containing SBA plate. Lipophilic corynebacteria develop colonies up to 2 mm in diameter after 24 h on Tween-supplemented agar. It has also been suggested that growth in brain heart infusion broth with and without supplementation of 1% Tween 80 be compared and strains which grow only in the supplemented broth can be called lipophilic. The identification protocols given in this chapter are, in principle, based on the identification system of von Graevenitz and Funke (143) mentioned above (Tables 4 and 5).

The currently recommended identification systems include the API (RAPID) Coryne system (bioMérieux, Marcy l'Etoile, France) and the RapID CB Plus system (Remel, Lenexa, Kans.). The API Coryne system contains 49 taxa in its present database (version 2.0). In a comprehensive multicenter study, it was found that 90.5% of the strains belonging to the taxa included were correctly identified, with additional tests needed for correct identification for 55.1% of all strains tested (60). The results were highly reproducible if the manufacturer's recommendations for use were rigorously followed. It was concluded that the system is a useful tool for the identification of the diverse group of coryneform bacteria encountered in the routine clinical laboratory. The RapID CB Plus system correctly identified 80.9% of the strains to the genus and the species levels, and an additional 12.2% strains were correctly identified to the genus level but with less accurate species designations; it was also concluded that this system may perform well under the conditions of a routine clinical laboratory (58). However, it is always important to question critically the identifications provided by any commercial identification system and to correlate the results with simple basic characteristics such as macroscopic morphology and Gram staining results. Furthermore, it is important to note that for both commercially available identification systems the databases have not been updated since 1997 and therefore the recently described taxa are not covered.

For some identifications, the commercial API 50CH system (bioMérieux) has been found to be useful. For example, when applying the AUX medium (usually attached to the kit

C. xerosis	F	–	V	–	–	+	+	+	+	+	–	–	–	O/129 susceptible, propionic not detected

[a] Abbreviations and symbols: F, fermentation; O, oxidation; +, positive; –, negative; V, variable; ( ), delayed or weak reaction; ND, no data; REV, CAMP inhibition reaction.
[b] Propionic acid as a glucose fermentation product.
[c] Blood culture isolate (4) was also ONPG positive, oxidase positive, weakly maltose positive but negative by API Coryne, propionic acid was not detected; β-galactosidase was not observed using two methods (API Coryne, API Zym); API Coryne code obtained, 0101104.
[d] *C. diphtheriae* biotype *mitis* is nitrate reductase positive, and *C. diphtheriae* biotype *belfanti* is nitrate reductase negative.
[e] *C. simulans* (145) is a strong nitrite reducer at low and high concentrations; nitrate reduction may appear to be negative unless further tested using zinc dust; one strain was catalase negative (4).

for gram-negative nonfermenters [bioMérieux]) to the API 50CH system, utilization reactions which allow the differentiation of *Brevibacterium* spp. or some *Arthrobacter* spp. can be observed (40, 44).

A reference laboratory would also use chromatographic techniques for further characterization of coryneform bacteria. The presence of mycolic acids and their chain lengths can be detected by thin-layer chromatography (TLC), gas chromatography and mass spectrometry, or high-performance liquid chromatography (22). These methods can be useful for the differentiation of *Corynebacterium* spp. (mycolic acids of 22 to 36 carbon atoms) from the partially acid-fast bacteria (mycolic acids of 30 to 78 carbon atoms) but may also provide evidence that a coryneform bacterium is not a *Corynebacterium* (exceptions are *C. amycolatum*, *C. atypicum*, and *C. kroppenstedtii*) if mycolic acids are not detected. The detection of the diamino acid of the peptidoglycan by one-dimensional TLC is of certain value for determining the genus to which a particular strain belongs (Table 1). In some cases, partial hydrolysates of the peptidoglycan are separated by two-dimensional TLC to reveal the interpeptide bridge of the peptidoglycan in order to distinguish between genera having the same diamino acid in the peptide moiety. For example, some of the yellow-pigmented microbacteria and all curtobacteria have ornithine as their diamino acids, but microbacteria have (glycine)$_{1-3}$-ornithine as the interpeptide bridge, whereas curtobacteria possess ornithine only.

The analysis of CFAs by means of gas-liquid chromatography with the Sherlock system (MIDI Inc., Newark, Del.) is an extremely useful method for the identification of coryneform bacteria. This system is, in general, able to identify coryneform bacteria to the genus level, but identification to the species level is in most cases impossible, although the commercial database suggests that it is possible. This is because of the very closely related CFA profiles of coryneform bacteria belonging to the same genus (3) and because the quantitative profiles observed depend strongly on the incubation conditions. When a laboratory creates its individual database based on its own entries, species identification becomes possible in some cases (Bernard, unpublished). The mycolic acids of some corynebacteria (e.g., *C. auris*) are cleaved at the temperature (300°C) produced in the injection port of the system, resulting in fatty acids which were identified as, e.g., $C_{17:1\omega6c}$ to $C_{\omega9c}$, by the Sherlock system (47).

Molecular genetic-based identification systems for coryneform bacteria have been outlined in recent years. Restriction fragment length polymorphism analysis of the partly amplified and digested 16S rRNA gene has been demonstrated to be of use for the identification of species within the genera *Corynebacterium* and *Brevibacterium* (9, 140). Some corynebacteria may also be identified to the species level by examination of the length of the 16S-23S rRNA intergenic spacer region (1). rRNA gene restriction fragment polymorphism analysis (ribotyping) has been demonstrated to allow the identification of corynebacteria if three different restriction enzymes (BstEII, SmaI, and SphII) are used (5). Another interesting approach for the identification of true corynebacteria is the sequencing of a 434- to 452-bp fragment of the *rpoB* gene (using primers designated C2700F and C3130R), since this particular region of the gene displays a high degree of polymorphism within the genus *Corynebacterium* (77, 78). This approach for molecular identification needs to be evaluated with other genera. For pure taxononomic investigations of coryneform bacteria and in cases of growth of coryneform bacteria from difficult to obtain clinical material (122), full-length 16S rRNA gene

TABLE 5 Identification of medically relevant coryneform bacteria other than *Corynebacterium* spp.[a]

Taxon	Catalase	Fermentation/ oxidation	Motility	Nitrate reduction	Urease	Esculin hydrolysis	Acid production from:					Other traits

[a] Abbreviations and symbols: +, positive reaction; −, negative reaction; V, variable reaction; O, oxidation; F, fermentation.

sequencing might be indicated. Determination of the complete 16S rRNA gene sequence is a rational approach for identifying corynebacteria, since nearly all established species exhibit 3% or greater divergence except for *C. afermentans, C. coyleae,* and *C. mucifaciens* (<2%), *C. aurimucosum, C. minutissimum,* and *C. singulare* (<2%), *C. sundsvallense* and *C. thomssenii* (<1.5%), and *C. ulcerans* and *C. pseudotuberculosis* (<2%) (2). In very few selected cases, quantitative DNA-DNA hybridizations might be necessary but will be clearly restricted to the reference laboratory. Because of the ever-growing number of coryneform taxa encountered in clinical specimens, it becomes more difficult to readily differentiate all taxa biochemically, so it appears that sequencing studies are most likely to replace some of the biochemical testing in the near future.

The commercial MicroSeq 500 16S bacterial sequencing kit (Perkin-Elmer, Foster City, Calif.) has been applied to the identification of coryneform bacteria, but discordant results (with extensive phenotyping as the "gold standard") were observed for >30% of the *Corynebacterium* isolates, mainly because of the present database of the commercial system (136). However, due to the short running time of approximately 15 to 19 h, this and other similar systems will further spread to the routine clinical laboratory, in which case direct costs should drop and databases will be improved.

It is emphasized that unidentifiable, clinically significant coryneform bacteria should be sent to an established reference laboratory experienced in corynebacterial identification.

DESCRIPTIONS OF GENERA AND SPECIES

Genus *Corynebacterium*

C. accolens

C. accolens (101) is found in specimens from eyes, ears, the nose, and the oropharynx. Endocarditis of native aortic and mitral valves due to this agent has been described. Colonies are, as for all other lipophilic corynebacteria, convex, smooth, and <0.5 mm in diameter on SBA. *C. accolens* strains had initially been described to exhibit satellitism in the vicinity of *S. aureus* strains, attributable to its lipophilism (for the recommended method to demonstrate lipophilism, see "Identification and Typing Systems" above). *C. accolens* has a variable pyrazinamidase reaction but is negative for alkaline phosphatase, thus differentiating it from the morphologically and biochemically closely related CDC group G bacteria (Table 4). The API Coryne and RapID CB Plus systems correctly identify *C. accolens* (58, 60). *C. accolens* strains are susceptible to a broad spectrum of antibiotics.

C. afermentans subsp. *afermentans*

C. afermentans subsp. *afermentans* (116) is part of the normal human skin flora and has so far been isolated mainly from blood cultures. Colonies are whitish, convex with regular edges, creamy, and about 1 to 1.5 mm in diameter after 24 h of incubation. *C. afermentans* subsp. *afermentans* has an oxidative metabolism. The API Coryne system provides the numerical code of 2100004 for this species. About 60% of all strains of this taxon are CAMP reaction positive. *C. afermentans* subsp. *afermentans* can be differentiated from *C. auris* and *T. otitidis* (both of which give the same API numerical code) by the consistency of its colonies (*C. auris* is slightly adherent to agar) and morphology on Gram staining (*T. otitidis* has longer cells). Further differential reactions include the carbohydrate utilization reactions tested with

either the Biolog GP plate (Biolog, Hayward, Calif.) or the bioMérieux biotype 100 gallery (47). By chemotaxonomic means, both *C. afermentans* subspecies and *C. auris* contain mycolates, whereas *T. otitidis* lacks them, but these techniques are not applicable in a routine clinical laboratory. *C. afermentans* subsp. *afermentans* is generally susceptible to β-lactam antibiotics.

C. afermentans subsp. *lipophilum*

Strains belonging to the species *C. afermentans* subsp. *lipophilum* (116) have been isolated mainly from blood cultures as well as from superficial wounds. Colonies are, typically for lipophilic corynebacteria, convex, smooth, and <0.5 mm in diameter after 24 h. *C. afermentans* subsp. *lipophilum* has an oxidative metabolism and does not produce acid from any of the carbohydrates usually tested (Table 4). It is the only species of lipophilic corynebacteria which may exhibit a positive CAMP reaction. *C. afermentans* subsp. *lipophilum* is not included in the API Coryne database. The numerical profile observed for the species is 2100004, and so by that method it cannot be discerned from more robustly growing *C. afermentans* subsp. *afermentans, C. auris,* or *T. otitidis*. Strains are usually susceptible to β-lactam antibiotics.

C. amycolatum

C. amycolatum is part of the normal human skin flora but was not recovered from throat swabs from healthy persons (144). *C. amycolatum* is the most frequently encountered *Corynebacterium* species in human clinical material (64). It is also the most frequently isolated nonlipophilic *Corynebacterium* in dairy cows with mastitis (74). *C. amycolatum* strains are often multidrug resistant (59). Colonies are very typically dry, waxy, and grayish white with irregular edges and are 1 to 2 mm in diameter after 24 h of incubation. *C. amycolatum* actually has a fermentative metabolism, but when CTA media are used for the observation of acid production from carbohydrates, *C. amycolatum* appears to resemble an oxidizer (i.e., main acid production at the surface of the medium). Strains of *C. amycolatum* are remarkable for their variability in basic biochemical reactions (Table 4) and had been often misidentified in the past as the biochemically similar species *C. xerosis, C. striatum,* or *C. minutissimum* (46, 148, 154). These four species can be differentiated by the following reactions: *C. amycolatum* and *C. minutissimum* do not grow at 20°C, but *C. xerosis* and *C. striatum* do; in addition, *C. xerosis* does not ferment glucose at 42°C whereas the other three species do, and *C. minutissimum* and *C. striatum* produce alkali from formate but *C. amycolatum* and *C. xerosis* do not (148). When tested on Mueller-Hinton agar supplemented with 5% sheep blood, nearly all *C. amycolatum* strains were resistant to the vibriocidal compound O/129 (150-μg disks) (Oxoid, Basingstoke, United Kingdom), as indicated by no zone of inhibition around the disk (46). In contrast, only 4% of all *C. amycolatum* strains were resistant to O/129 when tested on Mueller-Hinton agar with 5% horse blood (83). The API Coryne system identifies this species very well, but in every case additional reactions must be carried out in order to confirm the identification of *C. amycolatum* (60). All *C. amycolatum* strains produce propionic acid as the major end product of glucose metabolism. In contrast to many other corynebacteria, *C. amycolatum* exhibits only weak or no leucine arylamidase activity. The identification may also be suggested by the absence of mycolic acids. In addition, it may be shown that acyl phosphatidylglycerol is a major phospholipid in *C. amycolatum,* in contrast to other *Corynebacterium* spp., in which other phospholipids are predominant.

C. appendicis

The one strain of *C. appendicis* described in the literature was isolated from a patient with appendicitis accompanied with abscess formation (151). This lipophilic species contains huge amounts of TBSA (up to 50% of all CFAs) not seen in any other *Corynebacterium* species. It is differentiated from CDC coryneform group F-1 bacteria by a positive alkaline phosphatase reaction but negative reactions for nitrate reduction and sucrose fermentation.

C. argentoratense

C. argentoratense (118) has been isolated from the human throat as well as, in one instance, from a blood culture (4). Colonies are cream colored, nonhemolytic, slightly rough, and 2 mm in diameter after 48 h of incubation. Phenotypically, *C. argentoratense* may appear to be very similar to (rare) ribose negative strains of *C. coyleae*. However, glucose fermentation by *C. argentoratense* is quite rapid compared to the slowly fermenting species *C. coyleae.* As well, CAMP-negative *C. argentoratense* produces propionic acid as a fermentation product, but CAMP-positive *C. coyleae* does not (4, 56). *C. argentoratense* is the only medically relevant *Corynebacterium* species expressing α-chymotrypsin activity, which can be observed in the API ZYM (bioMérieux) system; however, the blood culture isolate was not observed to produce that enzyme (4). Although *C. argentoratense* is phylogenetically closely related to *C. diphtheriae,* it does not harbor the *tox* gene coding for the diphtheria toxin.

C. atypicum

Although this species clearly belongs to the genus *Corynebacterium,* corynomycolic acids, like in *C. amycolatum* and *C. kroppenstedtii,* are not detected (69). *C. atypicum* is not lipophilic but shows only pinpoint colonies after 48 h of incubation. It is the only medically relevant *Corynebacterium* not expressing pyrazinamidase but β-glucuronidase activity.

C. aurimucosum

The initial description of *C. aurimucosum* was based on a single strain which exhibited slightly yellow and sticky colonies on 5% SBA plates but on Trypticase soy agar without blood had colorless and slimy colonies (150). The basic biochemical profile of this particular *C. aurimucosum* strain was similar to that of *C. minutissimum*. The number of *C. aurimucosum* strains was significantly enhanced when it was demonstrated that some former CDC coryneform group 4 bacteria actually belong to *C. aurimucosum* (21). It is important to note that many strains of *C. aurimucosum* exhibit a grayish black pigment that is not seen in any other true *Corynebacterium*. Strains that were originally designated "*C. nigricans*" (126) were shown to be a later synonym of *C. aurimucosum* (21). Some strains of *R. dentocariosa* can also exhibit a charcoal black pigment (21); these strains are differentiated from *C. aurimucosum* by being constantly nitrate reductase positive, a possible negative catalase reaction, and having branched-chain CFAs as opposed to straight-chain-type CFAs for *C. aurimucosum*. API Coryne codes for pigmented *C. aurimucosum* strains include 0000125, 2000125, and 2100327 (126).

C. auris

C. auris (47) has been isolated almost exclusively from the ear region. Colonies are dryish, are slightly adherent to but do not penetrate agar, become slightly yellowish with time, and have diameters ranging from 1 to 2 mm after 48 h of incubation. *C. auris* does not produce acid from any carbohydrates usually tested. However, utilization reactions applying either

the Biolog GP plate or the bioMérieux biotype 100 system may help in distinguishing *C. auris* from *C. afermentans* subsp. *afermentans* and *T. otitidis,* but in the clinical routine laboratory this can also be achieved by morphologic differentiation (see "*C. afermentans* subsp. *afermentans*"). All *C. auris* strains are strongly CAMP test positive. The API Coryne system provides the numerical code 2100004 for this species. Abundant degradation products of mycolic acids are indirectly observed when CFA patterns are determined with the Sherlock system (47). It is noteworthy that the MICs of β-lactam antibiotics for *C. auris* strains are elevated, but the molecular mechanism for this is not known at present (59).

C. bovis

Occasionally, but not in the recent era, human infections had been attributed to the lipophilic bovine species, *C. bovis*. Characterization of lipophilic-like corynebacteria based solely on the use of phenotypic tests was probably incorrect in the absence of modern polyphasic methods or identification schemes such as those found in Table 4. This species had not been definitively recovered for many years from human clinical material, as previously reviewed (64). Recently, however, a human blood culture isolate of *C. bovis* was identified based on a polyphasic approach, including phenotypic, chemotaxonomic, and genotypic characteristics, with an API Coryne code of 0101104 (4).

C. confusum

C. confusum has been isolated from patients with foot infections, a blood culture (52), and a breast abscess (4). Colonies are whitish, glistening, convex, creamy, and up to 1.5 mm in diameter after 48 h. Acid from glucose is produced only very weakly, becoming visible in the API Coryne or the API 50CH gallery only after 48 to 72 h. Weak growth under anaerobic conditions corresponds to slow fermentative acid production. It is advisable to incubate the API Coryne system after 24 h for another day in those cases in which the results for acid production are ambiguous (i.e., only a slight change in the color of the indicator). After 48 h of incubation, the APl Coryne system provides the numerical code 3100304 for this species; the breast abscess strain had a code of 3100104. Interestingly, the breast abscess strain was also CAMP positive, making it potentially more difficult to discern from *C. coyleae* isolates (4). *C. confusum* is correctly identified by the RapID CB Plus system (58). If glucose fermentation is judged to be negative, *C. confusum* strains can be misidentified as *C. propinquum.* However, in contrast to that species, *C. confusum* does not hydrolyze tyrosine and contains small amounts of TBSA (1 to 3%), whereas *C. propinquum* hydrolyzes tyrosine but does not contain TBSA. *C. confusum* is differentiated from *C. coyleae* and *C. argentoratense* by its ability to reduce nitrate.

C. coyleae

C. coyleae (56) has been isolated mainly from cultures of blood and other normally sterile body fluids, but it may also be recovered from genitourinary specimens (4; Funke, unpublished). Colonies are whitish and slightly glistening with entire edges and are about 1 mm in diameter after 24 h. The consistency of the colonies is either creamy or sticky. A slow fermentative acid production from glucose and a strongly positive CAMP reaction are the most significant phenotypic characteristics. *C. coyleae* is positive for cystine arylamidase, which is not observed for many other corynebacteria. Various API Coryne numerical codes have been observed, especially 2100304 and 6100304. *C. coyleae* is always positive for ribose fermentation, whereas the biochemically similar species *C. argentoratense* is variable for this reaction. The API Coryne database lists only 6% glucose-fermenting *C. coyleae* strains, and therefore, when applying this commercial identification system, the clinical microbiologist may not receive a correct identification (60). However, the two numerical profiles given above combined with a positive CAMP reaction are highly indicative of *C. coyleae.* This species is correctly identified by the RapID CB Plus system (58).

CDC Group F-1 Bacteria

CDC group F-1 bacteria (119) have not been given a species name. Although genetically distinct, no distinguishing phenotypic markers that clearly allow their separation from other defined *Corynebacterium* spp. have been found. The characteristics of the CDC group F-1 bacteria are consistent with the definition of the genus *Corynebacterium* in all respects. The strains are lipophilic and are the only lipophilic fermentative *Corynebacterium* species able to hydrolyze urea. Of note is the negative alkaline phosphatase reaction (Table 4). CDC group F-1 strains are usually susceptible to penicillin but are often resistant to macrolides.

CDC Group G Bacteria

CDC group G bacteria possess all chemotaxonomic features of true corynebacteria but cannot be given a species name since it has so far been impossible to find phenotypic traits allowing for a unanimous definition (119). At least some strains of CDC group G have been found to be consistent with *C. tuberculostearicum* (Bernard, unpublished). These lipophilic strains can be separated from *C. jeikeium* by anaerobic growth and fermentative acid production from fructose (115). Further biochemical features of CDC group G bacteria are given in Table 4. The API Coryne system correctly identifies CDC group G bacteria. They might be multidrug resistant, but the most frequently observed resistance is to macrolides and lincosamides.

C. diphtheriae

In 2003, the complete genome sequence of a *Corynebacterium diphtheriae* strain representative for the diphtheria outbreak in the former Soviet Union states in the 1990s was determined (11). The genome consists of a single circular chromosome of 2,488,635 bp with no plasmids. A complete set of enzymes for the glycolysis, gluconeogenesis, and pentose-phosphate pathways are present, as well as all the de novo amino acid biosynthesis pathways. Fimbrial and fimbria-related genes and sialidase (neuraminidae) genes, as well as iron uptake systems, have been detected as pathogenicity factors.

C. diphtheriae is commonly divided into four biotypes, *gravis, mitis, belfanti*, and *intermedius*; biotype differentiation is recommended by WHO (29, 30), although biotypes cannot be assigned separate subspecies status (120), nor is biotyping satisfactory for epidemiologic tracking. Initially, these biotypes were defined by differences in colony morphology and biochemical reactions (Table 4). However, only *C. diphtheriae* biotype *intermedius* can be identified on the basis of colonial morphology (small, gray, or translucent lipophilic colonies) (20) as well as positive dextrin fermentation. Other *C. diphtheriae* biotypes produce larger (up to 2 mm after 24 h) white or opaque colonies (Fig. 3b), which are indistinguishable from one another. The lipophilic *C. diphtheriae* biotype *intermedius* occurs only rarely in clinical infections, and *C. diphtheriae* biotype *belfanti* strains almost never harbor the diphtheria toxin gene.

Presumptive identification of *C. diphtheriae* (as well as of *C. pseudotuberculosis* and *C. ulcerans*) may be made by testing suspicious gram-positive rods for the presence of cystinase (as detected by using Tinsdale medium or diagnostic tablets [Rosco, Taastrup, Denmark]) and the absence of pyrazinamidase (diagnostic tablets are available from Key Scientific Products, Round Rock, Tex.). The API Coryne system identifies *C. diphtheriae* strains, with additional tests needed for the differentiation of *C. diphtheriae* biotype *mitis,* *C. diphtheriae* biotype *belfanti,* and *C. diphtheriae* biotype *intermedius* (60). Usually, *C. diphtheriae* strains do not ferment sucrose, but in Brazil sucrose-positive strains have been described (23). Large amounts of propionic acid are produced as the end product of glucose metabolism (36). *C. diphtheriae* strains are distinct from all other coryneform bacteria (except *C. pseudotuberculosis* and *C. ulcerans*) in their CFA patterns by the presence of a large volume of $C_{16:1\omega7c}$ (3).

Diphtheria Toxin Testing

It is recommended that at least 10 colonies of *C. diphtheriae* and related species be tested for diphtheria toxin by the Elek method, modified as described by Engler (32), in a laboratory with personnel skilled in performing the test and in interpreting the test results. The modified Elek method described by the WHO Diphtheria Reference Unit was initially used to characterize strains from the 1990s epidemic in Russia and Ukraine and was found to be faster and less technically problematic than the original version. Antitoxins from various suppliers (e.g., Swiss Serum and Vaccine Institute, Bern, Switzerland; Pasteur Mérieux, Lyon, France; CDC Biological Products Division, Atlanta, Ga.), applied to blank filter disks at 10 IU/disk, have been successfully used with the modified Elek test (32), and precipitin lines can be read as early as 24 h (Fig. 4). A similar modification of the Elek test, which can test up to 24 isolates on the same plate, has been described (112). A 3-h enzyme-linked immunosorbent assay for the detection of diphtheria toxin from clinical isolates of *Corynebacterium* spp. has been developed by the WHO Diphtheria Reference Unit (33).

PCR-based methods for the detection of the diphtheria toxin gene *(tox)* in isolated bacteria have been developed and validated (29, 70). Recently, a real-time fluorescence PCR assay for detecting the A and B subunits of the *tox* gene has been described and evaluated directly with clinical specimens (96). *tox* PCR assays applied directly to clinical specimens are acceptable, particularly because isolation is not always possible for patients already receiving antibiotics. However, a PCR-positive patient from whom bacteria are not isolated or without a histopathologic diagnosis and without an epidemiologic linkage to a patient with a laboratory-confirmed case of diphtheria should be classified as having a "probable case" of diphtheria, since to date there are insufficient data to conclude that a PCR-positive result always implies diphtheria. Also, detection of the toxin gene in samples by PCR cannot automatically be attributed to one species, because *C. diphtheriae* as well as *C. ulcerans* and *C. pseudotuberculosis* may harbor the bacteriophage which carries the diphtheria toxin gene. Furthermore, *tox*-containing, nontoxigenic isolates have been described and characterized further (12). A comprehensive review on the biology and molecular epidemiology of the diphtheria toxin has been given by Holmes (72). Nontoxigenic strains of *C. diphtheriae,* i.e., those which do not express toxin in the Elek test or those which lack a detectable diphtheria toxin gene by PCR, have caused serious disease such as cases or outbreaks of skin disease and endocarditis and occasional mortality among homeless people, alcoholics, and intravenous drug abusers (37, 64, 111). For nontoxigenic *C. diphtheriae* strains circulating in the United Kingdom, it has been shown that the diphtheria toxin repressor *(dtxR)* genes are functional, so that if these strains are lysogenized by a bacteriophage, they could represent a reservoir for toxigenic *C. diphtheriae* (28).

Typing Methods

Outbreaks of *C. diphtheriae* in the states of the former Soviet Union and other locations have been studied by whole-cell peptide analysis, whole-genome restriction fragment length polymorphism analysis, ribotyping, pulsed-field gel electrophoresis, PCR-single-strand conformation polymorphism analysis of *tox* and *dtxR* (i.e., the regulatory element of the diphtheria toxin) as well as of the 16S-23S rRNA spacer region, amplified fragment length polymorphisms, random amplification of polymorphic DNA (RAPD), and multilocus enzyme electrophoresis (26, 27, 99, 108). An international database for *C. diphtheriae* ribotypes using endonuclease BstEII has been established (67). Recently, a spoligotyping system (similar to the spacer oligonucleotide typing for *Mycobacterium tuberculosis*) checking for the presence or absence of 21 different spacers has been described for *C. diphtheriae* (95). Sequencing studies with *C. diphtheriae* strains from the epidemic in the former Soviet Union have shown that point mutations within the *tox* gene were silent mutations, whereas multiple point mutations (which even led to amino acid substitutions) were observed for the *dtxR* gene, corresponding to the heterogeneity of outbreak strains as revealed by PCR-single-strand conformation polymorphism analysis (97). Molecular epidemiologic studies using RAPD have been used to rapidly screen a large number of *C. diphtheriae* strains to identify the epidemic clonal group associated with the outbreak in the former Soviet Union. Isolates derived from specific populations in the United States and Canada and characterized using multilocus enzyme electrophoresis, ribotyping, and RAPD were found to be members of persistent endemic strains, rather than being imported from other countries where diphtheria is endemic.

Antibiotic treatment is required to eliminate *C. diphtheriae* and prevent its spread; however, it is not a substitute for antitoxin prevention, with antibiotics of choice being penicillins or macrolides. Sporadic isolates of *C. diphtheriae* resistant to erythromycin or rifampin have been reported. Penicillin and some of the newer ketolides were tested against a large collection of geographically diverse strains and were found to generally demonstrate significant efficacy against *C. diphtheriae* but reduced ketolide activity against some Southeast Asian strains. It is believed that between 20 and 60% of adults in the United States lack protective antibodies to diphtheria toxin because of declining antibody titers in immunized persons and because many individuals were never immunized, which could pose a potentially significant public health risk and could result in the reemergence of this disease.

C. durum

C. durum (117) was originally described as being exclusively isolated from respiratory tract specimens. Well-characterized isolates have now been recovered from additional sites, including the gingiva, blood cultures, or abscesses (110). *C. durum* strains were originally isolated after 2 or 3 days from nonselective charcoal-buffered yeast extract plates inoculated with sputa or bronchial washings. *C. durum* is the

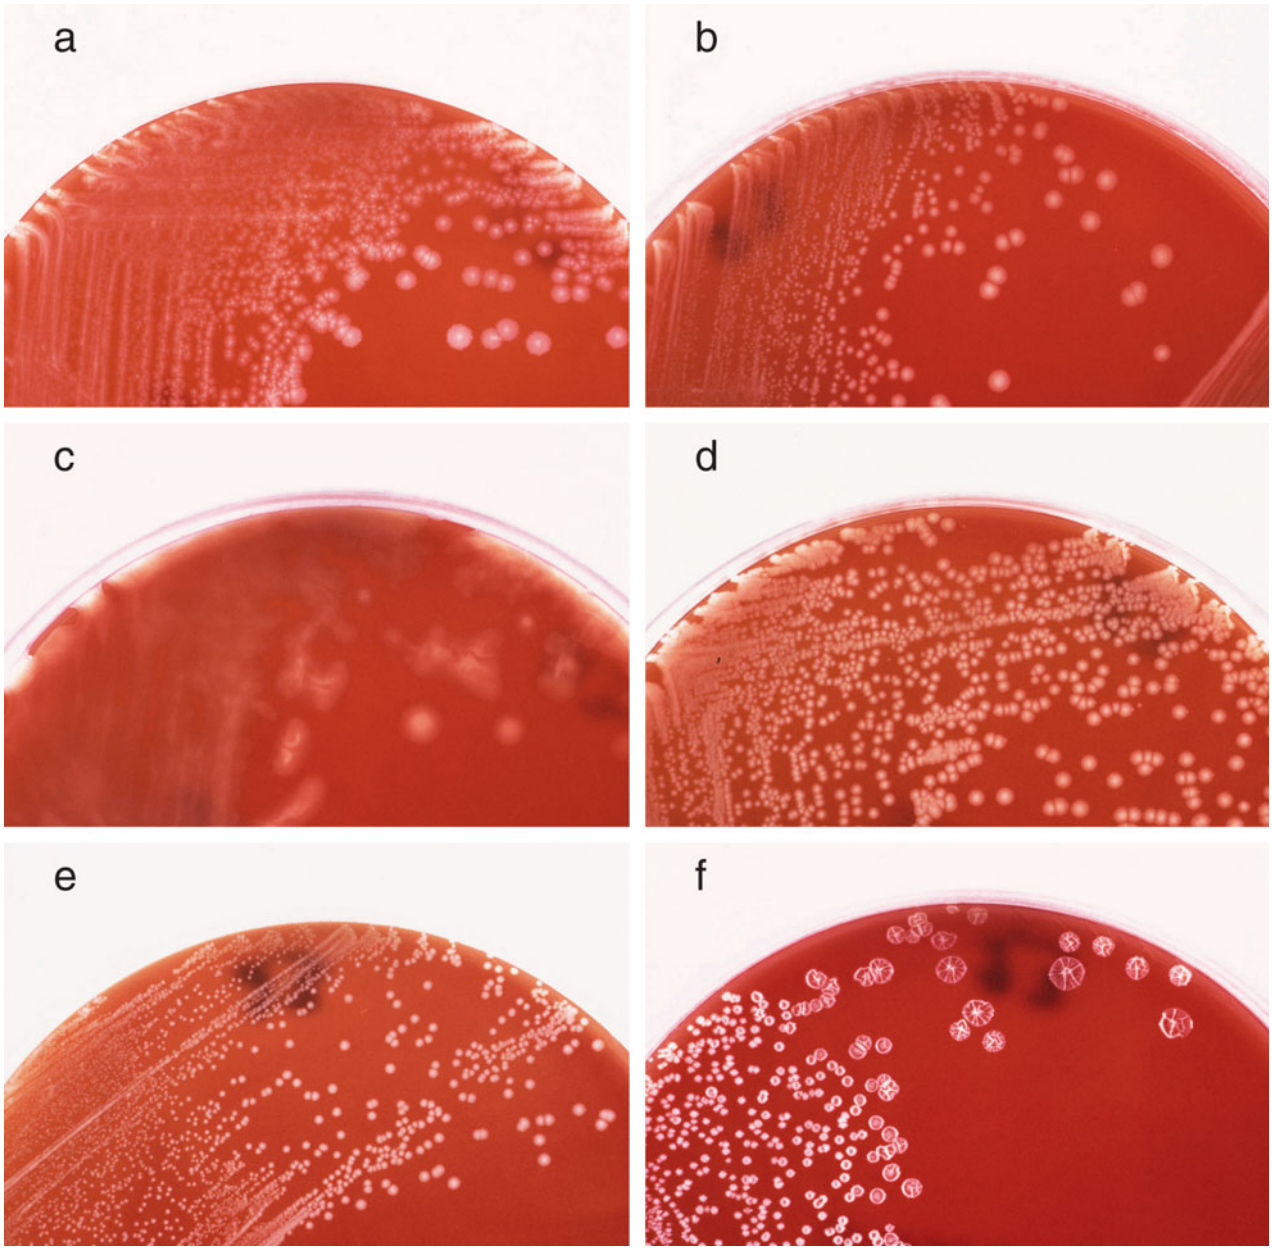

FIGURE 3 Colony morphologies of different coryneform bacteria after 48 h of incubation on SBA. (a) *C. amycolatum* LCDC 91-0077; (b) *C. diphtheriae* ATCC 14779; (c) *C. mucifaciens* LCDC 97-0202; (d) *C. striatum* ATCC 6940; (e) *D. hominis* ATCC 51325; (f) *R. dentocariosa* LCDC 95-0154; (g) *C. aurimucosum* HC-NML 91-0032 (after 96 h); (h) black-pigmented *Rothia dentocariosa* HC-NML 77-0298 (after 96 h); (i) *C. diphtheriae* biotype *gravis* colonies on a Tinsdale agar plate. Panel i was kindly provided by C. Hinnebusch and M. Cohen, UCLA School of Medicine, Los Angeles, Calif.

most frequent *Corynebacterium* isolated from throat swabs from healthy persons (144). Its pathogenic potential is unclear at present. *C. durum* is a peculiar nonlipophilic organism that forms colonies of only 0.5 to 1 mm in diameter after aerobic incubation for 72 h. The original description of this bacterium cited beige and rough colonies with convolutions, with an irregular margin, and strongly adhering to agar if grown under aerobic conditions (117). However, strains described in a later publication were found to be sometimes smoother and not necessarily adherent to agar (110). Gram staining of aerobic cultures shows long and filamentous rods, with occasional "bulges," but true *C. durum* isolates do not have *C. matruchotii*-like "whip handles" (Fig. 1d and e). Long forms are not otherwise found among other *Corynebacterium* species, nor are they observed for *C. durum* when cells are grown in a 10% CO_2-enriched

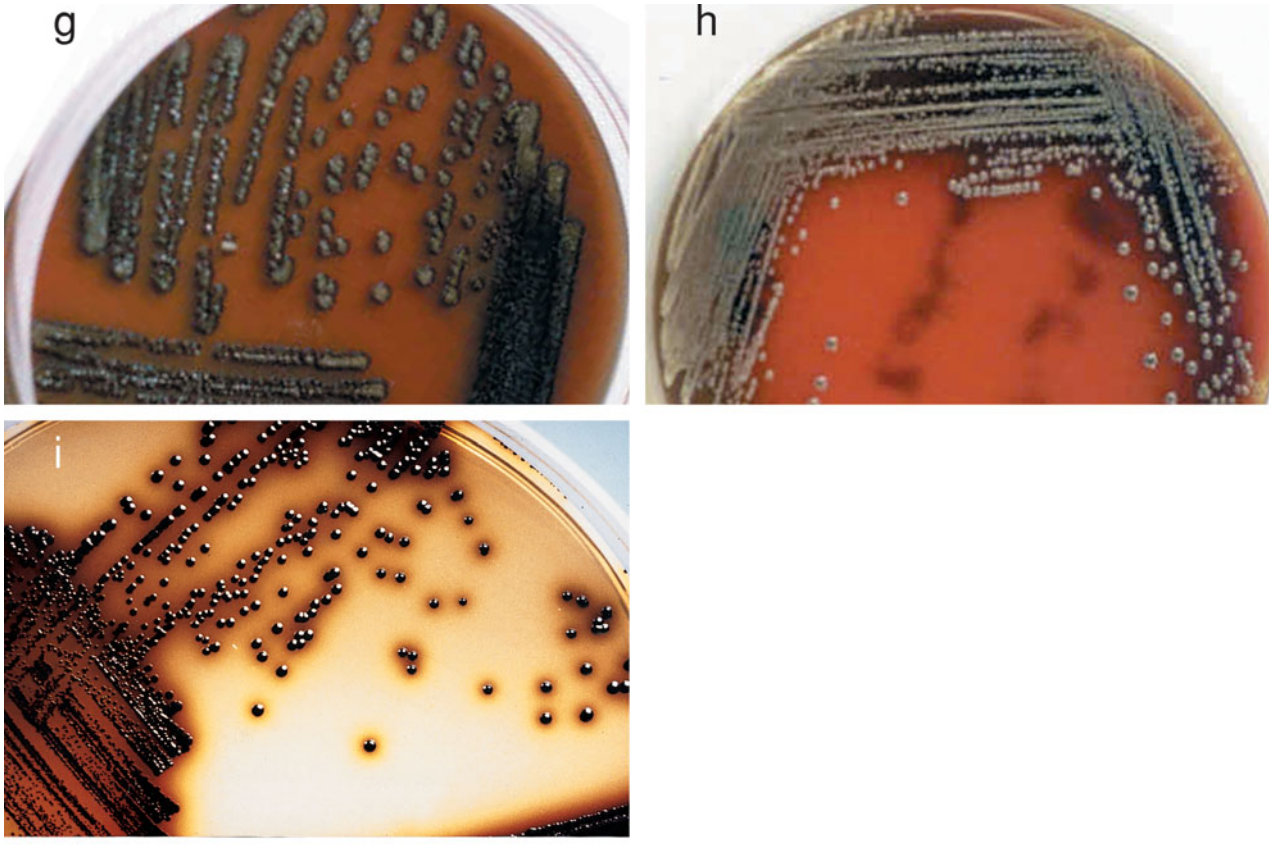

FIGURE 3 *(Continued)*

atmosphere (117). Strains grow only weakly under anaerobic conditions. They always reduce nitrate, and some may exhibit weak and delayed urease and esculinase activities. The majority (but not all [144]) of *C. durum* strains ferment mannitol, which is another very unusual feature for true corynebacteria (Table 4). API Coryne codes observed for *C. durum* include 3000135, 3001135, 3040135, 3400115, 3400135, 3400305, 3400325, and 3400335 (117), as well as 3040325, 3040335, 3440335, and 3441335 (110). This suggests that most strains are negative for alkaline phosphatase and all appear to be negative for pyrrolidonyl arylamidase. Only a small number of *C. durum* strains have been tested with the RapID system, and all were correctly identified (58). It is most likely that some strains identified as *C. matruchotii* in the past may actually have been *C. durum* strains and that differentiation can be difficult if phenotypic methods alone are used. Both species produce propionic acid as a fermentation product (4). *C. durum* usually ferments galactose and very often mannitol, whereas *C. matruchotii* is usually negative for those sugars. The *C. matruchotii* type strain exhibits α-glucosidase activity, which is not observed in *C. durum* (117). It has been shown that some *C. durum* strains also express β-galactosidase activity and ferment ribose (144).

C. falsenii

C. falsenii strains (129) have so far been isolated only from sterile body fluids. Colonies are whitish, glistening, and smooth with entire edges and are 1 to 2 mm in diameter after 24 h. After 72 h, most strains described to date

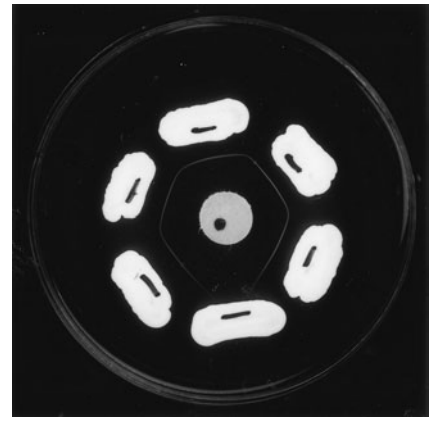

FIGURE 4 Modified Elek test (see the text) with antitoxin disk in the center. Strains are (clockwise starting at noon) NCTC 3984 (weakly toxin-positive *C. diphtheriae* biotype *gravis*), NCTC 10648 (strongly toxin-positive *C. diphtheriae* biotype *gravis*), a test strain (which was found to be a toxin producer), NCTC 10356 (nontoxigenic *C. diphtheriae* biotype *belfanti*), another test strain (also a toxin producer), and (again) NCTC 10648. The photo was kindly supplied by K.-H. Engler (WHO Diphtheria Reference Unit, Central Public Health Laboratory, London, United Kingdom).

exhibit a yellowish pigment that becomes even more intense after 120 h. This pigment is not observed in any other nonlipophilic *Corynebacterium* encountered in clinical specimens, except in the rarely found species *C. xerosis* (the colonies of the latter are dry, in contrast to *C. falsenii* colonies). The most characteristic biochemical features of *C. falsenii* are a slow but fermentative acid production from glucose, a weak pyrazinamidase reaction, and a weak urease activity which becomes visible in either Christensen's urea broth or the API Coryne system after overnight incubation only. API Coryne codes observed for *C. falsenii* are 2101104 and 2101304 (4, 129).

C. freneyi

This species has been outlined based on the study of three strains (113). All these strains had been isolated from skin-related material. There is now evidence that *C. freneyi* is also isolated from genitourinary specimens (43). *C. freneyi* is phylogenetically closely related to *C. xerosis*. Colonies of *C. freneyi* are whitish, dry, and rough, have irregular edges, and are 0.5 to 1 mm in diameter after 48 h of incubation, but *C. freneyi* strains are nonlipophilic. The basic biochemical profile (Table 4) is also similar to that of *C. xerosis*. All *C. freneyi* strains studied so far exhibit α-glucosidase activity, which is not frequently observed in other *Corynebacterium* species (very few *C. amycolatum* and all *C. xerosis* strains express this enzyme). *C. freneyi* can be differentiated from *C. xerosis* by glucose fermentation at 42°C and growth at 20°C, whereas *C. xerosis* is negative for these two reactions.

C. glucuronolyticum

C. seminale is a junior synonym of *C. glucuronolyticum* (24, 39). This species is probably part of the normal genitourinary flora of males, while its presence in females is uncertain. Colonies are whitish-yellowish, convex, and creamy, and they measure 1 to 1.5 mm in diameter after 24 h. The fermentative species *C. glucuronolyticum* is remarkable for its variability in basic biochemical reactions (Table 4). It is the only medically relevant, large-colony *Corynebacterium* species exhibiting β-glucuronidase activity. When urease activity is present, it is abundant in Christensen's urea broth, becoming positive after only 5 min of incubation at room temperature (39). *C. glucuronolyticum* is also one of the very few corynebacteria which are able to hydrolyze esculin. All *C. glucuronolyticum* strains are CAMP reaction positive (Fig. 2). With the exception of strains which are alkaline phosphatase positive, the API Coryne strip identifies *C. glucuronolyticum* well (60), although the profiles obtained from human strains may differ from those of animal isolates (24). Propionic acid is one of the major end products of glucose metabolism. *C. glucuronolyticurn* strains are often tetracycline resistant and may also exhibit resistance to macrolides and lincosamides (59). 16S rRNA gene sequences derived from fluids of patients with prostatitis have been found to be homologous with sequences derived for this species, indicating that *C. glucuronolyticum* might be involved in selected cases of prostatitis (137).

C. imitans

C. imitans was originally isolated from a nasopharyngeal specimen of a child suspected of having throat diphtheria, as well as from three adult contacts (41). This was the first well-documented case of person-to-person transmission of a *Corynebacterium* other than *C. diphtheriae* in a nonhospital setting. Additional strains of *C. imitans* have been recovered from blood cultures (4). Colonies are whitish-grayish and glistening, with entire edges; are creamy; and measure 1 to 2 mm in diameter. The strain did not produce a brown halo on Tinsdale medium but was tellurite reductase positive. Interestingly, Neisser staining was positive for polar bodies. Pyrazinamidase activity was weak only, as was fermentation of sucrose, which may lead to the initial misidentification as an atypical *C. diphtheriae* strain. It is not unlikely that *C. imitans* may also have been misidentified as *C. minutissimum* in the past, since the basic biochemical reactions of the two taxa are quite similar (Table 4). However, *C. imitans* is CAMP reaction positive and does not hydrolyze tyrosine, whereas the opposite reactions are observed for *C. minutissimum.* The API Coryne system provided the numerical codes 1100325, 2100324, and 3100325 for *C. imitans,* indicating a negative α-glucosidase reaction, whereas all *C. diphtheriae* strains express this enzyme. *C. imitans* strains do not produce propionic acid as a fermentation product, unlike *C. diphtheriae* (4), and the CFA composition profiles for each species qualitatively differ, as *C. diphtheriae* and closely related species have a unique pattern among the *Corynebacterium* spp. Diphtheria toxin assays using the Elek test or a PCR for the *tox* gene were all negative for *C. imitans* strains (4, 41). *C. imitans* is resistant to O/129, while *C. diphtheriae* is not.

C. jeikeium

C. jeikeium is one of the most frequently encountered corynebacteria in clinical specimens (64). Nosocomial transmission has been described. Recently, the complete genome sequence of a *C. jeikeium* strain has been determined (138), indicating that the lipophilic phenotype of *C. jeikeium* originates from the absence of fatty acid synthase. *C. jeikeium* is often resistant to multiple antibiotics (including penicillin and gentamicin), but this cannot be used as a taxonomic characteristic because the phenotypically closely related CDC group G bacteria may also demonstrate multidrug resistance. Quantitative DNA-DNA hydridization experiments had shown that *C. jeikeium* includes two genomospecies for which penicillin and gentamicin MICs are low, but as they could otherwise not be differentiated phenotypically from the resistant *C. jeikeium* strains, they were not proposed as independent species (115). Colonies of *C. jeikeium* are tiny, low, entire, and grayish white. *C. jeikeium* is a strict aerobe which may oxidatively produce acid from glucose and sometimes from maltose but not from fructose (CDC group G bacteria are positive for acid production from fructose). The RapID CB Plus system correctly identifies *C. jeikeium,* as does the API Coryne system if ancillary tests are used (58, 60). As for all other lipophilic corynebacteria, imperfectly cleaved mycolic acids coeluting with CFAs at or near equivalent chain lengths of 14.966 to 15.000 or of 16.7 to 16.8 have never been observed among *C. jeikeium* strains (3; Bernard, unpublished).

C. kroppenstedtii

C. kroppenstedtii (18) is a rarely recovered species originally isolated from the sputum of a patient with pulmonary disease. Additional strains have been isolated from a lung biopsy specimen, sputum, a breast abscess, and patients with granulomatous lobular mastitis (4, 106). Apart from *C. amycolatum* and *C. atypicum,* it is the only *Corynebacterium* species lacking mycolic acids. Colonies are grayish, translucent, slightly dry, and less than 0.5 mm in diameter after 24 h of incubation at 37°C. *C. kroppenstedtii* is lipophilic and is one of the few medically relevant *Corynebacterium* species exhibiting esculinase activity. Other biochemical characteristics are given in Table 4. API Codes of *C. kroppenstedtii* are 0101104,

2040104, and 2040105 (4). It can be differentiated from *C. durum*, *C. matruchotii*, and *C. glucuronolyticum* by its colony morphology and from *C. glucuronolyticum* also by its negative CAMP reaction.

C. lipophiloflavum

C. lipophiloflavum (45) is represented by only a single strain, which has been isolated from vaginal discharge from a patient with bacterial vaginosis. It has the same biochemical screening pattern as *C. urealyticum*, except that it exhibits a strong yellow pigment and weaker urease activity (Table 4). In contrast to most *C. urealyticum* strains, the *C. lipophiloflavum* strain observed was not multidrug resistant.

C. macginleyi

C. macginleyi (119) has been isolated almost exclusively from eye specimens, whether from diseased (53) or healthy conjunctiva. Colonies are typical for lipophilic corynebacteria (see above). When grown on Tween 80-SBA plates (better growth is usually found on plates supplemented with 0.1% Tween 80 than on those supplemented with 1.0% Tween 80), some *C. macginleyi* strains exhibit a rose pigment which is not seen for any other lipophilic *Corynebacterium* species. *C. macginleyi* is one of the very few *Corynebacterium* species not expressing pyrazinamidase activity (Table 4). Most strains ferment mannitol, while the majority of other corynebacteria are unable to do so. The API Coryne system correctly identifies *C. macginleyi* (60). Strains belonging to this species are susceptible to a broad spectrum of antibiotics (53).

C. matruchotii

C. matruchotii is thought to be a natural inhabitant of the oral cavity, particularly on calculus and plaque deposits, and so has been much studied by oral microbiologists (110). Otherwise, it is a very rare human pathogen. Microcolonies appear flat, filamentous, and spider-like, but macrocolonies have a variable appearance. *C. matruchotii* demonstrates a very unusual appearance by Gram staining in that so-called whip handles (i.e., filamentous bacteria with a single short bacillus adjacent to the end of the filament, creating the illusion of a whip) are observed (Fig.1e). This microscopic presentation is consistent even when isolates that had been preserved for many years in a culture collection are stained. It has recently been demonstrated that heterogeneity existed among *C. matruchotii* strains obtained from international culture collections and that some strains represented were misidentified *C. durum* isolates (110). *C. matruchotii* strains are consistently negative for galactose, whereas *C. durum* strains can be positive. The API Coryne system database does not contain *C. matruchotii;* the numerical codes observed for *C. matruchotii* include 7000325, 7010325, and 7050325.

C. matruchotii-Like Strain

This species is represented by a single strain, ATCC 43833 (110). It had been deposited in ATCC as *C. matruchotii,* but it is a distinct species as revealed by dot-blot hybridization and 16S rRNA gene sequencing data. Colonies are pinpoint to 0.1 mm in diameter, grayish white, with a smooth, nonadherent texture. Biochemical screening reactions are similar to those of *C. minutissimum,* except that strain ATCC 43833 exhibits esculinase activity in the API Coryne system. The numerical API Coryne profile for this unvalidated taxon is 2140325.

C. minutissimum

C. minutissimum is part of the normal human skin flora. Its association with erythrasma is highly questionable (154). Colonies of *C. minutissimum* are whitish-grayish, shiny, moist, convex, and circular; have entire edges; and are about 1 to 1.5 mm in diameter after 24 h. Most of the colonies are creamy, but some may also have a sticky consistency. *C. minutissimum* strains have a fermentative metabolism and produce acid from sucrose variably. Very few *C. minutissimum* strains are also able to produce acid from mannitol (154). The API Coryne system identifies *C. minutissimum,* with additional tests being necessary for most of the strains (60). Many *C. minutissimum* strains are pyrrolidonyl arylamidase positive. *C. minutissimum* strains exhibit DNase activity (154), and nearly all strains hydrolyze tyrosine, whereas only a very few strains exhibit a positive CAMP reaction. Lactic and succinic acids are the major end products of glucose metabolism (36, 154). Some isolates possess TBSA in their cell membranes. Nearly all *C. minutissimum* strains are susceptible to O/129 (150-μg disk); i.e., they exhibit an inhibition zone around the disk (usually between 20 and 35 mm in diameter).

C. mucifaciens

C. mucifaciens (48) has been isolated mainly from blood cultures and other sterile body fluids, but it has also been recovered from abscesses, soft tissue, and dialysate (4). Colonies are very distinct because they are slightly to overtly yellow and very mucoid (Fig. 3c) (with very few strains not being mucoid [Funke, unpublished]). *C. mucifaciens* is the only presently known *Corynebacterium* species exhibiting such mucoid colonies; this characteristic strongly reminds the bacteriologist of *Rhodococcus equi* colonies. An extracellular substance (probably polysaccharides) causing connective filaments between the cells has been demonstrated as the ultrastructural correlate of the mucoid colonies. Colonies are about 1 to 1.5 mm after 24 h of incubation and have entire edges. They appear less mucoid after extended incubation for 96 h. *C. mucifaciens* has an oxidative metabolism. It consistently produces acid from glucose, but acid production from sucrose is variable. The API Coryne numerical codes 2000004, 2000104, 2000105, 2100104, 2100105, 6000004, 6100104, and 6100105 have been observed for *C. mucifaciens,* suggesting that occasionally glucose oxidation may be too slow to be observed by that method. *C. mucifaciens* is enzymatically less active than *R. equi,* which exhibits α- and β-glucosidase activities not observed for *C. mucifaciens.* In addition, *C. mucifaciens* produces acid from fructose and may produce acid from glycerol and mannose, but acid production from these sugars is not seen in *R. equi* strains. Tuberculostearic acid can be detected in amounts of 1 to 2% of the total CFAs. β-Lactam antibiotics and aminoglycosides show very good activities against *C. mucifaciens.*

C. propinquum

C. propinquum is the closest phylogenetic relative of *C. pseudodiphtheriticum* (104, 123) and has the same niche (i.e., the oropharynx) as *C. pseudodiphtheriticum.* Colonies are whitish and somewhat dryish, have entire edges, and measure 1 to 2 mm in diameter after 24 h of incubation. This species reduces nitrate and hydrolyzes tyrosine but does not hydrolyze urea (Table 4). The API Coryne system and the RapID CB Plus system correctly identify *C. propinquum* strains (58, 60).

C. pseudodiphtheriticum

C. pseudodiphtheriticum is part of the normal oropharyngeal flora. As described in Table 3, this species has been well

documented to cause pneumonia in various patient populations. Colonies are whitish and slightly dry, have entire edges, and measure 1 to 2 mm in diameter after 48 h of incubation. This nonfermenting species reduces nitrate and hydrolyzes urea but does not produce acid from any of the commonly tested carbohydrates (Table 4). Some strains hydrolyze tyrosine. The API Coryne system and the RapID CB Plus system correctly identify *C. pseudodiphtheriticum* strains (58, 60). For this species, imperfectly cleaved mycolic acids coeluting with CFAs have been demonstrated (3). *C. pseudodiphtheriticum* strains are susceptible to β-lactam antibiotics, but resistance to macrolides and lincosamides has been observed.

C. pseudotuberculosis

C. pseudotuberculosis is phylogenetically closely related to *C. diphtheriae* (104, 123), may harbor the diphtheria toxin gene, produces propionic acid as a fermentation product, and contains large amounts of the CFA $C_{16:1\omega7c}$ (3). Colonies are yellowish white, opaque, convex, and about 1 mm in diameter after 24 h. Like *C. ulcerans,* *C. pseudotuberculosis* is positive for urease and the CAMP inhibition test (complete inhibition of the effect of *S. aureus* β-hemolysin on sheep erythrocytes is achieved by streaking the presumed *C. pseudotuberculosis* strain in a right angle toward *S. aureus* and overnight incubation; a β-hemolysin inhibition zone in the form of a triangle is observed, as is the case for *A. haemolyticum* [Fig. 2]). *C. pseudotuberculosis* is not susceptible to O/129, whereas *C. ulcerans* strains are (74). *C. pseudotuberculosis* is variable for both nitrate reduction and sucrose fermentation. The API Coryne system and the RapID CB Plus panel correctly identify this species (58, 60).

C. resistens

This recently defined species (103) has entire, grayish-whitish, and glistening colonies and is lipophilic. It is unusual in having a negative pyrazinamidase reaction, which differentiates it from the phenotypically related *C. jeikeium* or CDC coryneform group G strains. In addition, *C. resistens* grows slowly under anaerobic conditions, whereas *C. jeikeium* is unable to do so. The *C. resistens* strains reported in the literature were resistant to penicillin, cephalosporins, aminoglycosides, clindamycin, and ciprofloxacin but remained susceptible to glycopeptides. It is presently unknown whether true *C. resistens* strains are often misidentified as *C. jeikeium* in the routine laboratory.

C. riegelii

C. riegelii strains were originally described as being isolated from females with urinary tract infections (49), but additional strains have been recovered from blood cultures, including cord blood (4). Colonies are whitish, glistening, and convex; have entire margins; and measure up to 1.5 mm in diameter after 48 h of incubation. Some colonies are of a creamy consistency, whereas others are sticky. *C. riegelii* strains exhibit a very strong urease activity with Christensen's urea broth, becoming positive within 5 min after inoculation at room temperature. A very peculiar characteristic of *C. riegelii* is the slow fermentation of maltose but not glucose. No other defined *Corynebacterium* exhibits this feature (Table 4). The weak anaerobic growth of *C. riegelii* corresponds to the weak fermentative metabolism. The API Coryne system codes observed for *C. riegelii* include 0101224, 2001224, and 2101224.

C. simulans

This species has been delineated from some *C. striatum*-like strains (145). The three strains described in the original publication came from skin-related specimens (foot abscess, lymph node biopsy specimen, and boil). Two additional strains have been characterized, one from bile and one from a blood culture (4). Colonies of *C. simulans* (grayish white, glistening, creamy, and 1 to 2 mm in diameter) are very similar to those of *C. minutissimum, C. singulare,* and *C. striatum,* all of which are the closest phylogenetic neighbors. *C. simulans* is the only valid *Corynebacterium* species described to date that reduces nitrite. Further characteristics which differentiate *C. simulans* from the closely related nonlipophilic, fermentative corynebacteria are the inability to acidify ethylene glycol and the inability to grow at 20°C (in contrast to *C. striatum*). API Coryne profiles include 0100305, 2100105, 2100301, 2100305, and 3000125 (including the falsely negative nitrate reduction reaction because of the strong nitrite reduction).

C. singulare

C. singulare colonies are circular and slightly convex with entire margins and are of a creamy consistency, as observed for *C. minutissimum* and *C. striatum* (121). Key biochemical reactions are like those for *C. minutissimum,* except that urease activity is observed (Table 4). The numerical API Coryne system profile is 6101125, indicative that pyrrolidonyl arylamidase activity is observed. Like *C. minutissimum* and *C. striatum*, *C. singulare* also hydrolyzes tyrosine. *C. singulare* can be differentiated from the much more frequently isolated *C. minutissimum* with use of the bioMérieux biotype 100 gallery, but this is not a usual clinical microbiology laboratory test. *C. singulare* does not produce propionic acid as a fermentation product, differentiating it from *C. amycolatum*.

C. striatum

C. striatum is part of the normal human skin flora. Nosocomial transmission of *C. striatum* has been documented (86). Colonies are convex, circular, shiny, moist, and creamy with entire edges and are about 1 to 1.5 mm in diameter after 24 h of incubation. Some investigators have described *C. striatum* colonies as somewhat like those of small coagulase-negative staphylococci. *C. striatum* has a fermentative metabolism, and acid production from sucrose is variable. The API Coryne system identifies *C. striatum,* but additional tests are needed in most of the cases (60). All *C. striatum* strains hydrolyze tyrosine, and some strains are CAMP reaction positive; however, the CAMP reaction of *C. striatum* strains is usually not as strong as that of other CAMP test-positive species (e.g., *C. auris* or *C. glucuronolyticum*). Lactic and succinic acids are the major end products of glucose metabolism (36). All *C. striatum* strains are susceptible to O/129. Resistance to macrolides and lincosamides due to the presence of an rRNA methylase has been described. *C. striatum* may also be resistant to quinolones and tetracyclines.

C. sundsvallense

C. sundsvallense (4, 14) is a newly described species that has been isolated from blood cultures, a vaginal swab, and a sinus drainage from an infected groin. Colonies of this nonlipophilic species are buff or slightly yellowish and adherent to agar and have a sticky consistency. Gram staining shows bulges or knobs at the ends of some rods, and these are not seen in any other corynebacteria. Fermentation of glucose, lactose, and sucrose is slow (Table 4). *C. sundsvallense* can be

differentiated from *C. durum* by its positive α-glucosidase reaction and its inability to ferment galactose. It is further differentiated from *C. matruchotii* by expressing urease but not nitrate reductase activity and by not producing propionic acid as an end product of glucose metabolism (4, 14).

C. thomssenii

C. thomssenii (153) is a rarely found species, originally repeatedly isolated from a patient with pleural effusion; a second strain was recovered from the environment in Canada (4). This species is fastidious and slowly growing, resulting in colonies <0.5 mm after 48 h, but it is not lipophilic. After 96 h, colonies are molar tooth-like, very sticky, and slightly adherent to agar. The clinical strain of *C. thomssenii* is the only *Corynebacterium* species expressing *N*-acetyl-β-glucosaminidase activity, which can be observed in either the API Coryne or the API ZYM system. Acid is slowly and fermentatively produced from glucose, maltose, and sucrose, and the resulting API Coryne code for *C. thomssenii* is 2121125.

C. tuberculostearicum

C. tuberculostearicum was recently revived for a never validly published taxon and also included a strain of the unvalidated species "*C. pseudogenitalium*" (35). This lipophilic species has some variable biochemical key reactions (Table 4) and can be differentiated from CDC group G and *C. accolens* only through the presence of TBSA. However, as CFA analysis cannot be routinely performed in every clinical laboratory, it is unknown how many tentatively identified CDC group G strains are in fact *C. tuberculostearicum* strains. Unfortunately, the published report on *C. tuberculostearicum* did not provide any further features to differentiate this species from the phenotypically closely related CDC group G bacteria.

C. tuscaniae

C. tuscaniae, a recently described species, has been isolated from blood cultures of a patient suffering from endocarditis (114). *C. tuscaniae* does not grow under anaerobic conditions, which distinguishes this species from the phenotypically closely related *C. minutissimum*. In addition, *C. tuscaniae* hydrolyzes hippurate but not tyrosine, whereas *C. minutissimum* has opposite reactions (Table 4). *C. tuscaniae* colonies are rounded and regular, in contrast to the biochemically closely related *C. amycolatum* colonies, which exhibit irregular edges.

C. ulcerans

Phylogenetically, *C. ulcerans* (120) is, together *with C. pseudotuberculosis*, the closest relative of *C. diphtheriae* (104, 123) and contains significant amounts of $C_{16:1\omega7c}$. *C. ulcerans* can harbor the diphtheria toxin gene, but differences in the receptor-binding and translocation domains have been described, and a *C. ulcerans* diphtheria toxin-specific PCR has been developed (128). Disease associated with this bacterium is rare, but if the organism is recovered from pseudomembranous material, the disease must be treated like a case of diphtheria (29, 30). Recent reports have described the transmission of *C. ulcerans* from domestic dogs and cats to humans (84). Colonies are somewhat dry, waxy, and gray-white with light hemolysis, being 1 to 2 mm in diameter after 24 h. *C. ulcerans* may be differentiated from *C. diphtheriae* by urease activity and a CAMP inhibition reaction (Table 4). Strains of *C. ulcerans* are positive for glycogen, starch, and trehalose fermentation. The API Coryne system and the RapID CB Plus identification strip correctly identify *C. ulcerans* (58, 60).

C. urealyticum

C. urealyticum is one of the more frequently isolated, clinically significant corynebacteria in clinical specimens (64). *C. urealyticum* is strongly associated with urinary tract infections. Recovery of this bacterium is often associated with urine with an alkaline pH, resulting in struvite crystals. As for all other lipophilic corynebacteria, colonies are pinpoint, convex, smooth, and whitish-grayish on regular SBA. *C. urealyticum* is a strict aerobe and has very strong urease activity (Table 4). Commercial identification systems correctly identify *C. urealyticum. C. urealyticum* is almost always multidrug resistant (64, 130), but rare penicillin-susceptible strains have also been described.

C. xerosis

Colonies are dry, granular, and yellowish, have irregular edges, and are 1 to 1.5 mm in diameter after 24 h. It must be emphasized that nearly all "*C. xerosis*" strains that appeared in the literature before 1996 may have been misidentified *C. amycolatum* strains (46). *C. striatum* strains were also misidentified as *C. xerosis* in the past. *C. xerosis* has a fermentative metabolism, is variable for the presence of nitrate reductase, but always expresses α-glucosidase as well as leucine arylamidase activities. Because *C. xerosis* was thought to be rarely encountered in clinical specimens, it was not included in the API Coryne system version 2.0 database. The numerical profiles observed for *C. xerosis* strains include 2110325 and 3110325. The RapID CB Plus system correctly identifies *C. xerosis* (58). Lactic acid is the major end product of glucose metabolism, and strains are susceptible to O/129.

Biochemical Reactions for Other Genera

The key biochemical reactions for the genera other than *Corynebacterium* are given in Table 5.

Genus *Turicella*

T. otitidis is almost exclusively isolated from clinical specimens from the ear region, but it does not cause otitis media with effusion in children (73). Colonies are whitish, convex, and creamy, have entire edges, and measure 1 to 1.5 mm in diameter after 48 h of incubation. Some young colonies show a greenish appearance when taken away from the plates with a swab. The distinctive Gram stain morphology of *T. otitidis* is shown in Fig. 1b. Differentiation from *C. auris* and *C. afermentans* subsp. *afermentans* is readily achieved by morphologic features, but utilization reactions may also assist in the differentiation of these taxa (47). All *T. otitidis* strains are strongly CAMP reaction positive and give the numerical code 2100004 in the API Coryne system. The MICs of β-lactam antibiotics for many strains are very low; some strains might be resistant to macrolides and clindamycin (59).

Genus *Arthrobacter*

Arthrobacter spp. might be part of the indigenous normal human flora, but their main habitat is soil. *A. cumminsii* seems to be a normal commensal in humans and appears to be the most frequently isolated *Arthrobacter* species in human clinical specimens (54). *Arthrobacter* colonies are usually whitish-grayish, slightly glistening, and creamy and are 2 mm or greater in diameter after 24 h. *A. cumminsii* is slightly smaller than the other arthrobacters and may also exhibit a sticky consistency (54). *Arthrobacter* spp. usually do not oxidize any of the carbohydrates routinely tested and do not express a cheese-like smell, as is often found for the phenotypically closely related brevibacteria. Some arthrobacters are motile,

whereas brevibacteria are always nonmotile. Like brevibacteria, *Arthrobacter* spp. express DNase and have gelatinase activity (44). The identification of arthrobacters to the species level might be achieved by carbohydrate utilization tests, but this is recommended for the reference laboratory only. The recently described *A. albus* is phylogenetically closely related to *A. cumminsii* but might be differentiated phenotypically by being resistant to desferrioxamine, whereas *A. cumminsii* is susceptible. *A. cumminsii* has a distinctive CFA pattern, with $C_{14:0i}$ and $C_{14:0}$ each representing 2 to 4% of all CFAs (54). The penicillin MICs for most *Arthrobacter* strains are low (44). Aminoglycosides and quinolones show only very weak activities against *A. cumminsii* strains (54).

Genus *Brevibacterium*

Some *Brevibacterium* spp. are part of the normal human skin flora. Colonies are whitish-grayish (or yellowish like *B. luteolum* [146]), convex, and mostly creamy, and are 2 mm or greater in diameter after 24 h. *B. mcbrellneri* colonies have a more granular appearance and are dryer than those of other brevibacteria. Some brevibacteria may develop a yellowish or greenish pigment after prolonged incubation. Many *Brevibacterium* strains isolated from human clinical material give off a distinctive cheese-like odor. Brevibacteria are nonmotile, are halotolerant (6.5% NaCl), and form methanethiol from methionine, but this test is specific for brevibacteria only when it is read within 2 h (40). Brevibacteria can be identified to the species level by carbohydrate utilization tests. More than 90% of all clinical *Brevibacterium* isolates are *B. casei* (40). *B. sanguinis* is very similar to *B. casei* and can be differentiated from this species by susceptibility to thallium acetate (147). The MICs of β-lactam antibiotics for brevibacteria are often elevated (59, 139).

Genus *Dermabacter*

D. hominis strains are part of the normal skin flora. Colonies are whitish, convex, of a creamy or sticky consistency, and 1 to 1.5 mm in diameter after 48 h (Fig. 3e). *D. hominis* strains are sometimes mistaken for small-colony coagulase-negative staphylococci. The Gram stain result is distinctive, with coccobacillary or coccoidal forms (Fig. 1c). The key biochemical reactions are given in Table 5. *D. hominis* is one of the few coryneform bacteria with a variable reaction for xylose fermentation. It is the only catalase-positive coryneform bacterium (except *Actinomyces neuii* [36]) that is able to decarboxylate lysine and ornithine (61). The API Coryne system and the RapID CB Plus panel correctly identify this species (58, 60). *D. hominis* strains may be resistant to aminoglycosides (61, 139).

Genus *Rothia*

This genus presently comprises five validated species, of which only two are clinically relevant: *R. mucilaginosa* (formerly designated *Stomatococcus mucilaginosus*), *R. dentocariosa* (the type species), as well as *R. dentocariosa* genomovar II (19, 81). The last organism has not been formally named because it has not been possible to biochemically distinguish it from authentic *R. dentocariosa* sensu stricto (genomovar I) (81). Some of the former CDC coryneform group 4 bacteria (Fig. 3h) were also shown to be representatives of *R. dentocariosa* (21). These grayish strains were isolated primarily from respiratory materials, pus, or blood cultures, in contrast to *C. aurimucosum* strains, which were derived from the female urogenital tract.

Colonies of *R. dentocariosa* are whitish (or more rarely grayish black), raised, and smooth or rough or have a "spoke wheel" form (Fig. 3f), and they are up to 2 mm in diameter after 48 h. *Rothia* strains usually grow slightly better in a CO_2-enriched atmosphere. The biochemical features of *R. dentocariosa* are given in Table 5. The API Coryne system correctly identifies *R. dentocariosa* (60). Its CFA composition is of the branched-chain type (3), which allows differentiation from the biochemically similar species *C. durum, C. matruchotii,* and *Actinomyces viscosus* (see chapter 56), all of which also occupy the oropharynx. *R. dentocariosa* may also be confused with *D. hominis* and *Propionibacterium avidum* (see chapter 55) (142), both of which, in contrast, always exhibit smooth colonies. As shown in a study on the pharyngeal bacterial flora of healthy adults, one-third of all *R. dentocariosa* strains isolated were negative for the key biochemical reaction catalase (144). The MICs of aminoglycosides for some *R. dentocariosa* strains are elevated, whereas penicillins usually show good in vitro activities against *Rothia* strains.

Genus *Exiguobacterium*

It is not known whether exiguobacteria are part of the indigenous bacterial flora of humans. Colonies of *E. acetylicum* are smooth, golden-yellow to orange, and up to 2 mm in diameter after 24 h of incubation. Acid from carbohydrates is rapidly produced by fermentative metabolism. Exiguobacteria are motile and often oxidase positive. They might be confused with microbacteria, but CFA analysis provides a clear-cut distinction between the two genera (Table 1). The pathogenic potential of *E. acetylicum* seems to be rather low, since it has been isolated from different sources (e.g., skin, wounds, and cerebrospinal fluid [71]), but case reports on infectious diseases due to *E. acetylicum* are not extant. Cases of pseudobacteremia due to *E. acetylicum* have been observed.

Genus *Oerskovia*

O. turbata is usually acquired from the environment (e.g., soil). Colonies are pale yellow to phosphorous yellow, convex, and creamy; they penetrate agar; and they are approximately 1 to 2 mm in diameter after 24 h. *O. turbata* rapidly produces acid from sugars by fermentation; it also exhibits a very strong esculin reaction. The genus is well identified by the API Coryne system (60). *O. turbata* does not hydrolyze xanthine or hypoxanthine, whereas the related *C. cellulans* is able to do so.

Genus *Cellulomonas*

Cellulomonas strains are usually acquired from the environment. Colonies are first whitish or pale or bright yellow, but after 7 days nearly all *Cellulomonas* strains are somewhat yellow. Colonies vary between 0.5 and 1.5 mm in diameter after 24 h, are convex and creamy, and have entire edges. *Cellulomonas* spp. are variable for the fermentation of mannitol. Other key biochemical reactions of *Cellulomonas* spp. are given in Table 5. The majority of *Cellulomonas* strains express cellulase activity, demonstrated by incubating a heavy bacterial suspension (McFarland no. 6 standard) with a piece of sterile copy paper in a 0.9% NaCl solution for 10 days, resulting in dissolution of the paper (55). The recently described *C. denverensis* can be differentiated from *C. hominis* by its positive reaction for D-sorbitol fermentation (7).

Genus *Cellulosimicrobium*

Colonies of *C. cellulans* are similar to those of *O. turbata* (see above) and also pit the agar. In addition, *C. cellulans* exhibits

a biochemical screening profile which is very similar to that of *O. turbata* (Table 5). However, *C. cellulans* hydrolyzes either xanthine or hypoxanthine whereas *O. turbata* does not, and *O. turbata* strains might be motile whereas *C. cellulans* strains are not (71, 125). The recently described *C. funkei* strains can be differentiated from *C. cellulans* (former *O. xanthinolytica*) by their negative inulin and raffinose fermentation reactions (8); in addition, *C. funkei* strains are motile but *C. cellulans* strains are not.

Genus *Microbacterium*

Microbacteria account for the majority of yellow-pigmented coryneform bacteria isolated from clinical specimens. All shades of yellow pigment are observed, ranging from pale to bright yellow and orange. Most of the strains are catalase positive, but catalase-negative strains might be observed. Some microbacteria grow under anaerobic conditions but only weakly. Some microbacteria are nitrate reductase negative, which distinguishes them from the phenotypically closely related genus *Cellulomonas*, all presently defined species of which are nitrate reductase positive (Table 5). Microbacteria may ferment mannitol but not xylose, whereas the lack of xylose fermentation has not been observed for *Cellulomonas* strains described so far.

Species identification is almost impossible since for many defined *Microbacterium* species the type strain is the only representative, preventing the creation of a comprehensive database. Final identification to the species level is best achieved by chemotaxonomic (interpeptide bridges) and molecular genetic (e.g., 16S rRNA gene sequencing) investigations. The most frequently isolated, validated microbacteria in clinical specimens include *M. oxydans, M. paraoxydans, M. aurum,* and *M. lacticum* (66, 82).

Microbacteria are usually susceptible to vancomycin (except *M. resistens* [50]), but susceptibility to other antimicrobial agents is unpredictable (in particular, resistance to aminoglycosides has been observed [42]), and therefore every individual clinically significant strain must be tested.

Genus *Curtobacterium*

Curtobacteria are very infrequently isolated yellow- or yellow-orange-pigmented oxidative coryneform bacteria. In contrast to most microbacteria, they produce acid from carbohydrates very slowly (within 4 to 7 days) (38). Curtobacteria are usually nitrate reductase negative but strongly hydrolyze esculin (Table 5). *C. pusillum* and related strains have a most unusual CFA composition that is not observed in any other coryneform bacteria, with a ω-cyclohexyl fatty acid identified as feature 7 ($C_{18:1\omega7c/\omega9c/\omega12t}$) representing more than 50% of all CFAs (38). Again, the differentiation of curtobacteria is very difficult and should be performed in a reference laboratory. The MICs of macrolides and rifampin for curtobacteria are very low.

Genus *Leifsonia*

Leifsonia aquatica is very rarely encountered in clinical specimens. It is always motile, does not hydrolyze either gelatin or casein, and has a stronger DNase activity than most microbacteria (65). *L. aquatica* is the only species within the genus *Leifsonia* which is able to grow in broth enriched with 5% NaCl (34). Its yellow pigment develops relatively slowly within 3 to 4 days. The MICs of vancomycin for some *L. aquatica* strains were shown to be elevated (8 μg/ml) (65), but the precise mechanism of this resistance is not known.

Genera *Janibacter, Pseudoclavibacter/ Zimmermannella,* and *Knoellia*

Strains belonging to genera *Janibacter, Pseudoclavibacter/ Zimmermannella,* and *Knoellia* have been derived from the environment, foods, or animals but have also been recovered recently from clinical materials and characterized using 16S rRNA gene sequencing. These taxa were described as having white, creamy, or yellowish pigment, and all were nonmotile. *Janibacter, Pseudoclavibacter/Zimmermannella,* and *Knoellia* were oxidative, and *Brachybacterium* strains were fermentative. All strains tested so far were susceptible to vancomycin. Since no comprehensive biochemical data based on a large number of strains are available at present, these genera were not included in Table 5.

Genus *Arcanobacterium*

The genus *Arcanobacterium* comprises six species, all of which except *A. pluranimalium* exhibit beta-hemolysis on SBA. The three medically relevant species, *A. haemolyticum*, *A. pyogenes*, and *A. bernardiae,* are all catalase negative. All species show a fermentative glucose metabolism, with succinic and lactic acids as their major end products. All arcanobacteria grow and express hemolysis best in a CO_2-enriched atmosphere.

The colonies of the type species, *A. haemolyticum*, are 0.5 mm in diameter after 48 h of incubation at 37°C, and two morphotypes have been described: one rough type isolated mainly from the respiratory tract and one smooth type isolated mainly from wounds. The biochemical reactions of *A. haemolyticum* are given in Table 5. Of major value for the identification of *A. haemolyticum* is the so-called CAMP inhibition test (see the description of the CAMP inhibition test in the section on *C. pseudotuberculosis*) (Fig. 2). The protein responsible for this phenomenon is a phospholipase D excreted by *A. haemolyticum*, and this protein is genetically and functionally similar to the ones expressed by *C. ulcerans* and *C. pseudotuberculosis*. *A. haemolyticum* and the two other medically relevant arcanobacteria are correctly identified by the API Coryne system (60).

A. pyogenes colonies are the largest of all arcanobacterium colonies, with diameters of up to 1 mm after 48 h of incubation. Of all the arcanobacteria, this species also shows the sharpest zone of beta-hemolysis on SBA. The protein responsible for hemolysis, named pyolysin, is also an important virulence factor in vivo. Gram stains may show some branching rods. *A. pyogenes* is the only *Arcanobacterium* species of medical relevance that expresses β-glucuronidase activity and that is capable of fermenting xylose.

A. bernardiae (57, 105) shows glassy, whitish colonies of <0.5 mm in diameter after 48 h. Some colonies have a creamy consistency, whereas others are sticky. Gram staining shows relatively short rods without branching. Most *A. bernardiae* strains belong to the very few coryneform bacteria that are able to ferment glycogen. Another peculiar feature of *A. bernardiae* strains is their ability to produce acid faster from maltose than from glucose.

The MICs of all β-lactams, rifampin, and tetracycline for arcanobacteria are very low, whereas aminoglycosides and quinolones have reduced activities against arcanobacteria (Funke, unpublished). Macrolides also exhibit excellent activities against arcanobacteria and are an alternative to β-lactam antibiotics for the treatment of infections, since treatment failures due to β-lactam antibiotics because of the inability of β-lactam antibiotics to act intracellularly have been reported.

ANTIMICROBIAL SUSCEPTIBILITIES

The susceptibility patterns for each taxon were given with the descriptions of each taxon (see above). Since the antimicrobial susceptibility of coryneform bacteria is not predictable in every case, susceptibility testing should always be performed with clinically significant isolates (see "Clinical Significance"). Due to the emergence of vancomycin-resistant gram-positive organisms, it has become inappropriate to recommend glycopeptides as first-line drugs for the treatment of infections caused by coryneform bacteria. It is also noteworthy that some coryneform bacteria (e.g., *Microbacterium resistens*) are intrinsically vancomycin resistant.

The Clinical and Laboratory Standards Institute has recently published testing conditions and interpretive criteria for susceptibility testing of coryneform bacteria by use of a broth microdilution method (13). Direct colony suspensions equivalent to a 0.5 McFarland standard are prepared, and strains are incubated in cation-adjusted Mueller-Hinton broth with 2 to 5% (vol/vol) lysed horse blood at 35°C in ambient air for up to 48 h. Interpretive categories for the MICs obtained are presently available for 16 antimicrobial agents including newer drugs like quinupristin-dalfopristin (63) or linezolid (51). Very few studies comparing broth microdilution and disk diffusion results for susceptibility testing of coryneform bacteria (149) have been performed.

In the past, MICs have been determined by either the E test (AB Biodisk, Solna, Sweden) or the agar dilution or broth microdilution method. The results of the E test have been shown to correlate well with those of both the broth microdilution and the agar dilution methods for *Corynebacterium* spp. (92, 152). The E test should be carried out on Mueller-Hinton agar supplemented with 5% sheep blood. The same medium is used for the agar dilution method (59), but this method is not applicable in the routine laboratory; rather, it should be used in studies with individual antimicrobial agents.

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

The guidelines related to when coryneform bacteria should be identified to the species level (see "Clinical Significance") are also applicable for evaluating and interpreting culture results; i.e., whenever coryneform bacteria are identified to the species level, the results should be reported.

In the rare case of microscopically suspected *C. diphtheriae* (i.e., a positive Neisser staining result), the physician in charge of the patient should be notified immediately, although culture results and toxin testing results become available only later.

It is evident that repeated isolation of a predominant strain of a coryneform bacterium or a coryneform bacterium growing in pure culture suggests an etiological relationship to the patient's disease. If coryneform bacteria are present in blood cultures, the physician in charge should be notified immediately, and it should be emphasized when reporting this result that the clinical significance of the coryneform bacteria must be carefully examined by cooperation between the microbiology laboratory and the physician. In our experience, one positive blood culture out of two or three aerobically and anaerobically incubated pairs of blood cultures is hardly ever clinically significant (except in cases of treated endocarditis). Care must be taken in the interpretation of the results for those patients for whom half or more of the blood specimens taken for culture become positive for coryneform bacteria, in particular when lipophilic corynebacteria are cultured, since not all blood samples taken from patients with endocarditis due to lipophilic corynebacteria may eventually become positive.

On the other hand, coryneform bacteria should be reported as "normal flora" when they are grown in equal or smaller numbers from nonsterile sites together with other resident flora. It is suggested that the primary isolation plates be retained for at least 72 h before they are discarded in order to have the opportunity to assess the bacterial population retrospectively.

APPENDIX 1

Genus *Gardnerella*

The genus *Gardnerella* does not have a particular phylogenetic relationship to any of the established genera described in this chapter. It is remotely related to the genus *Bifidobacterium* (94), and these genera share some important features, such as production of acetic and lactic acids as fermentation products. A 16S rRNA gene PCR product selected for detection of a *G. vaginalis*-specific sequence was found to have some less-than-specific homology with several *Bifidobacterium* species (100). *G. vaginalis* is the only species belonging to the genus *Gardnerella*. Studies on the ultrastructure of the cell wall of *G. vaginalis* have demonstrated that it has a cell wall similar to but much thinner than the cell walls of other gram-positive bacteria (i.e., there is a smaller peptidoglycan layer) (124). Lysine is the diamino acid of the cell wall, and CFAs are similar to those detected in *Actinomyces* spp., *Arcanobacterium* spp., and *Corynebacterium* spp., with $C_{16:0}$ and $C_{18:1\omega9c}$ predominating. The G+C content of 42 to 44 mol% is lower than that of every other genus described in this chapter.

Gram stains show thin gram-variable rods or coccobacilli (Fig. 1f). Catalase is not produced, and cells are nonmotile and have a slow fermentative metabolism.

Natural habitat

G. vaginalis can be found in the anorectal flora of healthy adults of both sexes as well as in that of children (10). It is also part of the endogenous vaginal flora in women of reproductive age. The optimal pH for the growth of *G. vaginalis* is between 6 and 7. The organism can also be recovered from the urethras of the male partners of women with bacterial vaginosis (BV) (10).

Clinical significance

G. vaginalis is associated with BV; its causative role in the syndrome is controversial (131, 132). Recurrent BV is due to reinfection rather than to relapse (i.e., overgrowth of the previously colonizing biotype). In pregnant women, BV may lead to preterm birth, premature rupture of membranes, and chorioamnionitis (10). *G. vaginalis* may also be recovered from cultures of blood from patients with postpartum or postabortal fevers and may also cause infections in newborns. Although it might be recovered from the urethras of males, its association with disease in males is questionable. Serious infections in sites other than those associated with the genital tract or obstetrics are rare but have been reported.

Collection, transport, and storage of specimens

Vaginal and extravaginal specimens can be collected with cotton-tipped swabs. It is best to take one swab for direct examination and to take another swab for culture if necessary, such as for epidemiologic studies. If culture media cannot be directly inoculated, then the swab should be placed in a transport medium (e.g., Amies) and culture should be done within 24 h. It is noteworthy that *G. vaginalis* is susceptible to sodium polyanethol sulfonate (SPS), so an SPS-free medium (or an SPS medium supplemented with gelatin) should be used in order to achieve optimal recovery of *G. vaginalis* from blood culture systems whenever *G. vaginalis* is suspected.

Isolation and identification

The gold standard for the diagnosis of BV is direct examination of vaginal secretions and not the culture of *G. vaginalis,* since *G. vaginalis* can also be recovered from healthy women. A bedside test for BV is examination of the vaginal discharge to detect the typical "fishy" trimethylamine odor, which is enhanced after alkalinization with 10% KOH. The typical smear of vaginal discharge from BV patients shows "clue cells" (bacteria covering epithelial cell margins) together with mixed flora consisting of large numbers of small gram-negative (predominantly *Prevotella* and *Porphyromonas* spp.) and gram-variable *(G. vaginalis)* rods and coccobacilli, whereas lactobacilli are almost always absent. It is recommended that a standardized Gram staining interpretative scheme be used in order to improve the reproducibility of this method (102, 132). Detection of *G. vaginalis* in vaginal specimens processed using a DNA probe-based system, Affirm VPIII (Becton Dickinson), has been reported to be useful as a surrogate for wet mount cell examination (6). Although not recommended for routine laboratory procedures, the isolation of *G. vaginalis* can support the diagnosis of BV. Vaginal swabs are cultured on Vaginalis agar (see chapter 20 for the preparation) and should be semiquantitatively streaked out with a loop. Incubation is at 35 to 37°C in a 5% CO_2-enriched atmosphere or in a candle jar. Beta-hemolysis is observed on human or rabbit blood-containing media but not on SBA. Plates may be checked for the growth of diffuse beta-hemolytic colonies of <0.5 mm in diameter after 24 h, but very often *G. vaginalis* is best observed after 48 h. Gram staining of the suspected colonies confirms the diagnosis of *G. vaginalis.*

Eight *G. vaginalis* biotypes had been proposed on the basis of the reactions for lipase, β-galactosidase, and hippurate hydrolysis (107), with biotypes 1, 5, and 6 being most common. The diagnostic value of these biotypes is questionable since they have not been demonstrated to be associated with certain diseases or certain forms of disease. They may have some value for longitudinal studies, but molecular genetic typing methods are likely to be superior to biotyping. *G. vaginalis* strains are consistently α-glucosidase and starch hydrolysis positive, but only 90% of all *G. vaginalis* strains hydrolyze hippurate. The API Coryne system identifies *G. vaginalis* well (60). Confirmation of the identification of *G. vaginalis* can also be achieved by antimicrobial agent disk inhibition tests with 50 μg of metronidazole (inhibition present), 5 μg of trimethoprim (inhibition present), and 1 mg of sulfonamide (inhibition absent).

"*G. vaginalis*-like" organisms recovered from patients with BV have been demonstrated to represent *Actinomyces turicensis* strains (141). *G. vaginalis* can be differentiated from these organisms in that it has acetic acid as the main end product of glucose fermentation and is unable to produce acid from xylose, whereas *A. turicensis* strains have succinic acid as the end product and produce acid from xylose.

Antimicrobial susceptibilities

Metronidazole is the drug of choice both for local therapy of BV and for systemic therapy of extravaginal infections caused by BV-associated flora. Systemic infections due to *G. vaginalis* alone can be treated with ampicillin or amoxicillin, since β-lactamase-producing *G. vaginalis* strains have not been observed so far. Susceptibility testing for *G. vaginalis* is not recommended.

Nocardia, Rhodococcus, Gordonia, Actinomadura, Streptomyces, and Other Aerobic Actinomycetes*

PATRICIA S. CONVILLE AND FRANK G. WITEBSKY

35

TAXONOMY

The word "actinomycete" is derived from two Greek roots (actino- and -mycete) meaning "ray" (and hence also "rod") and "fungus," respectively. The anaerobic organisms now in the genus *Actinomyces* and the aerobic organisms grouped together as the "aerobic actinomycetes" were previously presumed to be related to one another on the basis of shared features of organismal and colonial morphology. The aerobic actinomycetes, a group for which no agreed-upon operational definition currently exists, are now known to be an evolutionarily heterogeneous assemblage of genera. At some stage they all form gram-positive rods, and most of the more commonly isolated species exhibit at least rudimentary branching under certain growth conditions; all grow better under aerobic than anaerobic conditions, a feature distinguishing them from organisms in the genus *Actinomyces*. The organisms containing mycolic acids in their cell walls (included in the genera *Dietzia, Gordonia, Nocardia, Rhodococcus,* and *Tsukamurella*) are rather closely related on the basis of molecular genetic studies (51, 221); these mycolic-acid-containing genera appear phylogenetically more closely related to the genera *Corynebacterium* and *Mycobacterium* (both of which are sometimes considered to be aerobic actinomycetes) than to the other non-mycolic-acid-containing genera usually also included with the aerobic actinomycetes. According to a recent classification scheme, the various genera are placed in several different suborders, emphasizing the lack of close evolutionary relationships among some of them (221). Regardless of their actual evolutionary relationships, several genera (such as *Gordonia* and *Rhodococcus*) exhibit similar colonial and microscopic morphologic features.

The number of recognized pathogenic species of aerobic actinomycetes has been rising rapidly. Only genera containing species of clinical significance are dealt with in this chapter; the genus *Tropheryma* is discussed in a separate chapter. Ultimately the increasingly fine discrimination of species may result in delineation of important species-specific differences in geographic distribution, pathogenic and other biological mechanisms, disease associations, and antimicrobial susceptibility patterns. However, the enormous proliferation of distinct species for which association with human disease has been claimed presents several problems for the clinical microbiologist. First, phenotypic testing has been rendered virtually useless for accurate discrimination among species. Particularly for the aerobic actinomycetes, the number of phenotypic tests available in the clinical laboratory (and in most research laboratories) is far too small for differentiation among so many species, and often information on the percent positivity for a specific reaction in a given species is not known. Furthermore, precisely the same biochemical testing format has generally not been employed with isolates of all the species being compared, making the usefulness of multistudy comparisons uncertain. Second, some types of testing, such as analysis of cell wall constituents and of whole-cell sugars, are available in only a few research settings and are rarely of use for species level identification. Some general information regarding these features is provided herein, but the references should be consulted for performance procedures and additional details. Third, only nucleic acid-based techniques are currently adequately discriminatory, reproducible, and sufficiently widely available to be useful for precise species identifications in clinical laboratories. Fourth, because of the growing problems with accurate species determinations, the clinical literature is rife with erroneous identifications; nowhere is this problem more apparent than with organisms in the genus *Nocardia*. Additionally, as some species have been described on the basis of only a single isolate, and for others only a handful of reports exist, little if any meaningful clinical information can be associated with many species names. Particularly when molecular methods are not available, precise identification of isolates may be impossible—and is also frequently not of immediate clinical utility.

There are a few terminological issues that, while they pertain to all bacteria, seem to cause confusion particularly frequently with regard to the aerobic actinomycetes. First, for every bacterial species, there is only one "type strain," the strain on which the original description of the species was based. Other strains that are thought to belong to the same species as a given type strain could be referred to as "reference strains," but they are not type strains. Second, the term "sensu stricto" means "in the strict sense." The term, when used with a species name, should be restricted to mean organisms belonging to that particular species, as determined by the best available methods. So, to refer to isolates

* This chapter contains information presented in chapter 35 by June M. Brown and Michael M. McNeil in the eighth edition of this Manual.

that are "*Nocardia asteroides* sensu stricto" should mean isolates that by molecular methods are identical to the type strain of *N. asteroides* (ATCC 19247^T).

DESCRIPTION OF THE GENERA

Actinomadura

The microscopic and colonial morphology of organisms in the genus *Actinomadura,* which contains approximately 57 validly named species, is very similar to those in the genus *Streptomyces*. Microscopically, they are thin, short, branching gram-positive rods (175) (see Fig. 2A) that are modified acid-fast stain negative. Colonies are wrinkled, some aerial mycelium may be present, and the color of the colonies may vary considerably among different isolates (Fig. 1A). Cell walls contain the sugar madurose, a feature shared only with organisms in the genus *Dermatophilus*.

Amycolata and *Amycolatopsis*

The genera *Amycolata* and *Amycolatopsis* were proposed by Lechevalier et al. for nocardia-like organisms that were gram positive (Fig. 2B) and modified acid-fast negative (152). Aerial hyphae are frequently produced (Fig. 1F). Among the species transferred to the genus *Amycolatopsis* was *Nocardia orientalis,* two isolates of which were reported from clinical specimens (99). A study based on 16S rRNA sequences recommended combining the genera *Amycolata* and *Pseudonocardia* into an emended genus, *Pseudonocardia* (252). Currently there are 4 validly named species in the genus *Amycolata* and 26 validly named species in the genus *Amycolatopsis*.

Dermatophilus

The two species currently making up the genus *Dermatophilus* are probably not closely related to most of the other organisms considered in this chapter; by molecular methods this genus was placed in the suborder *Micrococcineae*, whereas the majority of the aerobic actinomycete human pathogens were placed in the suborder *Corynebacterineae* (221). *Dermatophilus congolensis* colonies are somewhat heaped, are opaque, show β-hemolysis on blood agar, and may develop a yellow to orange color with age (275). Aerial mycelium may be produced if the organism is grown in an atmosphere of increased CO_2; the organisms are facultatively anaerobic (95). The microscopic morphology is unusual and striking; this branching organism, with hyphae 0.6 to 1.0 μm in diameter, develops both longitudinal and transverse septa (Fig. 2D). The resulting chains of coccoid cells may occur in as many as eight parallel rows (275). The organisms are gram positive but modified acid-fast negative. The coccoid cells may develop into motile zoospores under favorable environmental conditions.

Dietzia

The species *Dietzia maris* was removed from the genus *Rhodococcus* because of chemotaxonomic and 16S rRNA sequence differences from *Rhodococcus* species (203). Two additional species have since been included in the genus. These organisms apparently rarely, if ever, branch, but like organisms in the genus *Rhodococcus*, they may show coccal and rod forms and are modified acid-fast positive (89).

Gordonia

The biology of the genus *Gordonia* has been recently reviewed (7). Colonies are typically orange and usually wrinkled (Fig. 1I). On Gram stain, *Gordonia* species appear coryneform and show no significant branching; these organisms could easily be mistaken for a component of normal oral flora in sputum specimens (154) (Fig. 2C). The genus "*Gordona*" (now *Gordonia*), originally described by Tsukamura, was revived in 1988 by Stackebrandt et al. (222) to contain species with mycolic acids of approximately 46 to 66 carbon atoms in length (90) and a predominant menaquinone of nine isoprene units. *Gordonia* and *Rhodococcus* were also found to be separable on the basis of their 16S rRNA sequences. There are approximately 19 validly named species in the genus.

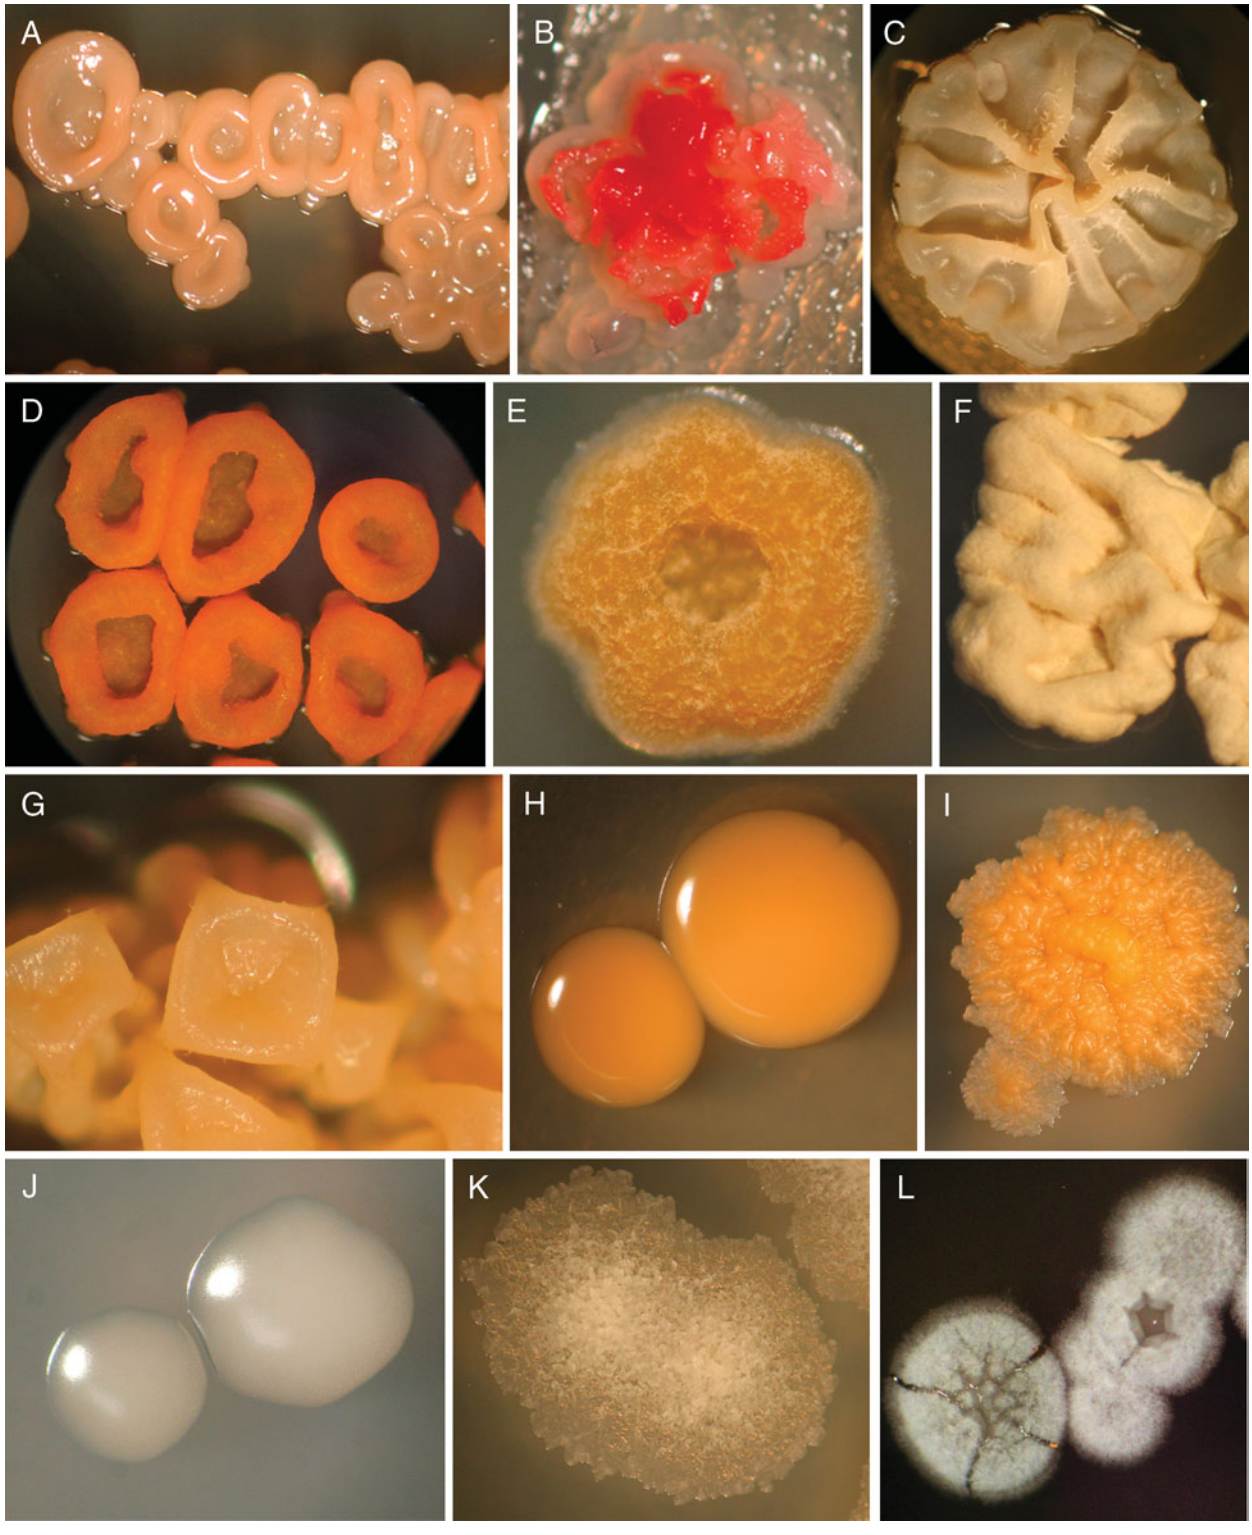
Nocardia

The most commonly isolated aerobic actinomycete human pathogens belong to the genus *Nocardia*. In direct Gram smears, organisms generally appear as very long, obviously branching, thin (0.5 to 1.0 μm in diameter), and finely beaded gram-positive rods (Fig. 2E, F, and N). Unlike the individual cells composing a streptococcal chain, the beads generally do not abut one another. Occasionally, chains, or what appear to be clumps, of beads are the only clue to the presence of a *Nocardia*-like organism (Fig. 2F). Organisms may not be detectable with a Gram stain, and a modified acid-fast stain should be done on direct patient material when a nocardial infection is suspected. While nearly all isolates of *Nocardia* are modified acid-fast positive, not all organisms, or even the entirety of a given organism, will necessarily retain the acid-fast stain (Fig. 2H and O) (see "Microscopic Morphology" below). Particularly when prepared from cultures, smears may show streptococcus-like chains or small branching filaments, probably as a result of the fragile nocardial mycelium breaking during smear preparation (189, 190).

Colonial morphology varies from species to species and frequently varies from isolate to isolate within a species. Colonies can be white, gray, buff, salmon, or orange (Fig. 1D, E, G, and L). Colony color may best be seen on the reverse when colonies are grown on translucent media, as color may become obscured on the surface by powdery aerial hyphae typically produced. Such aerial hyphae are formed to at least some extent by nearly all nocardial isolates, but they are also found with isolates in other aerobic actinomycete genera.

Of the nearly 70 species of *Nocardia* currently recognized, over 25 have been reported as human isolates, and several others have been reported as pathogens of other animals. Importantly, isolates in many reports of infection, even in the recent literature, are incorrectly identified because of failure to use optimal identification methods.

A brief account of the nomenclatural history of the designation "*Nocardia asteroides*" is necessary to clarify a confusing and widely unappreciated taxonomic issue. In 1888 Edmond Nocard obtained an isolate of an organism thought to be the causative agent of bovine farcy; this organism was given the name *Nocardia farcinica* by Trevisan in 1889, and thereupon it became the type strain for both the genus and species. Gordon and Mihm (98) found, using their battery of phenotypic tests, that *N. farcinica* could not be distinguished from isolates to which the name *Nocardia asteroides* had been applied. Because of some uncertainty relating to the isolate obtained by Nocard and what was presumed to be the conspecificity of the organisms then known as *N. farcinica* and *N. asteroides*, an appeal was made to the Judicial Commission to have the type species of the genus changed to *N. asteroides,* with strain ATCC 19247^T selected as the type strain of the species. The appeal was accepted, but the isolate



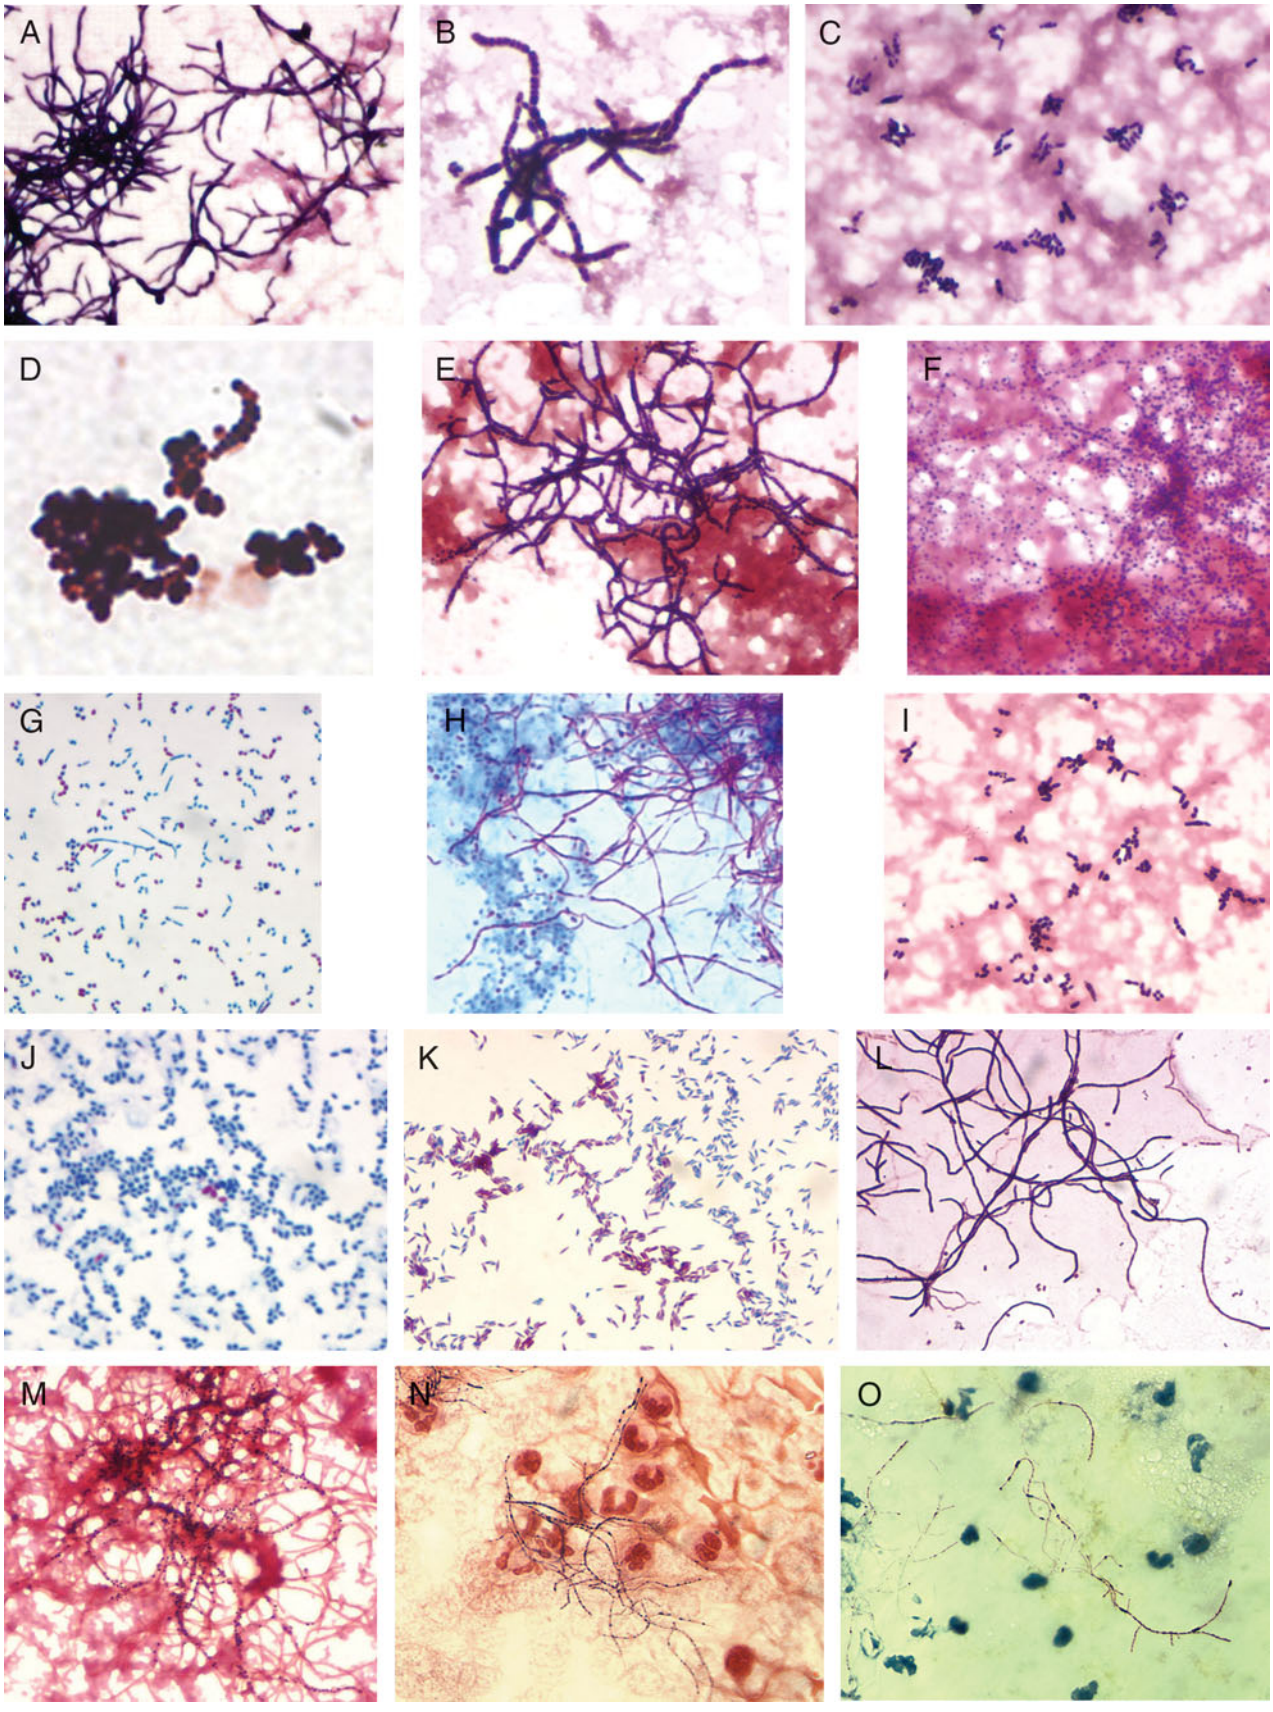


FIGURE 1 Colonial morphology of type strains of various aerobic actinomycetes grown on Sabouraud dextrose agar (Emmons modification). While appearances are typical for the species illustrated, the extent of possible colonial variation within a given species is not known. (A) *Actinomadura latina* at 21 days; smooth umbilicate colonies with no aerial hyphae; (B) *Actinomadura pelletieri* at 10 days; ropy but smooth-surfaced colony with no aerial hyphae; (C) *Streptomyces griseus* at 10 days; rugose colony with some aerial hyphae; (D) *Nocardia brasiliensis* at 10 days; umbilicate colonies; sparse aerial hyphae present, but visible only on microscopic inspection of colonies; (E) *Nocardia carnea* at 25 days; aerial hyphae present; (F) *Amycolatopsis orientalis* at 21 days; aerial hyphae present; (G) *Nocardia otitidiscaviarum* at 7 days; rugose colony; sparse aerial hyphae present, visible only on careful microscopic inspection; (H) *Rhodococcus equi* at 10 days; smooth colonies with no aerial hyphae; (I) *Gordonia bronchialis* at 10 days; irregular but smooth surface with no aerial hyphae; (J) *Tsukamurella pulmonis* at 10 days; smooth colonies with no aerial hyphae; (K) *Tsukamurella strandjordii* at 10 days; rough colonies with no aerial hyphae; (L) *Nocardia cyriacigeorgica* at 10 days; dense powdery aerial hyphae cover most or all the surface of the colonies.

of *N. farcinica* was retained as the type strain for that particular species, as not all were convinced that the two species were truly identical.

Nocardiopsis

The genus *Nocardiopsis* was originally described by Meyer to accommodate an organism that at the time was called *Actinomadura dassonvillei* but differed chemotaxonomically and in certain colonial morphologic features from other organisms in the genus *Actinomadura*. The cell wall of this organism does not contain madurose. The substrate mycelium fragments into coccal forms, and the aerial hyphae fragment into variable-sized spores. Colonies are described as wrinkled or folded; the aerial mycelium varies from sparse to abundant (178). Currently, there are approximately 27 validly named species in the genus, and PCR primers specific for the genus *Nocardiopsis* have been described (209).

Pseudonocardia

Currently, there are approximately 24 validly published species names in the genus *Pseudonocardia*. See "*Amycolata*" above.

Rhodococcus

Species in the genus *Rhodococcus* tend to form smooth to mucoid colonies that may become increasingly pigmented and appear rougher with age. Colony color may vary from essentially colorless through yellow to red (Fig. 1H). At 37°C colonies may be only about 1 mm in diameter after 24 h of incubation. An aerial mycelium is generally not macroscopically visible but may occasionally be seen microscopically (89). The microscopic morphology of rhodococci can range from coccoid to bacillary depending on species and specimen type and on the stage of growth of the organism; cells may be observed intracellularly in macrophages (64). The organisms exhibit a rod-coccus growth cycle; rod forms are best visualized by growing isolates in a liquid medium, and under such conditions some branching of individual cells may be found. Generally, however, the organisms appear as gram-positive, beaded to solidly staining coccobacilli (Fig. 2I). Rhodococci are aerobic, catalase positive, and nonmotile; they are modified acid-fast positive, but the modified acid-fast stain needs to be performed and interpreted with particular care when dealing with isolates that may belong to this genus, as only a tiny fraction of the cells may retain the stain (Fig. 2J). Acid-fast smears prepared from isolates growing on trypticase soy agar with 5% sheep blood or chocolate agar may appear to be acid-fast negative (78). An important caveat regarding *Rhodococcus* species and *Gordonia* species is that they can easily be dismissed as "diphtheroids" because of their Gram stain morphology (Fig. 2C and I) and their frequent failure to develop obvious pigmentation during the first few days of growth. There are chemotaxonomic and 16S rRNA sequence differences between the two genera (see Table 5) (90). The genus and the species often included within it have been the subject of several recent reviews (19, 92, 103). Some data suggest that it may be justifiable to separate the species into several additional genera (103). There are approximately 34 validly named species in the genus.

Streptomyces

Species in the genus *Streptomyces* form branching, gram-positive rods (from 0.5 to 2.0 μm in diameter) that may appear more solidly gram positive than is typical for *Nocardia* species. Filaments may be fragmented (166), and beading may be seen (Fig. 2L and M). Members of the genus are modified acid-fast negative. The colonial morphology of these organisms may be similar to that of *Nocardia* species; an aerial mycelium is generally formed (Fig. 1C). The genus and species level taxonomy of this huge group, which contains approximately 517 validly named species, remains problematic (5, 172). Many of these species have been patented because of the commercially useful products they synthesize (5).

Tsukamurella

The genus *Tsukamurella* (named to honor the microbiologist Michio Tsukamura) was created to accommodate organisms with mycolic acids with chains of 62 to 78 carbon atoms in length (90); menaquinones of the MK-9 type are predominant (90). *Tsukamurella* species generally appear as long, straight to slightly curved, thin rods with no apparent branching; they are gram positive and modified acid-fast positive (Fig. 2K). Colonies tend to be small and can be smooth to rough but do not produce an aerial mycelium; the color varies from whitish to orange (Fig. 1J and K). The type species of the genus, *T. paurometabola* (corrected from *T. paurometabolum*), was previously known as *Corynebacterium paurometabolum*. There are approximately eight validly named species in the genus.

FIGURE 2 Microscopic morphology of various aerobic actinomycetes. (A) *Actinomadura latina;* Gram stain from Tween-albumin broth (TAB) at 4 days; long, branching, relatively solidly staining rods. (B) *Amycolata autotrophica;* Gram stain from TAB at 4 days; long, beaded rods with some branching. (C) *Gordonia bronchialis;* Gram stain from TAB at 4 days; coryneform rods with no obvious branching. (D) *Dermatophilus congolensis;* Gram stain from SAB at 14 days in CO_2; dense aggregates of cells of varying sizes; note chains of longitudinally and transversely dividing cells. (E) *Nocardia abscessus;* Gram stain from TAB at 4 days; long, branching rods; this is a rather solidly staining example, but some beading can be seen. (F) *Nocardia abscessus;* Gram stain from TAB at 10 days; long, beaded, branching rods; note that the beads generally do not abut one another. (G) *Nocardia farcinica;* modified acid-fast stain from horse blood agar at 2 to 3 days; many coccal forms are present; it is mostly these that are staining modified acid-fast positive. (H) *Nocardia veterana;* modified acid-fast stain from TAB at 25 days; some long, branching forms are staining modified acid-fast positive. (I) *Rhodococcus equi;* Gram stain from TAB at 4 days; coccobacilli and short coryneform rods without obvious branching. (J) *Rhodococcus equi;* modifed acid-fast stain from charcoal yeast extract agar at 10 days; only a small percentage of the cells stain positive. (K) *Tsukamurella pulmonis;* modified acid-fast stain from Lowenstein-Jensen medium at 4 days; thin rods, many of which stain positive. (L) *Streptomyces griseus;* Gram stain from SAB at 4 days; long, branching, fairly uniformly staining rods with little beading evident. (M) *Streptomyces candidus;* Gram stain from TAB at 10 days; long, thin, branching rods not distinguishable from *Nocardia* species. (N) Direct Gram stain of sputum which grew a *Nocardia* species; note lacey network of long, thin, branching, beaded rods. (Courtesy Daniel P. Fedorko.) (O) Direct modified acid-fast stain of *Nocardia* sp. in the same specimen as in panel N; the beads are purplish, but the intervening areas of the organism stain positive. (Courtesy Daniel P. Fedorko.)

NATURAL HABITATS

While the aerobic actinomycetes are widely distributed in the environment, the extent to which particular species are geographically restricted is not well known. Their primary ecological niche is probably the decomposition of plant material (172).

Epidemiology and Transmission

The majority of infections caused by aerobic actinomycetes stem from environmental sources, and even most nosocomial infections appear attributable to an environmental source such as dust from construction work (23). There has not yet been a documented case of direct patient-to-patient spread of an aerobic actinomycete infection without the intermediation of another human agent or of environmental contamination.

Most of the reports of outbreaks and pseudo-outbreaks of infection caused by aerobic actinomycetes have been attributed to *Nocardia* species. A 1979 outbreak in a renal intensive care unit involved at least seven patients. A patient on the unit was found to have been excreting, for 7 months from a nephrostomy, what was eventually identified as *N. asteroides*. An investigation resulted in the isolation of the organism from air and dust in the unit. The environmental contamination probably arose more from aerosols produced during disposal of the nephrostomy urine (115, 160, 227). Reports from other institutions involving *Nocardia* species also suggested nosocomial transmission and involved renal transplant recipients (12, 109), heart transplant patients (79), and patients with postoperative wound infections (23, 259).

A seven-patient outbreak of *Gordonia bronchialis* sternal wound infections was traced to a nurse from whose hands and other body sites the organism was isolated; it was also isolated from two of the nurse's dogs (204).

Two pseudo-outbreaks of infection with *N. asteroides* associated with the use of the BACTEC 460 TB system and inadequate needle sterilization have been reported (159, 193).

An outbreak of pseudoinfection attributed to *T. paurometabola*, involving specimens from 10 different patients and attributed to a common source somewhere in the laboratory, has also been reported (10).

CLINICAL SIGNIFICANCE

Table 1 lists the majority of species of aerobic actinomycetes, other than those in the genus *Nocardia,* that have been isolated from human specimens to date. Table 2 contains a listing of species of *Nocardia* that have been reported as human isolates to date. More commonly isolated species of aerobic actinomycetes of particular significance are dealt with in the sections below. For many of the newly described species there is a paucity of data to establish that the organisms were indeed agents of disease or to establish any clinically significant differences, such as in geographic distribution or susceptibility pattern, among the species. The source of bacterial names used is J. P. Euzéby (*List of Bacterial Names with Standing in Nomenclature;* http://www.bacterio.net). Representative examples of colonial and microscopic morphologies are shown in Fig. 1 and 2.

Actinomadura

A useful clue to the identification of organisms in the genus *Actinomadura* is the nature of the lesion from which an isolate originates. Most commonly this organism causes a mycetoma, a chronic, invasive, slowly progressive infection usually occurring in the foot ("Madura foot") and nearby anatomic structures, and nearly always resulting from traumatic implantation of the organism. Draining sinuses are typically present in a mycetoma; macroscopically visible grains (organism aggregates or microcolonies) may be visible in the discharge from the lesions. There are not adequate data available to allow using grain color for species or even genus level discrimination of the etiologic agent. The infection occurs most frequently in tropical regions, where people are more likely to walk barefoot. The word "mycetoma" is used only to describe the clinical nature of the infection, not the etiologic agent. Actinomycotic mycetomas are caused by aerobic actinomycetes; eumycotic mycetomas are caused by true fungi. Organisms in this genus have very rarely been implicated in other types of infection. Only three species have been reported as pathogens: *Actinomadura latina, A. madurae*, and *A. pelletieri*, with *A. madurae* being most commonly isolated. A set of 21 phenotypic tests was found useful for species level identification of isolates causing mycetoma (234). The same study also suggested that additional species other than the few commonly said to be etiologically involved remained to be described. In many reports mentioning the species causing mycetomas, identification has been made solely on the basis of the histological appearance of the grains, on the basis of a small number of phenotypic tests, or in ways not specified in any detail (45, 137, 163, 164). As with virtually all the aerobic actinomycetes, molecular methods are the only practical procedures for clinical or even reference laboratories to use for definitive species level identification of organisms in this genus.

Amycolata and *Amycolatopsis*

There are no recent reports documenting human infection caused by species in either of the genera *Amycolata* and *Amycolatopsis*. A newly described species, *Amycolatopsis palatopharyngis*, was isolated from what was described as "the infected palatopharyngeal mucosa" of an elderly male, but no further clinical information was provided (116). Three recently described species and several other aerobic actinomycete species may be causative agents of equine placental infection and abortion (145).

Dermatophilus

D. congolensis causes dermatitis in a wide variety of animals worldwide, including cattle, horses, goats, and sheep, but has only rarely been noted as a cause of human infection (233). In humans, the organism has been reported to cause a variety of cutaneous manifestations, including scaling and exudative lesions, pustules, pitted keratolysis (86), and "hairy" leukoplakia of the tongue (37). Filamentous and coccoid forms of the organism may be visualized directly in tissue specimens. Optimal therapy has not been defined, but infections may be self-limiting. *Dermatophilus chelonae* has been reported to cause disease in several species of animals (168, 257).

Dietzia

Only *Dietzia maris* has been associated with human infection. In one reported case the organism was isolated from blood and from an intravascular catheter; biochemical and chemotaxonomic studies of the isolate were performed (20), but the isolate was noted to be modified Kinyoun-stain negative, although *D. maris* would be expected to be modified acid-fast positive. The other reported case involved infection of a hip prosthesis; a variety of identification techniques were employed, including 16S rRNA

[a] Data in this table are based largely on the English-language literature accessible through web-based search engines; the species listing provided should not be regarded as complete. Several of the review articles refer to reports that we have not reviewed ourselves. In some cases, insufficient data are presented to determine whether or not the organism isolated was in fact a cause of disease. Many of the isolates were identified only phenotypically; the application of modern molecular identification techniques might have resulted in a different identification from that reported.

[b] The reference for the isolation of this species is the publication initially describing the organism as listed in J. P. Euzéby, *List of Bacterial Names with Standing in Nomenclature*; http://www.bacterio.net.

[c] The review articles mention several additional *Streptomyces* species that have been reported as human isolates.

sequencing, which showed 98% similarity with the *D. maris* type strain (197). The patient responded to treatment with teicoplanin.

Gordonia

There have been relatively few reports of infections attributed to species in the genus *Gordonia* (Table 1). One of the very few clusters of infection attributable to any aerobic actinomycete involved seven patients who developed sternal wound infections following coronary artery bypass surgery (204). The organism involved, *Gordonia bronchialis* (then called *Rhodococcus bronchialis*), was identified by biochemical testing and cell wall mycolic acid analysis. There have also been case reports of bacteremia, central nervous system (CNS) infections, pulmonary disease, and soft tissue infection caused by various *Gordonia* species. An immunocompromised state and the presence of foreign bodies appear to have been contributing factors for some of the patients. The techniques and interpretive criteria used to identify the organisms involved differ significantly among the various reports. For Table 1, when an isolate was not assigned to a particular species, or when such identification details as were presented made the identification problematic, cases were attributed to *Gordonia* species (Table 1).

Nocardia

Nocardia infections generally result either from trauma-related introduction of the organism or, particularly in immunocompromised patients, from inhalation and the resulting establishment of a pulmonary focus. It should be noted that the brain is one of the most common secondary sites of infection (190). A great advance in the clinically useful categorization of pathogenic nocardial isolates was provided by Wallace and his coworkers (249). They divided organisms phenotypically resembling *N. asteroides* into six different drug pattern types and one additional miscellaneous group. With more recent work, numerous different species have been described within this set of organisms, which came to be known as the *Nocardia asteroides* complex, and included *N. farcinica* (drug pattern type V), *Nocardia nova* (drug pattern type III), and isolates of drug pattern types I, II, IV, and VI. Subsequent work has resulted in the description of at least one separate species in almost all these drug pattern types. Undoubtedly, by using current species definition criteria, numerous species of *Nocardia* remain to be described. Roth et al., in their examination of the nearly complete 16S rRNA gene sequence of 74 *Nocardia* strains representing 25 established species, noted 10 taxa that appeared to be substantially different from each one's most closely related species. These 10 taxa probably represent undescribed species (207).

Given the current state of the literature, it is possible to make only the most tentative statements regarding geographic distribution and disease correlates of different species. Fortunately, with the use of a few selected phenotypic tests (see below), it is possible to assign some isolates in this genus to certain species or species groups with moderate confidence and thus to make some predictions regarding their likely antimicrobial susceptibility patterns. Nonetheless, susceptibility testing of all clinically significant isolates is recommended.

Nocardia abscessus

Nocardia abscessus was formally named in 2000 by Yassin et al. (271). ATCC strain 23824, the reference strain of *N. asteroides* drug pattern type I (207, 226), was one of the

[a] Unless otherwise noted, the reference for the isolation of each of these species is the publication initially describing the organism as listed in J. P. Euzéby, *List of Bacterial Names with Standing in Nomenclature*. http://www.bacterio.net.

[b] The role of an organism was considered unclear if the site of isolation was unknown, if it was isolated from only one patient without substantial corroborating information that the isolate was a pathogen, or if it was obtained only once from respiratory specimens or other unspecified sites from more than one patient, without information establishing the pathogenicity for any isolate. The role was considered possible if it was isolated more than once from one patient, but without other significant information provided. The role was considered probable if it was isolated from more than one patient from a mycetoma or skin abscess. The role was considered definite if a substantial amount of corroborating data was provided.

isolates found to be *N. abscessus* on the basis of 16S rRNA sequencing and DNA-DNA hybridization. Several of the strains in the report naming the species were from abscesses; in a subsequent report from Japan, several isolates from pulmonary sources and one from a brain abscess were reported (128). Two isolates have been reported from Germany, one from pericardial fluid (258) and the other from a posttraumatic wound (114). In their description in 1988 of the antimicrobial susceptibility patterns of 78 clinical isolates of *Nocardia* from various sources, Wallace et al. noted that 20% of the isolates had this drug pattern type. By the testing procedures and interpretive criteria employed, the organisms were susceptible to amikacin, ampicillin, carbenicillin, broad-spectrum cephalosporins, minocycline, and sulfamethoxazole; half of the isolates had high MICs to imipenem (249).

Nocardia asteroides and the "*N. asteroides* Complex"

There are innumerable reports of human infection attributed to *N. asteroides;* at least until recently, it has probably been considered to be the most commonly isolated human pathogenic *Nocardia* species. Notably, molecular analyses of the pathogenic isolates attributed to this species that have been conducted thus far have indicated that all belong to some other named or as-yet-unnamed species.

Infection has been reported to occur in patients immunocompromised as a result of human immunodeficiency virus (HIV) infection (198); systemic lupus erythematosis (100); chronic granulomatous disease (71); malignancies of various types (230); and organ transplantation including bone marrow (47), heart (194), kidney (160), liver (81), and lung (119). Trauma (218) and the presence of intravenous

catheters (161) also predispose patients to infection. In immunocompromised patients the lung appears to be the most common initial site of infection, presumably acquired by inhalation from an environmental source. Infection may become disseminated, and the organism has been isolated from almost every conceivable body site, including blood (141), natural and prosthetic cardiac valves (68, 253), testes (156), thyroid (41), and peritonsillar abscess (1). Ocular involvement can occur either as a metastatic lesion (138) or as a result of ocular trauma (117). The brain is a relatively frequent site of metastatic infection (218). In a report on 21 patients with nocardial meningitis, 43% were noted to have a concomitant brain abscess (29).

The term "*N. asteroides* complex" has been used for organisms phenotypically resembling the *N. asteroides* type strain. However, several distinct species have now been described within that complex, and precisely what the complex is intended to designate is often no longer clear. The designation should be used, if at all, only if the species intended to be included are clearly stated.

Nocardia brasiliensis

N. brasiliensis appears to be the most common cause of actinomycotic mycetoma (see "*Actinomadura*" above) in the Western Hemisphere, especially in Mexico (44, 45). The organism probably occurs worldwide; there are reports of infection from Australia (85), West Bengal (164), and Europe (165) and many from North America (216). A variety of cutaneous manifestations in addition to mycetoma have been reported, including cellulites, abscesses, and lymphocutaneous infection. Nearly all cases are a result of trauma, including that caused by thorns (165), cat scratch (27), and insect bite (191). Most of the trauma-related infections have occurred in immunocompetent individuals. Disseminated infection, usually originating from a pulmonary focus, has also been reported (216); such infections are more likely to occur in immunocompromised patients (140). Some cases, such as one of a brain abscess resulting from dissemination from a pulmonary focus (184), do occur in patients who appear to be immunocompetent. However, most of the cases of invasive disease, as well as some of the cases of cutaneous infection, attributed to *N. brasiliensis* prior to 1995 may have been due to *N. pseudobrasiliensis*. In that year Wallace et al. (247) reported that a subset of organisms that had been identified as *N. brasiliensis* but were predominantly associated with noncutaneous invasive disease appeared to belong to another taxon, formally named *N. pseudobrasiliensis* the following year (208). Unlike true *N. brasiliensis* isolates, most *N. pseudobrasiliensis* isolates hydrolyze adenine, are susceptible to ciprofloxacin and clarithromycin, and are resistant to minocycline. The two species also differed in their mycolic acid patterns, 16S rRNA gene sequences, and restriction fragment length polymorphism (RFLP) patterns for both the 16S rRNA and 65-kDa heat shock protein genes.

Nocardia brevicatena Complex

Brown et al. suggested in 1997 that *Nocardia* isolates sharing both an unusual drug susceptibility pattern and one or another of three different RFLP patterns of an amplified portion of the 65-kDa heat shock protein gene should be considered to form the *Nocardia brevicatena* complex (B. A. Brown, R. W. Wilson, V. A. Steingrube, Z. Blacklock, and R. J. Wallace, Jr., *Abstr. 97th Gen. Meet. Am. Soc. Microbiol.* 1997, abstr. C-65, p. 131, 1997). These organisms included 19 clinical isolates from the United States, 10 clinical isolates from Australia, and three ATCC reference strains of *N. brevicatena*. The 19 U.S. clinical isolates had the type II *N. asteroides* drug pattern (249), being sensitive to ampicillin, carbenicillin, broad-spectrum cephalosporins, minocycline, sulfamethoxazole, and kanamycin. All 32 isolates studied were also susceptible to amikacin and tobramycin but resistant to gentamicin. There have been no subsequent reports of clinical isolates or taxonomic studies of these organisms. Given the different RFLP patterns involved, several different species may be included in the complex. Some workers include *N. paucivorans* in this complex. The 16S rRNA sequences of the type strains of the two species are 99.5% similar, but DNA-DNA hybridization results indicate that *N. brevicatena* and *N. paucivorans* are separate species (269).

Nocardia cyriacigeorgica

N. cyriacigeorgica (spelling corrected from the original *N. cyriacigeorgici*) was described on the basis of an isolate obtained from the sputum of a patient with chronic bronchitis (272). Subsequent isolates were obtained from brain abscesses in an immunocompromised patient (84) and from a patient with pneumonia following a near-drowning incident, from whom *N. farcinica* and several other pathogens were also isolated (240). Isolates of this species were reported to constitute 13 of 96 (14%) clinical isolates of *Nocardia* from Thailand (199) and 13 of 86 (15%) of such isolates from Belgium (254). It should be noted that the 16S rRNA sequence of the type strain of this species (1,400 bp) is identical to that of the reference strain of "*N. asteroides* drug pattern type VI" (ATCC 14759) (207, 226). As there are no published results of DNA-DNA hybridization studies of these two strains, it is remotely possible that they may in fact belong to different species. In the original work describing the different *N. asteroides* drug pattern types, type VI was the most commonly isolated variety (35%) (249), so should DNA-DNA hybridization prove them to be the same, *N. cyriacigeorgica* may be the most frequent human nocardial pathogen, at least in areas where actinomycotic mycetomas are relatively rare. Note that if one speaks of "*N. asteroides* drug pattern type VI sensu stricto," this should mean isolates corresponding (using the best available methods) to the isolate deposited as the "reference" strain of this drug pattern type. However, the designation "*N. asteroides* drug pattern type VI" is not a valid species name. This drug pattern type was initially characterized by resistance to penicillin and susceptibility to broad-spectrum cephalosporins (249).

Nocardia farcinica

The organisms initially described by Wallace et al. as belonging to the group "*N. asteroides* drug pattern type V" (249) were subsequently found to belong to *N. farcinica* (250). Isolates of this species are perhaps the most resistant of all *Nocardia* isolates; they are typically resistant to cefotaxime, cefamandole, ampicillin, gentamicin, and tobramycin and susceptible to amikacin, sulfamethoxazole, and usually also to ciprofloxacin and imipenem (249). Isolates that showed in vitro resistance to trimethoprim-sulfamethoxazole have been reported to respond to meropenem alone (112) and to the combination of linezolid and minocycline (155). This species may have a particular propensity for causing disseminated disease; Wallace et al. reported that among 30 patients for which disease extent was known, 57% had disseminated disease and one-third had CNS involvement (250). Most patients infected by this species, especially those with disseminated disease, have some type of immunocompromise (231, 250), but cutaneous and other infections have been reported to occur in the apparently immunocompetent as well (210). The lung is a common site of involvement, affecting 43% of

patients in one review, while 30% had brain or meningeal involvement (231). The organism has been isolated from blood from a number of patients (50) and from many other sites in addition to the lungs and the CNS; more unusual sites have included the eye of a patient who washed her contact lenses in basin-stored water (75), the site of a cochlear implant (147), and the larynx of an immunocompromised patient for whom no other site of involvement was detected (56). Isolates of this species were also reported to make up 34 of 96 (35%) clinical isolates of *Nocardia* from Thailand (199) and 38 of 86 (44%) of such isolates from Belgium (254). The complete genomic sequence of a clinical isolate (*N. farcinica* IFM 10152) has been determined (121). The genome was found to consist of a single circular chromosome; two circular plasmids were also present. Among the notable findings were the presence of three copies of the rRNA operon and a number of genes that were thought to contribute to the virulence and drug resistance of the organism.

Nocardia nova

N. nova was described by Tsukamura in 1982 and was distinguished from *N. asteroides* by several phenotypic tests (236) and confirmed to be a separate and distinct species by DNA-DNA hybridization (266). Wallace et al. found that 18% of 78 clinical isolates fell into their type III pattern, characterized by susceptibility to ampicillin and erythromycin and resistance to carbenicillin (249). In a subsequent study of 223 clinical isolates, employing both biochemical and susceptibility testing procedures, 17% of the isolates, as well as the type strain of *N. nova*, had similar characteristics, including the type III drug pattern; these isolates were all then considered members of *N. nova* (248). Of the patients for whom clinical information was available, 35% were thought to have disseminated disease; organisms were obtained from many sites, including blood, lung, CNS, skin and soft tissue, joints, and cornea. An upper extremity sporotrichoid form of nocardiosis attributed to *N. nova* in an HIV-positive patient who sustained a thumb injury while working in a field has been reported (120). More recent investigations have revealed that the organisms identified as *N. nova* by phenotypic testing, as well as by the RFLP patterns obtainable from the *hsp*65 gene, actually may belong to other species in addition to *N. nova*, including *N. africana*, *N. kruczakiae*, and *N. veterana* (59). These species can be distinguished from one another and from *N. nova* sensu stricto only by detailed molecular analysis. Isolates identified only by phenotypic testing as belonging to one or another of these species are probably best reported as members of the "*N. nova* complex."

Nocardia otitidiscaviarum

The initial isolate of the species *N. otitidiscaviarum*, described by Snijders in 1924, was obtained from the infected middle ear of a guinea pig; for a time this species was known as *N. caviae* (97). This species is a relatively infrequent cause of human infection. Clark et al. reviewed 28 cases of cutaneous infection, including several of mycetoma, attributed to this species; many of those for which information was available were considered trauma related (52). There are a few reports of infection at other sites, including brain abscess (110), pyothorax (273), catheter-related infection (153), and disseminated infection (195). This species is relatively reliably identified on the basis of its decomposition reactions; it decomposes xanthine and hypoxanthine but not casein or tyrosine. In a recent molecular study of numerous clinical isolates, several different sequences were obtained from nine different strains that had been phenotypically identified as *N. otitidiscaviarum* (192). These results were interpreted as suggesting the presence of several different species within this group, but some of the results also suggested that individual isolates might contain two or more differing copies of the 16S rRNA gene.

Nocardia paucivorans

The species *N. paucivorans* was described by Yassin et al. in 2000 on the basis of a respiratory tract isolate from a patient with chronic lung disease (269). A subsequent isolate was reported from a patient with cerebral nocardiosis; by the susceptibility testing procedure used, the isolate was susceptible to nearly every drug tested (76). Another isolate from a brain abscess attributed to this species that showed 98.4% 16S rRNA gene similarity to a "reference" strain has also been reported; this organism was susceptible by the procedure employed to all drugs tested (258). An isolate from a mitral valve has been reported (28), and 2 of 86 (2.3%) clinical isolates from Belgium were identified as belonging to this species (254). The sensitivity pattern of two of the reported isolates is similar to that of drug pattern type II (see "*Nocardia brevicatena*" above), but both appeared susceptible to gentamicin.

Nocardia pseudobrasiliensis

N. pseudobrasiliensis is more often a cause of noncutaneous invasive infection, although it can cause cutaneous infection as well. Most infections have occurred in immunocompromised patients; cases have been reported from North and South America, Japan, and Australia (30, 127, 247) (see "*Nocardia brasiliensis*" above).

Nocardia transvalensis

N. transvalensis was originally described in 1927 on the basis of an isolate from an African patient with a mycetoma. In 1992 McNeil et al. reported on 16 patients from whom isolates attributed to this species had been obtained (173). The isolates from 10 of the patients were considered clinically significant; the other isolates were considered colonizers or of uncertain significance. A variety of sites of infection were involved; some of the infections were disseminated, and several patients were known to be immunocompromised. Wilson et al. subsequently distinguished four taxa that they proposed be grouped together as the "*N. transvalensis* complex" (260); included among these was the type strain of *N. transvalensis*. All isolates were considered resistant to at least one of the aminoglycosides tested, and the majority were resistant to amikacin, suggesting that they might all be grouped with organisms exhibiting drug pattern type IV, originally defined as resistance to all aminoglycosides and susceptibility to ciprofloxacin (249). There are a few other case reports of disseminated infection attributed to this species, including one in a liver transplant patient (255) and one in a heart transplant patient (157). The isolate from the heart transplant patient developed sulfonamide resistance during the course of treatment (157). A total of 11 clinical isolates assigned to this species have been reported from Japan and Thailand (131, 199).

Nocardia veterana

N. veterana was first described on the basis of an isolate obtained from the bronchial lavage fluid of a patient with pulmonary lesions, but that isolate was thought not to be clinically significant (104). Subsequently, there appeared several case reports that indicated that this species could cause human disease; these included reports of a patient with a mycetoma (132), three patients with pulmonary disease (200), and ascitic fluid infection in an HIV patient

(87). In a subsequent report of three additional clinical isolates, two of which were shown to have been causative agents of pulmonary disease, it was noted that the isolates had an antimicrobial susceptibility pattern essentially identical to the patterns of *N. africana* and *N. nova* (60), demonstrating that species identification could not be definitively established by susceptibility testing alone. It was also noted that the isolates of this species that were studied showed 16S rRNA gene similarities to the type strains of *N. africana* and *N. nova* of 99.0 and 97.7%, respectively. In a collection of 101 isolates initially identified as *N. nova*, further analysis using molecular procedures indicated that at least 15 were most probably isolates of *N. veterana* (R. W. Wilson, P. S. Conville, L. Mann, B. A. Brown-Elliott, C. Crist, F. G. Witebsky, and R. J. Wallace, Jr. *Abstr. 104th Gen. Meet. Am. Soc. Microbiol.* 2004, abstr. U-075, p. 636).

Nocardiopsis

Nearly all the very few infections attributed to organisms in the genus *Nocardiopsis* have been attributed to *N. dassonvillei*. In a letter to the editor regarding a case of actinomycetoma attributed to this species, it was stated that *N. dassonvillei* was "regularly encountered" at the Centers for Disease Control and Prevention, with 21 isolates having been identified from 1981 through 1986; no clinical details were provided (2). There are also a few case reports attributing other types of infection to this species (Table 1). One other species in the genus has been reported as isolated from a human specimen (Table 1).

Rhodococcus

The most commonly isolated pathogen in the genus *Rhodococcus* is *Rhodococcus equi*. While other species have occasionally been reported to cause disease (Table 1), it is impossible to obtain reliable species level identifications without resorting to molecular methods (19, 92). *R. equi* itself may be split into several different species (170). Infections caused by *R. equi* have been the subject of several reviews (8, 63, 134, 232). The organism has long been known as a significant pulmonary pathogen in horses (hence the species name) (201). The initial report of human disease caused by the organism (reported as *Corynebacterium equi*) involved a patient on high-dose steroids with a pulmonary abscess; he had worked briefly in stockyards contaminated with animal feces shortly before the onset of his illness (88). Herbivore manure provides an ideal growth medium for the organism, and inhalation of the organism is presumed to be the major mode of infection in horses (201) and is probably also the principal mechanism for human infections. Direct inoculation and oral ingestion are other possible routes of infection (256). Most patients who develop *R. equi* infection are immunocompromised, and at least until recently approximately two-thirds of infected patients were also HIV infected (256). Essentially any body site can be involved, but the lung is a site of involvement in approximately 80% of immunocompromised patients and at least 40% of immunocompetent patients infected with this species. Bacteremia has been reported in >80% of immunocompromised patients and approximately 30% of immunocompetent patients (256). Pulmonary cavitation is a frequent finding. Malacoplakia, an aggregation of histiocytes containing concentrically layered basophilic structures known as Michaelis-Gutmann bodies, has been noted as a histopathologic finding in several studies (102, 232). Two virulence-associated antigens (VapA and VapB) encoded by plasmids have been identified; isolates producing the VapA antigen are the predominant, possibly the sole, cause of disease in horses, but isolates producing the VapA antigen, the VapB antigen, or neither antigen have been isolated from human cases of infection (194). A combination of antimicrobials is generally used for the treatment of infections. Agents used include aminoglycosides, erythromycin, imipenem, quinolones, rifampin, and vancomycin; linezolid may also be efficacious (256). Some rifampin-resistant strains with *rpoB* gene mutations have been reported (9).

Streptomyces

The most common type of infection attributed to species in the genus *Streptomyces* is mycetoma (see "*Actinomadura*" above), and the most commonly mentioned etiologic agent is *Streptomyces somaliensis*, although in many reports the identification procedures employed could not have ensured that other species were not involved. There are a few reports implicating other species in the genus as occasional pathogens. In case reports of bacteremias attributed to *Streptomyces bikiniensis* (180) and *Streptomyces thermovulgaris* (77), molecular methods were used in identifying the isolates, and such methods were described in detail in a case report of a mycetoma attributed to *Streptomyces albus* (166). While the majority of isolates from nonmycetomatous lesions probably represent either contamination or colonization, these organisms are capable of occasionally causing disease.

Tsukamurella

There are case reports attributing a variety of infections to different species in the genus *Tsukamurella* (Table 1). In the older literature there are a few reports of infection attributed to *Rhodococcus aurantiacus*, such as pulmonary infection, meningitis, peritonitis, and subcutaneous abscesses (43, 237). Recently, *R. aurantiacus* ATCC 25938 (the initial type strain of the species), which has had a convoluted taxonomic history (58), has been placed in *T. inchonensis* (133, 268). Organisms isolated from clinical material and thought to belong to this genus have generally been found to resemble strain ATCC 25938. The organisms reported to cause an outbreak of pseudoinfection (10) (and quite possibly most or all of the organisms involved in clinical infections and identified as *T. paurometabola*) were in fact almost certainly what is now called *Tsukamurella inchonensis*.

Other Genera

Some other genera of aerobic actinomycetes do have roles in human diseases but are unlikely to be encountered in the clinical laboratory. Organisms in three genera of thermophilic aerobic actinomycetes, *Saccharomonospora*, *Saccharopolyspora*, and *Thermoactinomyces*, have been implicated in the etiology of hypersensitivity pneumonitis. Spores of these organisms may be encountered when performing air sampling; molecular methods are helpful for species level identification when needed (108, 264). There are currently approximately 7, 10, and 8 validly published species names in the genera *Saccharomonospora*, *Saccharopolyspora*, and *Thermoactinomyces*, respectively. *Crossiella equi* is an aerobic actinomycete that can cause equine placentitis (70), but there are no reports of human infection attributed to this organism.

COLLECTION, TRANSPORT, AND STORAGE

In temperate climates the respiratory tract is the most frequent portal of entry for the aerobic actinomycetes and therefore the primary site of nocardial infections in the immunocompromised host. Sputum is the most easily obtained pulmonary

specimen, and examination of several fresh early-morning samples collected on separate days (90, 251) may maximize the chances of organism recovery; recovery of an aerobic actinomycete from multiple samples may help to establish the clinical significance of the isolated organism (90, 142). *Nocardia* species may, however, be difficult to recover from sputum even in documented cases of pulmonary infection (190), either because of low numbers of organisms present in the sample or because contaminating bacteria in the sample may overgrow the more slowly growing aerobic actinomycetes. More invasive procedures, such as bronchoalveolar lavage or fine needle or open lung biopsy, may be required to obtain a definitive diagnosis (190). These more invasive procedures may be necessary for diagnosis of as many as 44% of primary pulmonary infections (85); macrophage-rich samples may be necessary to maximize recovery of organisms such as rhodococci, which tend to localize within these cells (64).

Exudates from abscesses or mycetomas should be delivered to the laboratory in a sterile container for examination for characteristic granules and for smear and culture. In the case of disseminated cutaneous lesions or small lesions secondary to trauma, a skin biopsy can be useful. The use of swabs is not recommended, as fibers can make smear interpretation difficult (251). To optimize isolation of *Dermatophilus*, scabs or crusty lesions should be removed and soaked in sterile distilled water, and the fluid should be inoculated onto blood agar plates (275).

In immunocompromised patients the aerobic actinomycetes, especially *Nocardia*, can disseminate to almost any organ. A biopsy sample or aspirate, when obtainable, may be the best specimen to evaluate for the presence of such organisms. Normally sterile body fluids should be collected in a sterile container and sent immediately to the laboratory. *Nocardia* isolates are infrequently recovered from cerebrospinal fluid, even if numerous brain lesions are present, because the organisms may be confined to the brain abscess itself. Blood should be inoculated directly into blood culture media; many commercially available blood culture or lysis centrifugation systems have been shown to support the growth of *Nocardia* species. Various aerobic actinomycetes have been implicated as the cause of catheter-related bacteremia; potentially infected catheter tips should be transported to the laboratory in a sterile container and cultured by appropriate methods.

In all cases where infection with an aerobic actinomycete is suspected, it is of utmost importance that the laboratory be notified of the suspected diagnosis. This will ensure that samples will receive appropriate handling, that the correct direct smears will be prepared, and that the sample will be inoculated onto the appropriate media and incubated for an extended period of time at the appropriate temperature.

All samples should be transported promptly to the laboratory following the specimen collection and handling procedures outlined in chapters 5 and 20.

DIRECT EXAMINATION

Careful microscopic examination of clinical specimens suspected of containing aerobic actinomycetes is extremely important. The observation of organisms characteristic of *Nocardia* and other aerobic actinomycetes should alert laboratory personnel to inoculate appropriate media and to extend incubation at the appropriate temperature. In addition, the detection of organisms directly in the patient specimen may assist in the interpretation of culture results.

Smears can be made directly from sputum, drainages, and aspirates; however, liquid specimens such as bronchoalveolar lavage or normally sterile body fluids that are not excessively cellular should be concentrated before smear preparation and media inoculation. For tissue samples, smears can be made from ground material and from touch preps. Two important stains that should be used in the clinical laboratory for direct samples are the Gram stain and the modified acid-fast stain. Histopathologic examination of fixed tissue by use of special stains may also reveal the presence of organisms (262).

The modified acid-fast stain used on direct specimens may more accurately reflect the true partially acid-fast nature of the organisms than do modified acid-fast stains prepared from colonial growth (Fig. 2O). The modified acid-fast stain uses a weaker decolorizer (1% H_2SO_4) than does the mycobacterial stain (3% HCl) (see chapters 21 and 36 for details on reagent preparation and staining methodology). Because of the difficulty of standardizing this technique, it is imperative that positive and negative controls be run simultaneously with patient smears. The control slides can be made from growing suspensions of *Streptomyces* species (negative control) and *Nocardia* species (positive control). Smears should be evaluated by experienced laboratory personnel, and the quality of the stain itself should be evaluated before results are reported. *Gordonia, Nocardia, Rhodococcus,* and *Tsukamurella* (and possibly *Dietzia*) are known to be partially acid fast with this stain.

Careful attention should be paid to the cellular material present in the sample. Phagocytized gram-positive or acid-fast organisms can sometimes be seen within macrophages and mononuclear cells; in the modified acid-fast smear these may appear as beaded cells with strongly acid-fast granules within non-acid-fast or weakly acid-fast rods (189).

In cases of suspected actinomycetoma, aspirated material should be examined grossly for the presence of granules by spreading the sample in a sterile petri dish. Granules found should be washed and crushed. Smears should be prepared from the crushed material and appropriate media should be inoculated.

Recently, Couble et al. reported on a method for direct detection of *Nocardia* isolates from clinical samples by using PCR along with DNA probes directed to a portion of the 16S rRNA gene. Analysis of 18 patient samples that were culture positive for various *Nocardia* species gave positive results for all samples; specimens containing *Mycobacterium tuberculosis* gave negative results (65). Further assessment of this technique will be needed to assess its clinical utility.

ISOLATION

Blood agar, chocolate agar, brain heart infusion agar, Sabouraud dextrose agar, and Lowenstein-Jensen medium will support the growth of aerobic actinomycetes. *Dermatophilus congolensis* may not grow on Sabouraud dextrose agar or Lowenstein-Jensen medium (275). Buffered charcoal yeast extract agar (BCYE) is particularly useful for the recovery of *Nocardia* species. Specimens from sterile sites or concentrated sterile body fluids can be inoculated directly onto these media. Specimens from respiratory sites, skin, and other potentially contaminated sites, such as mycetomas, should additionally be inoculated onto selective media, such as modified Thayer Martin agar (183) and selective BCYE (containing polymyxin B, anisomycin, and either vancomycin or cefamandole) (244). Sabouraud agar with added chloramphenicol may not be useful, as it may also suppress the growth of some *Nocardia* species (105). A specialized medium for the recovery of *R. equi,* using a Mueller-Hinton agar-based

medium with added ceftazidime and novobiocin, has been described (246).

Cultures for aerobic actinomycetes should be handled as fungal cultures, thus ensuring that the cultures will be held and regularly examined over an extended period. Two BCYE plates (for samples from sterile sites) or selective BCYE plates (for respiratory or other potentially contaminated sites) should be inoculated. One BCYE or selective BCYE should be incubated at 30°C and the other at 35°C, both in ambient air. It should be noted, however, that *Streptomyces* species may show best growth at 25°C and that *D. congolensis* grows better and shows enhanced production of aerial hyphae in increased CO_2 (275). For all cultures, plates should be held for a minimum of 2 weeks, preferably for up to 3 weeks, and should be sealed to prevent dehydration.

A low-pH decontamination procedure has been successfully used for pretreatment of heavily contaminated specimens suspected of harboring *Nocardia* species. The sample is diluted 1:10 in 0.2 M HCl–0.2 M KCl at pH 2.2, mixed, and allowed to stand for 3 to 5 min, after which it is inoculated onto selective and nonselective media (26, 244). Murray et al. report a drop in viability of *Nocardia* species after 30-min exposures to *N*-acetyl-L-cysteine (NALC), NaOH-NALC, or Zephiran-TSP (182). The key to improved recovery of *Nocardia* from NaOH-NALC-treated specimens may be a shorter exposure to the decontaminating reagents (15 min), as is in fact also recommended for the recovery of mycobacteria (136).

Aerobic actinomycetes have been recovered from blood by using a variety of commercially available blood culture systems, including conventional two-bottle systems, biphasic bottles, systems using radiometric and nonradiometric detection, and lysis-centrifugation systems. By use of various blood culture systems, aerobic actinomycetes have been recovered after 3 to 19 days of incubation, which in some cases included the incubation times of terminal subcultures (180, 242). Studies employing newer blood culture systems have resulted in a recommendation that extended incubation is no longer necessary (15); however, such studies have not established that such shorter incubation would generally be adequate for the isolation of aerobic actinomycetes. If the possibility of bacteremia with a member of one of these genera is anticipated, it would be advisable to request fungal blood cultures or to perform terminal subcultures if the incubation period of routine blood cultures cannot be extended.

Cultures from all sources should be examined daily for the first week of incubation and then weekly thereafter, preferably using a dissecting microscope, which will allow detection of tiny colonies. Such microscopic examination is particularly important for specimens that contain contaminating flora, as an aerobic actinomycete can be quickly overgrown by more rapidly growing organisms. Care should also be exercised when examining Lowenstein-Jensen or Middlebrook media for mycobacteria or when examining BCYE plates for *Legionella* species, as *Nocardia* and other aerobic actinomycetes will grow on these media.

IDENTIFICATION

Microscopic Morphology

Gram-stained and modified acid-fast-stained smears should be prepared as the initial step in organism identification. Numerous fields should be reviewed to determine the most prevalent morphology and to detect the sometimes rare branching forms. Care should be taken not to confuse perpendicular aligning of the organisms with true branching (Fig. 2).

A properly prepared and carefully interpreted modified acid-fast smear can assist in the preliminary identification of the organism (Fig. 2G, H, J, and K). Quality control slides should be stained along with stains of colonies from cultures. With the modified acid-fast stain, the background should be blue; slides that have a pink background may be inadequately decolorized and should be repeated. The smear should be scanned for areas where individual cells can be seen or areas where single layers of cells allow clear differentiation of cell borders. The acid-fast reaction of tightly packed clumps of organisms may not represent the true partially acid-fast nature of the cells; be wary of large clumps of cells which all appear to be acid-fast positive. Acid-fast cells will be clearly red; cells that stain purple or light pink may or may not be truly acid fast. A stain that shows an unambiguous acid-fast positive reaction may frequently show only a few clearly red cells, with a majority of blue cells. Frequently, only the "beads" will appear acid-fast positive. If modified acid-fast stain results are ambiguous, transfer of the organism to a lipid-rich medium, such as Lowenstein-Jensen medium or Middlebrook 7H11 agar, and repeat staining may give a more clear-cut stain result. Similar enhancements of the acid-fast reaction have been noted after growth in glycerol nutrient broth, litmus milk, or media containing certain amino acids (142, 239). Acid fastness may become more evident as colonies age; the acid-fast reaction has been reported to be most reliable when performed from colonies after 1 to 4 weeks of growth (239). Occasionally, coccoid forms of *Streptomyces* may appear partially acid fast; hyphae, however, are acid-fast negative. Because of the difficulties of interpretation of the modified acid-fast smear, results of this stain should be considered preliminary and must be used only in conjunction with results from other tests.

Slide Cultures

Slide cultures may be used to evaluate the microscopic morphology of actively growing cultures. Small blocks of a minimal agar (such as tap water agar) are inoculated on the side with the organism of interest, and a coverslip is placed on the top of the block. The slide culture is incubated in a humid environment at 25°C for 2 to 3 weeks and examined regularly for the characteristic features of the various genera. Vegetative mycelia (also called substrate hyphae) grow beneath the surface of the agar and show various degrees of branching. *Gordonia* and *Tsukamurella* show rudimentary to no branching, while the branching of *Actinomadura*, *Nocardia*, and *Streptomyces* is generally extensive. Vegetative hyphae of *Amycolata*, *Amycolatopsis,* and *Nocardia* fragment into bacillary, coccal, or square forms; the vegetative hyphae of *Actinomadura* and *Streptomyces* show little to no fragmentation. The substrate growth of *Rhodococcus* initially appears as short rods, which either remain unchanged in shape or evolve into filaments with side projections or into filaments with elementary to extensively branched hyphae. These forms all rapidly fragment to a coccal or short rod form (113). The rhodococcal colony itself is a mass of these coccoid or coccobacillary forms. The vegetative hyphae of *D. congolensis* are characteristic for the genus and show long, tapering filaments which branch laterally at right angles, with septa forming in transverse and longitudinal planes (113).

Colonial Morphology

The colonial appearance of members of the aerobic actinomycetes is extremely variable among genera and even between isolates of the same species (Fig. 1). Environmental factors such as growth medium, incubation temperature, air

circulation, presence of CO_2, and age of culture can affect the size and consistency of the colonies and the production of aerial hyphae (21, 142). Some species produce a diffusible pigment that can vary from strain to strain (142) (see genus and species descriptions above for information on specific colonial morphologies).

Aerial Hyphae

Aerial hyphae project away from the surface of the colony into the air but may not be apparent until 7 to 14 days for most species that form such hyphae. *Nocardia* and *Streptomyces* usually produce abundant aerial hyphae that give the colonies their characteristic powdery or velvety appearance (Fig. 1E and L); rare strains of *Nocardia* produce sparse or no aerial hyphae (Fig. 1D and G). *Actinomadura, Amycolata*, and *Amycolatopsis* show variable production of aerial hyphae. *Rhodococcus* may rarely form rudimentary aerial hyphae (113). Of the genera that are partially acid fast, only *Nocardia* regularly produces aerial hyphae. The presence of spores and their relative number and arrangement on the aerial hyphae can also give some clue to the genus identification (113).

Phenotypic Identification

Limitations

Given the increasing number of species of aerobic actinomycetes, the use of only a limited number of phenotypic tests to obtain exact species or even genus level identification has become impossible. When a precise identification is required for a significant patient isolate, referral to a reference laboratory for molecular testing is strongly recommended.

Genus Assignment

To determine the genus of an unknown isolate, observation of colonial morphology, specifically the presence of aerial hyphae, is especially important. *Nocardia* and *Streptomyces* generally produce aerial hyphae, with other less commonly isolated genera also showing this morphologic trait (see Table 5). Results of a carefully prepared and carefully interpreted modified acid-fast smear will help to distinguish *Nocardia* from the other genera.

Nocardia and *Tsukamurella* (both modified acid-fast positive organisms) are resistant to lysozyme and show good growth in lysozyme broth; of these, only *Nocardia* species show aerial hyphae. *Gordonia* shows variable growth in lysozyme broth but does not show aerial hyphae. Lysozyme catalyzes the hydrolysis of certain polysaccharides in the cell wall, resulting in a weakening of the cell wall. Berd (21) recommends the use of a very small inoculum into glycerol broth with 0.005% lysozyme and a second similarly inoculated glycerol broth without lysozyme as a control. After 4 weeks of incubation, results are interpreted by comparing organism growth in the broths with and without lysozyme. All *Nocardia* isolates tested in one study (Brown et al., *Abstr. 97th Gen. Meet. Am. Soc. Microbiol.* 1997) were resistant to lysozyme, except for 10 lysozyme-susceptible isolates that belonged to the *N. brevicatena* complex. Lysozyme broth is commercially available from Remel (Lenexa, Kans.) and BD Diagnostics (Sparks, Md.).

Species Assignment

Biochemicals

Some useful phenotypic tests are not commercially available. Tables 3 and 4 present antibiotic susceptibility patterns and basic biochemical results that may provide preliminary identifications of frequently isolated *Nocardia* species or complexes obtained from clinical specimens. Most (but not all) of the isolates of a given species show the results listed in Table 4. When performing biochemical tests, it is extremely important to include appropriate positive and negative controls to ensure that tests are inoculated, incubated, and interpreted correctly. See "Evaluation, Interpretation, and Reporting" below for recommendations on reporting preliminary identifications obtained using these methods.

Acetamide Hydrolysis

The enzyme acylamidase hydrolyzes acetamide with the production of ammonia after incubation for 7 days at 35°C. The appropriate color change in the medium must be seen, as acetamide may be assimilated but not hydrolyzed (Remel Technical Information TI #60012-A). A positive result is a distinguishing characteristic for *N. farcinica* (250).

Antibiotic Susceptibility Testing

While various species of *Nocardia* are known to have typical antibiotic susceptibility patterns (Table 3), the use of these patterns alone for species identification should be avoided. Species belonging to "complexes" (for example, the members of the *N. nova* complex) may have identical antibiograms (59).

Arylsulfatase

The enzyme arylsulfatase hydrolyzes the bond between the sulfate group and the aromatic ring of potassium phenolphthalein disulfate incorporated in the medium. With the addition of an alkali (sodium carbonate), free phenolphthalein is released, resulting in a change of color to red in the medium (136). The CDC Actinomycete Laboratory uses a modified methodology of the Kubica method, increasing the phenolphthalein concentration from 0.001 M to 0.008 M. The test can be read at 3 days and again at 2 weeks, with most strains of *N. nova* showing positive results by 14 days. Arylsulfatase medium is available commercially, but the concentration of phenolphthalein in the product being used must be considered when comparing results obtained with results reported in the literature.

Acid Production with Carbohydrates

The "Gordon" method utilizes basal medium with individual carbohydrates; the pH indicator bromcresol purple is used (96). Oxidation of carbohydrates results in a change in medium color from purple to yellow (acid) after 3 weeks of incubation at 25 or 35°C (21). The media are not available from commercial sources.

Utilization of Carbohydrates as a Sole Carbon Source

The "Goodfellow" method tests the ability of organisms to utilize various carbohydrates as a sole source of carbon. Basal medium with a single carbon source added is inoculated with an organism suspension; positive results are noted as heavier growth on medium containing the carbohydrate than is observed on basal medium without carbohydrates, after 3 weeks of incubation at 25 or 35°C (91). The media are not available commercially.

When preparing media for both the Gordon and Goodfellow tests, some substrates must be filter sterilized rather than autoclaved.

Other Compounds as a Sole Source of Carbon

The ability of organisms to utilize compounds such as sodium citrate and gluconate as a sole carbon source is also frequently used in identification schemes.

Esculin Hydrolysis

The esculin hydrolysis test determines the ability of an organism to hydrolyze the glycoside esculin through the action of the enzyme esculinase. This test is commercially available in broth or agar form.

Gelatin Hydrolysis

The ability of an organism to produce the proteolytic gelatinases (which liquefy or hydrolyze gelatin) helps to differentiate *N. brasiliensis* and *N. pseudobrasiliensis* from the other *Nocardia* species (139). This medium is commercially available from several sources. After inoculation the test is incubated at 35°C for up to 7 days; tubes must be placed at 4°C for 15 min prior to checking for hydrolysis (139).

Middlebrook Opacification

Flores and Desmond (80) describe the ability of isolates of *N. farcinica* to opacify Middlebrook 7H10 or 7H11 agar within 2 to 10 days of incubation at 28 or 35°C. Opacification was not seen with isolates of *N. asteroides*, although in a study of a limited number of organisms, rare isolates of *N. otitidiscaviarum* and *Rhodococcus terrae* were positive for this characteristic (42).

Nitrate Reduction

This procedure tests the ability of an organism to reduce nitrate to nitrites or free nitrogen gas through the action of nitrate reductase (169). The medium is available from commercial sources.

Substrate Decomposition

The differential abilities of organisms to degrade or hydrolyze the amino acid tyrosine, the purine adenine, the purine derivatives xanthine and hypoxanthine, and the milk protein casein have been shown to be useful for differentiation of some members of *Nocardia*, *Rhodococcus*, and *Tsukamurella* (139). Typically, heavy inocula of the test organisms are placed on each of the substrate-containing agars; positive reactions are seen as clearing of the medium surrounding the colonial growth. All tests should be evaluated weekly; casein results should be recorded after 14 days' total incubation, xanthine after 3 weeks of incubation, and adenine, hypoxanthine, and tyrosine after 4 weeks' total incubation. Not all of these substrates are commercially available.

Temperature Studies

Growth at various temperatures can help differentiate among *Tsukamurella* species and among the thermophilic actinomycetes. Replicates of the same medium (usually sheep blood agar or Sabouraud dextrose agar) are inoculated with a standardized inoculum and incubated at 35 and 45°C; after 3 days of incubation (139) the amounts of growth on the two tubes or plates are compared to determine temperature tolerances. If the presence of a thermotolerant species is suspected, additional media should be incubated at 50°C.

Urease

Urease hydrolyzes urea with the production of ammonia. Wauters et al. recommend the use of a 1% urea broth with cresol red as an indicator (254). Commercially prepared urease test media are also available.

Test Systems

Several studies investigating the use of commercial panels for the identification of *Nocardia* and other aerobic actinomycetes have been published. Test systems studied include the API Zym panels (bioMérieux, Durham, N.C.) (25), Rapid Anaerobe ID and Haemophilus/Neisseria ID panels (Dade Behring, Deerfield, Ill.) (22), the API 32C Yeast panel (bioMérieux) (181), the API (Rapid) Coryne panel (with an extended database) (bioMérieux), and the RapID CB Plus System (Remel, Lenexa, Kans.) (82, 83). To date, there is insufficient evidence to establish the utility of any of these tests for the identification of the increasing number of described species.

Identification schemes proposed by Kiska et al. (139) and Wauters et al. (254) utilize phenotypic and/or enzymatic tests and have been shown to be useful for the identification of several of the commonly isolated *Nocardia* species. Neither of these algorithms has been extensively evaluated by other investigators, nor have studies been done with recently described species.

Cell Wall and Cell Membrane

Some characteristics of the cell wall and cell membranes of genera of the aerobic actinomycetes are given in Table 5. Analysis of whole-cell hydrolysates using paper and thin-layer chromatography has been used to identify various forms of diaminopimelic acid and sugars present in the peptidoglycan layer of the cell walls; the type of sugars present, combined with the type of diaminopimelic acid, allowed classification of the various genera into cell wall types (67, 224).

Since members of the aerobic actinomycetes and related genera are known to contain elevated levels of cell wall lipids, analysis of the variations in chain length, differences in the degree of saturation, and the presence of various functional groups on cell wall lipids has been evaluated for identification to the genus or species level (241). McNabb et al. used high-performance liquid chromatography and the Microbial Identification System (MIDI, Inc., Newark, Del.) to analyze the fatty acids of aerobic actinomycetes. Their results showed distinct clustering of genera into two groups based on the presence or absence of branching of the cell wall fatty acids. Results also showed significant heterogeneity among species subsequently found to be heterogeneous by molecular methods (171).

Mycolic acids, high-molecular-weight fatty acids with an α-branched, β-hydroxy structure, are thought to contribute to the staining characteristics and pathogenicity of these organisms (16). The corynebacteria and mycobacteria (which also contain mycolic acids) and those aerobic actinomycetes containing mycolic acids can be differentiated based on the number of carbon atoms of their constituent mycolic acids (Table 5). It should be noted that the number of carbon atoms making up the mycolic acids of some genera varies from one report to another.

A variety of methods have been used to evaluate the cell wall lipids and mycolic acids of the aerobic actinomycetes, including thin-layer chromatography (179), gas chromatography with mass spectrometry (11), and high-performance liquid chromatography (38). By using these methods, differences have been noted among nocardiae belonging to the *N. asteroides* complex, among *Rhodococcus* species, and among the genera *Dietzia*, *Gordonia,* and *Rhodococcus* (39, 187, 188).

Isoprenoid quinones are present in the cell membranes of most bacteria; they function in electron transport, oxidative phosphorylation, and perhaps active transport (241). Menaquinones, the type of isoprenoid quinone present in the cell membranes of the aerobic actinomycetes, vary in the number of isoprene units and in the degree of unsaturation of the C_3 isoprenyl side chain. These variations have been

found to be helpful in the differentiation of members of the aerobic actinomycetes to the genus level (57, 267). Menaquinone analysis has been particularly useful for distinguishing *Nocardia* species from other mycolic acid-containing aerobic actinomycetes (Table 5).

The equipment required for modern chromatographic procedures is generally available only in research or reference laboratories. In addition, these techniques are not applicable for identification to the species level.

Molecular Identification

Molecular techniques are currently the only methods that can provide definitive identification of most isolates of aerobic actinomycetes. These methods have the added benefit of providing identifications in a fraction of the time needed for biochemical tests.

PCR and REA

The use of PCR enables the identification of aerobic actinomycetes that have unique gene regions (chapter 16). This method has been applied to various genes such as the 16S rRNA gene (for genus level identification of *Nocardia* and *Nocardiopsis* species and species level identification of *R. equi*), the *choE* gene (*R. equi*), and a putative nonribosomal peptide synthetase gene (*N. farcinica*) (18, 32, 146, 151, 209).

PCR paired with restriction endonuclease analysis (REA) is useful for the identification of commonly isolated *Nocardia* species. The procedure takes advantage of the presence of sites within the variable regions of an organism's gene sequence (chapter 16). With REA of a portion of the heat shock protein gene (HSP), Steingrube et al. were able to differentiate among eight species of *Nocardia* and the six drug pattern types of *N. asteroides* described by Wallace (225, 229, 249). Refinement of this technique with a different restriction endonuclease set eliminated the intraspecies variability seen with the initial method and allowed recognition of *A. madurae*, *R. equi*, and *T. paurometabola* (226). In 2000, an REA technique utilizing a portion of the 16S rRNA gene which allowed differentiation of 10 species of *Nocardia* was described. Comparison of identifications obtained by REA of the 16S rRNA gene and by REA of the HSP gene showed good correlation between the two methods for most *Nocardia* isolates. Some isolates, however, gave discrepant or unknown RFLP patterns with either or both of the two genes. Subsequent 16S rRNA gene sequencing showed these isolates to be different from species already described (61). By using REA of the two gene regions, reliable identifications can be obtained for the species listed in Table 6. Species not listed are not identifiable by using the 16S rRNA gene and the listed combinations of restriction endonucleases. Two or more species, including numerous newly described species, may give identical RFLP patterns with REA of the 16S rRNA gene as determined experimentally or deduced from the 16S rRNA sequences of the organisms as listed in GenBank. RFLP patterns from REA of the HSP gene for some recently described species are not determinable, due to the lack of HSP gene sequence data. As the number of recognized species increases, the applicability of the REA method will be diminished.

In addition to its use for the identification of *Nocardia* species, REA has been used for differentiation among numerous genera of aerobic actinomycetes and for identification of some species of thermophilic actinomycetes (63, 108).

Other Molecular Methods

Ribotyping (chapter 16) has been used to identify isolates of *N. farcinica* (176) and to discriminate among four members of the *N. asteroides* complex (150). Ribotyping of *Rhodococcus* species has shown specific patterns for all rhodococcal type

[g] —, not needed for identification.

strains and heterogeneous patterns for members of *R. equi* and *R. rhodochrous* (126, 149).

The use of the PCR-randomly amplified polymorphic DNA (RAPD) technique (chapter 16) has shown species-specific patterns for some species of *Nocardia;* Isik et al. report that *N. nova, N. pseudobrasiliensis, N. transvalensis,* and isolates identified as *N. asteroides* show a variety of patterns (122); it is not clear if the variations reported by these authors represent the presence of additional unrecognized species, within-species variation, or both.

The use of DNA probes has been evaluated for *Streptomyces* species (223), and Brownell reported that six different probes were needed to hybridize with isolates identified as "*N. asteroides*" (33).

Gene Sequencing

Gene sequencing has become a powerful tool for the identification of this complex group of organisms. Sequence analysis of the 16S rRNA gene has been used for the species level identification of members of nearly all genera of the aerobic actinomycetes (7, 17, 116, 133, 166, 185, 203, 207, 264).

The presence of a variable region, located near the 5′ terminus of the gene (61), has made partial 16S rRNA sequencing of a 500-bp region of the gene a useful method for the presumptive identification of many *Nocardia* species. Cloud et al. (54) compared identifications obtained with the MicroSeq 500 System (Applied BioSystems, Foster City, Calif.) with results obtained using phenotypic identifications and with sequencing results from a 999-bp region of the same gene. The 500-bp-based identification of 94 clinical isolates representing 10 species showed 72% agreement with identification obtained by phenotypic methods and 90% agreement with those obtained by sequencing a larger portion of the gene. Sequencing a larger region of the gene is necessary for the separation of members of some species pairs which have identical or nearly identical sequences within the 500-bp region (for example, *N. abscessus* and *N. asiatica,* which differ by 1 bp, and *N. elegans* and *N. veterana,* which have no base pair differences in this region). Patel et al. used the MicroSeq 500 system to determine the 16S rRNA gene sequences of 28 reference strains and 71 clinical isolates and found significant sequence heterogeneity among isolates identified as *N. asteroides* drug pattern type II, *N. nova, N. otitidiscaviarum,* and *N. transvalensis*. This method was also shown to be useful for the identification of *Gordonia, Rhodococcus, Streptomyces,* and *Tsukamurella* species to the genus level (192). At present, the MicroSeq 500 System is capable of distinguishing among the more commonly isolated *Nocardia* species. However, as the number of described species increases, the number of species that can be unambiguously identified using 500-bp sequences will probably decrease.

Sequence analysis of a 441-bp fragment of the 65-kDa heat shock protein gene has been shown to have sufficient variation to allow identification of 42 type or reference strains of *Nocardia* (206) and may be more discriminatory than sequence analysis of the 16S rRNA gene.

The use of an alternative gene, the *secA1* gene, has been reported (P. S. Conville, A. M. Zelazny, and F. G. Witebsky. *Abstr. 105th Gen. Meet. Am. Soc. Microbiol.* 2005, abstr. C-152, p. 134). Analysis of the *secA1* gene sequences of 31 species of *Nocardia* has shown this gene to be more variable than the 16S rRNA gene; it therefore provides greater discrimination among *Nocardia* species. In addition, in the case of genes that code for essential proteins, translation of the gene sequence into an amino acid sequence may be useful to eliminate some within-species microheterogeneities.

For some genera, such as *Nocardia*, sequence analysis of more than one gene may be useful for the recognition of new species.

There is no consensus on how similar sequences must be to consider isolates to belong to the same species. This is a very real problem with isolates of *Nocardia,* as some species possess 16S rRNA gene sequences that are between 99.5 and 99.8% similar to those of another species, yet are distinct species by DNA-DNA hybridization (59, 269). In addition, users of gene sequence data must be careful to consider gene similarity data in relation to the size of the region sequenced; some sequence differences may not be significant if a larger portion of the gene is analyzed (53).

The presence of multiple 16S rRNA genes in *N. nova* isolates has recently been reported (62). It is unclear how the presence of multiple genes with significant sequence differences will affect the ability to identify these isolates.

Species described based on characteristics of a single isolate present problems for laboratories attempting to make identification decisions; the phenotypic characteristics described may not reflect the typical reactions of the species that would be determined if more isolates were analyzed (123). In addition, for single isolates there is no information available concerning sequence variability (49) (see also chapter 19).

Users of any sequence database used for species identification should be aware of the limitations inherent in that database. The GenBank database includes the most extensive collection of sequences, and an informed user can utilize it to make identification decisions. The proprietary database used with the MicroSeq System (Applied BioSystems) for the identification of *Nocardia* species is limited in the species represented and in the number of sequences of each species it contains. Cloud et al. expanded this database with additional entries to obtain better matches for query organisms (54). The Ribosomal Differentiation of Medical Microorganisms (RIDOM) is a quality-controlled database (177), but the portion pertaining to *Nocardia* is not available for public use. Ideally, the isolate from which the top-choice sequence was obtained should be the type strain of the species, and because of method improvements, it should have been submitted after 1995. Any top choice that appears to be out of place with other closely related sequences should be further examined to ensure that it has not appeared as a result of errors in its sequence or its identification.

DNA-DNA Hybridization

Despite the lack of a single standardized DNA-DNA hybridization procedure (220), the use of the procedure may be required for definitive species level discrimination of some isolates which have a high degree of sequence similarity (59).

TYPING SYSTEMS

In a study of *N. farcinica* isolates recovered from heart transplant recipients, Exmelin et al. compared the use of RAPD and ribotyping techniques for strain typing. They found RAPD better able than ribotyping to differentiate outbreak strains from unrelated strains (79). For strain typing with RAPD, isolates initially must be proven to belong to the same species; in this case chemotaxonomic and phenotypic methods identified the outbreak strains as *N. farcinica* (79). Blümel et al. used pulsed-field gel electrophoresis to demonstrate the relatedness of 18 isolates of *N. farcinica* from postoperative wound infections in a surgical ward over an 11-year period; these isolates were unrelated to isolates recovered from other environmental locations (23).

Recently, Yamamura used repetitive sequence-based PCR (rep-PCR) to distinguish strains identified as *N. asteroides* from unrelated clinical isolates and from different ecologic sources (265). This study showed each isolate to have a distinct banding pattern.

SEROLOGIC METHODS

Serologic methods for the detection of antibody response to nocardial infections have been shown to be lacking in sensitivity and specificity. A variety of methodologies and antigens have been evaluated, including immunodiffusion, complement fixation, enzyme-linked immunosorbent assay, and immunoblot techniques. Cell-free culture filtrates, cell homogenates, and specific high-molecular-weight proteins have been studied as sources of antigens. Most methods show considerable cross-reactivity with antibodies produced against *M. tuberculosis*. Such cross-reactivity is problematic, as tuberculosis usually is included in the differential diagnosis of patients with suspected pulmonary or CNS nocardiosis. In addition, serologic assays may not be sensitive enough to detect antibodies in patients who have diminished immunologic responses, and these are the very ones who are most prone to nocardial infections (6, 24, 118, 213, 227, 228).

SUSCEPTIBILITY TESTING

The Clinical Laboratory Standards Institute (CLSI, formerly NCCLS) has published an approved standard for susceptibility testing of both mycobacteria and aerobic actinomycetes (186). The recommended procedure for the aerobic actinomycetes is broth microdilution (55). The applicability of the procedure to the genera other than *Nocardia,* such as *Rhodococcus,* is currently under discussion. Incubation of plates is at 37°C in ambient air for 3 to 5 days, the length of time depending on the particular species being tested. Both an MIC value and an interpretation of the MIC result should be provided. Currently the interpretive breakpoints for three drugs, amikacin, minocycline, and sulfamethoxazole, differ from the breakpoints recommended for rapidly growing aerobic bacteria (55).

Susceptibility testing should be performed on all isolates of aerobic actinomycetes thought to be of possible clinical significance and especially for isolates from patients for whom a sulfonamide cannot be used. It is recommended that laboratories not performing such testing on a regular basis send isolates to an experienced reference laboratory. Antimicrobial agents recommended for primary susceptibility testing are amikacin, amoxicillin-clavulanic acid, ceftriaxone, ciprofloxacin, clarithromycin, imipenem, linezolid, minocycline, sulfamethoxazole or trimethoprim-sulfamethoxazole, and tobramycin. Agents to be considered for secondary testing include cefepime, cefotaxime, doxycycline, or moxifloxacin, and gentamicin. A few drugs with trailing endpoints, such as the sulfonamides and linezolid, may present interpretive problems. Most isolates of *Nocardia* species are susceptible to trimethoprim-sulfamethoxazole; one should be careful not to assume too readily that an isolate is resistant to this combination of drugs. Additionally, most, if not all, isolates of *Nocardia* species are susceptible in vitro to linezolid (35).

Table 3 shows the typical susceptibility patterns for the different *Nocardia* species for which adequate data are available.

EVALUATION, INTERPRETATION, AND REPORTING

The aerobic actinomycetes are widespread in the environment. Therefore, particularly when an aerobic actinomycete is isolated in culture without having been visualized in the direct patient specimen, it may be impossible for the laboratory to know if the isolate is the result of specimen or laboratory contamination, patient colonization, or actual infection. Some indication of the quantity of organism present should be given for any isolate of an aerobic actinomycete. Discussion between the clinical and laboratory staff is extremely useful for selection of additional patient specimens and laboratory procedures for determination of the clinical significance of an isolate from a given patient. Identification of an organism to the genus level may help determine its significance. However, even for accurate genus assignment, molecular methods may need to be employed.

When an isolate is reported to the species level, the laboratory should be certain that clinicians are aware of the reliability of the identification method used. It is possible to identify the more commonly encountered aerobic actinomycetes, particularly *Nocardia* species, with moderate accuracy to the species level by using phenotypic methods (Table 4) (254), but some will inevitably be misidentified by such procedures. Precise identification can be achieved only by molecular methods. For accurate determination of both identification and susceptibility pattern, referral to a laboratory with expertise in working with these organisms may be necessary.

We gratefully acknowledge the assistance of Yvonne R. Shea in the preparation of the colony photographs.

Mycobacterium: General Characteristics, Laboratory Detection, and Staining Procedures*

GABY E. PFYFFER

36

Many species within the genus *Mycobacterium* are prominent pathogens, e.g., the members of the *Mycobacterium tuberculosis* complex as well as *M. leprae* and *M. ulcerans.* In addition, numerous species of environmental mycobacteria called nontuberculous mycobacteria (NTM) (formerly "atypical mycobacteria" or "mycobacteria other than tubercle bacilli") are responsible for various kinds of mycobacterioses.

Tuberculosis remains a major global public health problem (35). The actual global prevalence of *M. tuberculosis* infection is 32%, corresponding to approximately 1.9 billion people (51). According to the World Health Organization (229), there were 8.8 million estimated new cases (case rate, 140/100,000) of pulmonary tuberculosis, including 3.9 million smear-positive (and hence highly infectious) cases, in 2003. An estimated 1.9 million people died of tuberculosis, including patients coinfected with human immunodeficiency virus (HIV; 229,000). Analysis of epidemiological trends suggests that numbers of new cases are rising globally, but more people are being cured and death rates are falling (229). Reducing the burden of tuberculosis depends largely on how rapidly DOTS (directly observed therapy, short course) programs can be implemented. Among the prime obstacles for DOTS program expansion are shortages of trained staff, lack of political commitment, weak laboratory services, and the global impact of multidrug resistance (54), together with often inadequate management of multidrug resistance cases as well as people infected with HIV. In the Western Hemisphere, the number of reported cases is steadily decreasing (approximate case rate, 6.8/100,000), reflecting the effectiveness of prevention strategies and control measures implemented by the health authorities, among them the use of more rapid and efficient laboratory algorithms to detect *M. tuberculosis* and susceptibility testing with antituberculosis drugs. In this context, the clinical mycobacteriology laboratory plays an important role (55, 71).

With the advent of new laboratory techniques, new NTM species are being discovered, some of which are sources of diseases in humans (153). Rapid and reliable identification of NTM is thus mandatory but is becoming increasingly complex. The level of service and the choice of methods should, finally, be determined by the patient population served by the laboratory and by the resources available.

TAXONOMY AND DESCRIPTION OF THE GENUS

The genus *Mycobacterium* is the only genus in the family *Mycobacteriaceae* (216) and is related to other mycolic acid-containing genera. The high G+C contents of the DNA of *Mycobacterium* species (61 to 71 mol%, except that of *M. leprae* [55 mol%]) (144) are within the range of those of members of the other mycolic acid-containing genera, *Gordonia* (63 to 69 mol%), *Tsukamurella* (68 to 74 mol%), *Nocardia* (64 to 72 mol%), and *Rhodococcus* (63 to 73 mol%) (38).

Mycobacteria are aerobic (though some species are able to grow under a reduced-O_2 atmosphere), non-spore-forming, nonmotile, slightly curved or straight rods, 0.2 to 0.6 μm by 1.0 to 10 μm, which may branch. Colony morphology varies among the species, ranging from smooth to rough and from nonpigmented (nonphotochromogens) to pigmented. Colonies of the latter type are regularly or variably yellow, orange, or, rarely, pink, usually due to carotenoid pigments. Some species require light to form pigment (photochromogens); other species form pigment in either the light or the dark (scotochromogens). Aerial filaments are very rarely formed and never visible without magnification. Filamentous or mycelium-like growth may sometimes occur but, on slight disturbance, easily fragments into rods or coccoid elements (144).

The cell wall peptidoglycolipid contains *meso*-diaminopimelic acid, alanine, glutamic acid, glucosamine, muramic acid, arabinose, and galactose. Mycolic acids (number of carbon atoms ranging from 70 to 90), together with free lipids (e.g., trehalose-6,6′-dimycolate), provide for a hydrophobic permeability barrier (106, 112). Other important fatty acids are waxes, phospholipids, and mycoserosic and phthienoic acids. Various patterns of cellular fatty acids (number of carbon atoms ranging from 10 to 20) are found as well, among which is tuberculostearic (10-*R*-methyloctadecanoic) acid, a unique cell component for a number of members of the *Actinomycetales* (106).

The high content of complex lipids of the cell wall prevents access of common aniline dyes. Although not readily stained by Gram's method, mycobacteria are usually considered gram-positive. Once stained with special procedures, however, mycobacteria are not easily decolorized, even with

* This chapter contains information presented in chapter 36 by Gaby E. Pfyffer, Barbara A. Brown-Elliott, and Richard J. Wallace, Jr., and in chapter 37 by Véronique Vincent, Barbara A. Brown-Elliott, Kenneth C. Jost, Jr., and Richard J. Wallace, Jr., in the eighth edition of this Manual.

acid-alcohol; i.e., they are acid fast. However, acid fastness can be partly or completely lost at some stage of growth by a proportion of the cells of some species, particularly the rapidly growing ones.

A natural division exists between slowly and rapidly growing species of mycobacteria. Slow growers require more than 7 days to produce colonies on solid media from a dilute inoculum under ideal culture conditions. Rapid growers, by definition, require less than 7 days when subcultured on Löwenstein-Jensen (L-J) medium but may take several weeks to appear upon primary culture from clinical specimens.

NUTRITIONAL REQUIREMENTS AND GROWTH

Most species adapt readily to growth on relatively simple substrates, using ammonia or amino acids as nitrogen sources and glycerol as a carbon source in the presence of mineral salts. A few species (e.g., *M. haemophilum* and *M. genavense*) are fastidious and require supplements such as mycobactin, hemin, or other iron compounds. To date, *M. leprae* has not been cultured outside living cells. Growth of mycobacteria is stimulated by carbon dioxide and by fatty acids which may be provided in the form of egg yolk or oleic acid, even though the latter is toxic in higher concentrations (≥1%) and has to be neutralized by albumin.

With the genome of *M. tuberculosis* deciphered some years ago, functional genomics have provided new insights into its physiological and metabolic regulation and relation to virulence. For instance, genes involved in pathways of carbon metabolism (e.g., *fadD28*) and in electron transport (*nhA* and *cydA*) and genes encoding glycan biosynthesis (e.g., *Fbp*) have been described previously (219).

Optimum temperatures for growth vary widely among species (from <30 to 45°C). Compared to that of other bacteria, the growth of most mycobacterial species is slow, with generation times of up to approximately 20 h on commonly used media. Depending upon the species, visible colonies may appear after a few days to 6 weeks of incubation under optimum conditions.

SUSCEPTIBILITY TO PHYSICAL AND CHEMICAL AGENTS

Mycobacteria are able to survive for weeks to months on inanimate objects if protected from sunlight. Members of the *M. tuberculosis* complex, for instance, survive for several months on surfaces or in soil or cow dung, from which other animals may be infected (123). Mycobacteria are easily killed by heat (>65°C for at least 30 min) and by UV (sun) light but not by freezing or desiccation. They are more resistant to acids, alkalies, and some chemical disinfectants than most other nonspore-forming bacteria. Quaternary ammonium compounds, hexachlorophene, and chlorhexidine are bacteriostatic at best. The concentration of malachite green in egg-based media (e.g., L-J medium) was selected to maximize the growth of mycobacteria while inhibiting that of other microorganisms. Other commonly used sterilants, such as ethylene oxide and formaldehyde vapor, as well as disinfectants such as chlorine compounds, 70% ethanol, 2% alkaline glutaraldehyde, peracetic acid, and stabilized hydrogen peroxide, are effective in killing *M. tuberculosis*. However, agents that are inactivated in the presence of organic matter (e.g., alcohols) cannot be relied upon to disinfect sputum and other protein-containing materials. With iodophors, the bactericidal effect depends on the content of available iodine as well as on the presence of organic matter (14).

HABITATS

The genus *Mycobacterium* includes obligate pathogens, opportunistic pathogens, and saprophytes. The major ecological niche for the *M. tuberculosis* complex and *M. leprae*, incapable of replication in the inanimate environment, is tissues of humans and warm-blooded animals. In contrast, the NTM are free-living mycobacteria and are usually found in association with watery habitats such as lakes, rivers, and wet soil, etc. Some human pathogenic NTM species, however, have yet to be recovered from soil or water, e.g., *M. ulcerans, M. haemophilum, M. asiaticum, M. shimoidei,* and *M. szulgai* (5). Some other NTM species have rarely been recovered from natural waters or soils but are readily recovered from tap water in settings where disease caused by NTM is frequent or cultures from clinical specimens are often positive. Examples are *M. kansasii, M. xenopi, M. malmoense*, and *M. simiae* (5). The *M. avium* complex (MAC), *M. gordonae,* and rapidly growing mycobacteria have been recovered from tap water as well and also occur in association with nosocomial disease and pseudooutbreaks (5, 83, 208). Although not components of the normal bacterial flora of humans or animals, NTM may be isolated from the skin, upper respiratory tract, and intestinal and genital tracts of asymptomatic individuals (57). Due to their ubiquitous nature, the question of their clinical significance is important but not always easy to answer (5).

A well-known source for positive cultures is bronchoscopes and related devices. Organisms isolated were *M. tuberculosis* (170), *M. xenopi* (12), and *M. chelonae* (66), as well as other NTM.

CLINICAL SIGNIFICANCE AND DESCRIPTION OF SPECIES

With the advent of molecular techniques for appropriate identification, close to 200 mycobacterial species have now been described. This chapter will focus on the slowly growing mycobacteria; rapidly growing mycobacteria are described in chapter 38.

M. tuberculosis Complex

The *M. tuberculosis* complex taxon includes *M. tuberculosis, M. bovis* (*M. bovis* subsp. *bovis, M. bovis* subsp. *caprae,* and *M. bovis* BCG), *M. africanum, M. microti, M. canettii,* and *M. pinnipedii,* which form a tight, discrete group of organisms and display >95% DNA-DNA homology. Recent comparative genomics using the complete DNA sequence of *M. tuberculosis* have provided information on regions of the genome that are deleted in other members of the complex (4, 67). Identification to the species level is justified for epidemiologic, public health, and therapeutic reasons.

M. tuberculosis

M. tuberculosis has an extremely low level of genetic variation, suggesting that the entire population of *M. tuberculosis* organisms resulted from clonal expansion after an evolutionary bottleneck some 35,000 years ago (C. Gutierrez, S. Brisse, R. Brosch, M. Fabre, B. Omais, M. Marmiesse, P. Supply, and V. Vincent, *Abstr. 26th Annu. Congr. Eur. Soc. Mycobacteriol.*, abstr. L-3, 2005).

In today's industrialized world, a higher prevalence of tuberculosis occurs among the medically underserved ethnic minorities, the urban poor, homeless persons, prison inmates, alcoholics, intravenous drug users, the elderly in general, foreign-born persons from areas of high prevalence, and contacts of persons with active tuberculosis. Today, HIV infection is the greatest known risk factor for progression of

latent infection to active tuberculosis. Combined HIV and tuberculosis infections, especially in combination with drug resistance, have caused outbreaks with extremely high mortality rates (30, 31). Groups with a higher likelihood of progression also include individuals with underlying medical conditions, persons who have been infected within the past 2 years, children ≤4 years old, and persons with fibrotic and cancerous lesions detected on chest radiographs.

M. tuberculosis is carried in airborne particles (droplet nuclei) generated when patients with pulmonary tuberculosis cough. These particles, 1 to 5 μm in diameter, are kept suspended by normal air currents. Infection occurs when a susceptible person inhales the droplet nuclei. Once in the alveoli, the organisms are engulfed by alveolar macrophages. Usually, the host cell-mediated immune response limits the multiplication and spread of *M. tuberculosis*. However, some bacilli can remain viable but dormant for many years after the initial infection. Patients latently infected with *M. tuberculosis* usually have a positive purified protein derivative (PPD) skin test but are asymptomatic and not infectious. In general, persons with a latent infection have a 10% risk during their lifetime for development of active tuberculosis. By contrast, patients with HIV infection have a 10 to 15% risk per year for progression to manifest disease (2).

Tuberculosis in adults is a slowly progressive process characterized by chronic inflammation and caseation and formation of cavities. These foci may rupture into the bronchi, allowing very large numbers of organisms to spread to other areas of the lungs and to be aerosolized by coughing, hence infecting other persons. The clinical features of pulmonary tuberculosis are cough, weight loss, night sweats, low-grade fever, dyspnea, and chest pain. Extrapulmonary manifestations of *M. tuberculosis* infection include cervical lymphadenitis, pleuritis, pericarditis, synovitis, meningitis, and infections of the skin, joints, bones, and internal organs (85). Relative to the ordinary clinical picture of tuberculosis, pulmonary disease in AIDS patients often differs in radiologic findings, is usually rapidly progressive, and disseminates more frequently, sometimes even without the formation of granulomas.

In culture, colonies of *M. tuberculosis* are off-white and rough on solid media (Fig. 1), although on moist media they may tend to be smoother. In addition to the classical

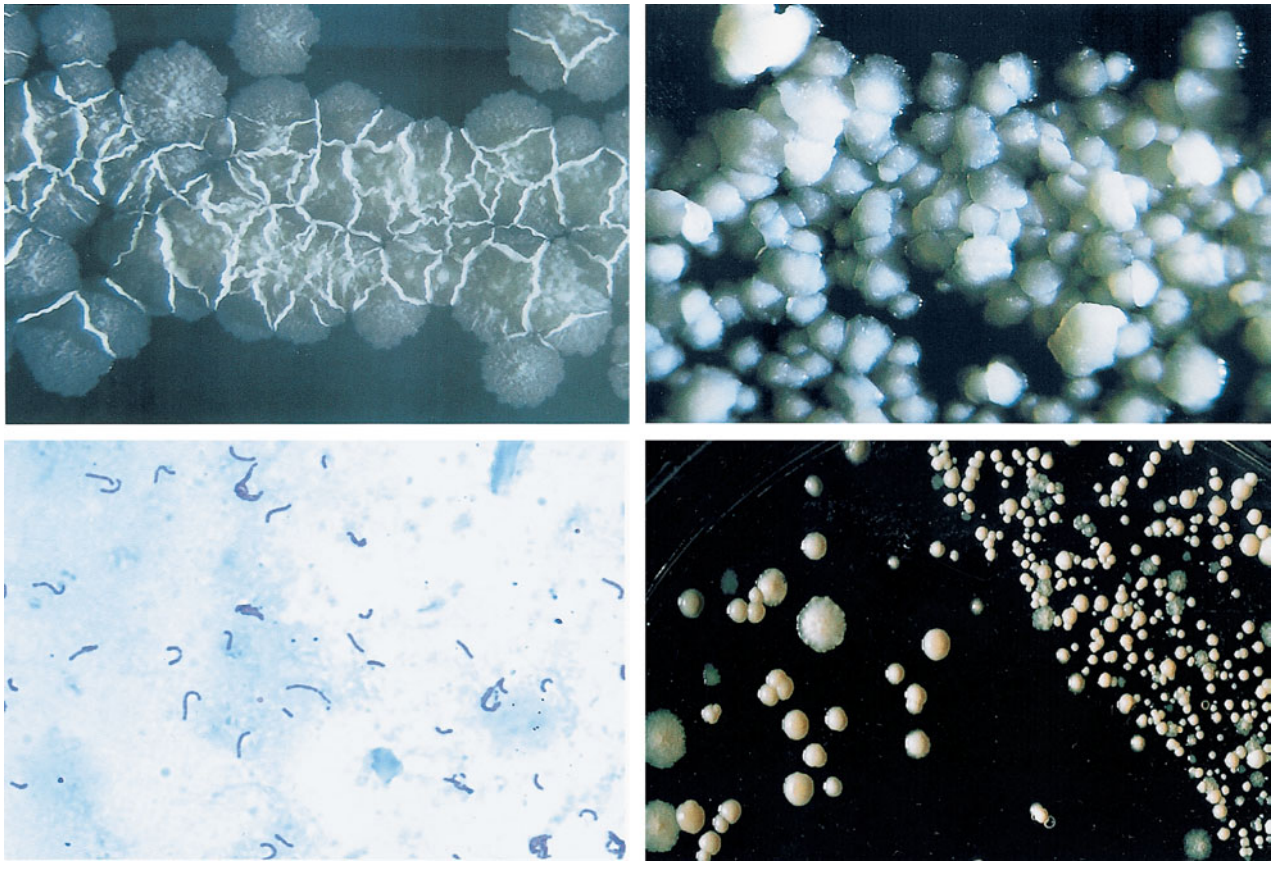

FIGURE 1 (top left) *Mycobacterium tuberculosis* on Middlebrook 7H10 agar. Note the dry and rough colonies, sometimes with a nodular or wrinkled surface.

FIGURE 2 (top right) *Mycobacterium bovis* BCG on Middlebrook 7H10 agar. Colonies may be flat as well as round with irregular edges.

FIGURE 3 (bottom left) Acid-fast staining (Ziehl-Neelsen) of *Mycobacterium microti*. Note the characteristic curved ("croissant-like") microscopic morphology. (Photograph kindly provided by D. van Soolingen, RIVM, Bilthoven, The Netherlands.)

FIGURE 4 (bottom right) *Mycobacterium canettii* on Middlebrook 7H10 agar. Note the heterogeneous colony morphology consisting of some flat and smooth but predominantly domed and glossy colonies. (Photograph kindly provided by D. van Soolingen.)

M. tuberculosis, there exists an Asian variant which is susceptible to thiophene-2-carboxylic acid hydrazide. In contrast to *M. tuberculosis*, Asian variant strains often contain few to no IS*6110* elements in their genomes (see chapter 37).

M. bovis

M. bovis causes tuberculosis in warm-blooded animals such as cattle, dogs, cats, pigs, parrots, badgers, and some birds of prey but also in primates and humans. Human disease is very similar to that caused by *M. tuberculosis* and is treated accordingly, except that pyrazinamide is inefficient due to the inherent resistance of most *M. bovis* strains. The organism grows poorly on L-J medium, but growth is stimulated if glycerol is replaced by pyruvate. In contrast to most members of the *M. tuberculosis* complex, *M. bovis* is able to grow in a reduced-O_2 atmosphere. Colonies on egg-based media are small and rounded, with irregular edges and a granular surface, and on agar media colonies are small and flat (216).

M. bovis subsp. *caprae* (6, 53), easily recognized by its susceptibility to pyrazinamide, is not only seen in cattle but accounts for 31% of human *M. bovis*-associated tuberculosis cases, mostly as pulmonary manifestations, in Germany (107). *M. bovis* subsp. *caprae* thus adds to the agents of human tuberculosis contracted from animals.

M. bovis BCG

In many parts of the world, *M. bovis* bacillus Calmette-Guérin (BCG) is still used for vaccine purposes. It was distributed by Calmette in 1924 to laboratories around the world and has been maintained in vitro by serial passages. Today, there exists a genetically heterogeneous conglomerate of BCG strains (Fig. 2) (11, 183) which predominantly conform to the properties described for *M. bovis* except that they are more attenuated in virulence. In rare instances, BCG may disseminate as a complication of intravesical BCG immunostimulation against bladder cancer (1).

M. africanum

M. africanum is a cause of human tuberculosis in tropical Africa. Colonies of *M. africanum* resemble those of *M. tuberculosis*, and physiological and biochemical properties position the organism between *M. tuberculosis* and *M. bovis*. Prior to molecular genetics methods, the definition of *M. africanum* was difficult and its validity was questioned by some authors. Recent genotypic analyses based on variable-number tandem repeats and other molecular characteristics have set *M. africanum* clearly apart from other members of the complex (64, 206). Likewise, Mostowy et al. (126) and Niemann et al. (133) consider *M. africanum* a unique species within the *M. tuberculosis* complex. The distribution of deleted sequences suggests that *M. africanum* subtype II isolates are situated among strains of "modern" *M. tuberculosis* while subtype I isolates are heterogenous and constitute two distinct evolutionary branches within the *M. tuberculosis* complex.

M. microti

Originally isolated from rodents such as voles and shrews, *M. microti* causes naturally acquired tuberculosis in guinea pigs, rabbits, llamas, cats, and other warm-blooded animals. It has been identified as a causative agent of tuberculosis in both immunocompetent and immunosuppressed humans (204). Usually revealing a characteristic, "croissant"-like morphology in stained smears (Fig. 3), the organism normally fails to grow in culture. At least the vole type of *M. microti* can easily be recognized upon spacer oligotyping (see chapter 37) since it contains an exceptionally short genomic direct repeat region resulting in identical two-spacer sequence reactions (204).

M. canettii

M. canettii was first collected by Georges Canetti back in 1969. van Soolingen et al. (205) and Pfyffer et al. (147) reported *M. canettii* causing lymphadenitis in a child and generalized tuberculosis in an HIV-positive patient, respectively. Its natural reservoir was unknown. The facts that both patients were exposed in Africa and that more cases of cervical lymphadenitis have been reported from Djibouti (56) support the hypothesis that *M. canettii* may be more abundant on the African continent. In 2002, pulmonary manifestation of *M. canettii* infection was reported (122).

With its smooth, round, and glossy colonies (Fig. 4), it differs considerably from all other members of the *M. tuberculosis* complex and can even be mistaken for an NTM. Studies by Brosch et al. (20) and Marmiesse et al. (113) of 20 regions where insertion-deletion events took place in the genome of *M. tuberculosis* suggest that *M. canettii* diverged first from the rest of the *M. tuberculosis* complex. Based on variable-number tandem repeat genotyping and analysis of *hsp65* gene polymorphism in 44 strains of *M. canettii,* Fabre et al. (56) confirmed that *M. canettii* is the most probable source species of the *M. tuberculosis* complex rather than just another branch of the taxon. In fact, it is assumed that *M. canettii* appeared some 2.8 million years ago and may, therefore, be the ancestor of all members of the *M. tuberculosis* complex. Moreover, the amount of synonymous nucleotide variation in housekeeping genes suggests that early tubercle bacilli were contemporaneous with the early hominids in East Africa and have thus been coevolving with their human hosts much longer than previously thought (Gutierrez et al., *Abstr. 26th Annu. Congr. Eur. Soc. Mycobacteriol.*).

M. pinnipedii sp. nov.

On the basis of host preference and phenotypic and genotypic characteristics, the new member of the *M. tuberculosis* complex *M. pinnipedii* has been defined by Cousins et al. (37). Pinnipeds appear to be the natural host, but the organism is also pathogenic for guinea pigs, rabbits, Brazilian tapirs (*Tapirus terrestris*), possibly cattle, and humans. Infections with the "seal bacillus" manifest with granulomatous lesions in the lymph nodes, lungs, pleura, and spleen and are able to disseminate.

M. leprae

Estimates from the World Health Organization put the global prevalence of leprosy (Hansen's disease) at 11 million people, with the majority of cases occurring in south and southeast Asia, Africa, and Latin America (202). Since multidrug therapy consisting of dapsone, rifampin, and clofazimine (230) has been introduced, the prevalence rate has dropped by 85% and leprosy has been eliminated in 98 countries. The number of new cases (about 600,000 to 700,000 per year) has, however, shown no substantial decline despite multidrug therapy (228). In the past centuries, leprosy occurred on a large scale also in Europe, in particular in Norway. Even though the disease has remained endemic in small pockets in the United States (Texas, California, Louisiana, Hawaii, and Puerto Rico) (114), the majority of infections now seen in North America have been acquired abroad. These imported cases appear to present a negligible risk for transmission within the United States.

Leprosy is a chronic, granulomatous, and debilitating disease (77). Its principal manifestations include anesthetic

skin lesions and peripheral neuropathy with nerve thickening. The term leprosy encompasses a continuous spectrum of disease, from a form with very few demonstrable bacilli (tuberculoid leprosy) to a progressive, widespread form with massive numbers of organisms due to the absence of cell-mediated immunity (lepromatous leprosy). The majority of leprosy patients show manifestations between these two polar forms and are clinically unstable. Medical complications arise from nerve damage and immune reactions (77).

Shedding from the nose, rather than from skin lesions, is important for transmission, which results most likely from prolonged and intimate contact with a person with multibacillary disease. The natural reservoir for *M. leprae* is not well established, but naturally occurring infections in the nine-banded armadillo *(Dasypus novemcinctus)* have been documented in Texas and Louisiana.

M. leprae differs from all other mycobacteria in that it cannot be cultured in vitro. There is, to date, one single report in which *M. leprae* was claimed to show sparse growth in a special medium at 32°C (135). By tradition, the diagnosis of leprosy is essentially a clinical one, based on finding one or more signs of disease which are supported by the presence of acid-fast bacilli (AFB) on slit skin smears or in skin biopsy specimens. In the case of lepromatous disease, nodules and plaques are the preferred sites for biopsies, which will reveal numerous AFB. Conversely, in patients with tuberculoid leprosy, the rims of lesions should be biopsied and usually only a few or no AFB are found. A number of PCR assays have been established to conclusively identify the organism (140, 142).

Nontuberculous Mycobacteria Frequently Involved in Human Disease

Slowly Growing Species

M. avium Complex

MAC organisms have been isolated from water, soil, plants, and other environmental sources. They are important pathogens of poultry and swine but were not recognized as a cause of human disease until the 1940s. Generally, these organisms are of low pathogenicity. Single positive specimens with low numbers of AFB as colonizers are not infrequently observed in individuals without apparent disease. This complicates the interpretation of culture results, particularly from specimens of the respiratory tract (5, 57). However, as a result of the AIDS pandemic, the MAC has become the most common environmental NTM causing disease in humans.

Before the advent of AIDS, the most common presentation of MAC infection was pulmonary disease showing several different clinical patterns, i.e., tuberculosis-like infiltrates, nodular bronchiectasis, solitary nodules, and diffuse infiltrates in immunocompromised patients (209). Tuberculosis-like upper lobe fibrocavitary disease due to the MAC occurs typically in white men 45 to 60 years of age who are heavy smokers, many of whom abuse alcohol, and some of whom have preexisting lung disease. The clinical presentation is similar to that of tuberculosis. Nodular bronchiectasis occurs usually in elderly, nonsmoking women with no predisposing disorders of the lungs or immune system other than associated bronchiectasis ("Lady Windermere syndrome") (46). These patients usually present with persistent cough only. The MAC is also isolated from up to 20% of young adults with cystic fibrosis, particularly in the southeastern United States, but its contribution to the disease process has not been established (100). Further, it is also the leading cause of localized mycobacterial lymphadenitis in children, especially in those 1 to 5 years of age (223). The lymphadenitis is usually unilateral and involves lymph nodes in the submandibular, submaxillary, or periauricular area. Less frequent are thoracic infections in otherwise healthy children (59).

Although disseminated MAC infections in non-AIDS patients are extremely rare (87), patients with AIDS may present with disseminated or focal infections (86). Disseminated infection occurs mostly when the CD4 count is below 100 cells/mm^3. Bacteremia occurs in almost all such patients, its magnitude ranging from <1 to 10^2 CFU/ml. The organism is found almost exclusively in circulating monocytes. Almost any organ (e.g., lungs and intestines) may be involved, with levels of mycobacteria as high as 10^{10} CFU/g of tissue. Focal infections commonly involve the lungs or the gastrointestinal tract and occasionally also peripheral lymph nodes (89).

MAC organisms are well-known for their heterogeneous colony morphology. Glossy, whitish colonies may often occur together with smaller, translucent colonies. A third, less frequent morphology resembles the dry and flat colonies of *M. tuberculosis*. Some MAC strains may develop a yellowish pigment with age. The MAC comprises a heterogeneous group of AFB that are divided into the two species *M. avium* and *M. intracellulare*. Serovars 1 to 6, 8 to 11, and 21 are *M. avium*, and serovars 7, 12 to 20, and 22 to 28 are *M. intracellulare*. Inclusion of *M. scrofulaceum* (serovars 41 to 43) in the group as the *M. avium-M. intracellulare-M. scrofulaceum* complex is no longer appropriate, given the advances in mycobacterial systematics (214, 215). *M. avium* and *M. intracellulare* are easily distinguishable by genetic methods, such as the use of DNA probes, 16S rRNA gene sequencing, and analysis of the restriction enzyme patterns of the 65-kDa heat shock protein gene *(hsp)* (185). There is evidence for a third species within the MAC which is generally referred to as the MAC-X (215). Those strains are recognized by the commercial DNA MAC AccuProbe (Gen-Probe, San Diego, Calif.) but not by the *M. avium* and *M. intracellulare* probes (Gen-Probe). More than 90% of MAC organisms isolated from AIDS patients are *M. avium* (as are most of the pathogenic isolates from pigs and cattle). In these patients, distinct serovars of *M. avium* have been found to account for the majority of infections (serovars 4, 6, 8, 9, and 11 [95] and serovars 1, 4, and 8 [165]).

Based on phenotypic and genetic characteristics, three subspecies of *M. avium* have been proposed: *M. avium* subsp. *avium, M. avium* subsp. *paratuberculosis* (187), and *M. avium* subsp. *silvaticum.* The latter is an obligate pathogen of ruminants (Johne's disease). In humans *M. avium* subsp. *paratuberculosis* is suspected to be involved in Crohn's disease. With the many new genetic tools available, taxonomy of this group becomes more difficult. Results of comparative DNA sequencing (49) are consistent with the hypothesis that *M. avium* subsp. *paratuberculosis* type I strains are an evolutionary intermediate between *M. avium* subsp. *avium* and *M. avium* subsp. *paratuberculosis* type II isolates or share a subset of *M. avium* subsp. *avium* type-specific loci through horizontal transfer. Recently, a new subspecies of *M. avium, M. avium* subsp. *hominissuis*, has been proposed by Mijs et al. (121).

M. genavense

M. genavense is a slowly growing NTM that was isolated in 1991 from the blood of an AIDS patient in Geneva,

Switzerland (19), and subsequently in the United States and in several European countries (39, 57, 195). It has been associated with enteritis, genital and soft tissue infections, and lymphadenitis in HIV-positive and in HIV-negative immunocompromised individuals. Clinically, disseminated disease in HIV-positive patients is similar to that caused by the MAC. However, stool specimens are more often smear-positive in *M. genavense* infections (136). *M. genavense* is also the most common cause of mycobacterial disease in a variety of pet birds, including parrots and parakeets (84, 152).

Analysis of the 16S rRNA gene sequences indicates that this species is most closely related to *M. simiae*. The organism was first isolated in BACTEC 13A medium, but only after extended incubation (6 to 8 weeks). It fails to grow on L-J medium, 7H11 agar, or other media commonly used for the isolation of mycobacteria. Middlebrook 7H11 agar supplemented with mycobactin J (Allied Monitor, Fayette, Mo.), however, supports the growth of *M. genavense* (39), as do microaerophilic conditions (156), the radiometric BACTEC 7H12 PZA test medium (197), and the addition of blood and charcoal to acidified Middlebrook agar (155).

M. haemophilum

M. haemophilum was first isolated in 1978 from a subcutaneous lesion in a patient with Hodgkin's disease (169). Approximately 50% of infections have been in patients with AIDS, with a relatively large number reported from New York City (25). The other cases have been in other immunosuppressed individuals (169, 210) but also in immunocompetent pediatric patients with localized cervical lymphadenopathy (168) or with a pulmonary nodule (220). The classical clinical presentation is that of multiple skin nodules appearing in clusters or without a definite pattern, commonly involving the extremities, and occasionally associated with abscesses, draining fistulas, cellulitis, and osteomyelitis (57).

M. haemophilum infections may be underrecognized because of the organism's predilection for a low incubation temperature (30°C) and its unique requirement for ferric ammonium citrate or hemin for growth. If *M. haemophilum* is suspected in a clinical specimen but culture remains negative, the organism may be recovered by using a chocolate agar plate.

M. kansasii

In the United States and many other countries, *M. kansasii* is second only to the MAC as a cause of NTM lung disease (5, 57). The organism has been cultured from tap water in municipalities around the world where clinical disease occurs. *M. kansasii* lung disease is common in mine workers in both the United Kingdom and South Africa (35) and differs from that due to the MAC in that the response to chemotherapy is much better (5).

Chronic pulmonary disease resembling classical tuberculosis is the most common manifestation of *M. kansasii* infection; it often involves the upper lobes. Extrapulmonary infections are uncommon and include cervical lymphadenitis in children (232), cutaneous and soft tissue infections, and musculoskeletal disease (13). *M. kansasii* infection rarely disseminates, except in patients with severely impaired cellular immunity (e.g., due to organ transplants) or in patients with AIDS (5).

M. kansasii is a photochromogenic species. Studies of the base sequences of the 16S rRNA gene suggest that phylogenetically it is closely related to the slowly growing, nonpigmented species *M. gastri*. Molecular studies have defined five genotypes of *M. kansasii*, all of which are able to cause human disease (148).

M. malmoense

The species name *M. malmoense* is derived from the city of Malmö in Sweden, where the first strains were isolated from patients in 1977. Disease due to this organism was later found in other European countries (5, 81, 194). It remains rare in the United States (21), Canada (3), and other areas of the world. However, in these countries, *M. malmoense* infection may be more common than suspected, because it may require 8 to 12 weeks to isolate some strains, which is longer than many laboratories in North America hold mycobacterial cultures.

Patients with *M. malmoense* infection are usually young children with cervical lymphadenitis or adults with chronic pulmonary disease (5, 57), mostly middle-aged men with previously documented pneumoconiosis. Extrapulmonary and disseminated infections have rarely been reported. The species has been recovered from soil and water (5).

M. marinum

M. marinum causes cutaneous infections as a result of trauma to the skin and subsequent exposure to contaminated freshwater fish tanks ("fish tank granuloma") or salt water (109). The disease occurs worldwide. In the United States, it is most common in southern coastal states (92). The most typical presentation is a single papulonodular lesion confined to one extremity, usually the elbow, knee, foot, toe, or finger. It appears 2 to 3 weeks after inoculation and, with time, may become verrucous or ulcerated (57). A second type resembles cutaneous sporotrichosis, in which the primary inoculation is followed by spread along the lymphatics. More severe complications include tenosynovitis, arthritis, bursitis, and osteomyelitis. Disseminated infections, including infections in patients with AIDS or persons undergoing systemic steroid therapy, have been rare.

M. marinum is photochromogenic and requires incubation at 28 to 30°C upon primary isolation. Recently, Israeli *M. marinum* isolates from humans and fish were compared by direct sequencing of the 16S rRNA and *hsp65* genes, restriction mapping, and amplified fragment length polymorphism analysis. Surprisingly, significant molecular differences separated all clinical isolates from the piscine isolates (201).

M. simiae

M. simiae was first isolated in 1965 from monkeys. Clinical isolates have come from a few geographic areas, including the southwestern United States (5, 164), Israel (88), and the Caribbean (5). The organism has been recovered from tap water in some of these areas, and most positive cultures from humans have come from single positive specimens with low colony counts, suggesting that most positive cultures represent environmental contamination. Clinical manifestations such as osteomyelitis and chronic pulmonary and disseminated disease are rare (for references, see reference 57). Cases of *M. simiae* infection mimicking MAC infection in AIDS patients have been reported (88). *M. simiae* is one of the very few NTM synthesizing niacin. Unless tested for pigment production under the influence of light, it may be misidentified as *M. tuberculosis* by inexperienced observers.

M. szulgai

M. szulgai was first described as a distinct species in 1972. Its distribution appears to be worldwide, but the natural reservoir is unknown. Patients are almost exclusively middle-aged men presenting with chronic pulmonary disease

indistinguishable from tuberculosis (196). The remaining presentations include rare cases of bursitis, cervical adenitis, tenosynovitis, cutaneous infections, and osteomyelitis (5, 57). Cases of *M. szulgai* infection in AIDS patients and disseminated disease in an immunocompetent patient have been reported as well.

Although *M. szulgai* is closely related to *M. malmoense* based on the 16S rRNA gene sequences, phenotypic distinction between the two species is easy. *M. szulgai* is scotochromogenic at 37°C and photochromogenic at 25°C (97).

M. ulcerans

The frequency of *M. ulcerans* infection has long been underestimated due to difficulties in isolating the pathogen. Today, *M. ulcerans* infection is the third most frequent mycobacterial disease in humans after tuberculosis and leprosy. In Africa the disease is known as Buruli ulcer, and in Australia it is known as Bairnsdale ulcer (5, 57, 68). Closely associated with tropical wetlands, *M. ulcerans* most likely proliferates in mud beneath stagnant waters. Disease likely occurs via direct contact with a contaminated environment or via water-dwelling fauna such as insects. It typically begins as a painless lump under the skin at the site of previous trauma on the lower extremities. After a few weeks, a shallow ulcer develops at the site of the lump. *M. ulcerans* produces a toxin that causes necrosis (203). The type of disease ranges from a localized nodule or ulcer to widespread ulcerative or nonulcerative disease including osteomyelitis. If untreated, severe limb deformities with contractures and scarring are common. There is growing evidence that *M. ulcerans* also produces disease in wild animals such as lizards, opossums, koala bears, armadillos, rats, mice, and cattle (151).

Failure to cultivate this organism in the past was due to its fastidious, heat-sensitive nature (optimum temperature, 30°C) as well as to a long generation time relative to that of other environmental mycobacteria. Many conventional decontamination protocols used in mycobacteriology interfere with the viability of *M. ulcerans*. Treatment with mild hydrochloric acid (final concentration, 0.03 N) (138) or oxalic acid (233) as a decontamination agent provides the best results. A mixture of polymyxin B, amphotericin B, nalidixic acid, trimethoprim, and azlocillin (PANTA) may control secondary contamination. Good recovery of *M. ulcerans* is obtained on L-J medium with glycerol (137, 233). Reduced oxygen tension enhances the rate of recovery in the BACTEC 460TB system (137). Molecular techniques have been developed which may help to lead to more rapid diagnosis (162).

M. xenopi

M. xenopi was first isolated in 1957 from skin lesions on an African toad *(Xenopus laevis),* but it was not recognized as a human pathogen until 1965. By 1979, 50 cases of *M. xenopi* infections in humans had been reported, primarily from the United Kingdom, France, Denmark, Australia, and the United States (5, 57). In some areas such as Canada and southeast England, it is second only to the MAC as an NTM clinical isolate (5). A recent case report of *M. xenopi* spondylodiscitis in an AIDS patient not only highlights its potential pathogenic role but also points to the uncertainties in therapeutic management (119). Increased isolation of *M. xenopi* from clinical specimens may also be due to improved laboratory techniques (50). The optimum growth temperature for the species is 45°C, and it seems to occur frequently in hot-water systems. Nosocomial infection and pseudo-infection via water storage tanks in hospitals have been described previously (176).

Pulmonary disease is the most common manifestation of infection (5, 93), usually occurring in male adult patients with underlying lung disease such as chronic obstructive pulmonary disease or bronchiectasis. Extrapulmonary infections such as septic arthritis (96), spondylitis (42), and dissemination (98) in immunocompromised individuals have also been described.

Nontuberculous Slowly Growing Mycobacteria Rarely Recovered or Rarely Causing Human Disease

Several species of slowly growing mycobacteria including *M. gordonae*, *M. scrofulaceum*, and the *M. terrae* complex are not infrequently recovered but are rarely associated with human disease. Some of the case reports of infections attributable to these mycobacteria, especially from the era before the introduction of molecular laboratory techniques, lack sufficient documentation of identification or disease association. Other species (such as *M. asiaticum* and *M. shimoidei*) are so rarely recovered that most laboratories will never see them.

M. asiaticum

M. asiaticum was not recognized as a distinct species until 1971, although it had previously been isolated from monkeys. The first published report of human disease described five patients in Australia with pulmonary disease (17). The organism has since infrequently been isolated from patients with respiratory disease in the United States and elsewhere (184). Cases of bursitis and tenosynovitis have been described. *M. asiaticum* is similar to *M. gordonae*, differing primarily in that *M. gordonae* is scotochromogenic whereas *M. asiaticum* is photochromogenic (214).

M. celatum

First described in 1993 (23), *M. celatum* has been isolated from diverse geographic areas, e.g., throughout the United States, Finland, and Somalia, and mostly from respiratory tract specimens but also from stool and blood. In one study, 32% of the patients from whom it was isolated were infected with HIV (23). *M. celatum* has also been isolated from immunocompetent patients, e.g., from a child suffering from lymphadenitis and from an elderly female patient with a fatal pulmonary infection.

M. celatum shares morphological and biochemical characteristics with the MAC, *M. malmoense*, and *M. shimoidei* and can, thus, not be identified with conventional tests. Within the bacterial chromosome, *M. celatum* has two copies of the 16S rRNA gene (157). Several subtypes (1 to 3) have been identified (23), with the use of 16S rRNA gene sequencing or restriction fragment length polymorphism analysis of the gene encoding the 65-kDa heat shock protein (149). Due to high similarities in the 16S rRNA gene sequence with that of *M. tuberculosis,* a few strains have been misidentified as members of the *M. tuberculosis* complex by using a commercially available DNA probe (189) or as *M. xenopi* on account of similar biochemical and cultural features. Unlike *M. xenopi*, *M. celatum* usually shows resistance to even high concentrations of rifampin (23).

M. gordonae

M. gordonae is the most commonly encountered nonpathogenic species in clinical mycobacteriology laboratories. This scotochromogenic species is widely distributed in soil and water. A pseudo-outbreak associated with drinking water

in a French hospital underlined the necessity for proper maintenance of water supply equipment (108). In only 1 of 38 published reports of *M. gordonae* infection was there convincing evidence that the organism played a role in disease (214). There are also reports of peritonitis in patients undergoing continuous ambulatory peritoneal dialysis (75). Eckburg et al. (52) have reviewed clinical and chest radiographic findings among persons with sputum cultures positive for *M. gordonae* and concluded that it is a nonpathogenic colonizing organism, even among persons with local or general immune suppression and abnormal chest X-ray findings.

M. scrofulaceum

The name *M. scrofulaceum* was derived from scrofula, a historical term used to describe mycobacterial infections of the cervical lymph glands. Until the 1980s, *M. scrofulaceum* was the most common cause of mycobacterial cervical lymphadenitis in children. Since then it has been replaced primarily by the MAC (223). Other types of clinical disease are rare. They include pulmonary disease, conjunctivitis, osteomyelitis, meningitis, granulomatous hepatitis, and disseminated disease (for references, see reference 57). *M. scrofulaceum* accounted for 14% of the isolates tested in respiratory specimens collected from South African miners (34).

M. shimoidei

M. shimoidei was first described in 1988 in a Japanese patient with chronic cavitary lung disease. Only a few clinical cases have been reported since (115). It is a thermophilic organism growing well at 45°C. Biochemically, the organism is similar to the *M. terrae* complex but can be separated by catalase and β-galactosidase tests. The unique sequences of the 16S rRNA gene and the 16S-23S rRNA gene spacer region allow unambiguous identification of the organism (104).

M. terrae Complex

The *M. terrae* complex consists of three species, *M. terrae, M. nonchromogenicum,* and *M. triviale*. Clinical disease due to *M. terrae* is generally limited to pulmonary disease and tenosynovitis of the hand following local trauma (173). *M. nonchromogenicum*, ubiquitous in the aquatic environment, was the cause of bacteremia in an AIDS patient (116). Separation of the members of the complex, especially *M. terrae* from *M. nonchromogenicum*, requires molecular methods.

New Species of Nontuberculous Mycobacteria

Most new NTM species have been described within the last 5 to 10 years (192). Much less is known about these species than about those mentioned previously, and clinical cases of infection are limited to a very few.

M. bohemicum

M. bohemicum is a bright yellow-pigmented species originally described in 1998 after being isolated from a patient with Down's syndrome and tuberculosis (158). Rare cases of cervical lymphadenitis in children (193) have been reported, as well as a fatal case of an elderly female with generalized eczema, lesions, and scattered nodules that spread from her hands (191). Isolates have been recovered from veterinary (goat) and environmental (freshwater) sources (191). For identification, analysis of the 16S rRNA gene sequence is required (158, 193).

M. branderi

M. branderi was first described in 1992 after characterization of 14 respiratory isolates collected in Finland. Since then, *M. branderi* has also been isolated from an infected hand wound (222). Identification of the organism requires 16S rRNA gene sequence analysis (103, 222), which shows that the species is most closely related to *M. celatum, M. cookii,* and *M. xenopi*.

M. conspicuum

M. conspicuum was first isolated in 1995 from two AIDS patients with disseminated disease (180). The organism grew at 22 to 31°C and produced pale yellow colonies on solid media. Unusually, the strains do not grow at 37°C except in BACTEC 12B medium. Based on its 16S rRNA gene sequence, it is most closely related to *M. asiaticum* and *M. gordonae*. To date, only two strains have been isolated. Since the organism prefers a rather low temperature for growth, it may, however, be missed in the laboratory.

M. heckeshornense

M. heckeshornense was described in 2000 as a scotochromogenic species (159, 163) recovered in multiple cultures from the lung of an immunocompetent patient with severe bilateral cavitary disease. On the basis of its unique 16S rRNA and 16S-23S spacer gene sequences, it appears to be a new species (159, 163). *M. heckeshornense* is reported to grow poorly on Middlebrook agar and egg-based media. Colonies resemble those of *M. xenopi.*

M. heidelbergense

The nonphotochromogenic organism *M. heidelbergense* was described in 1997 as an isolate from a child with recurrent cervical lymphadenitis (70). An *M. heidelbergense* infection was also found to mimic a lung tumor in a previously healthy woman. Biochemically, *M. heidelbergense* is indistinguishable from *M. malmoense* but unable to grow under microaerophilic conditions. Sequencing of the 16S rRNA gene, however, positions the organism on a branch separate from *M. malmoense* but within a group of slowly growing mycobacteria with a high degree of similarity to *M. simiae* (70).

M. interjectum

M. interjectum was recovered from children with chronic lymphadenitis (45) and from an AIDS patient with diarrhea (69). Colonies are smooth and scotochromogenic. Visible growth is produced within 21 to 28 days. Fatty acid patterns revealed by gas-liquid chromatography are similar to those of *M. scrofulaceum*. By 16S rRNA gene sequencing, the organism is shown to be most closely related to *M. simiae*.

M. intermedium

The photochromogenic species *M. intermedium* was repeatedly isolated from a patient with chronic pulmonary disease and can be easily confused with *M. asiaticum,* although differences exist in colony morphologies (118).

M. kubicae

Described in 2000 (63), most strains of the scotochromogenic organism *M. kubicae* have been isolated from respiratory sources. Its pathogenic potential remains, however, unknown. Based on sequence analysis of the 16S rRNA gene, it clusters with the group of *M. simiae*-related slow growers.

M. lacus

The new species *M. lacus* was cultured from the synovia of a 68-year-old female presenting with bursitis of the elbow following a local trauma. Granulomas were detected in the bursa upon its excision (200).

M. lentiflavum

M. lentiflavum was first described in 1996 as a cluster of slowly growing pigmented organisms. The majority of the isolates were from respiratory specimens. The organism has been reported as an etiological agent of cervical lymphadenitis and of disseminated infection in an HIV-positive patient. It does not grow at 45°C (181). The organism has a bright yellow pigment and distinct patterns of mycolic acids and cellular fatty acids.

M. palustre

The only strain of *M. palustre* isolated so far originated from a 4-year-old girl with lymphadenitis. Gene sequencing indicates a close relationship with *M. kubicae* and *M. simiae*-like organisms (190).

M. parmense

Closely related to *M. lentiflavum* and *M. simiae*, *M. parmense* has been isolated from a cervical lymph node of a 3-year-old child (58).

M. sherrisii

Five strains (some of which were of clinical origin), previously considered to be *M. simiae* serotype 2, have recently been characterized as a novel group of mycobacteria. Qualitative whole-genomic DNA hybridization analysis confirmed that this group is genetically distinct from *M. simiae* and *M. triplex* (171).

M. triplex

M. triplex was characterized in 1996 as an unusual cluster of slowly growing mycobacteria that strongly resembled the MAC (62) but were DNA MAC probe negative. The majority of organisms were from either lymph nodes or respiratory samples. *M. triplex* has caused disseminated mycobacteriosis in an HIV-positive patient during antiretroviral therapy and in a liver transplant patient. According to 16S rRNA gene sequencing, the organism is most closely related to *M. genavense* and *M. simiae*. It differs from *M. simiae* in not producing any pigment and from *M. genavense* in growing easily on solid media (62).

M. tusciae

The yellow pigmented organism *M. tusciae*, first described in 1999, has been found in tap water but also in a few clinical specimens, i.e., in a lymph node of an immunocompromised child and in a respiratory specimen from a patient with cystic fibrosis (198).

SAFETY AND TRANSPORT ISSUES

Laboratory Safety Procedures

Nosocomial transmission of *M. tuberculosis* from patients or specimens is of major concern to health care workers (24). Because of the low infective dose of *M. tuberculosis* for humans (50% infective dose, <10 bacilli), specimens from suspected or known cases of tuberculosis must be considered potentially infectious and handled with appropriate precautions (32). Control of aerosols and other forms of mycobacterial contamination is achieved in the laboratory by the use of properly functioning biological safety cabinets (BSC), centrifuges with safety carriers, and meticulous processing techniques (see also chapter 8).

Classification of mycobacteriology laboratory practices should be based on risk assessment (i.e., volume of tests, types of testing, prevalence of tuberculosis, and frequency of multidrug-resistant *M. tuberculosis*). Biosafety level 2 practices and facilities are required for laboratory work assessed as low risk. Aerosol-generating manipulations should be conducted in a class I or II BSC. More rigorous biosafety level 3 practices and level 3 facilities are required for laboratories associated with higher risk. These laboratories process specimens for mycobacterial culture and propagate and manipulate cultures of *M. tuberculosis* (e.g., perform identification and susceptibility testing). Such practices require that laboratory access be restricted, that directional airflow be used to maintain the laboratory under negative pressure, and that workers wear special laboratory clothing and gloves. Biosafety level 3 practices and facilities are required for those laboratories growing *M. tuberculosis* to high volumes, working with large numbers of resistant isolates, or performing tests with unknown risk. For a detailed description of safety requirements in the mycobacteriology laboratory, refer to the Centers for Disease Control and Prevention and National Institutes of Health biosafety guide for laboratories (32).

All respiratory protective devices (respirators) used in the workplace should be certified by the National Institute for Occupational Safety and Health (NIOSH) (130). Respirators that contain a NIOSH-certified N-series filter with a 95% efficiency (N-95) rating are appropriate for use. They meet the recommendations from the Centers for Disease Control and Prevention for selection of respirators for protection against *M. tuberculosis*, i.e., (i) the unloaded filter must filter particles 0.3 μm in diameter with an efficiency of 95% at flow rates of up to 50 liters/min; (ii) the respirator must be qualitatively or quantitatively fit tested to obtain a face seal leakage rate of no more than 10%; (iii) it must fit different facial sizes and characteristics, which is accomplished by making the respirators available in at least three sizes; and (iv) it must be checked for face piece fit by the person wearing the respirator each time it is worn in accordance with Occupational Safety and Health Administration (OSHA) standards. Surgical masks are not NIOSH-certified respirators and must not be worn to provide respiratory protection.

The determination of when and if to use respiratory protective devices in the laboratory should be based on risk assessment. A respirator program should be implemented by the laboratory and should include a written protocol describing situations when respirator use is necessary and procedures addressing (i) selection of the appropriate respirator, (ii) conducting of fit testing, and (iii) training of personnel in the use, fit checking, and storage of the respirator.

All work involving specimens or cultures, such as making smears, inoculating media, adding reagents to biochemical tests, opening centrifuge cups, and performing sonication, must be carried out in a BSC. The handling of all specimens suspected of containing mycobacteria (including specimens processed for other microorganisms), with the exception of centrifugation for concentration purposes, must be done within the BSC. Specimens that are to be taken out of the BSC should be covered before transport. All work surfaces, including bench tops and the inside of the BSC, should be cleaned with an appropriate disinfectant before and after work. Effective disinfectants include Amphyl (Reckitt Benckiser North America, Wayne, N.J.) and other phenol-soap mixtures and 0.05 to 0.5% sodium hypochlorite (concentration varies according to the nature of the contaminated surface). Five-percent phenol is no longer recommended as a surface disinfectant due to the documented toxicity of this compound to personnel. UV light is a useful adjunct for surface decontamination and may be used to radiate the work area when it is not in use. Centrifuges should be

used with aerosol-free safety carriers to contain debris in the event that tubes break. Use of electric incinerators rather than open flames is recommended. The excess inoculum from inoculating loops, wire, or spades may be removed by dipping the tool into a container of 95% ethanol in washed sand prior to insertion into an incinerator. Disposable inoculating loops are recommended, as are syringes with permanently attached needles if needles are required. An autoclave should be available in an easily accessible area and used to decontaminate infectious waste before removal to disposal areas.

Personnel should be regularly monitored with the Mantoux PPD skin test (annually and more often if a conversion in the laboratory or the institution has been documented) to demonstrate conversions. Those with positive skin tests should be evaluated for active tuberculosis with a chest X ray and clinical evaluation. Physical examinations should be performed when necessary. New converters should be referred to the employee health and infection control departments for epidemiological evaluation. Laboratories should have written protocols describing procedures for handling laboratory accidents. In case of a laboratory accident with possible formation of aerosols, personnel should hold their breath as much as possible, make sure that BSC are on and centrifuges are turned off, and then leave the room with the door closed for at least 30 min (the amount of time depends on the type of accident and the amount of risk). Using appropriate respiratory protection devices, personnel can return to the accident area to clean the spill. PPD-negative personnel should be skin tested at 3 and 6 months after the accident. The QuantiFERON-TB Gold (Cellestis, Valencia, Calif.) cellular immune response assay may have a role in such testing in the near future (116a). Persons who are immunocompromised should be discouraged from working in the mycobacteriology laboratory (32).

Transportation and Transfer of Biological Agents

Mycobacteria are on the list of infectious agents being regulated for shipping and transfer. Recent, more stringent regulations for the transportation of biological agents have been enacted in the United States to ensure that the public and workers in the transportation chain are protected from exposure to any infectious agents (for other countries, please consult the specific regulations). Protection is achieved through (i) the requirements for rigorous packaging that will withstand rough handling and contain all liquid material within the package without leakage to the outside, (ii) appropriate labeling of the package with the biohazard symbol and other labels to alert the workers in the transportation chain to the hazardous contents of the package, (iii) documentation of hazardous contents of the package should such information be necessary in an emergency situation, and (iv) training of workers in the transportation chain to familiarize them with the hazardous contents in order to be able to respond to emergency situations.

The reader is referred to the following regulatory documents for further information.

Public Health Service. 42 CFR Part 72. *Interstate Transportation of Etiologic Agents.* This regulation is in revision to harmonize it with the other U.S. and international regulations. A copy of the current regulation may be obtained from the Internet at http://www.cdc.gov/od/ohs/biosfty/shipregs.htm.

Department of Transportation. 49 CFR Parts 171–178. *Hazardous Materials Regulations.* Applies to the shipment of both biological agents and clinical specimens. Information may be obtained from the Internet at http://www.access.gpo.gov/cgi-bin/cfrassemble.cgi?title=199849.

U.S. Postal Service. 39 CFR Part 111. *Mailability of Etiologic Agents.* Codified in the *Domestic Mail Manual 124:38: Etiologic Agents Preparations.* A copy of the *Domestic Mail Manual* may be obtained from the Government Printing Office by calling 1-202-512-1800 or from the Internet at http://www.access.gpo.gov/cgi.bin/cfrassemble.cgi?title=199839.

OSHA. 29 CFR Part 1910.1030. *Occupational Exposure to Bloodborne Pathogens.* Provides minimal packaging and labeling requirements for transport of blood and body fluids. Information may be obtained from the local OSHA office or from the Internet at http://www.osha.gov/pls/oshaweb/owadisp.show_document?p_table=STANDARDS&p_id=10051.

International Air Transport Association. *Dangerous Goods Regulations.* These regulations provide packaging and labeling requirements for infectious substances and materials, as well as for clinical specimens that have a low probability of containing an infectious substance. A copy of the *Dangerous Goods Regulations* may be obtained by calling 1-800-716-6326 or through the Internet at http://www.iata.org/ps/publications/9065.htm.

There is also a Saf-T-Pak CD including updates available at http://www.saftpak.com/cdupdatedetails.htm.

Permits *must* be obtained for importation and exportation of biological and infectious agents. These are obtained by contacting the Centers for Disease Control and Prevention, Atlanta, Ga. (http://www.cdc.gov).

COLLECTION AND STORAGE OF SPECIMENS

General Rules

Many different types of clinical specimens may be collected for mycobacteriological analyses (90). The majority originate from the respiratory tract (sputum, tracheal and bronchial aspirates, and bronchoalveolar lavage specimens), but urine, gastric aspirates, tissues, biopsy specimens, normally sterile body fluids such as cerebrospinal fluid, and pleural and pericardial aspirates are other commonly submitted specimens. Blood and fecal specimens are usually submitted from immunocompromised patients only.

Specimens should always be collected and submitted in sterile, leak-proof, disposable, appropriately labeled laboratory-approved containers without any fixatives. Waxed containers must not be used because they may yield false-positive AFB smear results (97). Generally, transport media or preservatives are not necessary owing to the robust nature of mycobacteria. Minute biopsy material (e.g., fine-needle aspirates) may be immersed in a small amount of sterile physiological saline. Collection should bypass areas of possible contamination as much as possible, e.g., tap water, since the presence of environmental mycobacteria may result in false-positive smear and/or culture results (208). In general, swabs are not optimal for the recovery of AFB since they provide limited material and the hydrophobicity of the mycobacterial cell envelope often compromises a transfer from swabs onto solid or into broth media. If transport to the laboratory is delayed more than 1 h, specimens (except blood) should be refrigerated at 4°C. Likewise, upon arrival in the laboratory, specimens should be refrigerated until processed (see chapters 5 and 20 for additional information on specimen collection).

Sputum

Sputum, expectorated or induced, is the principal specimen obtained for the diagnosis of pulmonary tuberculosis. An early-morning specimen should be collected on three consecutive days. Pooled sputum specimens are unacceptable for mycobacterial processing because of increased contamination (97). Since the yield of culture from smear-positive specimens is high, two AFB smear-positive specimens are considered enough for the initial evaluation of pulmonary tuberculosis (182). Nelson et al. (131) demonstrated that the majority of culture-proven pulmonary tuberculosis cases are diagnosed from the first or second sputum specimen and that only rarely is a third specimen of diagnostic value. Another study, however, still concluded that three respiratory specimens are needed despite highly sensitive culture techniques (76). Follow-up cultures should be considered because it is culture (and not smears) that yields a definite answer of whether chemotherapy has been effective (120). Children may have difficulties producing sputum. In this age group, a gastric aspirate is usually the specimen of choice for the diagnosis of pulmonary tuberculosis.

Bronchial Aspirates, Bronchoalveolar Lavage Specimens, Fine-Needle Aspirates, and Lung Biopsy Specimens

In some patients unable to produce sputum, invasive collection techniques such as bronchoscopy may be necessary to diagnose pulmonary tuberculosis or mycobacteriosis. Special care is imperative for cleansing the bronchoscope to avoid cross-contamination with AFB from a preceding patient who underwent bronchoscopy (12, 66, 170). Also, the bronchoscope should not be in contact with tap water, which may contain environmental mycobacteria. Specimens collected by other invasive techniques such as fine-needle aspiration and open-lung biopsy may be submitted in difficult-to-diagnose cases.

Gastric Lavage Fluids

Aspiration of swallowed sputum from the stomach by gastric lavage may be necessary for infants, young children, and the obtunded. Early-morning specimens from fasting patients are recommended in order to obtain sputum swallowed during sleep. Samples of 5 to 10 ml, adjusted to neutral pH, should be collected on three consecutive days. If they cannot be processed within 4 h, the laboratory should provide sterile disposable containers with 100 mg of sodium carbonate for collection. Nonneutralized specimens are not acceptable because long-term exposure to acid is detrimental to mycobacteria.

Urine

The first morning urine specimen should be collected on three consecutive days at midstream (by clean catch) into a sterile container. The first morning specimen provides the best results because organisms accumulate in the bladder overnight. A minimum of 40 ml of urine is usually required for culture. Twenty-four-hour pooled specimens and small-volume specimens (unless a larger volume is not obtainable) are unacceptable. Catheterization should be used only if a midstream sample cannot be obtained.

Body Fluids

As much body fluid as possible (e.g., cerebrospinal, pleural, peritoneal, pericardial, or synovial fluid) is aseptically collected by aspiration or during surgical procedures. Bloody specimens may be anticoagulated with sodium polyanethol sulfonate. Because certain body fluids (such as cerebrospinal fluid and peritoneal dialysis effluent) may contain very small numbers of mycobacteria, it is advisable to submit larger specimen volumes (e.g., >5 ml for cerebrospinal fluid) than are required for other specimen types to increase culture yields and the chance to detect mycobacterial organisms.

Tissues (Lymph Node, Skin, and Other Biopsy Material)

At least 1 g of tissue, if possible, should be aseptically collected into a sterile container. It must not be immersed in saline or other liquid or wrapped in gauze. For cutaneous ulcers, biopsy material should be collected from the periphery of the lesion and incubated at both 30 and 37°C. Specimens submitted in formalin are unacceptable for smear and culture. Minute biopsy material may be moistened with a small amount of sterile saline.

Abscess Contents, Aspirated Pus, and Wound Specimens

As much material as possible should be aspirated aseptically. In cutaneous lesions, material is aspirated from beneath the margin of the lesion. Also, for this type of specimen, a second set of cultures has to be incubated at 30°C since one of the organisms with a lower optimum temperature (e.g., *M. haemophilum, M. marinum,* or *M. ulcerans*) may be the infectious agent.

Blood

The majority of disseminated mycobacterial infections are due to the MAC; therefore, if this organism is isolated from blood, it is always associated with clinical disease (78). If blood has to be transported before inoculation of the medium, sodium polyanethylene sulfate, heparin, or citrate may be used as an anticoagulant; blood collected in EDTA and coagulated blood are not acceptable. Direct inoculation of blood onto a solid medium is not recommended. The MAC survives for prolonged periods in Isolator lysis-centrifugation tubes (Wampole Laboratories, Cranbury, N.J.). Therefore, processing of Isolator tubes can be delayed for 24 h if absolutely necessary (79). If blood cannot be immediately processed by the laboratory, it should be stored at room temperature. The use of Isolator blood sediments to inoculate BACTEC 12B medium is contraindicated because one of the components, polypropylene glycol, is inhibitory to mycobacteria in the BACTEC 12B system (213). An identical effect on the growth of mycobacteria has also been reported for the Septi-Chek AFB liquid medium and the Mycobacteria Growth Indicator Tube (MGIT) broth (65), but this is controversial (73).

For many years, the Isolator system and the radiometric BACTEC 13A blood culture bottle (BD Diagnostics, Sparks, Md.) were the only reliable and, therefore, recommended systems for mycobacterial blood cultures (7). Very recently, the BACTEC 13A medium was, however, discontinued. Therefore, cultures from blood and bone marrow specimens have to be obtained by using alternative media, e.g., the MYCO/F LYTIC bottles (BD) (7, 207) or the MB/BacT ALERT blood medium (bioMérieux, Marcy-L'Etoile, France) (74). A recent study demonstrated that the continuously monitored systems (BACTEC MYCO/F LYTIC and MB/BacT ALERT) were as sensitive as and faster for the detection of MAC bacteremia than the heretofore standard manual Isolator system and the radiometric BACTEC 13A medium (41).

Stool Specimens

Stool specimens (>1 g) have been used for detection of the MAC from the gastrointestinal tracts of patients with AIDS, in conjunction with specimens from other sites. Past recommendations have been that stool be cultured for mycobacteria only if the direct smear of unprocessed stool is positive for AFB. The sensitivity of the stool smear, however, is only 32 to 34% (124), suggesting that its results should not determine whether a culture for mycobacteria be performed. Screening with smears is, therefore, not an effective way to identify patients at risk for developing disseminated MAC infection (78, 79).

Inadequate Specimens

Processing of inappropriate clinical specimens for mycobacteria is a waste of both financial and personnel resources. There are quite a few reasons why a specimen should not be accepted (and the clinician should be notified), e.g., (i) too small an amount is submitted (ii) specimens consist of saliva, (iii) dried swabs are submitted (biopsy specimens are preferable), (iv) pooled sputum or urine is submitted, (v) sample containers are broken, and (vi) the interval between specimen collection and processing was too long (>7 days) (139). Clinical staff must be properly trained to prevent submission of unacceptable specimens.

ISOLATION PROCEDURES

Because mycobacteria are usually growing slowly and require long incubation times, a variety of microorganisms other than mycobacteria can overgrow cultures of specimens obtained from nonsterile sites. Appropriate pretreatment and processing procedures (homogenization, decontamination, and concentration [90, 97]), culture media, and conditions of incubation must be selected to facilitate optimum recovery of mycobacteria (see also chapter 37). In particular, pretreatment of specimens has to be done carefully, i.e., by eliminating contaminants as much as possible while not seriously affecting the viability of mycobacteria.

Processing of Specimens

Decontamination of a specimen should be attempted only if it is thought to be contaminated. Tissues or body fluids collected aseptically usually do not require pretreatment. If the need to decontaminate a specimen is not clear, the specimen may be refrigerated until routine bacteriologic cultures are checked the next day. It may, however, be easier to initially inoculate a chocolate agar plate to check for sterility before a sample is processed for mycobacteria.

Normally Sterile Specimens

Normally sterile tissue samples may be ground in sterile 0.85% saline or 0.2% bovine albumin and then inoculated directly to the media. Because body fluids commonly contain only small numbers of mycobacteria, they should be concentrated to maximize the yield of mycobacteria before inoculation of media, i.e., centrifuged at $\geq$3,000 $\times$ *g* for 15 min prior to inoculation of the sediment. If the volume of fluid submitted for culture is small and fluid cannot be obtained again, it may be added directly to liquid media.

Contaminated Specimens

The majority of specimens submitted for mycobacterial culture consist of a complex organic matrix contaminated with a variety of organisms. Mucin may trap mycobacterial cells and protect contaminating bacteria from the action of decontaminating agents. Thus, mycobacteria are recovered optimally from clinical specimens through the use of procedures which reduce or eliminate contaminating bacteria while releasing mycobacteria trapped in mucin and cells. Liquefaction of certain specimens, particularly sputum, is often necessary. Mycobacteria are then concentrated to enhance detection in stained smears and culture.

Digestion and Decontamination Methods

Sodium hydroxide, the most commonly used decontaminant, also serves as a mucolytic agent but must be used cautiously because it is only somewhat less harmful to tubercle bacilli than to the contaminating organisms. The stronger the alkali, the higher its temperature during the time it acts on the specimen, and the longer it is allowed to act, the greater will be the killing action on both contaminants and mycobacteria (105). Harsh decontamination can kill 20 to 90% of the mycobacteria in a clinical specimen (97). Homogenization should occur by centrifugal swirling, and this swirling should not be vigorous enough to allow material to rise to the cap. After agitation, there should be at least a 15-min delay before opening the tube to allow any fine aerosol droplets formed during the mixing to settle. All such procedures should be carried out in a class II BSC.

Most commonly, a combination liquefaction-decontamination mixture is used. *N*-acetyl-L-cysteine (NALC), dithiothreitol, and several enzymes effectively liquefy sputum. These agents have no direct inhibitory effect on bacterial cells; however, their use permits treatment with lower concentrations of sodium hydroxide, thereby indirectly improving the recovery of mycobacteria. Addition of cetylpyridinium chloride (CPC; see Appendix 1) to specimens mailed from remote collection stations to a central processing station has yielded good recovery of *M. tuberculosis* without overgrowth by contaminating bacteria (175), but based on our experience, this agent seriously compromises culture in the BACTEC 460TB system.

For rural areas, the use of sodium carbonate, CPC, and sodium borate has been recommended to allow *M. tuberculosis* to remain viable for 5 to 18 days (18). Under field conditions, liquefaction and concentration of sputum for acid-fast staining may be conducted by treating the specimens with equal volumes of 5% sodium hypochlorite solution (undiluted household bleach) and waiting 15 min before centrifugation (97, 166). Such a treated specimen can, however, not be cultured because the chemical seriously affects the viability of AFB. The major limitation is, therefore, that a second specimen must be collected for culture. The method is very useful, however, for rapid smear preparation and interpretation in laboratories that do not process specimens for culture or that do not have a BSC.

No one method of digestion and decontamination is ideal for all clinical specimens, for all laboratories, and for all circumstances. The laboratorian must be aware of the inherent limitations of the various methods used. Even under the best of conditions, all currently available procedures are toxic for mycobacteria to some extent. Thus, the best yield of mycobacteria may be expected to result from the use of the mildest decontamination procedure that sufficiently controls contaminants. Strict adherence to specimen processing protocols is mandatory to ensure survival of the maximal number of mycobacteria. Most laboratories process specimens in batches; current recommendations suggest that specimen batches should be processed daily (186). The most widely used digestion-decontamination method is the

NALC-2% NaOH method (97) (see Appendix 1), which is compatible with the radiometric BACTEC 460TB system and other commercially available newer broth culture systems. Pretreatment of clinical specimens with sodium dodecyl (lauryl) sulfate (SDS)-NaOH is, by contrast, not suitable for the MGIT cultivation method (145) since it results in poor recovery of mycobacteria and a delayed mean time to detection of AFB. Sodium hydroxide, oxalic acid, and to a lesser extent, mild HCl have a detrimental impact on the viability of *M. ulcerans* (138). A novel procedure for processing respiratory specimens utilizing C_{18}-carboxypropylbetaine has also been described previously (188). Although culture and smear sensitivity significantly improved compared to that with the NALC-NaOH procedure, the contamination rate was extremely high (20.8%).

Commonly used digestion-decontamination methods are described with step-by-step instructions in the guide by Kent and Kubica (97), the *Clinical Microbiology Procedures Handbook* (90), and Appendix 1 of this chapter. In general, the specimen is diluted with an equal volume of digestant and allowed to incubate for some time. A neutralizing buffer is added, and the specimen is centrifuged in order to sediment any AFB present. Centrifugation should be carried out at $\geq 3{,}000 \times g$ for 15 min to get maximum recovery. The sediment is then inoculated to the appropriate liquid and solid media.

Whatever method is used, care must be taken to prevent laboratory cross-contamination of patient specimens during processing due to aerosols (8, 22, 172). A single false-positive culture for *M. tuberculosis* could easily be the basis of a diagnosis of tuberculosis, with profound consequences for clinical management, epidemiologic investigations, and public health control measures (see chapter 2).

Optimization of Decontamination Procedures

While no contamination or very low rates of contamination indicate that the pretreatment conditions were too harsh and eliminated not only bacteria and fungi but also mycobacteria, a rate exceeding 5% of all digested and decontaminated specimens cultured is generally defined as excessive contamination. A high contamination rate suggests either too weak decontamination or incomplete digestion. One or a combination of several of the following measures may be used to help decrease the contamination rate.

1. Cautiously and slightly increase the strength of the alkali treatment. Be aware that 4% NaOH will in time probably kill most tubercle bacilli.
2. Use a selective medium (one containing antibiotics) in addition to a nonselective primary culture medium to inhibit the growth of bacterial and fungal contaminants. Selective 7H11 agar (Mitchison medium), Mycobactosel agar (BD), or the Gruft modification of L-J medium should be considered. The most useful media for recovering the MAC from stool specimens have been Mitchison's selective 7H11 agar and Mycobactosel L-J medium (231).
3. Make sure specimens are completely digested; partially digested specimens may not be completely decontaminated. Increase the NALC concentration to digest thick, mucoid specimens.
4. Use an alternative digestion-decontamination procedure for problem specimen types. Respiratory secretions from patients with cystic fibrosis, often overgrown with pseudomonads, can successfully be decontaminated with NALC-NaOH followed by the addition of 5% oxalic acid to the concentrated sediment.

To determine the decontaminating capabilities of each new batch of reagents, the laboratory may wish to inoculate blood agar plates with four to six decontaminated sputum specimens in addition to inoculating mycobacterial media. Numbers of contaminants that grow after 48 h of incubation at 35°C should be minimal to none (97).

Acid-Fast Staining Procedures

Smear microscopy is still one of the most rapid and most inexpensive ways to diagnose tuberculosis. In parallel, it is a rapid means to identify the most contagious patients. Normally, its predictive value for *M. tuberculosis* in expectorated sputum is >90% (111).

The common Gram stain is not suitable for mycobacteria. They may be Gram stain invisible, may appear as clear zones or "ghosts," or may appear as beaded gram-positive rods, particularly rapidly growing mycobacteria (199). Special acid-fast staining procedures are necessary to promote the uptake of dyes. Although the exact nature of the acid-fast staining reaction is not completely understood, phenol allows penetration of the stain, which is facilitated by higher temperatures as applied, for instance, with Ziehl-Neelsen staining. Mycobacteria are able to form stable complexes with certain arylmethane dyes such as fuchsin and auramine O. The cell wall mycolic acid residues retain the primary stain even after exposure to acid-alcohol or strong mineral acids. This resistance to decolorization is required for an organism to be termed acid fast. Certain staining protocols include a counterstain to highlight the stained organisms for easier microscopic recognition. Information about specific staining procedures (those for carbol fuchsin and fluorochrome) is given in chapter 21.

Because acid-fast artifacts may be present in a smear, it is necessary to view the cell morphology carefully. AFB are approximately 1 to 10 μm long and typically are slender rods, 0.2 to 0.6 μm wide, that may appear curved or bent. Individual bacilli may display heavily stained areas and areas of alternating stain, producing a beaded appearance. Assessing AFB morphology for presumptive identification of mycobacterial species has to be done with caution and requires ample training and experience of the laboratory personnel. In liquid medium, *M. tuberculosis* often exhibits serpentine cording, but cords are also seen with some NTM species (125). NTM may appear pleomorphic, showing as long filaments or coccoid forms, with uniform staining properties. *M. kansasii* organisms can often be suspected in stained sputum smears because of their large size and cross-banding appearance (9). Cells of rapidly growing mycobacteria may be <10% acid fast and may not stain with the fluorochrome stain (94). If the presence of a rapid grower is suspected and acid-fast stains, in particular fluorochrome stains, are negative, it may be worthwhile to stain the smear with carbol fuchsin and use a weaker decolorizing process. Organisms that are truly acid fast are difficult to overdecolorize. The laboratory must be aware that there are nonmycobacterial organisms with various degrees of acid fastness such as *Rhodococcus* species, *Nocardia* species, and *Legionella micdadei*, as well as the cysts of *Cryptosporidium, Isospora, Cyclospora*, and *Microsporidium* spores. Based on a recent study, Kinyoun's cold carbol fuchsin method is inferior to both the Ziehl-Neelsen and fluorochrome methods (179).

Each slide made from a clinical specimen should be thoroughly examined for the presence of AFB. When a carbol fuchsin-stained smear is read, a minimum of 300 fields should be examined (magnification of ×1,000) before the smear is reported as negative (90, 97). A fluorochrome

stained smear is read at a lower power (×250) than a carbol fuchsin stained smear; therefore, more material can be examined in a given period. At the lower magnification, a minimum of 30 fields of view should be examined. This requires as little as 90 s. This ease of detection of AFB with the fluorochrome stain makes it the preferred staining method for clinical specimens, although an inexperienced observer may misinterpret fluorescent debris as bacilli.

All smears in which no AFB have been seen should be reported as negative. Conversely, when acid-fast organisms are detected on a smear, the smear should be reported as AFB positive and the staining method should be specified. It is best to confirm positive smears by having them reviewed by another experienced reader. Ideally, all positive fluorochrome-stained smears should be confirmed by a carbol fuchsin-based staining method, e.g., Ziehl-Neelsen, and slides should be stored for future reference (97). The widely accepted practice of confirming positive fluorochrome stains may be challenged in the future. In a recent study, Murray et al. (127) demonstrated that applying a stain to a liquefied (dithiothreitol), concentrated sample and examining the sample before the decontamination process (NaOH) is the most effective method for the detection of AFB.

Information about the quantity of AFB observed on the smear should be provided. The recommended interpretations and reporting of smear results are given in Table 1. If only one or two organisms are seen on an entire smear, this result should be noted but not reported. Confirmation of this finding should be attempted by preparation of additional smears from the same specimen or, if possible, smears from a new specimen. Observations made with the fluorochrome smears should be converted into a format that equates these observations with those made with a 100× oil immersion objective.

However, the reliability of smear microscopy is highly dependent not only on the experience of the laboratory technician but also on the number of AFB present in the specimen. While 10^6 AFB/ml of specimen usually result in a positive smear, only 60% of the smears are positive if 10^4 AFB/ml are present (55).The overall sensitivity of the smear has been reported to range from 22 to 80% (111). An important factor influencing sensitivity is the minimum amount of sputum submitted to the laboratory. In a long-term study, the sensitivity of a concentrated smear from >5 ml of sputum was significantly greater than the sensitivity of a smear processed regardless of volume (211). Other factors influencing smear sensitivity include the type of specimens examined, staining techniques, the experience of the reader, the patient population being evaluated, and pretreatment or lack of pretreatment of the specimens (indirect versus direct smears). Respiratory specimens yield the highest smear positivity rate (111). In practice, the fluorochrome stain is more sensitive than the carbol fuchsin stain, even when smears are read at lower magnification, probably because the fluorochrome-stained smears are easier to read.

The specificity of the smear for the detection of mycobacteria is very high. Prolonged or very harsh specimen decontamination and short incubation of cultures may account for smear-positive, but culture-negative, results. Patients with pulmonary tuberculosis may have positive smears with negative cultures (for 2 to 10 weeks on average) during a course of appropriate treatment (101).

Cytocentrifugation of sputum has resulted in controversial results concerning the sensitivity of smear microscopy (166, 224). Concentration of sputum by centrifugation after liquefaction with 5% sodium hypochlorite is a possible means of increasing smear sensitivity, particularly in developing countries.

The diagnostic yield of acid-fast staining of body fluids is less than that of respiratory specimens because the number of mycobacteria is usually lower. A variety of techniques have been used to concentrate mycobacteria from cerebrospinal fluid and other body fluids, but comparative data are lacking. Centrifugation is not an effective way to concentrate mycobacteria in body fluids since mycobacteria have a buoyant density of approximately 1 and, therefore, many organisms remain in the supernatant (102). Sequential layering of several drops of uncentrifuged fluid onto a slide or polycarbonate membrane filtration is probably the most effective means of concentrating mycobacteria for microscopy (174).

With each new batch of staining reagents, good laboratory practice includes the preparation of a positive and a negative smear for internal quality assessment. Smears containing *M. tuberculosis* or an NTM (positive control) and a gram-positive organism, preferentially a *Nocardia* sp. strain which is not totally acid fast (negative control), may be prepared in advance. Cross-contamination of slides during the staining process and the use of water contaminated with NTM during staining procedures are potential sources of false-positive results (48, 208). Staining jars or dishes should not be used. Transfer of AFB in the oil used for microscopy may also occur. Troubleshooting protocols to prevent false-positive and false-negative smear results have been

TABLE 1 Acid-fast smear evaluation and reporting[a]

Report	No. of AFB seen by staining method and magnification		
	Fuchsin stain	Fluorochrome stain	
	×1,000	×250	×450
No AFB seen	0	0	0
Doubtful; repeat	1–2/300 F[b] (3 sweeps)[c]	1–2/30 F (1 sweep)	1–2/70 F (1.5 sweeps)
1+	1–9/100 F (1 sweep)	1–9/10 F	2–18/50 F (1 sweep)
2+	1–9/10 F	1–9/F	4–36/10 F
3+	1–9/F	10–90/F	4–36/F
4+	>9/F	>90/F	>36/F

[c] In all cases, one full sweep refers to scanning the full length (2 cm) of a smear 1 cm wide by 2 cm long.

established by the Association of State and Territorial Public Health Laboratory Directors and the Centers for Disease Control and Prevention (8).

Culture

In detecting as few as 10^1 to 10^2 viable organisms/ml of specimen, culture is more effective than smears. Media available for the recovery of mycobacteria (97) include nonselective and selective ones, the latter containing one or more antibiotics to prevent overgrowth by contaminating bacteria or fungi. Broth media are preferred for rapid initial isolation of mycobacteria.

Solid Media

Egg-Based Media

Egg-based media contain whole eggs or egg yolk, potato flour, salts, and glycerol and are solidified by inspissation. These media have a good buffer capacity and a long shelf life (several months when refrigerated) and support good growth of most mycobacteria. Also, materials in the inoculum or medium toxic to mycobacteria are neutralized. Disadvantages of these media include variations from batch to batch depending on the quality of the eggs used, difficulties in distinguishing colonies from debris, and the inability to achieve accurate and consistent drug concentrations for susceptibility testing. When egg-based media become contaminated, they may liquefy.

Of the egg-based media, L-J medium is most commonly used in clinical laboratories. In general, it recovers *M. tuberculosis* well but is not as reliable for the recovery of other species. Petragnani medium contains about twice as much malachite green as does L-J medium and is most commonly used for recovery of mycobacteria from heavily contaminated specimens. American Trudeau Society medium contains a lower concentration of malachite green than L-J medium and is, therefore, more easily overgrown by contaminants, but the growth of mycobacteria is less inhibited, resulting in earlier growth of larger colonies.

Agar-Based Media

Agar-based media are chemically better defined than egg-containing media. Agar-based media are transparent and provide a ready means for detecting early growth of microscopic colonies easily distinguished from inoculum debris. Colonies may be observed in 10 to 12 days, in contrast to 18 to 24 days with egg-based media. Microscopic examination can be performed by simply turning over the plate and examining it by focusing on the agar surface through the bottom of the plate at a magnification of ×10 to ×100. This type of examination may provide both earlier detection of growth than unaided visual examination and presumptive identification of the species of mycobacteria present. The use of plates with thinly poured 7H11 agar (10 by 90 mm; Remel, Lenexa, Kans.) facilitates this process as microcolonies are visible after 11 days (217). This method is an alternative to broth cultures for some laboratories. Agar-based media can be used for susceptibility testing. They do not readily support the growth of contaminants (97); however, the plates are expensive to prepare, and their shelf life is relatively short (1 month in the refrigerator). Care should be exercised in preparation, incubation, and storage of the media, because excessive heat or light exposure may result in deterioration and in the release of formaldehyde, which is toxic to mycobacteria.

Middlebrook medium contains 2% glycerol, which enhances the growth of the MAC. Nonantibiotic supplements may be helpful for recovery of other mycobacteria and for use in special situations. The addition of 0.2% pyruvic acid is recommended if the presence of *M. bovis* is suspected (47), and 0.25% L-asparagine or 0.1% potassium aspartate added to 7H10 agar maximizes production of niacin (99). The addition of 0.1% enzymatic hydrolysate of casein to the Middlebrook 7H11 formulation (the only difference from 7H10) improves the recovery of isoniazid-resistant strains of *M. tuberculosis*.

Selective Media

The addition of antimicrobial agents may be helpful in eliminating the growth of contaminating organisms. If a selective medium is used for a particular specimen, it should not be used alone but in conjunction with a nonselective agar- or egg-based medium. Egg-based selective media include L-J Gruft with penicillin and nalidixic acid and Mycobactosel L-J medium with cycloheximide, lincomycin, and nalidixic acid. Mitchison selective 7H11 (7H11S) medium and its modifications contain carbenicillin (especially useful for inhibiting pseudomonads), polymyxin B, trimethoprim lactate, and amphotericin B.

Heme-Containing Medium for the Growth of *M. haemophilum*

M. haemophilum will grow on egg- or agar-based media only if they are supplemented with hemin, hemoglobin, or ferric ammonium citrate (169). Thus, specimens from skin lesions, joints, or bone should be inoculated not only onto chocolate agar but also onto Middlebrook 7H10 agar with hemolyzed sheep erythrocytes, hemin, or a factor X disk or onto L-J medium containing 1% ferric ammonium citrate to enhance recovery of this organism. Broth media should be similarly supplemented. *M. haemophilum* can also be isolated from radiometric BACTEC 12B medium as well as from MB Redox broth (168).

Biphasic Media

The Septi-Chek system (BD) is a mycobacterial culture system consisting of a capped bottle containing 20 ml of modified 7H9 broth in an enhanced (20%) CO_2 atmosphere and a paddle containing three types of solid media, i.e., modified L-J medium, Middlebrook 7H11 agar, and chocolate agar, encased in a plastic tube. Bacterial contamination is detected on the chocolate agar. Cultures are inoculated by removing the bottle cap, adding the processed specimen, and then attaching the paddle to the bottle. Solid media are inoculated after 24 h of incubation in an upright position by inverting the bottles. A supplement containing glucose, glycerol, oleic acid, pyridoxal HCl, catalase, albumin, and antibiotics (PANTA) is added to the culture bottle before inoculation. During the incubation period, the bottles are periodically tipped to reinoculate the solid media as cultures are being read. The sensitivity of this system is comparable to that of the BACTEC 460TB system (91). Although the average time to detection of growth is longer than that with the radiometric BACTEC, it is shorter than that with conventional media.

Liquid Media

Broth media may be used for both primary isolation and subculturing of mycobacteria. Cultures based on liquid media

yield significantly more rapid results than solid medium-based cultures. Also, isolation rates for mycobacteria are higher. Middlebrook 7H9 and Dubos Tween albumin broths are commonly used for subculturing stock strains of mycobacteria and preparing the inoculum for drug susceptibility tests and other in vitro tests. 7H9 broth is used as the basal medium for several biochemical tests. Tween 80 can be added to liquid media and acts as a surfactant which allows the dispersal of clumps of mycobacteria, resulting in more homogeneous growth.

At present, a number of elaborate commercially available culture systems marketed for the isolation of mycobacteria range from simple bottles and tubes such as the MGIT (BD) and MB Redox (Heipha Diagnostica Biotest, Heidelberg, Germany) to semiautomated systems (the BACTEC 460TB system; BD) and fully automated systems (e.g., the BACTEC 9000 MB and BACTEC MGIT 960 [BD]; the ESP Culture System II [Trek Diagnostic Systems, Westlake, Ohio]; and the MB/BacT ALERT 3D system [bioMérieux]).

MB Redox

MB Redox (Heipha Diagnostica Biotest) is a nonradiometric medium based on a modified Kirchner medium enriched with growth-promoting additives, antibiotic compounds, and a colorless tetrazolium salt as a redox indicator which is reduced to colored formazan by actively growing mycobacteria. With the naked eye, AFB are detected in the medium as pink to purple pinhead-sized particles. Recovery rates are similar to those observed with other liquid systems (178). Overall, it is a cost-efficient alternative with the disadvantage that it requires much handling during visual reading.

MGIT

The MGIT (BD) contains a modified Middlebrook 7H9 broth in conjunction with a fluorescence quenching-based oxygen sensor (silicon rubber impregnated with a ruthenium pentahydrate) to detect the growth of mycobacteria. The large amount of oxygen initially present in the medium quenches the fluorescence of the sensor. The growth of mycobacteria or other microorganisms in the broth depletes the oxygen, and the indicator fluoresces brightly when the tubes are illuminated with UV light at 365 nm. For the manual version, a Wood's lamp or a transilluminator can be used as the UV light source, and in the automated BACTEC MGIT 960 system (see below), tubes are continuously monitored by the instrument. Prior to use, the 7H9 broth is supplemented with oleic acid-albumin-dextrose to promote the growth of mycobacteria and with PANTA to suppress the growth of contaminants.

Overall, the sensitivity and time to growth detection of the MGIT system are similar to those of the BACTEC 460TB system and have been superior to those of solid media in clinical evaluations (36, 146). However, contamination rates for the MGIT system are currently higher than those for the BACTEC 460TB system, probably owing to the enrichments added to the MGIT broth, which enhance the growth of both mycobacteria and nonmycobacterial organisms.

The principal advantages of the manual MGIT system over the BACTEC 460TB system include reduced opportunity for cross-contamination of cultures, no need for needle inoculation, no radioisotopes, and no need for special instrumentation other than the UV light source. Its limitations include higher contamination rates, masking of fluorescence by blood or grossly bloody specimens, and possible lack of compatibility with some methods of digestion and decontamination of specimens (145). For susceptibility testing of primary drugs, the MGIT is an equivalent replacement for the BACTEC 460TB system, in both the manual and automated versions (see chapter 77).

BACTEC 460TB System

^{14}C-labeled palmitic acid as a carbon source in the medium is metabolized by microorganisms into $^{14}CO_2$, which is monitored by the instrument. The amount of $^{14}CO_2$ and the rate at which the gas is produced are directly proportional to the growth rate of the organism in the medium.

An antimicrobial mixture serving as a growth-promoting supplement (PANTA; see above) is added to BACTEC 12B medium inoculated with decontaminated specimens in order to suppress residual contaminants. To potentially sterile specimens, polyoxyethylene stearate is added to enhance mycobacterial growth. For pretreatment of nonsterile specimens, the NALC-NaOH protocol is the method of choice, although some other procedures such as the SDS-NaOH method are compatible with the BACTEC 460TB system as well (167). Specimens processed by the Zephiran-trisodium phosphate, benzalkonium chloride, or CPC method can, however, not be used with the BACTEC 460TB system because residual quantities of these substances in the inoculum inhibit mycobacterial growth.

The use of the BACTEC 460TB method has significantly improved recovery rates and times of mycobacterial isolation from respiratory secretions and other specimens (161). Organisms in smear-positive specimens usually grow within a few days. The average detection time is 9 to 14 days for *M. tuberculosis* and <7 days for NTM. This short detection time is also obvious with smear-negative specimens and specimens from treated patients. BACTEC 13A medium, traditionally used for blood and bone marrow aspirate specimens, was recently discontinued. Other limitations of the BACTEC 460TB system include the inability to observe colony morphology, difficulty in recognizing mixed cultures, overgrowth by contaminants, cost, radioisotope disposal, and extensive use of syringes with its potential for needle punctures among laboratory technicians. Since it is only semiautomated, vials have to be transferred to the incubator once the growth index (GI) has been read by the instrument.

The BACTEC 460TB system allows efficient antimicrobial susceptibility testing as well (see chapter 77). Generally, the initial positive vial can be used directly for identification and drug susceptibility testing. It is good laboratory practice to confirm acid fastness and to subculture positive BACTEC vials to a chocolate agar to check for potential contaminants or, if suspected, for mixed cultures.

Automated, Continuously Monitoring Systems

Several automated, continuously monitoring systems have recently been developed for the growth and detection of mycobacteria, i.e., the BACTEC 9000 MB (BD), the BACTEC MGIT 960 (BD), the ESP Culture System II (Trek Diagnostic Systems), and the MB/BacT ALERT 3D (bioMérieux). All have in common that they are no longer based on the use of radioisotopes. The BACTEC 9000 MB system uses the same fluorescence quenching-based oxygen sensor as the MGIT system to detect growth. The technology used in the ESP Culture System II is based on the detection of pressure changes in the headspace above the broth medium in a sealed bottle resulting from gas production or

consumption due to the growth of microorganisms. The MB/BacT ALERT 3D system, finally, employs a colorimetric carbon dioxide sensor in each bottle to detect the growth of mycobacteria. Each of the systems includes a broth similar to 7H9 supplemented with a variety of growth factors and antimicrobial agents.

These systems have similar performance and operational characteristics. In clinical evaluations, recovery rates were similar to those of the BACTEC 460TB system and superior to those of conventional solid media (BACTEC 9000 MB [143], BACTEC MGIT 960 [72, 221], ESP Culture System II [225]; and MB/BacT ALERT 3D [150, 221]). Time to detection of mycobacteria is almost the same as in the radiometric BACTEC 460TB technique. Throughout, contamination rates reported have been higher with these new systems than with the BACTEC 460TB system. All share the advantages over the radiometric broth system of having no potential for cross-contamination by the instrument, being less labor-intensive, having continuous monitoring, using no radioisotopes, addressing safety more appropriately, and offering electronic data management. Since these systems are monitoring continuously, bottles are incubated in the instruments for their entire life in the laboratory. As a consequence, these systems are both instrument and space intensive. Some automated systems also lack the versatility of the BACTEC 460TB system in that direct inoculation of blood is, so far, not possible. The same holds for the incubation of cultures harboring mycobacteria with a lower optimum temperature such as *M. haemophilum*, *M. marinum,* and *M. ulcerans*. Except in the case of the BACTEC 9000 MB system, susceptibility testing applications for the primary antituberculosis drugs, including pyrazinamide (in some systems), are available (see chapter 77).

Medium Selection

Medium selection for the isolation of mycobacteria and culture reading schedules are usually based on personal preferences and/or laboratory tradition. Both should be optimized for the most rapid detection of positive cultures and identification of mycobacterial isolates. The variety of media and methods available today is sufficient to permit laboratories to develop an algorithm that is optimal for their patient population and administrative needs. Workload, financial resources, and in particular, the limited amounts of processed sediments are, however, restraining factors in working with too many different types of media. Thus, cultivation of mycobacteria always involves a compromise.

Today, it is generally accepted that the use of a liquid medium in combination with at least one solid medium is essential for good laboratory practice in the isolation of mycobacteria. The addition of a solid medium is advantageous for those strains which occasionally do not grow in liquid medium, aids in the detection of mixed mycobacterial infections, and can serve as a backup for broth with its higher contamination rate. All positive cultures, even if identified directly from the broth, must be subcultured to solid media to detect mixed cultures and to correlate direct identification results with colony morphology. The Septi-Chek system can be used as a stand-alone system. In contrast, the radiometric BACTEC 460TB system and the new, nonradiometric growth systems such as the BACTEC 9000, BACTEC MGIT 960, ESP Culture System II, and MB/BacT ALERT 3D cannot serve as stand-alone culture systems for mycobacteria for reasons stated above. In a recent meta-analysis of 10 published studies encompassing 1,381 strains from 14,745 clinical specimens, the BACTEC MGIT 960 and BACTEC 460TB systems revealed sensitivities and specificities in detecting mycobacteria of 81.5 and 99.6% and 85.8 and 99.9%, respectively. Combined with solid media, the sensitivities of the two systems increased to 87.7 and 89.7%, respectively (40).

Detection of colonies on solid medium certainly offers several advantages over detection of growth in broth, because colonial morphology can provide clues for identification and facilitate the selection of confirmatory tests, including DNA probe tests. However, smears from broth-based systems can sometimes provide microscopic clues such as cord formation (see above), and it is possible to use the sediment from such cultures for confirmation by gene probes before growth is detected on solid media. The criterion of cord formation for presumptive identification of *M. tuberculosis* should be applied with caution since the phenomenon is also being observed with some NTM species (9, 125).

Incubation

Temperature

The optimum incubation temperature for most cultures is 35 to 37°C. Exceptions to this rule include cultures obtained from skin and soft tissue suspected to contain *M. marinum, M. ulcerans, M. chelonae*, or *M. haemophilum,* which has a lower optimum temperature. For such specimens, a second set of media should be inoculated and incubated at 25 to 33°C. BACTEC 460TB vials should be incubated at 36 to 38°C because optimum metabolism of the radiolabeled substrate occurs at 37 to 37.5°C for most species. Lower temperatures increase detection time. The newer liquid medium-based culture automated systems do not offer the possibility to incubate at temperatures lower than 36 ± 1°C.

Atmosphere

Five to 10% CO_2 in air stimulates the growth of mycobacteria in primary isolation cultures using conventional media (10). Middlebrook agar requires a CO_2 atmosphere to ensure growth, while it is necessary to incubate egg media under CO_2 for only the first 7 to 10 days after inoculation, i.e., the log phase of growth. Subsequently, L-J cultures can be removed to ambient-air incubators if space is limited. In the absence of CO_2 incubators, plates may be incubated in commercially available bags with CO_2-generating tablets. Candle extinction jars are unacceptable for use in the mycobacteriology laboratory because the oxygen tension is less than that required for the growth of mycobacteria. Broth systems usually do not require incubation at increased CO_2 concentrations.

Time

Mycobacterial cultures on solid and in liquid media are generally held for 6 to 8 weeks before being discarded as negative. Specimens with positive smears that are culture negative should be held for an additional 4 weeks. The same is true for culture-negative specimens which were positive for mycobacteria by one of the nucleic acid-based amplification assays or for cases with a persisting suspicion of tuberculosis. Plates should be incubated with the medium side down until the entire inoculum has been absorbed. Once this has happened, media should be incubated inverted in CO_2-permeable polyethylene bags or sealed with CO_2-permeable shrink-seal or cellulose bands to prevent them from drying

up during the incubation period. Tubed media should be incubated in a slanted position with the screw caps loose for at least a week until the inoculum has been absorbed; they can then be incubated upright if space is at a premium. Caps on the tubes should be tightened at 2 to 3 weeks to prevent desiccation of the media. Specimens from skin lesions should be incubated for 8 to 12 weeks if the presence of *M. ulcerans* is suspected.

Reading Schedule

Mycobacteria are relatively slowly growing organisms, and thus cultures can be examined less frequently than routine bacteriologic cultures. All solid media should be examined within 3 to 5 days after inoculation to permit early detection of rapidly growing mycobacteria and to enable prompt removal of contaminated cultures. Young cultures (up to 4 weeks of age) should be examined twice a week, whereas older cultures may be examined at weekly intervals. Use of a hand lens for opaque media and a microscope for agar media will facilitate early detection of microcolonies.

Septi-Chek and the manual MGIT may be inspected for growth several times per week or daily for the first 1 to 2 weeks; Septi-Chek bottles should be inverted for reinoculation of the agar medium if growth is not observed. Afterwards, these systems are inspected twice weekly or weekly for growth.

For BACTEC 460TB vials, the reading schedule varies according to the laboratory workload. Low-volume laboratories may read cultures three times a week for the first 2 or 3 weeks and weekly thereafter for a total of 6 weeks, and high-volume laboratories may read cultures twice a week for the first 2 weeks and weekly thereafter. Some laboratories prioritize smear-positive specimens by separating them from smear-negative specimens and test the former more frequently. In addition, separation of "probable positive" cultures from negative ones will decrease the possibility of vial cross-contamination by the instrument. With more frequent testing of all specimens, however, earlier detection of positive cultures is expected. Readings of negative cultures in 12B medium usually remain below a GI of 10; a GI of 10 or more is considered presumptively positive. At this point, the vials should be separated and tested daily. Acid-fast staining is performed when the GI is >50 to determine whether the culture contains mycobacteria. The morphology of mycobacteria seen in smears from 12B medium may be used by experienced laboratory personnel to presumptively identify the *M. tuberculosis* complex and to decide how to proceed with identification methods (9). In addition, a smear of the broth from the vial may be Gram stained and/or the broth may be subcultured onto a sheep blood agar or chocolate agar plate to determine whether contamination is present. When the GI is 500 or more, BACTEC 460TB antimicrobial susceptibility testing can be performed (see below).

When using one of the new continuously monitoring systems (BACTEC 9000, BACTEC MGIT 960, ESP Culture System II, and MB/BacT ALERT 3D), technicians are automatically alerted by the instrument if a specimen turns positive. Irrespective of the system used, the acid fastness of the organism has to be confirmed by smear staining. Also, it is highly advisable to subculture the broth on a sheep blood or chocolate agar plate to rule out contaminants. Once the growth of AFB is detected, susceptibility testing can be performed, always following the instructions specified by the manufacturers.

IMMUNODIAGNOSTIC TESTS FOR TUBERCULOSIS

A variety of immunodiagnostic tests for tuberculosis based on the recognition of specific host responses to the infecting organism have been described previously. Historically, the first immunodiagnostic test was the tuberculin skin test. The shortcomings of this test include the inability to distinguish active disease from past sensitization and unknown predictive values (177).

Much effort has been devoted to the development of serological tests for tuberculosis, but no test has found widespread clinical use (43). The specificity of serological tests with crude antigen preparations is too low for clinical application. Specificity can be increased by using purified antigens, but since not all patients respond to the same antigens, the increased specificity often results in decreased sensitivity (33, 43). Sensitivity and specificity increase if enzyme-linked immunosorbent assay (44) results obtained with a set of purified antigens are combined. Antigens tested in serological assays are, for instance, the 38-kDa antigen, lipoarabinomannan, antigen 60, the antigen 85 complex, and glycolipids including phenolic glycolipid Tb1, 2,3-diacyltrehalose, and lipooligosaccharide. Weldingh et al. (218) have recently assessed the serodiagnostic potential of 35 *M. tuberculosis* proteins and identified four novel serological antigens.

A number of antigen capture assays based on enzyme-linked immunosorbent assays or radioimmunoassays or agglutination of antibody-coated latex particles have been described previously. The sensitivities of immunoassays for the detection of mycobacterial antigens in cerebrospinal fluid ranged from 65.8 to 100% and the specificities ranged from 95 to 100% in six major studies (43). Experience with sputum and other specimens is limited. The use of antigen tests cannot be recommended at this time.

Although broad experience is not yet available, the recently developed, commercially available whole-blood gamma interferon assays are promising candidates to improve the current level of diagnostic accuracy for tuberculosis infection, in particular if skin tests are equivocal. Guidelines for using the QuantiFERON-TB test (Cellestis Ltd.) (132) for diagnosing latent *M. tuberculosis* infection are available (117). Ferrara et al. (60) have demonstrated that the QuantiFERON-TB Gold test (Cellestis Ltd.) has higher specificity than the tuberculin skin test when used for selected populations. The QuantiFERON-TB Gold test is (i) less affected by BCG for vaccination than the common skin tests, (ii) able to discriminate responses due to NTM, and (iii) less prone to variability and subjectivity associated with placing and reading of the tuberculin skin test. Another approach is based on the overlapping *M. tuberculosis* antigens ESAT-6 and CFP-10 and similarly offers increased specificity over the PPD skin test when used in an ex vivo enzyme-linked immunospot (CTL Laboratory, Cleveland, Ohio) assay for gamma interferon detection for the diagnosis of *M. tuberculosis* infection from recent exposure (82, 110).

CROSS-CONTAMINATION

With the advent of molecular techniques designed for molecular epidemiology, cross-contamination linked either to laboratory procedures or, more rarely, to contaminated bronchoscopes can easily be proven (12, 66, 170). False-positive results may be generated at any step from specimen collection to reading of cultures (8, 61). Laboratory personnel should be alerted for a possible laboratory error if (i) the

culture result is not compatible with the clinical picture, (ii) there is a late-appearing cluster of cultures which have scanty growth (<10 colonies on solid medium) or a significant delay in recovering mycobacteria from a liquid system, (iii) there is a large number of isolates of a particular species that is usually rare in the laboratory or of an organism that is normally considered an environmental contaminant, or (iv) there is only one positive culture from multiple specimens submitted from a single patient. Practices which can lead to false-positive culture results are numerous and include inadequate sterilization of instruments or equipment (such as bronchoscopes), use of contaminated water for specimen collection or for laboratory procedures, transfer of organisms from one specimen to another through direct contact or via common reagents or equipment, mix-up of testing samples or lids of specimen containers, and failure to take precautions which minimize the production of aerosols, etc. Laboratory aspects of cross-contamination are addressed in more detail in the following section.

QUALITY ASSURANCE

General Aspects

Much of the information in this section was obtained from recent publications (5, 8, 90, 97, 128, 129). In addition to the specific recommendations listed here, standard components of laboratory quality assurance, such as personnel competency, procedure manuals, proficiency testing, and quality control (QC) of media, tests, and reagents, should be in place.

The Public Health Service introduced the levels of service concept for mycobacteriology laboratories in 1967. In this scheme, laboratories define the level of service which best fits the needs of the patient population they serve, the experience of their personnel, their laboratory facilities, and the number of specimens they receive. The concept of levels of service is supported by the Centers for Disease Control and Prevention and the American Thoracic Society (80). The College of American Pathologists proposed extents of service for participation in mycobacterial interlaboratory comparison surveys. American Thoracic Society levels I, II, and III correlate with College of American Pathologists extents 2, 3, and 4, respectively. Five types of mycobacteriology laboratories have been defined by the Clinical Laboratory Improvement Amendments (CLIA). These are modified from the extents described by the College of American Pathologists, but the definitions are awaiting consensus and thus may be modified in the future (226). All specimens submitted for mycobacterial examination should have cultures as well as smears performed. The American Thoracic Society and Centers for Disease Control and Prevention recommend that laboratories examine a minimum of 10 to 15 smears per week to maintain proficiency in performance and interpretation and that they process and culture 20 specimens per week to maintain proficiency in the culture and identification of *M. tuberculosis*. The Association of State and Territorial Public Health Laboratory Directors proposed that only two levels of service be designated: (i) specimen collection, specimen transport, and (optional) microscopy of at least 20 smears per week and (ii) complete mycobacteriology service from microscopy to complete species identification and drug susceptibility testing (212).

Personnel working in the clinical mycobacteriology laboratory must have proper training and certification in the specific functions that they perform. All laboratories performing mycobacteriology testing must be enrolled in a proficiency program which monitors a laboratory's performance by using external samples which are sent for testing. These programs must follow the specifications outlined by the CLIA.

Multiple test parameters are monitored by adherence to the quality assurance guidelines described in the recent NCCLS (now the Clinical and Laboratory Standards Institute) standard document (128). Acceptable results derived from testing QC reference strains do not guarantee accurate results with all clinical isolates. If inconsistent results are seen with clinical isolates, the test should be repeated in an attempt to ensure accuracy. Each laboratory should put its own policies into effect regarding the verification of atypical test results.

QC is vital for monitoring a laboratory's effectiveness in detecting and isolating mycobacteria. The CLIA and accreditation programs represent the minimum acceptable standards of practice (226), and laboratories performing mycobacterial testing should follow QC recommendations in the scientific literature and in ad hoc publications (8, 90, 128).

The laboratory must maintain a collection of well-characterized mycobacterial strains that are used for QC of test systems. These controls may be obtained from the American Type Culture Collection and proficiency testing programs. Frequently used stock cultures can be maintained on L-J slants or in 7H9 broth at 37°C or at room temperature if subcultured monthly. Cultures on L-J slants may be held for up to 1 year if stored at 4°C. Such maintenance is not recommended for strains with drug resistance. Freezing of organisms suspended in skim milk or broth medium and storage at −20 to −70°C is the best option for long-term maintenance of stock cultures.

Routine QC tests are recommended with new lots of media used with commercial systems (90). Laboratories that prepare their own media must also document the performance characteristics of each new lot.

QC of Smear, Culture, and Molecular Tests

Ideally, positive control slides should be prepared from a concentrated sputum sample obtained from a patient with active tuberculosis. In practice, many laboratories use suspensions of stock cultures or seeded negative sputa as positive controls for acid-fast staining procedures. The *Clinical Microbiology Procedures Handbook* (90) describes a method for preparing control slides. Control slides are also commercially available. An increase in the percentage of smear-positive but culture-negative specimens of >2% that cannot be attributed to a response to mycobacterial therapy or the presence of AFB in the negative controls suggests that water or reagents used in the pretreatment or staining procedures were contaminated with NTM (97). *M. gordonae* or the *M. terrae* complex is most often involved. A procedure for detection of AFB in working solutions and reagents is described in the Association of State and Territorial Public Health Laboratory Directors and Centers for Disease Control and Prevention document (8). AFB may also be carried over from one slide to another if slides are not set properly apart from each other during the staining process. AFB may also be found in the oil used with the immersion lens after a positive slide is examined. The sensitivity of the AFB smear is directly related to the relative centrifugal force (RCF, or *g* force) attained during centrifugation. Thus, laboratories should calculate the RCF of their centrifuge and periodically monitor and document that they are reaching sufficient RCF by checking the revolutions per minute with a tachometer (97).

Laboratories should also monitor contamination rates (percentages of specimens producing contaminating growth on culture media) for decontaminated specimens. Contamination rates of 3 to 5% are generally considered acceptable. Lower rates usually indicate that the decontamination procedure is too harsh and the procedure needs to be modified to minimize the lethal effect on mycobacteria. Contamination rates above 5% often indicate a too-weak decontamination which could compromise mycobacterial cultures due to overgrowth of contaminants. It should be emphasized that the widespread use of liquid media increases the generation of aerosols; as a consequence, the risk of contamination between samples also increases. Laboratories that handle large numbers of isolates of the MAC, *M. abscessus*, or specimens from patients with cystic fibrosis will probably have much higher contamination rates due to the high incidence of colonization of the sputum with gram-negative bacteria, especially *Pseudomonas aeruginosa*.

Culturing of mycobacteria is naturally prone to errors because of the multiple steps involved in processing of cultures, the viability of mycobacteria for long periods in the laboratory environment, and the large number of mycobacteria present in some specimens (22). False-positive cultures may result from mislabeling, specimen switching during handling, specimen carryover (including proficiency testing specimens), contaminated reagents, or cross-contamination between culture tubes or vials (22, 29). Inclusion of a positive control (e.g., a suspension of *M. tuberculosis*) in the processing of patient specimens is discouraged due to the risk of cross-contamination. Cross-contamination of culture vials in the BACTEC 460 TB system due to inadequately sterilized sample needles has been documented (15). Standardized laboratory procedures that minimize the potential for errors leading to false-positive cultures should be followed, and mechanisms should be in place to rapidly recognize the occurrence of false-positive cultures. Transfers or inoculation of cultures must be accomplished by using individual transfer pipettes, single-delivery diluent tubes, or disposable labware. The order in which specimens are processed and media are inoculated should be recorded. Processing of a negative control specimen following processing of patient specimens with the same digestion or decontamination solution can be used for detecting possible specimen contamination of the solutions (8). Alternatively, processing solutions may be planted directly. Laboratories should prospectively track positivity rates and establish a threshold which, when exceeded, will prompt an investigation (172). The significance of an isolate may be determined by reviewing the order in which specimens were handled for all manipulations (e.g., initial processing, liquid medium readings, and subculturing), the direct-smear results, the time to positivity, and the clinical history. Cross-contamination in the BACTEC 460TB system or other automated systems is probably rare if the manufacturer's recommendations for operation and maintenance are closely followed.

Since the introduction of molecular fingerprinting of *M. tuberculosis* strains, false-positive cultures have been demonstrated to occur more frequently than previously assumed, accounting for from 1 to more than 10% of positive cultures (154, 172). The deleterious impact of these undesirable events may be minimized if the evidence of false positivity is established in a timely manner and a rapid molecular method of fingerprinting is available. It has been suggested that single positive cultures of *M. tuberculosis* strains grown from AFB smear-negative specimens should be analyzed by a PCR-derived typing technique to rule out laboratory contamination (154). Cultures of strains with identical fingerprints isolated within a 1-week period from different patients should be considered probably falsely positive (172).

The Centers for Disease Control and Prevention and others have recommended that AFB smear results be available and that positive results be reported within 24 h of specimen receipt (8, 186). The time required for identification and susceptibility testing of *M. tuberculosis* should average 14 to 21 days and 15 to 30 days from the time of specimen receipt, respectively (8, 26, 227). Recently, Pascopella et al. (141) have evaluated laboratory reporting of tuberculosis test results and patient treatment initiation in California.

Nucleic acid amplification (NAA)-based assays require several levels of controls (e.g., to detect amplification inhibition as well as contamination between specimens) in addition to positive or negative controls (129). When used as approved by the Food and Drug Administration, NAA tests for *M. tuberculosis* infection diagnosis do not replace any previously recommended tests (28). Laboratories that test patient specimens by using research or home brew methods or commercially available NAA assays for nonapproved or off-label indications and report their results must validate the assays and establish their performance characteristics prior to diagnostic use. Available information is often insufficient to guide test interpretation. Approved guidelines for molecular diagnostic methods in clinical microbiology are available from the Clinical and Laboratory Standards Institute; in these documents, the development, validation, quality assurance, and routine use of NAA assays are addressed in detail (129). However, basing the identification of *M. tuberculosis* on a sole positive home brew PCR result is not recommended because the results of such assays vary considerably (8, 27).

Potential probes and/or primers must be selected for sensitivity by using multiple clinical and reference strains of the target organism. Additionally, specificity must be evaluated by testing for cross-hybridization with other organisms which may be present in patient samples (129).

Several types of validation tests are used to evaluate the presence of target nucleic acid in the sample and to determine that it was isolated in a manner in which the target has not been introduced. Testing to assess amplification should include positive and negative controls and controls for detection of the presence of inhibitors, such as endogenous nucleic acid. Other QC measures include those referring to assays of restriction enzymes and reagents, inspection of equipment, and laboratory design (i.e., separate areas for processing, amplification, and detection steps) (129). Excellent proficiency testing schemes to assess laboratory performance of NAA tests are currently available both in the United States (160) and in Europe (134).

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

Adequate funding and focused training are critical in maintaining state-of-the-art mycobacteriology laboratories (16, 128, 129, 226). Laboratories play a pivotal role in the diagnosis and control of tuberculosis, and every effort should be made to implement sensitive and rapid methods for the detection, identification, and susceptibility testing of the *M. tuberculosis* complex as well as other mycobacterial species. Specifically, these include (i) the use of fluorochrome staining for mycobacteria in smears, (ii) the use of a broth-based or microcolony method for culture, (iii) the use of rapid identification methods (e.g., gene probes and line probe

assays), and (iv) direct susceptibility testing of smear-positive specimen concentrates.

The 24-h turnaround time for AFB smear results presents a challenge for most laboratories. The daily processing of specimens required to meet this goal adds considerable expense to the laboratory budget. Turnaround time goals for AFB smear results should be established for each institution after consultation with infection control practitioners and infectious-disease specialists.

NAA assays offer the promise of same-day detection and identification of *M. tuberculosis*. Implementation of these new technologies presents several new challenges. Although the performance characteristics of many of these assays are quite good for smear-positive respiratory specimens, limited information exists on the use of these tests for the diagnosis of paucibacillary pulmonary or extrapulmonary disease. The new technology will supplement rather than replace culture. Culture will still be required to obtain organisms for susceptibility testing and detect mycobacteria other than *M. tuberculosis*.

The significance of the isolation of NTM may be difficult to assess since many species are opportunistic pathogens, and the reader is referred to the criteria suggested by the American Thoracic Society for the evaluation (5). In addition to these criteria, accurate identification of NTM will prevent rarely encountered pathogens from being mistaken for nonpathogenic species.

Thus, accurate and timely reporting of the results of AFB microscopy, culture, identification, and drug susceptibility testing is essential to the effective management of individual patients and to the appropriate implementation of public health and infection control measures.

APPENDIX 1
Commonly Used Digestion-Decontamination Methods

Refer to references 90 and 97 for details.

NALC-NaOH method

Reagents

Digestant: For each 100 ml, combine 50 ml of sterile 0.1 M (2.94%) trisodium citrate with 50 ml of 4% NaOH. The NaOH and citrate mixtures can be mixed, sterilized, and stored for future use. To this solution, add 0.5 g of powdered NALC just before use. Use within 24 h of addition of the NALC because the mucolytic action of NALC is inactivated on exposure to air.

Phosphate buffer: The buffer is 0.067 M and pH 6.8. Mix 50 ml of solution A (0.067 M Na_2HPO_4; 9.47 g of anhydrous Na_2HPO_4 in 1 liter of distilled water) and 50 ml of solution B (0.067 M KH_2PO_4; 9.07 g of KH_2PO_4 in 1 liter of distilled water). If the final buffer requires pH adjustment, add solution A to raise the pH or solution B to lower it.

BSA (optional): Use sterile 0.2% bovine serum albumin (BSA) fraction V (pH 6.8).

Procedure

1. Transfer up to 10 ml of specimen to a sterile, graduated, 50-ml plastic centrifuge tube labeled with appropriate identification. The tube should have a leakproof, aerosol-free screw cap. Add an equal volume of the NALC-NaOH solution. The final concentration of NaOH in the tube is 1%.

2. Tighten the cap completely. Invert the tube so that the NALC-NaOH solution contacts all the inside surfaces of the tube and cap, and then mix the contents for approximately 20 s on a Vortex mixer. If liquefaction is not complete during this time, agitate the solution at intervals during the following decontamination period.

3. Allow the mixture to stand for 15 min at room temperature with occasional gentle shaking by hand. Avoid movement that causes aeration of the specimen. A small pinch of crystalline NALC may be added to viscous specimens for better liquefaction. Specimens should remain in contact with the decontaminating agent for only 15 min, since overprocessing results in reduced recovery of mycobacteria. If more active decontamination is needed, slightly increase the concentration of NaOH.

4. Add phosphate buffer (pH 6.8) up to the 50-ml mark on the tube.

5. Centrifuge the solution for at least 15 min at $\geq 3{,}000 \times g$.

6. Decant the supernatant fluid into a splashproof discard container containing a suitable disinfectant. Do not touch the lip of the tube to the discard container. Wipe the lip of each tube with disinfectant-soaked gauze (separate piece for each tube) to absorb drips, and recap.

7. Using a separate sterile pipette for each tube, add to the sediment 1 to 2 ml of sterile, 0.2% BSA fraction V (pH 6.8) or 1 to 2 ml of phosphate buffer (pH 6.8), and resuspend the sediment with the pipette or by shaking the tube gently by hand. BSA may have a buffering and detoxifying effect on the sediment and increases the adhesion of the specimen to solid media. However, BSA may lengthen detection times (for instance, in the BACTEC 460TB system).

8. Inoculate the specimens onto appropriate solid culture media and into broth media. Use a separate disposable capillary pipette for each specimen to deliver 3 drops to solid medium.

9. Prepare a smear for acid-fast staining. Use a sterile disposable pipette to place 1 drop of the sediment onto a clean, properly labeled microscope slide, covering an area approximately 1 by 2 cm. Place the smears on an electric slide warmer at 65 to 75°C for 2 h to dry and fix them. Alternatively, air dry the smears and fix them by passing the slide three or four times through the blue cone of a flame (heat fixing does not always kill mycobacteria, and the slides are potentially infectious).

10. Refrigerate the remaining sediment for later use if needed (direct susceptibility testing, further treatment if the specimen is contaminated, etc.).

The NALC-NaOH method can be used to process gastric lavage specimens, tissues, stool, urine, and other body fluids. For neutralized gastric lavage specimens and other body fluids ($\geq$10 ml), centrifuge at $\geq 3{,}000 \times g$ for 30 min in sterile screw-cap 50-ml centrifuge tubes, decant the supernatants, resuspend the sediments in 2 to 5 ml of sterile distilled water, and proceed as for sputum. If a gastric lavage specimen is mucopurulent, add 50 mg of NALC powder per 50 ml of lavage fluid and vortex before centrifugation. Tissue that is not collected aseptically can be ground, placed in a tube, homogenized by vortexing, and processed as for sputum. For stool specimens, place approximately 1 g of a formed specimen or 1 to 5 ml of a liquid specimen in a total volume of 10 ml of 7H9 broth, sterile water, or sterile saline; vortex vigorously for 30 s; and then allow large particles to settle to the bottom of the tube for 15 min. Remove 7 to 8 ml of supernatant, place into a 50-ml centrifuge tube, and process as for sputum.

Sodium hydroxide method

Reagents

Digestant: NaOH solution (2 to 4%). Sterilize by autoclaving.

2 N HCl: Dilute 33 ml of concentrated HCl to 200 ml with water. Sterilize by autoclaving.

Phenol red indicator: Combine 20 ml of phenol red solution (0.4% in 4% NaOH) and 85 ml of concentrated HCl with distilled water to make 1,000 ml.

Phosphate buffer: The buffer is 0.067 M and pH 6.8. See the NALC-NaOH procedure for buffer preparation.

Procedure

Follow the steps described for the NALC-NaOH method, substituting 2% NaOH for the NALC-alkali digestant.

1. Transfer a maximum volume of 10 ml of specimen to a sterile 50-ml screw-cap plastic centrifuge tube. Add an equal volume of NaOH.

2. With the cap tightened, invert the tube and then agitate the mixture vigorously for 15 min on a mechanical mixer, or vortex

vigorously and let stand for exactly 15 min. If it is necessary to reduce excessive contamination, the NaOH concentration can be increased to 3 or 4%.

3. Add phosphate buffer (pH 6.8) up to the 50-ml mark on the tube. Recap the tube, and swirl by hand to mix well.

4. Centrifuge the specimen at ≥3,000 × *g* for 15 min, decant the supernatant, and add a few drops of phenol red indicator to the sediment. Neutralize the sediment with HCl. Thoroughly mix the contents of the tube. Stop acid addition when the solution is persistently yellow.

5. Resuspend the sediment in 1 to 2 ml of phosphate buffer or sterile 0.1% BSA fraction V.

6. Inoculate the resuspended sediment to appropriate culture media, and prepare a smear.

Zephiran-trisodium phosphate method

Principle

This system can be used when the laboratory cannot monitor the amount of time of exposure to the decontaminating agent, since the timing of this digestion-decontamination process is not critical. Benzalkonium chloride (Zephiran), a quaternary ammonium compound, together with trisodium phosphate selectively destroys many contaminants while having little activity on tubercle bacilli. Zephiran is bacteriostatic to mycobacteria, and so the digested, centrifuged sediment must be neutralized with buffer before being inoculated onto agar medium. The phospholipids of egg medium neutralize this compound. It is incompatible with the BACTEC 460TB system.

Reagents

Zephiran-trisodium phosphate digestant: Dissolve 1 kg of trisodium phosphate ($Na_3PO_4 \cdot 12H_2O$) in 4 liters of hot distilled water. Add 7.5 ml of Zephiran concentrate (17% benzalkonium chloride [Winthrop Laboratories, New York, N.Y.]), and mix. Store at room temperature.

Neutralizing buffer: Neutralizing buffer has a pH of 6.6. Add 37.5 ml of 0.067 M disodium phosphate solution to 62.5 ml of 0.067 M monopotassium phosphate solution (for preparation of buffer solutions, see the NALC-NaOH procedure).

Procedure

1. Transfer a maximum volume of 10 ml of specimen to a sterile, 50-ml screw-cap plastic centrifuge tube. Add an equal volume of the Zephiran-trisodium phosphate digestant.

2. Tighten the cap, invert the tube, and then agitate the mixture vigorously for 30 min on a mechanical shaker. Permit the material to stand, without shaking, for an additional 20 to 30 min at room temperature.

3. Centrifuge the specimen at ≥3,000 × *g* for 15 min, decant the supernatant, and add 20 ml of neutralizing buffer. Vortex for 30 s to thoroughly suspend the sediment in the buffer (the neutralizing buffer serves to inactivate traces of Zephiran in the sediment, which is critical if inoculation of an agar-based medium is intended).

4. Centrifuge the specimen again for 15 min.

5. Decant the supernatant, retaining some fluid to resuspend the sediment.

6. Inoculate egg-based medium, and make a smear. The phospholipids of egg medium provide neutralization for this quaternary compound.

Oxalic acid method

Principle

The oxalic acid method is superior to alkali methods for processing specimens consistently contaminated with *Pseudomonas* species and certain other contaminants. Specimens processed by this method may be used with the BACTEC 460TB system. This method can also be used to decontaminate a previously processed sediment when cultures are contaminated with *Pseudomonas*.

Reagents

5% oxalic acid
Physiological saline (0.85%)
4% NaOH
Phenol red indicator or pH paper

Procedure

1. Add an equal volume of 5% oxalic acid to 10 ml or less of specimen in a 50-ml centrifuge tube (1:1, vol/vol).

2. Vortex the solution, and then allow it to stand at room temperature for 30 min with occasional shaking.

3. Add sterile saline up to the 50-ml mark on the centrifuge tube. Recap the tube, and invert it several times to mix the contents.

4. Centrifuge for 15 min at ≥ 3,000 × *g*, decant the supernatant fluid, and add a few drops of phenol red indicator to the sediment. Alternatively, use pH paper.

5. Neutralize with 4% NaOH.

6. Resuspend the sediment, inoculate it to media, and make a smear.

CPC method

Principle

CPC, a quaternary ammonium compound, is used to decontaminate specimens, while sodium chloride effects liquefaction. CPC is bacteriostatic for mycobacteria inoculated onto agar-based media. This effect is not neutralized in the digestion process, and thus sediments from specimens treated with CPC should be inoculated only on egg-based media. This method is incompatible with the BACTEC 460TB system.

This method is a means of digesting and decontaminating specimens in transit (>24 h). Mycobacteria remain viable for 8 days in the solution.

Reagents

CPC digestant-decontaminant: Dissolve 10 g of CPC and 20 g of NaCl in 1,000 ml of distilled water. The solution is self-sterilizing and remains stable if protected from light, extreme heat, and evaporation. Dissolve with gentle heat any crystals that might form in the working solution. Other reagents used in processing include sterile water and sterile saline or 0.2% sterile BSA fraction V.

Procedure

1. Collect 10 ml or less of sputum in a 50-ml screw-cap centrifuge tube.

2. Inside a BSC, add an equal volume of CPC-NaCl, cap securely, and shake by hand until the specimen liquefies.

3. Package the specimen appropriately as specified by current postal regulations, and send it to a processing laboratory.

4. Upon receipt in the processing laboratory (allow at least 24 h for digestion-decontamination to be completed), dilute the digested-decontaminated specimen to the 50-ml mark with sterile distilled water and recap securely. Invert the tube several times to mix the contents.

5. Centrifuge at ≥3,000 × *g* for 15 min, decant the supernatant fluid, and suspend the sediment in 1 to 2 ml of sterile water, saline, or 0.2% BSA fraction V.

6. Inoculate the resuspended sediment onto egg medium, and make a smear.

Sulfuric acid method

Principle

The sulfuric acid method may be useful for urine and other body fluids that yield contaminated cultures when processed by one of the alkaline digestants.

Reagents

4% sulfuric acid
4% sodium hydroxide
Sterile distilled water
Phenol red indicator

Procedure

1. Centrifuge the entire specimen for 30 min at ≥3,000 × *g*. This may require several tubes.

2. Decant the supernatant fluids; pool the sediments if several tubes were used for a single specimen.
3. Add an equal volume of 4% sulfuric acid to the sediment.
4. Vortex, and let stand for 15 min at room temperature.
5. Fill the tube to the 50-ml mark with sterile water.
6. Centrifuge at ≥3,000 × *g* for 15 min, and decant the supernatant.
7. Add 1 drop of phenol red indicator, and neutralize with 4% NaOH until a persistent pale pink color forms.
8. Inoculate the media, and make a smear.

Mycobacterium: Laboratory Characteristics of Slowly Growing Mycobacteria*

VÉRONIQUE VINCENT AND M. CRISTINA GUTIÉRREZ

37

IDENTIFICATION OF MYCOBACTERIA

Mycobacteria should always be identified to the species level if possible. They are usually preliminarily identified by traits such as growth rate and pigmentation which will direct the selection of key biochemical tests to further characterize them. Unfortunately, different species may present convergent biochemical profiles and morphological features (Table 1). Similarly, variation occurs among strains, and the strains' properties may not match those of the type strain. Traditional methods are well established, standardized, reproducible, and relatively inexpensive but limited in scope to the species of which large numbers of strains have been studied. Thus, identification errors may result, especially because no characteristic phenotype has been identified for several recently described species recognized on the basis of new 16S rRNA gene sequences.

Alternative laboratory methods for mycobacterial identification include analysis of mycolic acids by chromatography, genetic investigations using nucleic acid probes, and nucleic acid sequencing. It is now recommended to undertake mycobacterial identification with a strategy combining phenotypic and genotypic tests. For obvious reasons, laboratories should perform identification of the *Mycobacterium tuberculosis* complex (MTBC) by using a rapid method (103) to facilitate prompt identification and reporting of results to physicians.

Phenotypic Tests

Table 1 shows characteristic test results for the most commonly encountered species. Detailed descriptions of methods, procedures, and controls can be found elsewhere (40, 48, 115; see also chapter 36).

Growth Rate and Preferred Growth Temperature

Growth rate refers to the length of time required to form mature, isolated colonies visible without magnification on solid media. Mycobacteria forming colonies within 7 days are termed rapid growers, while those requiring longer periods are termed slow growers. Genome analyses support this separation, since slowly growing mycobacteria have been shown to have only one copy of the genes encoding rRNA whereas rapidly growing mycobacteria, except for *M. chelonae* and *M. abscessus*, have two sets of those genes (6). Moreover, comparative 16S rRNA gene sequencing data clearly separate the rapidly growing mycobacteria from the slowly growing species (95).

Isolated colonies are observed after media are inoculated with 0.1 ml of a 10^{-4} dilution of a standard culture suspension (SCS) prepared at an optical density at 580 nm of 0.25 by using a tube with a 2-cm diameter; this roughly corresponds to a suspension of 1 mg (wet weight) of bacilli per ml (115). The cultures are incubated at 35 to 37°C. Some species have special nutrient or temperature requirements for growth (see the previous chapter for details). Cultures are observed at 5 to 7 days and weekly thereafter for visible colonies. Growth in relation to temperature can usually be adequately determined by observing cultures at 37 and 30°C. When more definitive identification is needed, isolates should be incubated at 28, 30, 35 to 37, and 42 or 45°C.

Pigmentation and Photoreactivity

Mycobacteria are classified into three groups based on the production of pigments. Photochromogens produce nonpigmented colonies when grown in the dark and pigmented colonies only after exposure to light. Scotochromogens produce deep-yellow- to orange-pigmented colonies when grown in either light or darkness (some strains show increased pigment production upon continuous exposure to light). Nonchromogens are nonpigmented in both the light and the dark or have only a pale yellow, buff, or tan pigment that does not intensify after light exposure. These responses to light exposure were originally delineated to aid in the identification of nontuberculous mycobacteria (NTM). Members of the MTBC, however, are considered nonchromogens, and pigmented mycobacteria may be preliminarily reported as NTM.

Testing for pigment production should be done on isolated colonies from young cultures. Three tubes of media are inoculated with an SCS diluted to yield isolated colonies as described above. Two tubes are wrapped to be shielded from light, and the third is left uncovered. When growth is detected in the unshielded tube, one of the wrapped tubes should be examined. If colonies are not pigmented, the newly unshielded tube with its cap loosened is exposed to light (100-W tungsten bulb or fluorescent equivalent, placed

* This chapter contains information presented in chapter 37 by Véronique Vincent, Barbara A. Brown-Elliott, Kenneth C. Jost, Jr., and Richard J. Wallace, Jr., in the eigth edition of this Manual.

TABLE 1 Distinctive properties of cultivable, slowly growing mycobacterial species encountered in clinical specimens[a]

[a] Modified from references 27, 29, 40, 48, 87, 105, 106, 109, 120, and 121. Plus and minus signs indicate the presence and absence, respectively, of the feature: V, variable; ±, usually present; −/+, usually absent; ND, not determined; ref. no., reference number. The percentage of strains positive in each test is given in parentheses, and the test result is based on these percentages.

[b] R, rough; Sm, smooth; SR, intermediate in roughness; Smt, smooth and transparent; Rt, rough and thin or transparent.

[c] P, photochromogenic; S, scotochromogenic; N, nonchromogenic (*M. szulgai* is scotochromogenic at 37°C and photochromogenic at 24°C; *M. palustre* is scotochromogenic at 37°C, and 85% of isolates are photochromogenic at 42°C).

[d] Probe identifies the MTBC.

[e] Requires hemin as growth factor.

[f] Arylsulfatase reaction at 14 days is positive.

[g] Young cultures may be nonchromogenic or possess only pale pigment that may intensify with age.

[h] Results for 3-day arylsulfatase reaction not available; 10-day arylsulfatase reaction positive.

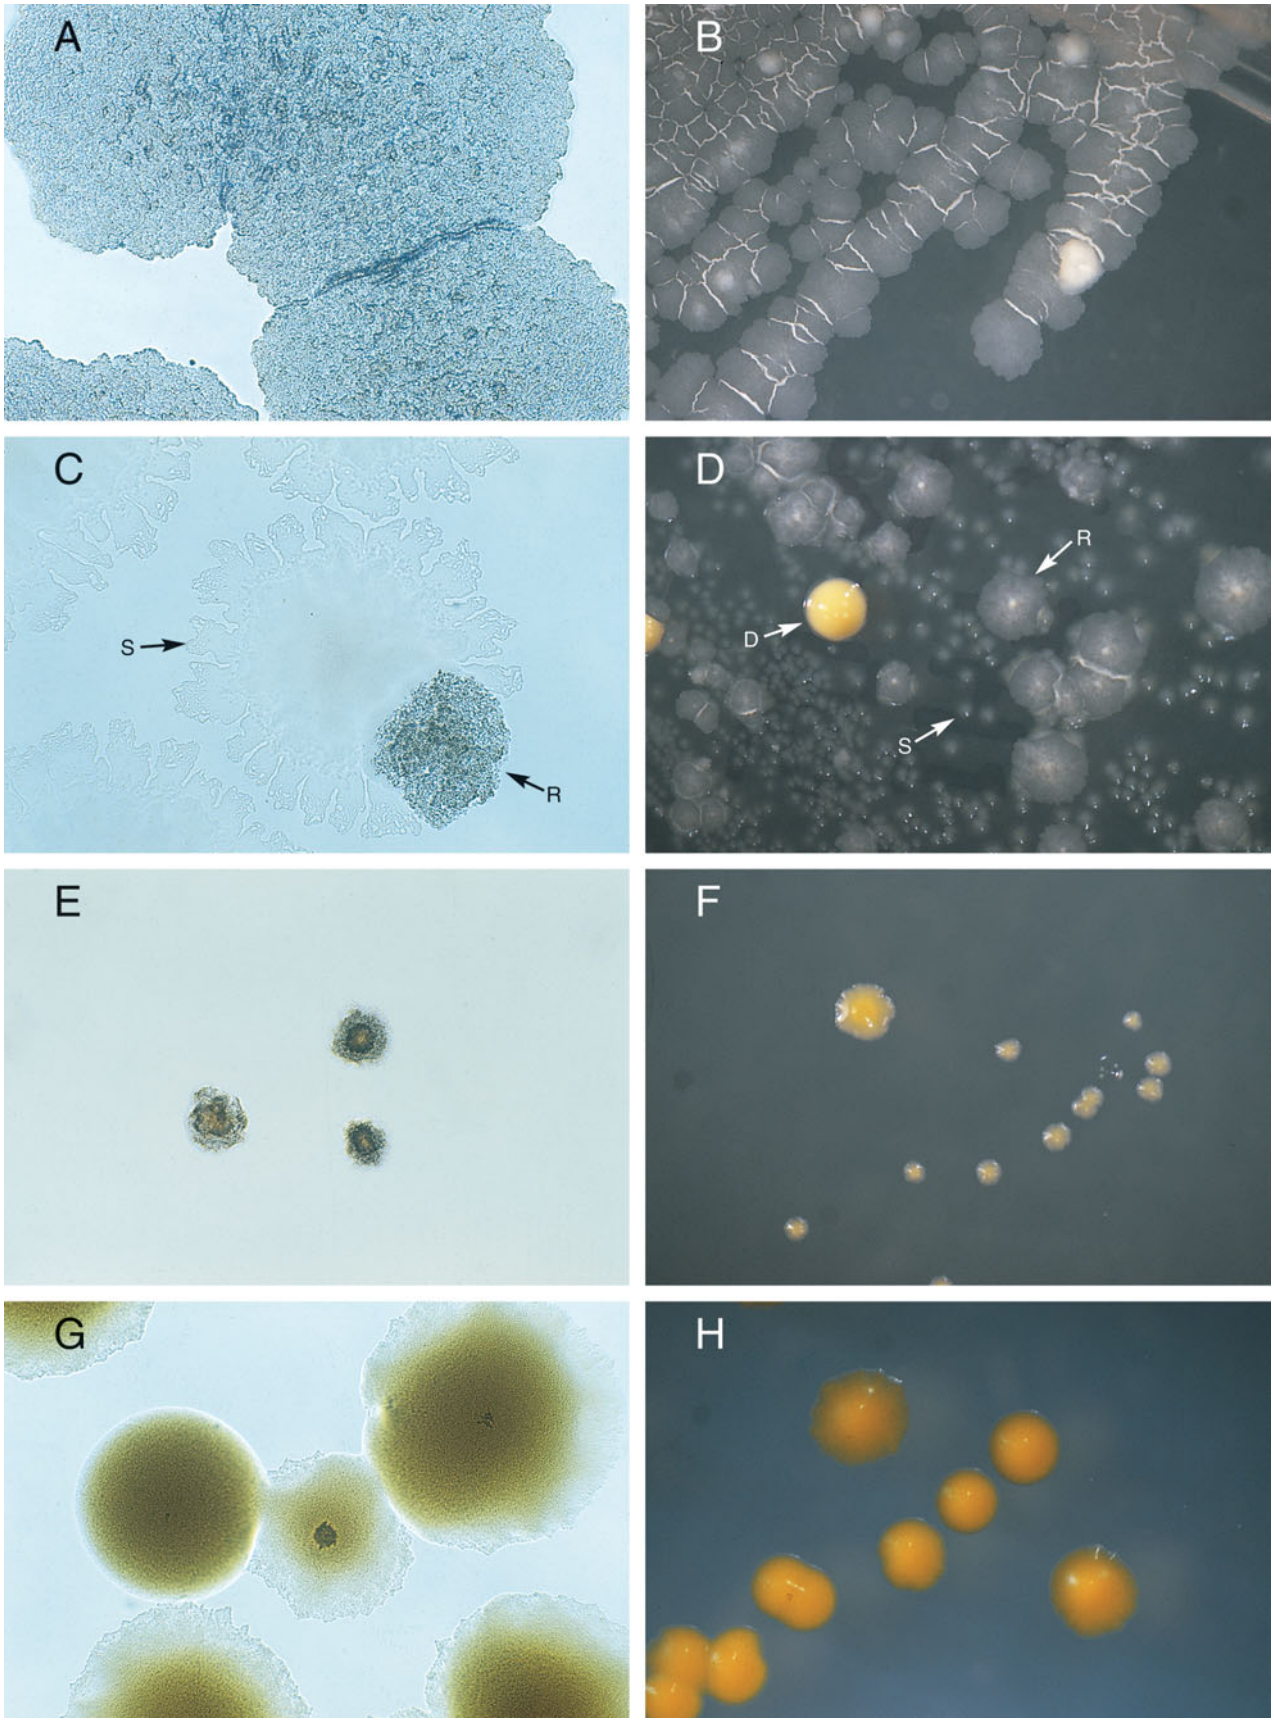
[i] A MAC nucleic acid probe that recognizes *M. avium*, *M. intracellulare*, and the "X" strains is commercially available.

20 cm from the culture) for 1 to 5 h. Maximal oxygenation of the culture (loose cap, isolated colonies) is necessary for induction of the pigment, which is controlled by an oxygen-dependent, photoinducible enzyme. The tube is then reshielded and reincubated, and the colonies in the light-exposed tube are compared with those in the shielded tube after 24 h. Variations within species occur.

Colony Morphology

Colony morphology of mycobacteria can be evaluated, according to the scheme developed by Runyon (84a), by microscopically observing young (5- to 14-day-old), isolated colonies on plates inverted under the 10× power objective of a stereomicroscope with transmitted light. The best medium is a clear solid one like Middlebrook 7H10 or 7H11 agar. The large numbers of NTM species have made it increasingly difficult to provide a tentative identification of an NTM species by this method, and so the information gained by this technique is often used to direct the diagnostic procedure to other, more specific tests. The morphology of *M. tuberculosis* usually allows for a tentative identification of this species. Examination of the morphologies of colonies is also important for the detection of mixed cultures. Figure 1 shows the colony types of some frequently isolated species.

Arylsulfatase



Arylsulfatase hydrolyzes the bond between the sulfate group and the aromatic ring of tripotassium phenolphthalein disulfate to form free phenolphthalein, which is easily detected by a red appearance when alkali is added. Arylsulfatase activity can be detected in all mycobacteria after prolonged incubation. Performing the test after only 3 days helps in identifying several slowly growing mycobacteria such as *M. xenopi* and *M. celatum*.

Cultures in Dubos liquid medium (2 ml) containing 0.08 M phenolphthalein disulfate (tripotassium salt) are tested after 3 days of incubation by adding 0.3 ml of 1 M Na_2CO_3. The development of pink indicates a positive reaction. *M. xenopi* and *M. avium* can be used as positive and negative controls, respectively.

Catalase

Catalase is an intracellular, soluble enzyme capable of degrading hydrogen peroxide into water and oxygen. Two tests are used to detect catalase activity, a semiquantitative test that reflects differences in enzyme kinetics and a heat tolerance test. The enzyme is detected by adding H_2O_2 to a culture and observing for the formation of bubbles in the reaction mixture.

The semiquantitative test divides the mycobacteria into two groups, those producing low catalase activity and those producing high catalase activity, based on the sizes of the columns of bubbles produced (less or more than 45 mm). A butt (not a slant) of a Löwenstein-Jensen (L-J) medium tube (16 by 150 mm) is inoculated with 0.2 ml of an SCS prepared as described above for growth rate determination. Tubes are incubated for 2 weeks at 35°C with the caps loosened. Then 1 ml of a reagent consisting of a 1:1 mixture of 10% Tween 80 and 30% H_2O_2 is added. Be sure to loosen the caps and place the tubes on an adsorbent surface in case bubbles overflow. The column of bubbles yielded is measured (in millimeters) after the tube has stood upright for 5 min at room temperature. *M. tuberculosis* H37Ra and *M. kansasii* can be used as controls for low and high catalase activity, respectively.

(Continued on next page)

(Continued)

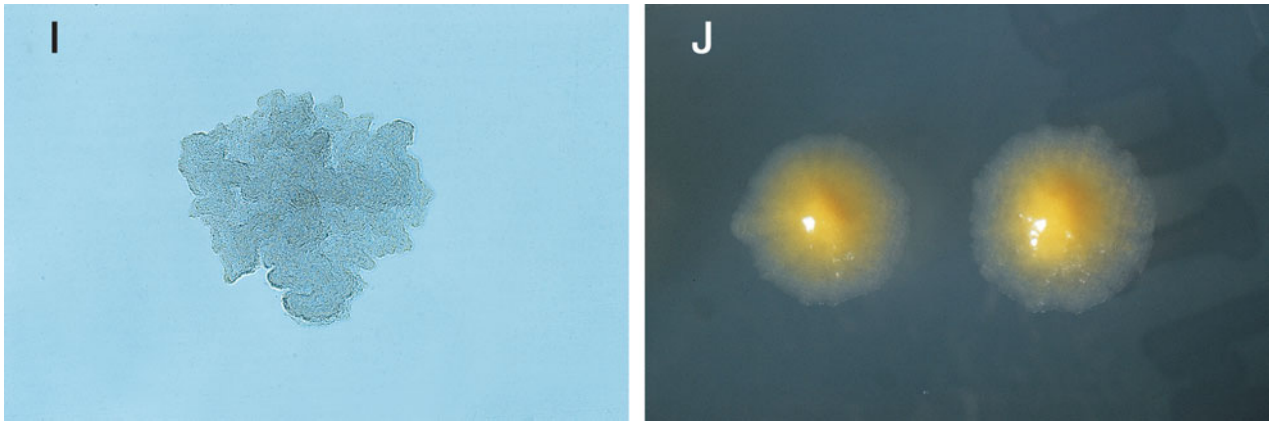


FIGURE 1 (A) *M. tuberculosis* growth after 15 days. Thin, nonpigmented, rough colonies are seen on 7H11 agar; cording is apparent. (B) *M. tuberculosis* growth after 10 days. Dry, buff, wrinkled colonies are visible on 7H11 agar. (C) *M. avium* growth after 10 days. A flat, nonpigmented, smooth (S) colony with an irregular edge and a compact, nonpigmented, rough (R) colony are seen on 7H11 agar. (D) *M. avium* growth after 10 days. Nonpigmented colony variants are visible on 7H11 agar; smooth-flat (S), dome (D), and rough (R) variants are indicated. (E) *M. xenopi* growth after 15 days. Nonpigmented, compact, rough colonies with irregular peripheries are seen on 7H11 agar; the colonies resemble a bird's nest. (F) *M. xenopi* growth after 15 days. Smooth, dome-shaped, and slightly yellow colonies are visible on 7H11 agar. (G) *M. gordonae* growth after 10 days. Orange, smooth, opaque entire colonies and orange, smooth, opaque colonies with irregular edge tints are seen on 7H11 agar. (H) *M. gordonae* growth after 10 days. Smooth, orange, hemispheric colonies are seen on 7H11 agar. (I) *M. kansasii* growth after 10 days in the dark. Nonpigmented, rough colonies are seen on 7H11 agar; stranding of bacilli is seen (similar to cording). (J) *M. kansasii* growth after 15 days. A smooth colony with the center elevated and thickened and with a thin, rough periphery is seen on 7H11 agar; it is orange after light exposure. (Photographs courtesy of Daniel Fedorko and Yvonne Shea, Department of Laboratory Medicine, Microbiology Service, National Institutes of Health, 2002.)

Niacin Accumulation Test

Niacin (nicotinic acid) functions as a precursor in the biosynthesis of coenzymes NAD and NADP. Although all mycobacteria produce nicotinic acid, some have a block in the NAD scavenging pathway and excrete niacin. The niacin accumulated in the culture medium is then detected by its reaction with a cyanogen halide in the presence of a primary amine. Niacin-negative *M. tuberculosis* isolates are extremely rare. A positive niacin test result should not be used alone to identify *M. tuberculosis*, however, because some strains of *M. simiae* and other mycobacteria, although infrequently encountered, also accumulate niacin. Performance of the supportive tests for nitrate reduction and 68°C catalase are necessary for confirming the identification of *M. tuberculosis*.

A niacin paper strip version is available commercially (BD, Sparks, Md., and Remel Inc., Lenexa, Kans.). A heavily grown L-J culture medium is covered with 1 ml of distilled water, and the tube is placed horizontally to allow extraction for 20 min. Then 0.5 ml of the liquid is transferred to a tube. The strip is inserted, and the tube is sealed immediately. After 15 min at room temperature, yellow coloration of the liquid (not the strip) indicates a positive test result. *M. tuberculosis* H37Ra and *M. avium* can be used as positive and negative controls, respectively.

Nitrate Reduction

Mycobacteria differ quantitatively in their abilities to reduce nitrate to nitrite. The nitrate reduction test is performed by adding 2 ml of $NaNO_3$ substrate to a bacterial heavy suspension prepared with two loopfuls of bacteria emulsified in 0.2 ml of distilled water. The tube is shaken manually and incubated upright for 2 h in a 37°C water bath. After the tube is removed from the bath, 1 drop of reagent 1 (50 ml of HCl in 50 ml of H_2O), 2 drops of reagent 2 (0.2 g of sulfanilamide in 100 ml of H_2O), and 2 drops of reagent 3 (0.1 g of *N*-napthylthylenediamine dihydrochloride in 100 ml of H_2O) are added to the SCS. Immediate development of a pink tone is considered to indicate positivity. *M. tuberculosis* H37Ra and *M. avium* can be used as positive and negative controls, respectively.

Pyrazinamidase

The enzyme pyrazinamidase hydrolyzes pyrazinamide (PZA) into ammonia and pyrazinoic acid, which can be detected by the addition of ferric ammonium sulfate. This test is most useful in separating *M. marinum* from *M. kansasii* and *M. bovis* from *M. tuberculosis*. In addition, one mechanism of PZA resistance of *M. tuberculosis* appears to be the inability of the organism to produce pyrazinoic acid, which is assumed to be the active component of the drug PZA. A pyrazinamidase-negative *M. tuberculosis* isolate is assumed to be PZA resistant as well.

The test medium consists of Dubos broth base containing 0.1 g of PZA, 2.0 g of pyruvic acid, and 15.0 g of agar per liter. The medium is dispensed in 5-ml amounts, autoclaved, and solidified in a tube in an upright position. The agar medium is heavily inoculated with growth from the culture so that the inoculum should be visible. After incubation at 37°C for 4 days, 1 ml of 1% ferrous ammonium sulfate is added. The preparation is observed for up to 4 h for a pink band in the agar, which indicates a positive test result. *M. avium* and uninoculated medium are used as positive and negative controls, respectively.

Sodium Chloride Tolerance

M. triviale is the only slowly growing mycobacterium able to grow in the presence of, or tolerate, 5% sodium chloride.

L-J medium containing 5% NaCl or lacking salt is inoculated with 0.2 ml of an SCS and incubated at 30 or 35°C. Growth or no growth is scored at 4 weeks. *M. triviale* and *M. tuberculosis* H37Ra can be used as positive and negative controls, respectively.

Inhibition by Thiophene-2-Carboxylic Acid Hydrazide

Inhibition by thiophene-2-carboxylic acid hydrazide (T2H) is used to distinguish niacin-positive *M. bovis* from *M. tuberculosis* and other nonchromogenic slowly growing mycobacteria. Most *M. bovis* isolates are susceptible to T2H, whereas *M. tuberculosis* and most other slowly growing mycobacteria are resistant.

Middlebrook 7H11 medium containing 10 μg of T2H (Aldrich Chemical Co., Milwaukee, Wis.) per ml is dispensed in 5-ml amounts onto slants. Tubes with and without T2H are inoculated with 0.2 ml of the 10^{-2} and 10^{-4} SCS dilutions. When growth is visible on the control tubes, the colonies are counted. The organism is recorded as resistant if growth on the T2H medium is >1% of the growth on the control. *M. tuberculosis* H37Ra and *M. bovis* can be used as positive and negative controls, respectively.

Tellurite Reduction

Tellurite reductase reduces colorless potassium tellurite into a black metallic tellurium precipitate. The tellurite reduction test is used to separate *M. avium* and *M. intracellulare* from most other nonchromogens. Some rapid growers can similarly produce a positive tellurite test result.

Two drops of a 0.2% aqueous solution of potassium tellurite are added to 5-ml cultures (7 days old) in Middlebrook 7H9. Cultures are incubated and examined daily for 4 days or more. A positive test result is shown by a jet black precipitate. *M. avium* and *M. kansasii* can be used as positive and negative controls, respectively.

Tween 80 Hydrolysis

Lipases produced by some mycobacterial species hydrolyze the detergent polyoxyethylene sorbitan monooleate (Tween 80) into oleic acid and polyoxyethylene sorbitol. Neutral red in the pH 7 test medium is bound by Tween 80 and has an amber color at a neutral pH. If Tween 80 is hydrolyzed, however, neutral red is no longer bound and reverts to its usual red color at pH 7. The Tween 80 hydrolysis test allows for differentiation among the slowly growing NTM species.

The substrate solution consists of 0.5 ml of Tween 80 in 100 ml of 0.067 M phosphate buffer (pH 7.0) to which 2 ml of a 1% aqueous solution of neutral red is added. The solution is dispensed in screw-cap tubes in 4-ml amounts and autoclaved. A loopful of bacteria is suspended in a tube and incubated at 37°C. A change in color from amber to pink or red is recorded after 24 h and 5 and 10 days of incubation as a positive reaction. *M. kansasii* and *M. avium* can be used as positive and negative controls, respectively.

Urease

The ability of an isolate to hydrolyze urea into ammonia and CO_2 is useful in identifying both scotochromogens and nonchromogens. *M. scrofulaceum* is urease positive, whereas *M. avium* and *M. intracellulare* organisms are urease negative. The urease test is particularly helpful in the recognition of pigmented strains of *M. avium*.

The test medium is prepared by mixing 1 part of urea agar base concentrate with 9 parts of distilled water and is dispensed in 4-ml amounts into tubes. A loopful of bacteria is emulsified in a test tube and incubated at 37°C for 3 days. A positive reaction is indicated by a pink to red color. *M. scrofulaceum* and *M. gordonae* can be used as positive and negative controls, respectively.

Mycolic Acid Analysis

Mycolic acid analysis has been recommended as one of several minimal criteria for the description of new mycobacterial species (115). Mycolic acids are high-molecular-weight (20 to 90 carbon atoms) alpha-substituted, beta-hydroxy fatty acids found in the cell walls of members of several other bacterial genera: *Corynebacterium, Rhodococcus, Gordonia, Dietzia, Nocardia*, and *Tsukamurella* (see also chapter 35).

High-pressure liquid chromatography (HPLC) of mycolic acid esters has been demonstrated to be a rapid and reliable method for identification of many *Mycobacterium* species. A standardized method that includes sample preparation and chromatographic analysis has been described previously (14). One to two loopfuls of cells grown on solid medium are suspended in a methanolic potassium hydroxide solution and saponified by heating. After acidification and extraction with chloroform, free mycolic acids are derivatized to para-bromophenacyl esters. Internal-standard molecular weight markers are added, and the sample is injected. The mycolic acid esters are separated on a reversed-phase C_{18} column by a methanol-methylene chloride gradient elution and detected by UV spectrophotometry (UV-HPLC). An extract prepared from *M. intracelluare* ATCC 13950 is used as a positive control and provides an external standard peak naming reference. The high biomass requirement of UV-HPLC can be reduced at least 200-fold by derivatizing mycolic acids to 6,7-dimethoxy-4-coumarinyl-methyl esters, which are measured by fluorescence detection HPLC (FL-HPLC). The increased analytical sensitivity of FL-HPLC allows the identification of acid-fast bacilli from smear-positive clinical specimens, liquid medium cultures, and minute amounts of biomass from solid medium (42). MTBC identification by FL-HPLC has been reported to achieve a sensitivity of 99% with BACTEC 12B medium with a growth index of ≥50 (42).

HPLC patterns can be identified to the species or group level by visual or mathematical means. A pattern atlas derived from a multicenter study of more than 350 strains, representing 23 species, that illustrates species patterns is available on the Centers for Disease Control and Prevention website at http://www.cdc.gov/ncidod/dastlr/TB/TB_HPLC.htm. Additionally, pattern overlays of closely related species have been presented along with pattern variations produced by strains of a single species. However, *M. tuberculosis* and *M. bovis* produce indistinguishable patterns. The standardized method (14) recommends a visual comparison of a sample HPLC pattern to an atlas of reference strain patterns in combination with the use of peak height ratios. This approach was reported to achieve an accuracy of 96.1% (104). Libraries that report both an identification and the quality of a match are commercially available (Pirouette and INSTEP software [Infometrix Inc., Woodinville, Wash.] and the Sherlock mycobacterium identification system [MIDI, Inc., Newark, Del.]).

Although HPLC initial equipment costs are high (approximately $50,000) and considerable expertise is required to operate nonautomated systems, material costs per test are economical compared with those for commercial molecular probes. Sample preparation is simple, and many mycobacterial

species or groups can be identified in a single analysis. However, mycolic acid analysis does not provide the specificity or the sensitivity of molecular approaches as described below.

Mycobacterial Genomes

The complete genome sequence of *M. tuberculosis* H37Rv comprises 4,411,529 bp and contains approximately 4,000 genes (20). *M. tuberculosis* has an extremely clonal population structure, with genomic variation caused largely by insertion sequence movement rather than point mutation (10, 46, 94). A recent study showed that, similar to *Yersinia pestis* (2) and *Salmonella enterica* serotype Typhi (49), the MTBC consists of a successful clonal population that recently emerged from a much more ancient and larger bacterial species group encompassing *M. canettii* and additional genetic groups of smooth strains (36).

Additional genome sequences are available or are being determined for several mycobacteria. More information can be found at the websites http://genolist.pasteur.fr/TubercuList/index.html for *M. tuberculosis* H37Rv, http://www.tigr.org/tigr-scripts/CMR2/GenomePage3.spl?database = gmt for *M. tuberculosis* CDC1551, http://www.sanger.ac.uk/Projects/M_bovis for *M. bovis*, and http://genolist.pasteur.fr/Leproma/index.html for *M. leprae.*

Genotypic Identification of Mycobacterial Strains

PCR-REA

In 1993, Telenti and colleagues proposed a method for rapid identification of mycobacteria to the species level based on PCR amplification of a 439-bp fragment of the gene encoding the 65-kDa heat shock protein *(hsp65)* followed by restriction enzyme digestion using BstEII and HaeIII (102). The method has been extensively used for the identification of slowly growing mycobacteria (77). *M. tuberculosis* is easily differentiated from the NTM by a characteristic band with HaeIII restriction endonuclease digestion. However, members of the MTBC are not discriminated by PCR-restriction enzyme analysis (PCR-REA). By contrast, most NTM can be recognized by their PCR-REA patterns. Several alleles have been identified in *M. gordonae* and *M. kansasii* yielding several distinct PCR-REA patterns for a single species (77). Some other gene sequences (including those of *rpoB, dnaJ*, and the 16S-23S rRNA gene spacer) have been tentatively used for PCR-REA, but none have been studied as extensively as that of *hsp65*.

The advantages of PCR-REA are that equipment is not very expensive and the method is relatively rapid and identifies most mycobacterial species, including some not identified by phenotypic methods and/or HPLC. The disadvantages are that it is a relatively complex procedure and, due to the increase of newly described species, it may not allow unambiguous species identification but may assign to groups of mycobacterial species. A multicenter evaluation of the method showed that differences in gel running conditions and lack of training in interpretation of patterns contributed to low accuracy (58). Furthermore, it is not commercialized or Food and Drug Administration (FDA) approved and it requires a significant amount of in-house validation.

Commercially Available Identification Probes

AccuProbe

Acridinium ester-labeled DNA probes based on the detection of rRNA (Gen-Probe Inc., San Diego, Calif.) specific for the MTBC, the *M. avium* complex (MAC), *M. kansasii*, and *M. gordonae* (as well as separate probes for *M. avium* and *M. intracellulare*) are FDA approved and commercially available. The current total test time for the AccuProbe assay is less than 2 h (17, 59). Briefly, target 16S rRNA is released from the organism by sonication. The labeled DNA probe combines with the organism's rRNA to form a DNA-rRNA hybrid. The labeled product is detected in a luminometer.

Tests with DNA probes can be performed using isolates from solid media or from broth cultures. Combining the probes with a broth culture system has the advantage of optimizing rapid detection and identification of mycobacteria present in clinical samples (17, 43). Procedural modifications are necessary for testing isolates recovered from liquid medium. An aliquot of the broth culture is concentrated by centrifugation, and the pellet is resuspended in culture identification reagent. Testing then follows the procedure for testing colonies from solid media (as described in the AccuProbe technical insert). To eliminate high nonspecific chemiluminescence, BACTEC (BD) 13A broth medium containing blood is pretreated with 100 μl of 10% sodium dodecyl sulfate–50 mM EDTA (pH 7.2) before microcentrifugation to allow lysis of the erythrocytes and sorbitolization of the membranes. Appropriate positive and negative control organisms should be included in each assay run.

It has been shown that specificity is 100% for testing of mycobacterial colonies. Sensitivity, however, varies with the species or species complexes: 95.2 to 97.2% for the MAC, 100% for the MTBC, 100% for *M. gordonae*, and 97.4 to 100% for *M. kansasii* (33, 59, 80, 108). Later studies using AccuProbe on more than 11,000 positive BACTEC cultures also showed 100% specificity and >85 to 100% sensitivity for all species tested (17, 79).

Advantages of this test include the simplicity and rapidity (within 2 h) with which mycobacteria can be identified. The use of a nonradioactive procedure and the extended shelf life of the chemiluminescent probes offer the potential for widespread application in most clinical laboratory settings (33, 59).

A few limitations of using AccuProbe have been described. These include misidentification of *M. celatum* as MTBC due to the similarity of the 16S rRNA genes of these two species in the probe region (92). The specificity of the MTBC probe has been increased by extending the length of the selection reagent incubation step to 10 min, and a temperature of 60 to 61°C is recommended to eliminate cross-reactivity with other species, including *M. terrae* and *M. celatum* (92). Greater biomass in the test suspensions may also result in decreased specificity of the test (92). It has been shown that the use of a higher cutoff (at 80,000 relative light units instead of 30,000 relative light units) may prevent false-positive results when the MAC probe is tested with broth cultures (19). As with all laboratory tests, the user is reminded that the probe should be repeated or the results should be confirmed by an alternate method if results do not correlate with clinical or cultural observations. The MTBC probe does not differentiate among members of the MTBC.

Strip Tests

Two line probe assays have been developed, one targeting the 16S-23S rRNA internal transcribed spacer region (INNO-LiPA Mycobacteria version 2; Innogenetics, Ghent, Belgium) and the other one targeting the 23S rRNA gene (GenoType Mycobacteria; Hain Lifescience, Nehren, Germany).

Strip assays are based on the reverse hybridization of biotinylated PCR products to their complementary probes immobilized as parallel lines on a membrane strip. Kits may be applied to strains subcultured on solid or in liquid media. Lines on the strips include probes for the identification of the

Mycobacterium genus and probes for the identification of various frequently encountered or clinically relevant mycobacterial species, 16 species in the INNO-LiPA Mycobacteria version 2 and 13 species in the GenoType Mycobacteria. The overall concordance with other identification methods (AccuProbe and PCR-REA of *hsp65* or 16S sequences) has been good when tested with reference strains and mycobacterial cultures from clinical specimens (60, 81, 86, 107).

The main advantage of the kits is that a range of several species can be identified by a single PCR assay, and unlike the AccuProbe, they do not require a tentative selection of the adequate probe. The kits are commercially available in Europe at the present time and available only for research in the United States. Tests are performed in 6 h, including the preliminary PCR amplification. They require several time-consuming washes. An automated machine, Auto-LiPA (Innogenetics), which runs the washes and ensures the gentle shaking necessary for several steps of the procedure, greatly contributes to time saving and ease of application in clinical laboratories. However, the cost of this apparatus may hamper its introduction into many laboratories.

DNA Sequencing

The availability of DNA sequencing technologies constitutes a great benefit for mycobacterial identification, owing to the peculiar slow growth of mycobacterial organisms. Recent improvements in automation of target amplification and sequence analysis have led to practical implementation of DNA sequencing in the clinical laboratory. Moreover, the cost has decreased dramatically (106). Sequencing of the entire 16S rRNA gene (*rrs* gene, approximately 1,500 bp) or the *hsp65* gene (approximately 4,400 bp) cannot be done in a routine clinical laboratory. However, identification of species-specific signatures within variable regions of these highly conserved genes allows the design of simple PCR protocols followed by the direct sequencing of the PCR-amplified products. Catalogues of sequences of mycobacterial species may be retrieved from databases (GenBank/EMBL website at http://www.ncbi.nlm.nih.gov) and conveniently imported and stored in a file in the laboratory. Liquid cultures or colonies from solid medium may be used for DNA extraction by boiling the sample without any further purification. The polymorphism of several conserved genes has been investigated for identifying mycobacterial species, such as the gene encoding the 32-kDa protein (91), the *dnaJ* gene (101), the *sod* gene encoding the superoxide dismutase (126), the *gyrB* gene coding for the gyrase subunit B (45), the *rpoB* gene coding for the RNA polymerase (51), the internal transcribed spacer 16S-23S sequence (67, 84), and the *secA1* gene coding for a key component of the major pathway of protein secretion across the cytoplasmic membrane (124). The most widely used targets are 16S rRNA (*rrs* gene) and the *hsp65* gene.

The strategy for sequencing and identification of the signature sequences of the 16S rRNA gene has been extensively described (52). Specific primers for mycobacteria (Table 2) have been designed for the amplification of the 16S rRNA gene to avoid contamination and enhance specificity. Amplification of a 1,030-bp region encompassing the 16S rRNA gene sequence is performed with primers 285 and 264. The sequencing reaction is performed with primer 244 by using sequencing kits for automated DNA sequencers to characterize the hypervariable region A, located on the 5′ side of the *rrs* gene, corresponding to *Escherichia coli* 16S rRNA gene positions 129 to 267. 16S rRNA genes reflect a limited conserved region of the entire genome, and the molecular clock of the marker is rather slow. Species of recent divergence thus may contain 16S rRNA gene sequences that are highly similar. Moreover, no single 16S rRNA gene interstrain nucleotide sequence difference value that unequivocally defines species boundaries has been established for the genus *Mycobacterium* (119). For instance, *M. szulgai* and *M. malmoense* present a 2-nucleotide difference only in the 1,384-nucleotide segment examined whereas some *M. intracellulare* serotypes reveal microheterogeneity with 1 to 7 different nucleotides in a 782-nucleotide segment (119). For routine identification, strains should be identified according to a 16S rRNA hypervariable region A matching the type strain sequence. Additional investigation using another molecular marker (e.g., *hsp65*) may be required for accurate identification since hypervariable region A cannot be used to discriminate between some species encountered in clinical specimens, i.e., *M. kansasii* and *M. gastri, M. ulcerans* and *M. marinum*, and *M. shimoidei* and *M. triviale* (52). In addition, no polymorphisms are present among the different species in the MTBC.

TABLE 2 Oligonucleotides used for mycobacterial identification by DNA sequencing

Target	Primer[a]	Sequence	Position[b]
rrs	285	5′ GAGAGTTTGATCCTGGCTCAG 3′	9–29
rrs	264	5′ TGCACACAGGCCACAAGGGA 3′	1046–1027
rrs	244	5′ CCCACTGCTGCCTCCCGTAG 3′	361–342
hsp65	Tb11	5′ ACCAACGATGGTGTGTCCAT 3′	396–415
hsp65	Tb12	5′ CTTGTCGAACCGCATACCCT 3′	836–817

[a] Primers are described in references 44 and 52.

[b] "Position" refers to the *E. coli* 16S rRNA gene numbering for the *rrs* gene and to the *M. tuberculosis* numbering for the *hsp65* gene.

Partial sequencing of the *hsp65* gene is performed using primers Tb11 and Tb12 (44) for the amplification of a 441-bp region (nucleotides 396 to 836 according to the numbering of the *M. tuberculosis hsp65* gene) (88). As indicated above for the PCR-REA method, several *hsp65* alleles may be identified within a species. The polymorphism in the *hsp65* gene allows unambiguous identification of species with close 16S rRNA gene sequences such as *M. gastri* and *M. kansasii*. As with the 16S rRNA gene, all MTBC members have the same *hsp65* allele except *M. africanum* and *M. canettii*, which show a single nucleotide polymorphism within the gene (30, 36).

Genotypic Markers for Species Identification within the MTBC

Although *M. tuberculosis* is the most prevalent tubercle bacillus isolated in clinical laboratories, identification of other members of the MTBC is of the utmost epidemiological importance and may govern the management of contact-tracing investigations and/or treatment. Incomplete identification of tubercle bacilli can lead to misdiagnosis of *M. bovis* BCG infections in patients treated for bladder cancer or misdiagnosis of nosocomial BCG infections in cancer patients (97, 116, 117). Moreover, the identification of *M. bovis* allows public health investigation and tracing of epidemics possibly due to cattle-to-human transmission (37). A retrospective study (1980 to 1997) of active pediatric tuberculosis in a United States-Mexico cross-border region showed that *M. bovis* accounted for 10.8% of all tuberculosis cases and for 33.9% of cases with positive cultures (23). The main risk factor was exposure to a zoonotic source, namely, ingestion of unpasteurized dairy products (7, 23). Similarly, rare agents of tuberculosis (*M. microti, M. canettii, M. caprae,* and *M. pinnipedii)* have to be properly identified for documentation of their epidemiology at the national level (37).

The MTBC members cannot be differentiated by the AccuProbe test. Similarly, the *hsp65* gene and the PCR-REA patterns are identical for *M. tuberculosis* and *M. bovis*. However, strains may be differentiated according to conventional identification tests (Table 1) as well as host range and virulence. The sequence polymorphism of the *oxyR* and *pncA* genes led to the development of allele-specific PCR tests which allow differentiation of *M. bovis* from all other MTBC members (25). The distribution of deletions (RD sequences) among the tubercle bacilli contributes to the identification of the different members of the MTBC: this approach is based on PCR tests only (Table 3). Since many laboratories use amplification procedures, it has been proposed that this PCR-based approach be incorporated into the laboratory routine by clinical mycobacteriology laboratories (68). A commercialized strip assay relying on *gyrB* probes has been recently developed for the differentiation of the MTBC members (Hain Lifescience). An evaluation study showed that the species were unequivocally identified but *M. tuberculosis* and *M. canettii* shared a common pattern (81). Moreover, as mentioned below, spoligotyping confirms the specific identification.

Molecular tests should be carried out on *M. tuberculosis* strains with phenotypes which do not fully match that of the type strain, e.g., strains which hybridize with the MTBC probe and do not yield rough, cream, cauliflower-like colonies or do not produce niacin or nitrate reductase. Monoresistance to PZA has been shown to be of poor predictive value as an initial screening tool for *M. bovis* (24, 38). If molecular analysis is not available in the laboratory, strains should be sent to a reference laboratory.

Direct NAA Tests

Three nucleic acid amplification (NAA) kits designed to detect MTBC bacilli directly from patient specimens are commercially available. The amplified *M. tuberculosis* direct test (AMTD; Gen-Probe) consists of transcription-mediated amplification of a specific 16S rRNA target performed at constant temperature for the detection of MTBC rRNA in smear-positive and -negative respiratory samples. The Amplicor *M. tuberculosis* PCR assay (Roche Molecular Systems, Branchburg, N.J.) consists of PCR amplication of a 584-bp region of the 16S rRNA gene sequence. Incorporation of dUTP instead of dTTP prevents carrier contamination in the amplification reaction, and the use of uracil-*N*-glycosylase enzymatically cleaves any contaminating amplicons from previous reactions.

Both of these tests are FDA approved for respiratory samples, the AMTD for both smear-positive and smear-negative specimens and the Amplicor for smear-positive specimens only. Moreover, investigators have shown that, with specific modifications, the tests may also detect *M. tuberculosis* in nonrespiratory specimens (76). The overall AMTD specificity ranged from 92.1 to 100%. For respiratory specimens, the sensitivity was between 91.7 and 100% for smear-positive specimens and decreased to between 65.5 and 92.9% for smear-negative specimens. For nonrespiratory specimens, the sensitivity was between 88 and 100% for smear-positive specimens and between 63.6 and 100% for smear-negative specimens (76). Regarding the Amplicor assay, specificity was similar to the AMTD value for smear-positive specimens and ranged from 90 to 100% for respiratory specimens and from 87.5 to 100% for extrapulmonary specimens. However, sensitivity was lower for smear-negative samples, from 50 to 95.9% for respiratory specimens and from 17.2 to 70.8% for extrapulmonary specimens. Inhibition has been detected in less than 1 to 5% of clinical specimens with the AMTD and up to 20% with the Amplicor assay. The Amplicor assay showed a significantly higher inhibition rate for nonrespiratory specimens and false-positive results were related to cross-reactions with mycobacteria other than tubercle bacilli (76).

The BDProbeTec strand displacement amplification (BD) is an isothermal enzymatic process that coamplifies sequences of IS*6110* (specific to the MTBC) and the 16S rRNA gene (common to most mycobacterial species). The process is based on the nicking of the recognition sequence in double-stranded DNA by a restriction endonuclease and further extension of that site with DNA polymerase that synthesizes a new strand of DNA while displacing the existing one. The sensitivity of the test has been shown to be between 98.5 and 100% for smear-positive specimens and between 33.3 and 85.7% for smear-negative and extrapulmonary specimens, with inhibition rates between 0.3 and 14% (76).

Since tuberculosis of the central nervous system is one of the most malignant forms of human tuberculosis, the rapid and accurate laboratory diagnosis of tuberculous meningitis is of prime importance. Conventional bacteriology methods are usually inefficient (negative microscopy and late positive culture if any). Recently, a systematic review and meta-analysis documented the diagnostic accuracy of NAA tests for tuberculous meningitis. The summary estimates were as follows: sensitivity, 0.56 (95% confidence interval [CI], 0.46 to 0.66); specificity, 0.98 (95% CI, 0.97 to 0.99); positive likelihood ratio, 35.1 (95% CI, 19.0 to 64.6); and negative likelihood ratio, 0.44 (95% CI, 0.33 to 0.60). Consequently, commercial NAA tests show a potential role in confirming tuberculous meningitis diagnosis, although their overall low sensitivity precludes the use of these tests to rule out tuberculous meningitis with certainty (66).

NAA tests can be performed in as few as 6 to 8 h on processed specimens and, therefore, offer the promise of same-day reporting of results for detection and identification of *M. tuberculosis*. Used as approved by the FDA, NAA tests for *M. tuberculosis* detection do not replace any previously recommended tests and supplement rather than replace culture (16). A recent multicenter study stressed the need for external quality control (64).

TABLE 3 Genotypic characteristics of the MTBC members[a]

Strain	*oxyR*/ 285	*pncA*/ 169	RD4	RD9	RD12	RD[b] specific
M. tuberculosis	G	C	+	+	+	TbD1[c]
M. bovis	A	G	−	−	−	
M. bovis BCG	A	G	−	−	−	RD1
M. africanum	G	C	+	−	+

M. pinnipedii	G	C	+	−	+	RDpin[f]

[a] Data from references 5, 11, 25, 31, 113, and 114. +, present; −, absent.
[b] RD locus numbering according to reference 31.
[c] TbD1 region is absent from "modern" *M. tuberculosis* only and present in all members of the MTBC (11).
[d] RDcan corresponds to a region specifically absent from *M. canettii* only that partially overlaps RD12 (11).
[e] RDmic corresponds to a region specifically absent from *M. microti* only that partially overlaps RD1 (11).
[f] RDpin corresponds to a region specifically absent from *M. pinnipedii* only that partially overlaps RD2 (11).

MYCOBACTERIAL STRAIN TYPING

Molecular Typing Methods for MTBC Strains

Historically, unusual drug susceptibility patterns and phage typing have been used for epidemiological studies of tuberculosis, but they have significant limitations. The description of the repetitive insertion sequence IS*6110* marked a major advance in the molecular epidemiology of tuberculosis (110). Since then, additional sequences of interest for *M. tuberculosis* fingerprinting have been described (32, 111). *M. tuberculosis* DNA fingerprinting has proven to be a powerful epidemiological tool for tracing of transmission groups and determination of their risk factors, for differentiation of exogenous reinfection and relapse, and for detection of laboratory cross-contamination, among other applications (15, 22, 111).

IS*6110* RFLP

The restriction fragment length polymorphism (RFLP) technique using the IS*6110* repetitive sequence as a probe was the first extensively used method for typing MTBC strains. IS*6110* is an insertion sequence present in variable copy numbers, from 0 to 26 in MTBC strains (15). A standardized protocol, based on the use of the restriction enzyme PvuII, has been proposed for IS*6110* RFLP comparison. Standardization of the procedure facilitates interlaboratory comparability of patterns (110).

The IS*6110* RFLP technique is widely applicable to *M. tuberculosis* since fewer than 0.1% of strains tested have no copies of the element (61). However, several sites of IS*6110* insertion are preferential loci for integration into the genome, contributing to reducing the potential diversity of fingerprint patterns (15). The RFLP technique requires approximatively 2 μg of high-quality DNA and hence has to be performed with large quantities of cells. A subculture of the isolate or heavy growth on the original slant and a long turnaround time are required. The technical steps are both labor-intensive and lengthy. Moreover, sophisticated computer image analysis software is required for image analysis, and the availability of well-trained users is sparse. Owing to these difficulties, the IS*6110* RFLP technique cannot be carried out in clinical laboratories and is limited to reference laboratories. PCR-based methods targeting IS*6110* have been developed to reduce the time lag for obtaining IS*6110* RFLP patterns. Although their differentiation levels are close to that of the IS*6110* RFLP technique, the methods suffer from similar drawbacks (lack of accuracy for strains with few IS*6110* copies and lack of expertise for the interpretation of the image patterns) and have not been widely applied (53, 55, 78).

Spoligotyping

The spoligotyping (which stands for "spacer oligotyping") method (Table 4) is based on the polymorphism of the direct repeat (DR) locus. This region, present in all MTBC strains in a unique locus, contains multiple, well-conserved 36-bp repeats interspersed with nonrepetitive short spacer sequences of 34 to 41 bp. Strains are tested by hybridizing their PCR-amplified DR regions to a membrane which consists of an array of 43 covalently bound oligonucleotides representing the polymorphic spacers identified in the *M. tuberculosis* H37Rv DR sequence and in the sequence of *M. bovis* BCG. The method has the clear advantage of being able to simultaneously discriminate among the members of the MTBC and differentiate the clinical isolates in one assay. Spoligotypes appear highly stable, suggesting that isolates with different spoligotypes are rarely related (111). Moreover, spoligotyping allows the identification of prevalent genotypes, especially the Beijing genotype, frequently encountered in China, in other regions of Asia, in the former USSR, and in other geographical areas (54). In the United States, the largest known epidemic associated with drug-resistant strains was due to the so-called "W" strain, an evolutionary branch of the Beijing family (8).

The discriminative power of spoligotyping is less than that of the IS*6110* RFLP technique, and the method tends to group strains in large clusters (111). Spoligotyping, however, is more discriminating for strains with no or few copies of IS*6110* and has been recommended for *M. bovis* since most *M. bovis* strains have few IS*6110* copies (111). Used for the detection of *M. tuberculosis* directly in clinical specimens, spoligotyping failed to yield reproducible patterns. Spoligotyping use in routine clinical laboratories may be difficult to implement due to the multistep hybridization procedures required by the method.

PCR Strategies Targeting Tandem Repeats

Genetic loci containing variable-number tandem repeats (VNTR) have been identified in the *M. tuberculosis* genome (32). VNTR are a source of allelic polymorphism which can be analyzed by amplification of each locus by using primers specific for flanking regions and estimation of the sizes of the PCR products, which reflect the number of VNTR copies. Results can be conveniently coded in a simple numerical format, corresponding to the number of repeated units in each locus. Initial VNTR typing based on limited sets of loci lacked discriminatory ability (55). However, a VNTR method based on 12 loci of a type of VNTR sequences called mycobacterial interspersed repetitive units (MIRUs) has been developed (89, 100). The 12 MIRU-VNTR loci present two to eight alleles which correspond to a potential of over 16 million different combinations. The method yields a discriminatory power close to that of IS*6110* RFLP typing (better for low-copy-number IS*6110* strains) and accurately clusters epidemiologically related strains (39, 56, 93, 99). The MIRU-VNTR method can be performed either in a manual format or on a fluorescence-based DNA analyzer with automation by using multiplex PCRs (99). A microfluidic labchip instrument has been used for rapid typing based on MIRU-VNTR (21). Thanks to its feasibility, portability, high reproducibility, and discriminatory power, the MIRU-VNTR technique is progressively replacing the IS*6110* RFLP method (9, 22, 53).

Whole-Genome Fingerprinting Methods

Promising results have been obtained with DNA arrays. The Affymetrix-GeneChip system has been applied to identify genomic deletions in *M. tuberculosis* isolates (46). It relies on the use of a high-density oligonucleotide microarray harboring 20 probe pairs targeted to every open reading frame and intergenic region of *M. tuberculosis* H37Rv, thus totaling 111,488 probe pairs after exclusion of noninformative probes. Hybridized DNA is detected with a confocal laser scanner. In a small-scale evaluation, the patterns of deletions detected were identical for epidemiologically related clones but differed between different clones, suggesting that the system is suitable for epidemiological studies (46). However, the system is not practical for analyzing large numbers of strains. High-density oligonucleotide microarrays will become commercially available to be used for clinical laboratory purposes in the future.

Single-nucleotide polymorphisms based on the synonymous mutations have been detected in *M. tuberculosis*. Since *M. tuberculosis* displays restricted allelic variation (94), the

TABLE 4 Characteristic spoligotypes of some MTBC members

Strain	Spoligotype[a]					
	1	9	19	29	39	43
M. tuberculosis H37Rv	■■■

increase in Crohn's disease has been reported stresses the potential exposure to aerosols carrying *M. avium* subsp. *paratuberculosis* and generated from the river (75).

M. kansasii Typing Methods

In Europe, the use of various molecular markers showed five subspecies within *M. kansasii* (3, 71). However, strains from the United States were shown to belong exclusively to subspecies I. These results demonstrate that subspecies I is predominant in the United States as it is in Europe and that this genotype I is highly clonal, with the same major genotype responsible for human infection worldwide (125).

Typing Methods for Other Slowly Growing NTM Species

For the other slowly growing species, information on the degree of polymorphism displayed by the different techniques is limited.

Molecular epidemiology of *M. intracellulare* can rely only on PFGE since the *M. avium* insertion sequences IS*1245* and IS*1311* are absent from all strains of *M. intracellulare* (35). Polymorphic PFGE patterns have been obtained for epidemiologically unrelated strains (62, 90).

IS*1395*, a specific insertion sequence, has been detected in *M. xenopi*. All *M. xenopi* strains have the element in 3 to 18 copies. Despite this high copy number, the element provides limited polymorphism, and unrelated strains were shown to share several bands in IS*1395* RFLP patterns. Comparable results were obtained with PFGE, suggesting high homogeneity of the *M. xenopi* genome (73).

Although rarely clinically significant, *M. gordonae* is a common laboratory contaminant and is frequently the cause of pseudo-outbreaks related to endoscopy, tap water, ice machines, or refrigerated fountains (118). Several molecular markers have been detected in *M. gordonae,* including the polymorphic GC-rich sequence (PGRS) and MPTR repetitive elements, also present in the MTBC and in *M. kansasii*, and two insertion sequences, IS*1511* and IS*1512*, which display high polymorphism (70). PFGE has also been successfully applied to *M. gordonae* (57).

The molecular epidemiology of *M. celatum* clearly differentiates *M. celatum* type 1 from *M. celatum* type 2 (69). A specific insertion sequence, IS*1407*, is present in *M. celatum* type 1 only. *M. celatum* type 2 displays polymorphic PFGE patterns, whereas *M. celatum* type 1 presents a single pattern.

A limited polymorphism was demonstrated within *M. haemophilum* with either a repetitive element in an RFLP study (50) or PFGE (123). Random amplification of polymorphic DNA typing also showed some polymorphism in *M. malmoense* (47). Two distinct repeated sequences, IS*2404* (83, 96) and IS*2406* (96), both present in high copy numbers (>50 copies), were identified in *M. ulcerans*. Interestingly, although comparative genetic analysis of *M. ulcerans* and *M. marinum* showed a very close phylogenetic relationship, both elements are absent from *M. marinum*. These data led to the hypothesis that *M. ulcerans* recently diverged from *M. marinum* by the acquisition of IS*2404* and IS2606, the species diversity being driven mainly by the genetic activity of the insertion sequences (96). Due to their high copy numbers, the two repeated elements are of poor value for typing *M. ulcerans* strains. Amplified fragment length polymorphism and IS*2404* RFLP analysis showed six types within *M. ulcerans* which correlated with the geographic origins of the strains (18). A novel-category VNTR allows the identification of eight genotypes within *M. ulcerans* and five genotypes within *M. marinum* (1, 98).

Mycobacterium: Clinical and Laboratory Characteristics of Rapidly Growing Mycobacteria*

BARBARA A. BROWN-ELLIOTT AND RICHARD J. WALLACE, JR.

38

TAXONOMY AND DESCRIPTION OF ORGANISMS

During the past 2 decades, there has been an increasing awareness of nontuberculous mycobacteria (NTM), including the rapidly growing mycobacteria (RGM), of which numerous species and phylogenetic groups are clearly established human pathogens. These include primarily the *Mycobacterium fortuitum* group; the *M. chelonae-M. abscessus* group, previously known collectively as the *M. fortuitum* complex; and to a lesser extent the *M. smegmatis* group. Three rare pathogens each belong to separate groups and have been associated with clinical disease: *M. mucogenicum*, *M. mageritense,* and *M. wolinskyi* (1, 4, 5, 47, 49, 64, 68).

The RGM are generally defined as nontuberculous species that grow within 7 days on laboratory media. Most clinically significant (pathogenic) species or groups are not pigmented. Only one pathogenic group (the *M. smegmatis* group) is pigmented, developing a slowly apparent or late pigment (4, 5, 68). All RGM contain long-chain fatty acids known as mycolic acids that can be quantitated using chromatographic techniques such as high-performance liquid chromatography (HPLC).

For many years, the *M. fortuitum* group comprised *M. fortuitum* (formerly *M. fortuitum* biovariant *fortuitum*), *M. peregrinum* (formerly *M. fortuitum* biovariant *peregrinum*), and the *M. fortuitum* third biovariant complex. Recent studies have shown that each of the latter two species comprise multiple additional species or "taxa" (47). *M. peregrinum* was found to contain two taxa originally designated *M. peregrinum* type I and type II (3). Taxonomic studies have now shown that isolates of *M. peregrinum* type II are human isolates of *M. senegalense* (60). In 1991, the third biovariant complex was described as containing two major subgroups (sorbitol positive and sorbitol negative) (63). In the last 7 years, seven new species have been identified from this "unnamed" complex. The sorbitol-positive subgroup currently consists of *M. houstonense, M. brisbanense,* and *M. mageritense*, and the sorbitol-negative subgroup consists of *M. porcinum, M. boenickei, M. neworleansense,* and *M. septicum* (28, 46, 47, 64, 65).

The *M. chelonae-M. abscessus* group is composed of at least three species, including *M. chelonae* (formerly *M. chelonae* subsp. *chelonae*), *M. abscessus* (formerly *M. chelonae* subsp. *abscessus*), and the newly described species *M. immunogenum* (5, 74).

The *M. smegmatis* group was initially described as composed of three species: *M. smegmatis* sensu stricto and two new species, *M. goodii* (4) and *M. wolinskyi* (4). Previously, these species were known as *M. smegmatis* types I, II, and III, respectively (68). This grouping was based on the absence of 3-day arylsulfatase activity in all three species. Current studies based on DNA sequence analysis suggest that *M. wolinskyi* is phylogenetically distinct from the other two species and likely belongs in a separate group (1).

M. mucogenicum, originally known as the *M. chelonae*-like organism, or MCLO, also constitutes a separate phylogenetic group distinct from all others, as does *M. mageritense* (1).

Unfortunately, many clinical laboratories do not take advantage of the new techniques for identifying isolates as identification of the RGM to the species level has traditionally been given low priority. This reluctance to provide identification to the species level partially reflects the lack of available simple, inexpensive, and accurate methods. Although combination analysis of results of biochemical tests, including those for carbohydrate utilization and susceptibility patterns, allows satisfactory identification of the majority of clinically significant isolates of RGM, these tests may be technically difficult to interpret and time-consuming for an inexperienced laboratory. Since no DNA probes are available in the United States for identification of the RGM and since HPLC alone cannot adequately identify most species of RGM, molecular testing by a reference laboratory is now necessary to accurately identify most of the 22 currently known pathogenic RGM to the species level.

CLINICAL SIGNIFICANCE

The RGM are opportunistic pathogens that produce disease in a variety of clinical settings. The three major clinically important species of RGM responsible for disease in humans include *M. fortuitum*, *M. chelonae,* and *M. abscessus*. Names of other potentially pathogenic and clinically significant RGM species have been included in Table 1 (4, 5, 47, 60, 64,

*This chapter contains information presented in chapter 36 by Gaby E. Pfyffer, Barbara A. Brown-Elliott, and Richard J. Wallace, Jr., and in chapter 37 by Véronique Vincent, Barbara A. Brown-Elliott, Kenneth C. Jost, Jr., and Richard J. Wallace, Jr., in the eighth edition of this Manual.

TABLE 1 Currently recognized species of RGM

Species	Characteristic				
	Established clinical significance	Pigmentation	Unique phenotype	Unique *hsp*65 REA pattern	Unique (complete) 16S sequence
Common human pathogens					
M. abscessus	Yes	No	No	Yes	Yes
M. chelonae	Yes	No	Yes	Yes	Yes

[a] *M. houstonense* is 100% identical to *M. farcinogenes*, and *M. peregrinum* (type I) is 100% identical to *M. septicum*.
[b] ND, not determined.
[c] RGM at 30°C, slowly growing at 35°C.
[d] Grows at 65°C.
[e] Grows on or degrades a variety of organic substrates.

65, 73, 74). RGM are presumed to be common in the environment but have been most often identified in tap water when associated with wound infections (15). The specific reservoir for *M. abscessus* chronic lung infections has yet to be identified.

Wound Infections

The most common infection seen with the RGM is posttraumatic wound infection. Aside from the injury, the patients are generally healthy, and drug-induced immune suppression is associated with minimal increase in risk for this type of infection. The *M. fortuitum* group accounts for approximately 60% of cases of localized cutaneous infections, but any of the 22 pathogenic RGM species listed in Table 1 can cause disease (4, 5, 60, 64, 65, 68, 73).

Traumatic wound infections, especially open fractures, often involve species within the *M. fortuitum* third biovariant complex (47, 63, 65). More than 75% of the infections reported in connection with a series of 85 isolates of the *M. fortuitum* third biovariant complex from the United States and the Queensland, Australia, state laboratory were associated with skin, soft tissue, or bone infections (63). The majority of infections occurred 4 to 6 weeks following puncture wounds or open fractures. Metal puncture wounds (48%) and motor vehicle accidents (26%) were the most common antecedent injuries, and approximately 40% of the injury sites involved the foot or leg. Stepping on a nail was the most frequently related scenario. None of the isolates in this series were studied by molecular techniques that would identify them as one of the newly described species within the *M. fortuitum* third biovariant complex (i.e., *M. houstonense, M. boenickei, M. porcinum,* or *M. mageritense*).

In a 1989 report (67), approximately 80% of RGM wound isolates related to cardiac surgery were from seven southern coastal states, including Texas, Louisiana, Georgia, Maryland, Alabama, Florida, and South Carolina. A second report published in the same year showed that 92% of 37 identified cases of surgical wound infection following augmentation mammaplasty were also in patients in southern coastal states, with the majority in Texas, Florida, and North Carolina (61).

Sporadic cases of localized wound infections following medical or surgical procedures, including needle injections, can occur with *M. chelonae* but are less common than those with *M. fortuitum*. The clinical picture of posttraumatic wound infection ranges from localized cellulitis or abscesses to osteomyelitis (70). Localized or disseminated infections with *M. chelonae* most frequently occur in patients receiving long-term corticosteroid treatment and/or chemotherapy, organ transplant recipients, and patients with rheumatoid arthritis or other autoimmune disorders or those receiving immunosuppressive therapy (62). However, immune suppression in diseases such as AIDS has not been a significant risk factor for development of localized or disseminated *M. chelonae* infections.

Less frequently, *M. wolinskyi* and the *M. smegmatis* group, including *M. goodii* and *M. smegmatis* sensu stricto, have been reported in cases of infection following traumatic injury and surgical or medical procedures such as cardiac surgery, breast reduction surgery, and face lift plastic surgery. Cellulitis and localized abscesses are the most common manifestations (4).

Starting in 2000, an outbreak of furunculosis caused by *M. fortuitum* on the lower extremities occurred in 32 otherwise healthy patients who were patrons of a nail salon in California. The organism was also cultured from contaminated foot baths, and shaving the legs prior to the foot bath and pedicure was identified as a risk factor (48, 75, 76). Other species, including *M. abscessus* and *M. mageritense*, have subsequently been recovered in other cases of furunculosis.

Pulmonary Infections

Chronic lung infections can occur with RGM, most often in nonsmoking older women with bronchiectasis (sometimes associated with the *M. avium* complex [MAC] as well). The causative agent in more than 80% of cases of pulmonary disease due to RGM is *M. abscessus* (24).

Similarities exist between patients infected with the MAC and those infected with *M. abscessus* such that a common pathogenicity or host susceptibility factor may be involved (24). Multiple cultures of *M. abscessus* from respiratory samples are usually associated with significant pulmonary disease.

Patients with cystic fibrosis (CF) may also become infected with *M. abscessus* (16, 37). Recovery of *M. abscessus* in this setting is being reported more frequently than previously. *M. abscessus* is the second most common species of NTM recovered from CF patients (after the MAC) and may be the most common species associated with clinical disease in this setting (37). Patients with CF also have bronchiectasis in addition to chronic, recurrent airway and parenchymal infections that may be the primary risk factors for susceptibility to NTM disease.

Rarely, other RGM, including *M. chelonae*, the *M. smegmatis* group, and *M. fortuitum,* can be involved in pulmonary disease. *M. fortuitum* has been reported as a pathogen in half of the

cases of chronic aspiration disease secondary to underlying gastroesophageal disorders such as achalasia (24). Pulmonary disease with *M. chelonae* and *M. smegmatis* has been described in only a few cases, including one case of lipoid pneumonia (4, 5, 58, 68, 70).

Hypersensitivity pneumonitis among metal grinders working in industrial plants with contaminated metalworking fluids has been associated with a newly described species of RGM, *M. immunogenum*. This species is able to grow and remain viable in degraded metalworking fluid (74). This species has not been reported to be recovered from open lung biopsy specimens from these patients.

Disseminated Cutaneous Disease

Disseminated cutaneous disease due to members of the *M. fortuitum* group (including *M. fortuitum*) is rare even in immunocompromised patients, including those with AIDS (5, 7, 70). In the modern taxonomic era, we have seen fewer than five well-documented cases of disseminated cutaneous disease due to *M. fortuitum*.

Disseminated cutaneous disease due to *M. chelonae* is much more common. It typically presents as multiple, chronic, painful red nodules, usually involving the lower extremities. These lesions then drain spontaneously, with the drainage usually acid-fast bacillus smear positive. Almost all patients are immunosuppressed, usually from low-dose corticosteroid therapy for diseases such as rheumatoid arthritis and other autoimmune diseases or organ transplantation. Although the disease is presumably a consequence of hematogenous spread, bacteremia is rarely identified. A portal of entry for the pathogen is rarely evident (5, 62, 71). For a series of 100 clinical isolates from skin and soft tissue, it was reported that 53% were from patients with disseminated cutaneous infections (62). Approximately 75% of cases of disseminated cutaneous infection are due to *M. chelonae,* and about 20% are due to *M. abscessus* (5, 70). Disseminated disease involves other sites (blood and internal organs) only in severely immunosuppressed individuals, although immune suppression such as that occurring with AIDS has not been a significant risk factor for the development of disseminated cutaneous or extracutaneous disease.

Disseminated cutaneous disease due to *M. abscessus* occurs rarely but is serious (70). Like those of disseminated *M. chelonae* disease, most cases occur in chronically immunosuppressed patients receiving corticosteroids, and the pathogen has no apparent portal of entry. Also like those of *M. chelonae* infection, cases of *M. abscessus* disseminated cutaneous infection rarely involve detectable bacteremia and/or endocarditis, but patients usually present with multiple draining cutaneous nodules, usually in the lower extremities.

Health Care-Associated Infections

Health care-associated disease with the RGM has been reported most commonly with *M. fortuitum*, *M. chelonae*, *M. abscessus*, and *M. mucogenicum*, although any species may be involved. Most infections follow contamination with tap water harboring the infecting RGM. Types of infections include postsurgical wound infections, catheter sepsis, infections following hemodialysis (27, 61, 70, 72), postinjection abscesses, vaccine-related outbreaks (5, 11, 22, 55, 57, 61), and otitis media following tympanostomy tube replacement (21). These have been seen as both sporadic cases and localized outbreaks. Recent outbreaks have involved cosmetic procedures such as liposuction (35) and infections following nail salon procedures (23, 48, 75, 76).

Central catheter-associated infections are the most common health care-associated infections due to the RGM (5, 43, 46, 70). They are the most common cause of RGM bacteremia, but the disease may also present as local wound drainage as part of an exit site or tunnel infection (5, 28, 43). Other types of catheters, including peritoneal catheters, ventriculoperitoneal shunts, and shunts for hemodialysis, can also become infected (5).

Surgical wound infections due to RGM are a well-recognized clinical entity. In the 1970s and 1980s, these were most commonly associated with augmentation mammaplasty and coronary artery bypass surgery, and multiple disease outbreaks occurred (57). Infections following these types of surgery are now less common, and mastectomies for breast carcinoma, liposuction, and knee replacements have replaced these procedures as the most common causes of disease.

Infections following the insertion of prosthetic devices, including prosthetic heart valves, artificial knees and hips, lens implants, and metal rods inserted into the vertebrae to stabilize bones following fractures, have also been described (4, 5, 70). Again, *M. fortuitum* is the most common pathogen, but any of the pathogenic RGM, including the *M. smegmatis* group, can be associated with this type of infection (4, 5). The infection usually presents with watery drainage, wound breakdown, and low-grade fever.

In addition to true outbreaks of infection, numerous health care-associated pseudo-outbreaks have been described. Contaminated or malfunctioning bronchoscopes (5, 25, 57), automated endoscope cleaning machines (33, 57, 61, 74), and contaminated laboratory reagents and ice (27, 31) have been implicated (61).

Bone and Joint Infection

Infection with the RGM may also result in bone and joint infection. Like bacterial disease, osteomyelitis may follow open bone fractures, puncture wounds, and hematogenous spread from another source. The most common scenario is an open fracture of the femur, often followed by orthopedic surgical procedures. The most frequent pathogen recovered in this setting is the *M. fortuitum* group, including two newly described species, *M. houstonense* and *M. boenickei* (5, 47).

Vertebral osteomyelitis has also been described (40, 45). Sarria and colleagues identified 15 cases, and clinical information was available for six of the cases. Four of the six cases of RGM vertebral osteomyelitis involved *M. fortuitum,* and all of the patients had some type of underlying condition (45).

Bone involvement secondary to a puncture wound is likely the second major cause of osteomyelitis. Infections most commonly involve the *M. fortuitum* group (5, 58, 59). *M. fortuitum* infections associated with prosthetic knees and joints have also been reported.

The two newly described species, *M. goodii* and *M. wolinskyi,* have also been associated with osteomyelitis. In a recent report, 13 (36%) of 36 patients with infection caused by these two species were diagnosed with osteomyelitis (4).

Generally, osteomyelitis due to RGM is treated with surgical debridement and antimicrobial therapy for a minimum of 6 months (5, 66).

MISCELLANEOUS DISEASES

Other diseases associated with the RGM are summarized in the following paragraphs.

CNS Disease

Central nervous system (CNS) disease involving the RGM is rare, but morbidity and mortality are high. Most of the reported cases have been associated with *M. fortuitum* (5, 12). In a review by Flor et al., 52 isolates of NTM were reported that were associated with meningitis, of which 12% were identified as *M. fortuitum* (19).

Treatment of CNS infections due to RGM is difficult and often requires extended multiple-antimicrobial treatment (6 to 12 months) in addition to surgical intervention (5).

Corneal Infections (Keratitis)

The number of RGM recovered from ocular infections has been increasing over the last 20 years. A retrospective review of cases of NTM keratitis from 1982 to1997 at an eye institute in Florida showed that 19 of 24 cases were due to RGM (20).

A review of the literature involving keratitis due to the NTM from 1965 to 1992 found that 21 (55%) of 38 isolates were identified as *M. fortuitum*, 16 (42%) of 38 belonged to the *M. chelonae-M. abscessus* group, and 1 (2%) was identified only as "group IV mycobacteria." However, prior to 1978, isolates from all of the cases reported were incompletely identified as "*M. fortuitum,*" so it is not possible to ascertain modern species classifications (6).

Since the early 1990s, other descriptions of eye infections associated with the RGM have been published, including cases occurring after keratoplasty and laser in situ keratomileusis (LASIK) surgery (5).

Corneal infections have an indolent course, and often scraping or biopsy following debridement of the epithelial layer is necessary to obtain appropriate specimens for culture. Treatment of patients with keratitis due to RGM is difficult. The most widely used antimicrobial treatment involves the use of topical aminoglycosides and/or systemic amikacin, gentamicin, kanamycin, or neomycin. Other topical therapies have also included clarithromycin drops for infections due to *M. abscessus* or *M. chelonae,* tobramycin for infections due to *M. chelonae,* and ciprofloxacin for infections due to the *M. fortuitum* group. However, most of these antimicrobials have been shown to penetrate poorly through intact corneal epithelium (5, 6).

For patients who do not respond to topical treatments, surgical intervention including penetrating keratoplasty, corneal graft, lamellar keractectomy, and/or superficial debridement is recommended and was required in the majority of the previously reviewed cases (20).

Cervical Lymphadenitis

Although the most common mycobacterial cause of lymphadenitis is *M. tuberculosis* in adults and the MAC in children, RGM have also been implicated. At least 19 cases of cervical lymphadenitis due to *M. fortuitum* have been reported in the literature. Details were not available for all of the cases reviewed (10, 70). The majority of the patients responded to therapy with either complete resolution or significant decrease in the sizes of the affected lymph nodes (10).

Treatment for RGM lymphadenitis usually involves incision and drainage, followed by a combination of antimicrobials that includes an initial course of intravenous amikacin and concludes with one or more oral antibiotics. The recommended duration of therapy is at least 6 months (5, 10, 66).

Otitis Media

The most common NTM species associated with chronic otitis media is *M. abscessus*. In a 1988 outbreak of 17 cases of otitis media in two ear-nose-throat clinics, patients presented with chronic ear drainage, with a perforated tympanic membrane and prior insertion of a tympanostomy tube (32). In another series of infections, 20 of 21 cases of sporadic chronic otitis media (some with associated mastoiditis) were due to *M. abscessus* following ear tube placement. Therapy included removal of the ear tubes, surgical debridement, and antibiotic therapy including initial amikacin for susceptible isolates and either cefoxitin or imipenem for 3 to 6 weeks, followed by long-term oral therapy with erythromycin (preclarithromycin era) or clarithromycin. Approximately one-half of the isolates from these cases were also aminoglycoside resistant, resulting from the long-term use of aminoglycoside ear drops (21).

Otitis media or mastoiditis due to RGM other than *M. abscessus* has been infrequently reported (70).

IDENTIFICATION OF RGM

Collection, Transport, and Storage of Specimens

Details of standard methods for collection, transport, and storage of specimens are included in chapter 20.

Direct Examination and Isolation Procedures

Direct examination and isolation procedures are generally detailed in chapter 36. Primary isolation of RGM requires culture at 28 to 30°C rather than 35°C for wound cultures, especially for recovery of *M. chelonae*.

Biochemical Testing

As previously stated, the RGM are defined as NTM that grow within 7 days (most species within 3 to 4 days) (41, 56). Until the advent of molecular techniques, conventional laboratory identification of the RGM was based primarily upon growth rate, pigmentation, colonial morphology, and results of selected biochemical tests. These standard tests include those for arylsulfatase production, tolerance to 5% NaCl, nitrate reductase activity, and iron uptake. All members of the *M. fortuitum* group and the *M. chelonae-M. abscessus* group exhibit a strongly positive arylsulfatase reaction at 3 days (5, 41, 56). The *M. smegmatis* group (*M. smegmatis* and *M. goodii*) and *M. wolinskyi* are similar in growth rates but do not exhibit arylsulfatase activity at 3 days (4, 68). Approximately 95% of the isolates of *M. smegmatis* (sensu stricto) and 80% of *M. goodii* isolates develop a late (7 to 10 days) yellow-orange pigmentation. *M. wolinskyi* differs from the other two species in that it remains nonpigmented (4, 68).

Previously, a study by the former International Working Group on Mycobacterial Taxonomy (30) showed that growth in 5% NaCl was discriminatory for *M. abscessus* and *M. chelonae*. In this study, 100% of the isolates of *M. abscessus* grew in the presence of 5% NaCl but only 17% of the isolates of *M. chelonae* were viable in the same medium. The same study also reported that *M. abscessus* isolates were citrate negative and that 100% of *M. chelonae* isolates grew in the presence of citrate as a sole carbon source (30). These data have subsequently been corroborated by other investigators (4, 77).

Routine conventional testing has generally proven inadequate for recognition of other established species of RGM, such as *M. peregrinum,* and is definitely lacking for identification of most of the newly described species of RGM (4, 5, 47, 74).

Supplemented Biochemical Testing: Carbohydrate Utilization

The supplementation of the standard biochemical tests with a test for the utilization of carbohydrates (mannitol, inositol, sorbitol, rhamnose, and citrate) (Table 2) has allowed more complete and accurate laboratory identification of established species and discrimination of some (but not all) newly described species (5, 56, 59). It is no longer acceptable to fail to identify RGM isolates to the species level, especially isolates considered to be clinically significant. This differentiation is most critical for *M. chelonae* and *M. abscessus* (5).

One point that should be emphasized is that many of the studies involving carbohydrate utilization by the RGM have been performed with media prepared in-house. There have been few studies of currently available commercial media to ascertain if these will provide equivalent results. With this in mind, the use of commercial products will require careful in-house validation. One example of this problem was noted by Conville and Witebsky in the identification of strains of *M. mucogenicum* by using commercially manufactured carbohydrates (14).

Antimicrobial Susceptibility Tests

As discussed above, other adjunctive nonmolecular tests, including antimicrobial susceptibility tests, have also been utilized for the identification of the RGM. The polymyxin B disk diffusion method is used to distinguish between the *M. fortuitum* group and the *M. chelonae-M. abscessus* group. Generally, isolates of the *M. fortuitum* group exhibit a partial or clear zone of inhibition of ≥10 mm around the polymyxin disk whereas isolates of the *M. chelonae-M. abscessus* group show no zone of inhibition (69). Isolates of the *M. fortuitum* group are usually susceptible to a broader range of antimicrobials, including amikacin, quinolones, sulfonamides, linezolid, and imipenem. Most of the isolates of this group appear to be intrinsically resistant to the macrolides through the presence of an inducible *erm* gene (36).

Although originally considered to be two subspecies within one species, *M. chelonae* and *M. abscessus* are in fact two separate species, and infections with these species have distinctly different clinical manifestations. *M. chelonae* is most often associated with skin and soft tissue infections, especially in patients receiving chronic steroid therapy (62), and is rarely a cause of chronic lung disease (24, 70). *M. abscessus* may also cause skin and soft tissue infections but is primarily a lung pathogen, being responsible for more than 80% of the chronic lung disease cases caused by RGM (5, 24, 70). Thus, it is extremely important to differentiate these RGM to the species level and perform susceptibility testing so that appropriate antibiotic therapy can be initiated (5, 66).

M. chelonae and *M. abscessus* also have different antimicrobial susceptibility patterns. One of the major differences between the two species is in resistance to cefoxitin. In agar disk diffusion tests, *M. chelonae* shows complete resistance to cefoxitin, with no partial or complete zones of inhibition, in contrast to the partial or complete zones of inhibition seen with *M. abscessus*. MICs of cefotoxin for isolates of *M. chelonae* are ≥ 256 μg/ml. *M. abscessus* is intermediately susceptible; modal MICs for *M. abscessus* isolates are 32 μg/ml. MICs of amikacin for isolates of *M. abscessus* are also lower, and *M. abscessus* is resistant to tobramycin, whereas tobramycin is more active than amikacin against *M. chelonae*. Additionally, isolates of *M. chelonae* are more susceptible in vitro to some of the newer antibiotics, including linezolid and gatifloxacin, than are isolates of *M. abscessus* (5).

With these differences in susceptibility patterns of the rapidly growing species in mind, tentative identification of the most commonly encountered species of RGM is possible and optimal therapeutic regimens can be designed. However, as with other phenotypic tests, susceptibility testing does not provide definitive species identification, which currently requires molecular testing for almost all RGM species (5).

HPLC Identification

HPLC analysis of mycobacterial cell wall mycolic acid content is routinely used in large reference or state health department laboratories to identify isolates of NTM (9, 53) but has been problematic with species of RGM (9).

HPLC can be helpful for placing RGM into groups but is not specific enough to identify them to the species level with a high degree of accuracy, even with the adoption of standardized growth conditions. Thus, laboratory identification based on HPLC analysis of mycolic acid profiles alone is not adequate for the identification of the pathogenic species of RGM.

MOLECULAR IDENTIFICATION METHODS

Nucleic Acid Probes

The INNO LiPA multiplex probe assay (Innogenetics, Ghent, Belgium) is a molecular biology-based product available outside the United States and utilizes the principle of reverse hybridization (54, 56). Biotinylated DNA obtained by PCR amplification of the 16S-23S internal transcribed spacer region is hybridized with specific oligonucleotide probes immobilized as parallel lines on membrane strips. The addition of streptavidin labeled with alkaline phosphatase and a chromogenic substrate results in a purple-brown precipitate on the hybridized lines. This system was evaluated with multiple species of mycobacteria, including some RGM. The main advantage of this system is that a large variety of species may be identified by a single assay without the need to select an appropriate probe. One limitation of the assay is the cross-reactivity that may be detected with strains of *M. fortuitum* (54, 56). Additionally, it failed to differentiate isolates of *M. chelonae* from those of *M. abscessus*.

Sequence Analysis Identification of RGM

16S rRNA Gene Sequence Analysis

Slowly growing mycobacterial species, with some exceptions such as *M. terrae,* contain one copy of the 16S rRNA operon, whereas the RGM, except for *M. chelonae* and *M. abscessus*, have two copies (2, 18). Routine sequencing of the entire 1,500-nucleotide sequence of the 16S rRNA gene is not feasible for most clinical laboratories. Two main hypervariable domains known as region A and region B are located on the 5′ end of the 16S rRNA gene. These regions correspond to the *Escherichia coli* positions 129 to 267 and 430 to 500, respectively. Hypervariable region A, especially, contains most of the species-specific sequence variations (so-called "signature sequences") in mycobacterial species, and sequencing of this region allows taxonomic identification of most mycobacteria, including most species of RGM (26, 29).

The MicroSeq 500 system (Applied Biosystems, Foster City, Calif.) analyzes approximately 500 bp of the 16S rRNA gene at the 5′ end, including hypervariable region A. Previous studies showed that the MicroSeq assay was able to identify

TABLE 2 Laboratory phenotypic features of the 15 most clinically important species of nonpigmented RGM[a]

Species or complex	Former designation(s)	Pigment	3-Day arylsulfatase	Nitrate reduction	Iron uptake	Carbohydrate utilization				Growth in 5% NaCl
						Mannitol	Inositol	Citrate	Sorbitol	
M. chelonae-M. abscessus group										
M. abscessus	*M. chelonae* subsp. *abscessus*	−	+	−	−	−	−	−	−	+

[a] +, ≥90%; −, <10%; ±, 11 to 89% or late.
[b] *M. peregrinum* (type 1) has the same REA pattern as the *M. fortuitum* third biovariant (sorbitol negative), whereas *M. peregrinum* (type 2) has the same REA pattern as *M. houstonense* (*M. fortuitum* third biovariant [sorbitol positive]). Biochemical testing is necessary for differentiation of these species.
[c] Tan appearance.

most isolates of RGM to the species level (13, 26, 39). Of the discordant isolates, 61% were unusual isolates that were difficult to identify by phenotypic methods and 56% could not be identified using molecular methods. MicroSeq is limited by the fact that analysis of the first 500-bp sequence cannot discriminate between several closely related RGM species, including *M. chelonae* and *M. abscessus, M. houstonense* and *M. senegalense, M. peregrinum* and *M. septicum,* and *M. houstonense* and *M. farcinogenes* (26, 60). Another major limitation of the MicroSeq system is that the database contains only one entry per species (the type strain). This is especially problematic with isolates that do not have an exact match in the database. Newly reported species are often not in the database. Therefore, the MicroSeq 500 system requires the use of additional sequence databases (13).

A reporting criterion such as (i) distinct species, (ii) related to a species, or (iii) most closely related to a species, depending upon the amount of sequence difference between the unknown isolate and the 16S rRNA gene database entries (39), has been recommended but not validated. This is important as currently there is no standard recommendation for a cutoff value used to interpret sequencing data (13, 26, 39).

Finally, the expense of the MicroSeq assay prevents its application in many clinical laboratories (26).

Sequencing of the *hsp65* Gene

Although the gene for the 65-kDa heat shock protein *(hsp*65*)* is highly conserved among species of mycobacteria, it exhibits greater interspecies and intraspecies polymorphism than the 16S rRNA gene sequence. This variability can be advantageous in the development of other strategies for the identification of genetically related species of the RGM (44, 54). Like most genes, it has both highly conserved and highly variable nucleotide regions (42). Most sequencing or restriction fragment length polymorphism analysis has utilized a 441-bp sequence identified by Telenti et al. (51) and often referred to as the Telenti fragment.

Studies based on DNA sequencing have demonstrated interspecies allelic diversity within the RGM (38). Detailed studies of several RGM species including *M. peregrinum*, *M. porcinum, M. senegalense, M. chelonae,* and *M. abscessus* have shown four to six sequence variants (sequevars) per species that differ by 2 to 6 nucleotides within the 441-bp Telenti fragment (44, 60, 65).

Additionally, unlike 16S rRNA gene sequence analysis, the *hsp*65 sequencing method was easily able to differentiate isolates of *M. abscessus* from those of *M. chelonae* (they differ by almost 30 bp in the 441-bp *hsp65* sequence compared to only 4 bp in the entire 1,500-bp 16S rRNA gene sequence). In contrast to 16S rRNA gene sequences, sequences of the *hsp65* gene allow even RGM species with a high degree of 16S rRNA gene similarity, such as *M. fortuitum, M. septicum, M. peregrinum, M. houstonense*, and *M. senegalense,* to be distinguished as distinct species (60).

A limitation of sequencing of the *hsp65* gene is that few or no sequences from more recently described RGM species are available in databases and detailed sequencing of older species (i.e., multiple strains) has not been done so only one sequence per species is generally available. This means that in-house validation is essential (34).

PCR-REA of the *hsp65* Gene

PCR-restriction enzyme analysis (PCR-REA) of the gene for the 65-kDA heat shock protein *(hsp)* has become a valuable tool used in the identification of the RGM.

The advantage of REA nonsequencing of the *hsp65* gene is that minor differences (sequevars) within the species rarely involve a restriction site, so most species have only one REA pattern. REA requires less equipment expenditure than sequencing. However, as in sequencing, the system is only as good as its database. Also, there is no commercial system for *hsp65* REA. Ten taxonomic groups of RGM were initially evaluated (a total of 129 reference and clinical isolates of RGM) with 24 restriction endonucleases, and BstEII, HaeIII, CfoI, and AciI were found to give the best species separation (50). A number of additional RGM species were described after this study, and most have shown unique or identifying restriction fragment length polymorphism patterns by this method. These species include *M. immunogenum* (74), *M. mageritense* (64), *M. porcinum* (47, 65), *M. boenickei* (47), *M. goodii* (4), *M. wolinskyi* (4), *M. septicum* (47), and *M. senegalense* (60). Species that could still not be separated include *M. houstonense* and *M. neworleansense* (47). Algorithms for identification of mycobacterial species including RGM by using PCR-restriction fragment length polymorphism analysis of the *hsp65* gene have been proposed (17).

Thus, currently the 441-bp Telenti fragment of the *hsp*65 gene remains the most useful sequence for REA identification of the RGM, although it has not been evaluated extensively in the pigmented RGM (4, 50, 51). The advantages of REA are that the method of identification does not rely upon growth rate and nutritional requirements, the equipment is relatively inexpensive, and the results for a large number of mycobacterial species can be generated rapidly. The disadvantages are that it requires knowledge of PCR and is a relatively complex procedure that requires extensive in-house validation since the method is not approved by the Food and Drug Administration.

Sequencing of Other Secondary Gene Targets

Other molecular targets for taxonomic identification, including the gene encoding the 32-kDA protein, the superoxide dismutase gene *(sod),* the *dnaJ* gene, the *rpoB* gene, the 16S-23S rRNA internal transcribed spacer, the *secA1* gene, and the *recA* gene, have been suggested for mycobacterial identification utilizing either REA or direct sequencing (1, 60, 65). However, preliminary data suggest that the sequences of these genes are more variable than that of the *hsp65* gene and to date these sequences have been less commonly utilized in the laboratory identification of the species of RGM (1, 56, 60, 65).

Molecular Typing Methods

PFGE

Pulsed-field gel electrophoresis (PFGE) is the most widely used method for molecular strain typing of the RGM. Although PFGE has never been standardized for RGM, most investigators concur that small (2- to 3-band) differences between isolates indicate that the isolates are closely related; differences of 4 to 6 bands indicate that the strains are possibly related, and ≥7-band differences indicate that the isolates are genetically different (52). Because unrelated strains of most RGM contain highly diverse PFGE patterns, this technique has been useful in epidemiological investigations. With recent modifications of the original method, it is now possible to perform PFGE on all species of RGM (79).

Clinical usage of PFGE for genetic comparison of *M. fortuitum* strains was detailed in a report of an outbreak

of respiratory tract colonization with this species in an alcoholism rehabilitation ward in Washington, D.C. (8). Since that report, several other epidemiological investigations of RGM by using PFGE have been performed (27, 33, 35, 72, 79).

RAPD-PCR

In the random amplified polymorphic DNA PCR (RAPD-PCR) using one arbitrary primer and low-stringency conditions, the primer hybridizes to both strands of template DNA, where it is matched or partially matched, resulting in strain-specific heterogeneous DNA products. Zhang and colleagues (78) applied the RAPD-PCR or arbitrarily primed PCR analysis method to comparing strains of *M. abscessus*. They were able to confirm several previous observations about prior outbreaks of nosocomial RGM infection, including a 1988 epidemic of otitis media due to aminoglycoside-resistant *M. abscessus* in children who had previously received tympanostomy tubes (32) and an outbreak associated with cardiac surgery (67).

The need for RAPD-PCR for strain typing of *M. abscessus* is now reduced as recent studies have shown the use of thiourea to prevent the DNA lysis that related to the Tris-borate-EDTA in the PFGE running buffer (79). Whether RAPD-PCR is less or more discriminatory as a typing method than PFGE for RGM has not been established.

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

The major species of RGM each have different virulence levels in different clinical settings, and they have different drug susceptibilities as well. *M. mucogenicum*, e.g., is a recognized cause of catheter sepsis but, when recovered from sputum, is usually a contaminant. Thus, all clinically significant RGM should be identified to the species level. The recommended species identification methods are evolving, with declining interest in and accuracy of phenotypic testing, including HPLC, and increasing availability and accuracy of molecular methods. Currently, molecular methods are preferred and generally are the only way to identify more recently described species such as *M. goodii, M. mucogenicum,* and *M. senegalense*. Phenotypic tests are still useful (e.g., citrate utilization to separate *M. chelonae* from *M. abscessus*) but work best when combined with molecular methods. Smaller labs should consider referring RGM isolates to a large reference laboratory.

*Neisseria**

WILLIAM M. JANDA AND CHARLOTTE A. GAYDOS

39

TAXONOMY OF THE GENUS *NEISSERIA*

At this time, members of the genus *Neisseria* are classified in the family *Neisseriaceae* along with the genera *Kingella*, *Eikenella*, *Simonsiella*, and *Alysiella*. This family is now placed in the β-subgroup of the Phylum *Proteobacteria*.

DESCRIPTION OF THE GENUS *NEISSERIA*

Members of the genus *Neisseria* are coccal or rod-shaped gram-negative organisms that occur in pairs or short chains. Diplococcal species have adjacent sides that are flattened, giving them a "coffee bean" appearance. Currently, *Neisseria* species (except the three *N. elongata* subspecies and *N. weaveri*) are the only true coccal members of the family *Neisseriaceae*. *N. elongata* subspecies and *N. weaveri* are medium to large, plump rods that appear in gram-stained smears as pairs or short chains (5, 51). All species in the genus *Neisseria* inhabit the mucous membrane surfaces of warm-blooded hosts. These organisms are aerobic and nonmotile and do not form spores; most species grow optimally at 35 to 37°C. Growth of *Neisseria* species is stimulated by CO_2 and humidity; some gonococcal isolates have an obligate requirement for CO_2 for initial isolation and growth of subsequent subcultures. Those *Neisseria* species that produce acid from carbohydrates do so by an oxidative pathway. All members of the genus are oxidase positive and, except for *N. elongata* subspecies *elongata* and subspecies *nitroreducens*, are catalase positive.

While most *Neisseria* species are not exacting in their nutritional requirements for growth, the pathogenic species, and *N. gonorrhoeae* in particular, are more nutritionally demanding. *N. gonorrhoeae* does not grow in the absence of cysteine and a usable energy source (i.e., glucose, pyruvate, or lactate). Some gonococcal strains display requirements for specific amino acids, pyrimidines, and purines as a result of defective or altered biosynthetic pathways. Demonstration of these growth requirements forms the basis for a typing method for gonococci called auxotyping (see below). The neisseriae can grow under anaerobic conditions if an alternative electron acceptor (e.g., nitrites) is present.

* This chapter contains information presented in chapter 38 by William M. Janda and Joan S. Knapp in the eighth edition of this Manual.

EPIDEMIOLOGY AND TRANSMISSION

N. gonorrhoeae is the causative agent of gonorrhea. In the United States, the incidence of gonorrhea increased during the 1960s and early 1970s, with the highest incidence—over 460 cases per 100,000 population—occurring in 1975. From the mid-1980s and into the 1990s, the incidence of gonorrhea steadily declined. In 1994, reported cases of *Chlamydia trachomatis* infection exceeded reported cases of gonococcal infection for the first time. The decline in the incidence of gonorrhea ceased toward the mid-1990s; from 1998 to 2002, the incidence of gonococcal infections plateaued at 128 to 130 cases per 100,000. In the United States, the incidence of gonorrhea remains high among sexually active teenagers and young adults, with the highest attack rates found among 15- to 19-year-old women (34). In regions where collected statistics include sexual orientation, rates of gonococcal infection more than tripled from 1995 to 2003 among men who have sex with other men (MSM) (30). Maintenance and transmission of gonorrhea are related to a social subset of "core transmitters" who have unprotected intercourse with multiple new partners and either are asymptomatic or choose to ignore symptoms (91). Both social risk factors (i.e., low socioeconomic status, urban residence, lack of education, poor access to health care, unmarried status, race/ethnicity, male homosexuality, prostitution, and histories of other sexually transmitted diseases) and behavioral risk factors (i.e., unprotected intercourse, multiple partners, other high-risk partners, and drug use) have been identified for targeting by outreach/intervention and sexually transmitted disease control programs.

The risk of acquiring gonorrhea is multifactorial and is related to the number and sites of exposure. For heterosexual males, the risk of acquiring urethral infection from an infected female is about 20% for a single exposure and up to 80% for four exposures. Due to anatomical considerations, the risk of infection for females from a single exposure to an infected male is about 50 to 70% (69). Anogenital sexual contact resulting in rectal infection is also efficient, and studies among MSM have demonstrated that urethral infection following fellatio with an infected partner may account for up to 26% of urethral infections diagnosed in this population (68).

N. meningitidis causes a disease spectrum ranging from occult sepsis with rapid recovery to fulminant fatal disease. The major virulence factor of disease-associated meningococci is the polysaccharide capsule. Thirteen meningococcal

capsular polysaccharide serogroups (A, B, C, D, H, I, K, L, X, Y, Z, W135, and 29E) have been described, and most infections are caused by organisms belonging to serogroups A, B, C, Y, and W135. Meningococci cause epidemic and endemic meningitis, and serogroups A, B, and C are responsible for 90% of cases globally. Humans are the only natural host for *N. meningitidis,* and the organism is spread from person to person via the respiratory route. Meningococci also may be carried asymptomatically in the oropharynx and nasopharynx. Carriage rates range from about 8 up to 20%, with older children and young adults having higher rates than young children. Carriage may be transient, intermittent, or persistent (105). Carriage strains may be encapsulated (groupable) or nonencapsulated (nongroupable) and result in the formation of serogroup-specific antibodies and broadly cross-reactive antibodies against several other outer membrane antigens. Individuals colonized with nongroupable strains also develop antibody titers against groupable strains, probably due to shared antigenic determinants. This immune response does not eliminate carriage, but it may protect the host from overt disease.

Worldwide, pathogenic clones of *N. meningitidis* composed of different serogroups, serotypes, serosubtypes, and immunotypes are responsible for both endemic and epidemic disease (95). Endemic meningococcal disease occurs at rates of 1 to 3 cases per 100,000 persons in the United States, and in 10 to 25 cases per 100,000 persons in developing countries (95, 100). In the United States, the annual incidence of meningococcal disease has been 0.8 to 1/100,000 population, with infants, the elderly, and the immunocompromised being at greatest risk. Attack rates are highest among children aged 3 months to 1 year and among older teenagers and young adults. Changes in meningococcal epidemiology in the United States during the 1990s have included increases in the incidence of community-acquired serogroup C infections and an increased incidence of disease among teenagers and young adults of high school and college age (54). Outbreaks on college campuses have been associated with bar patronage, drinking, cigarette smoking, and dormitory residence (57). Substantial amounts of meningococcal disease have also been reported among non-first-year students and students living in off-campus housing. With the licensure of the new tetravalent (serogroups A, C, Y, and W135) meningococcal conjugate vaccine (Menactra; Sanofi Pasteur, Inc., Swiftwater, Pa.) in January 2005, the Advisory Committee on Immunization Practices now recommends routine vaccination of adolescents aged 11 to 12 years, and for those past this age, routine immunization before entry into high school or college (29). With this approach, all adolescents will receive either the tetravalent polysaccharide or tetravalent conjugate meningococcal vaccine beginning at age 11 years by the year 2008.

CLINICAL SIGNIFICANCE

Members of the genus *Neisseria* that are found in humans include *N. gonorrhoeae*, *N. meningitidis*, *N. lactamica*, *N. sicca*, *N. subflava* (biovars subflava, flava, and perflava), *N. mucosa*, *N. flavescens*, *N. cinerea*, *N. polysaccharea*, and *N. elongata* subspecies *elongata*, *glycolytica*, and *nitroreducens*. *N. gonorrhoeae* subspecies *kochii*, an extremely rare isolate, has no official taxonomic standing. *N. canis* and *N. weaveri* are found as part of the normal respiratory tract flora of dogs, *N. denitrificans* is present in the respiratory tract of guinea pigs, and *N. macacae*, *N. dentiae*, and *N. iguanae* constitute part of the oral flora in rhesus monkeys, cows, and iguanid lizards, respectively. Most human *Neisseria* species are normal inhabitants of the upper respiratory tract and are not considered pathogens; occasionally these organisms may be isolated from infections, particularly in settings of underlying disease and/or immunosuppression. *N. gonorrhoeae* is always considered a pathogen, regardless of the site of isolation. *N. meningitidis* causes significant and often life-threatening disease but may colonize the nasopharynx without causing disease.

In males, *N. gonorrhoeae* causes an acute urethritis with dysuria and urethral discharge. The incubation period averages 2 to 7 days. After this time, 95 to 99% of infected males experience a purulent urethral discharge. About 2.5% of men presenting to sexually transmitted disease clinics are asymptomatic; the prevalence of asymptomatic urogenital gonorrhea in males in the general population may be as high as 5%. If left untreated, most cases of gonorrhea in men resolve spontaneously. Complications of ascending infection are uncommon and include epididymitis, penile lymphangitis, acute prostatitis, periurethral abscess, seminal vesiculitis, infections of the Tyson's and Cowper's glands, and urethral stricture.

In females, the primary gonococcal infection is present in the endocervix, with concomitant urethral infection occurring in 70 to 90% of cases. After an incubation period of 8 to 10 days, women may present with cervicovaginal discharge, abnormal or intermenstrual bleeding, and abdominal/pelvic pain. Gonococcal infection of the vaginal squamous epithelium of postpubertal women is uncommon, and in women with hysterectomies, the urethra is the most common site of infection. Symptoms of uncomplicated endocervical gonorrhea may resemble other conditions, such as cystitis or vaginal infections. Infection of Bartholin's and Skene's glands may occur in about one-third of women with genital infections, and careful manipulation of these glands can sometimes provide purulent material for direct examination and culture. Endocervical gonorrhea may complicate pregnancy and is a cofactor for spontaneous abortion, chorioamnionitis, premature rupture of membranes, premature delivery, and infant morbidity. Infants born to women with gonorrhea are at risk for developing conjunctival ("ophthalmia neonatorum") or pharyngeal gonococcal infection. Ascending infection may occur in 10 to 20% of infected women and can result in acute pelvic inflammatory disease (PID) manifested as salpingitis (infection of the fallopian tubes), endometritis, and/or tubo-ovarian abscess, all of which can result in scarring, ectopic pregnancies, sterility, and chronic pelvic pain (15). Symptoms of gonococcal PID include lower abdominal pain, abnormal cervical discharge and bleeding, pain on motion, fever, and peripheral leukocytosis. PID caused by *N. gonorrhoeae* generally occurs early in infection and often during or shortly after the onset of menstruation.

N. gonorrhoeae may also cause pharyngeal and anorectal infections. Oropharyngeal infections occur in MSM and heterosexual women who engage in orogenital sexual contact with an infected partner. Oropharyngeal gonococcal infections are usually asymptomatic and are diagnosed by culture of the organism from the throat (12). Rarely, oropharyngeal gonococcal infection may cause acute, exudative pharyngitis or tonsillitis with cervical lymphadenopathy (9). Anorectal gonococcal infection is seen in MSM as a result of unprotected anal intercourse. Women may also acquire rectal infections by this route, but most are due to perianal contamination with cervicovaginal secretions. Rectal infections are often asymptomatic, but some individuals may develop acute proctitis with anorectal pain, a mucopurulent discharge,

bleeding, tenesmus, and constipation 5 to 7 days following infection (82). Anoscopic examination of the anal canal reveals an edematous and erythematous rectal mucosa and a purulent discharge associated with the anal crypts.

In 0.5 to 3% of infected individuals, gonococci may invade the bloodstream, resulting in disseminated gonococcal infection (DGI) (71). Disseminated disease may develop following infection at genital or extragenital sites, and repeated bouts of DGI may occur in individuals with certain complement component deficiencies (i.e., C7, C8, or C9) (40). DGI is characterized by low-grade fever, chills, hemorrhagic skin lesions, tenosynovitis, migratory polyarthralgias, and frank arthritis. Skin lesions are usually painful and appear as papules that evolve into necrotic pustules on an erythematous base. Very few lesions may be present, and most are found on the extremities. In 30 to 40% of cases, organisms from the bloodstream may localize in one or more joints to cause a purulent, destructive gonococcal arthritis (11). Joint involvement is usually asymmetric and commonly involves knee, elbow, wrist, fingers, or ankle joints. Rare complications of DGI include endocarditis and meningitis. Gonococcal endocarditis usually involves the aortic valve and follows a rapid and destructive course (90). Gonococcal meningitis has features typical of meningitides caused by other organisms. Pericarditis, pericardial effusions, and adult respiratory distress syndrome may also complicate gonococcal bacteremia. DGI may also present atypically in those with underlying diseases, including human immunodeficiency virus infection and systemic lupus erythematosus (59).

In addition to gonococcal ophthalmia neonatorum, ocular infections have been reported in adults who become infected via genital secretions (55). Laboratory personnel working with cultures may also become accidentally infected if care is not taken to protect the eyes. Eye infection results in painful periorbital cellulitis, profuse purulent discharge, conjunctival injection, eyelid edema and erythema, and epithelial and stromal keratitis. *N. cinerea* has also been reported to cause conjunctival infections, so it is important to perform confirmatory identification tests on gram-negative, oxidase-positive diplococci recovered from ocular sites (37).

Gonococcal infections in children during the newborn period are the result of ocular contamination during vaginal delivery. However, gonococcal infections beyond the immediate neonatal period are indicators of sexual abuse (3). In female children, *N. gonorrhoeae* causes vaginitis with a discharge, rather than cervicitis, because the epithelium of the prepubertal vagina is composed of columnar epithelial cells, which are the cell types that *N. gonorrhoeae* preferentially infects. With the onset of puberty, these vaginal cells are replaced by stratified squamous epithelium that is not susceptible to gonococcal infection. Urethral infection in male children resembles that seen in adults, and pharyngeal and rectal gonococcal infections, as in adults, are usually asymptomatic in children.

The clinical manifestations of infection with *N. meningitidis* can be highly variable, ranging from transient bacteremia with low-grade fever to fulminant, rapidly fatal disease. In all cases, the meningococcal strain becomes established in the upper respiratory tract and enters the bloodstream to initiate systemic disease. Invasive disease occurs in those who are newly infected with a strain against which bactericidal meningococcal serogroup-specific antibodies are lacking. Concurrent viral or mycoplasmal respiratory tract infections facilitate systemic invasion by the organism. The risk of meningococcal disease is also higher among those with complement component deficiencies (e.g., C5, C6, C7, C8, and C9) (41). Other underlying conditions, such as hepatic failure, systemic lupus erythematosus, multiple myeloma, and asplenia, may also predispose to serious meningococcal disease.

The clinical spectrum of meningococcal disease includes meningoencephalitis, meningitis with or without meningococcemia, meningococcemia without meningitis, and bacteremia without septic complications. These presentations may occur discretely or can blend into one another during clinical disease progression. Classic signs of meningitis (e.g., confusion, headache, fever, and nuchal rigidity) may be seen only in about one-half of the patients, and vomiting may be part of the presentation, particularly in children. Meningococcemia and organism dissemination are heralded by the development of a pink, maculopapular eruption that becomes petechial. Rapidly progressive disease may result in purpuric or ecchymotic skin lesions that are hemorrhagic and necrotic. Fulminant shock may dominate the clinical picture of meningococcal meningitis and acute meningococcal sepsis (100). Gangrenous changes in the extremities may occur due to peripheral vasoconstriction, and death may supervene as a result of disseminated intravascular coagulation. The classic finding of acute hemorrhagic necrosis of the adrenal glands represents the hallmark of the Waterhouse-Friderichsen syndrome (1). Meningococcal meningitis with sepsis may have a mortality rate of up to 30%.

N. meningitidis may also cause acute or chronic meningococcemia without meningitis. Patients present with fever, headache, malaise, and leukocytosis, and meningococci are recovered from blood cultures. By that time, the patient is usually clinically well and no therapy or a short course of therapy is administered. Patients with chronic meningococcemia are usually symptomatic, with a presentation clinically similar to the gonococcal arthritis-dermatitis syndrome. Individuals with deficiencies in late complement components, other hypocomplementeric states (e.g., systemic lupus erythematosus), and human immunodeficiency virus infection are also at risk for serious meningococcal disease (41).

Meningococcal pneumonia occurs infrequently and presents as a community-acquired infection that is indistinguishable clinically from other acute bacterial pneumonias. Pneumonia occurs primarily in older individuals with preexisting pulmonary compromise (102). Diagnosis is complicated by the presence of the organisms in the nasopharynx, resulting in contamination of expectorated sputum specimens. Bacteremic epiglottitis and supraglottitis have also been reported in association with serogroup B, C, and Y meningococcal infections (89). Other infections associated with *N. meningitidis* that result from hematogenous dissemination include osteomyelitis, arthritis, cellulitis, endophthalmitis, and spontaneous bacterial peritonitis.

Meningococcal conjunctivitis has been described in adults, children, and neonates and may develop as a complication of systemic meningococcal disease or as a primary infection (6). Complications limited to the eye include corneal ulcers, keratitis, subconjunctival hemorrhage, endophthalmitis, and iritis. *N. meningitidis* may also be isolated from the male urethra, the female genital tract, and the anal canal. In these sites, meningococci may cause infections that are clinically indistinguishable from gonococcal infections, including acute purulent urethritis, cervicitis, salpingitis, and proctitis (74). Orogenital, anogenital, and oroanal sexual practices are believed to be responsible for the presence of meningococci in these anatomic sites (97).

NEISSERIA GONORRHOEAE

Collection, Transport, and Storage of Specimens

Details of specimen collection are given in chapters 5 and 20.

The collection of specimens for diagnosis of gonococcal infection depends on the sex and sexual practices of the patient and on the clinical presentation. In all cases, specimens from genital sites should be collected. If the patient has a history of orogenital or anogenital sexual contacts, collection of oropharyngeal or anal canal specimens is also appropriate. In cases of suspected DGI, blood cultures and specimens from genital and extragenital sites should be obtained. Appropriate sites for culture are summarized in Table 1.

Specimens should be collected with Dacron or rayon swabs. Calcium alginate may be toxic to gonococci, and some brands of cotton swabs may contain fatty acids that may be inhibitory for gonococci. These swab types should be used only if specimens are inoculated directly onto culture growth media or are transported in nonnutritive swab transport media. Some transport media contain charcoal to inactivate toxic materials present in the swab material or in the specimen itself. Instruments used to facilitate specimen collection (e.g., vaginal specula) should be lubricated with warm water or saline because water- and oil-based lubricants may also inhibit organism growth.

The role of the clinical microbiology laboratory in diagnosing gonococcal infections in children involves the proper handling of appropriately collected specimens and the accurate identification of isolated organisms. For prepubertal females, specimens should be obtained from the vagina or urethra, the oropharynx, and the rectum and inoculated onto media as described below. Vaginal specimens are collected by swabbing the vaginal wall for 10 to 15 s to absorb any secretions, or, if the hymen is intact, the specimen is collected from the vaginal orifice. Specimens for diagnosis of rectal, urethral, and oropharyngeal gonococcal infections in children are collected as for adults.

Maximal recovery of gonococci is obtained when specimens are plated directly onto growth medium after collection. However, this technique might not always be possible or practical and various transport systems are available, as described below.

Nonnutritive Swab Transport Systems

Stuart's or Amies buffered semisolid transport media are used for transport of swab specimens for *N. gonorrhoeae*. Some swab transport systems use sponges soaked with transport medium, while others use a semisolid medium with or without activated charcoal. Studies with newer swab collection devices (Copan Transystems; Copan Diagnostics, Inc., Corona, Calif., now marketed as BBL CultureSwab Plus, BD Biosciences, Sparks, Md.) suggest that semisolid Amies transport medium with or without charcoal may preserve the viability of gonococci for as long as 48 h, although the viability of many gonococcal isolates may decrease noticeably after 24 h. Semisolid transport media are superior to devices that use medium-soaked sponges. Sponge materials in some swab transport systems may contain substances (e.g., sulfur or quaternary ammonium compounds) that may inhibit or injure fastidious organisms such as gonococci. While some recent studies have shown that gonococci may survive refrigeration in some swab transport systems up to 48 h (7), other studies have demonstrated that refrigeration beyond 6 h may result in significant reductions in viable organisms, regardless of the transport system used (39, 56). In order to prevent loss of organism viability, swab specimens submitted in transport medium should not be refrigerated and should be inoculated onto growth medium within 6 h after collection.

Culture Medium Transport Systems

Transport of specimens already inoculated onto culture media presents several advantages over swab transport systems. Commercially available systems include JEMBEC plates containing various selective media (Remel, Inc., Lenexa, Kans.), the Gono-Pak (BD Biosciences), and the InTray GC system (BioMed Diagnostics, Inc., San Jose, Calif.) (16). While the Gono-Pak and JEMBEC products require refrigerated storage, the sealed InTray system permits storage of the medium at room temperature for up to 1 year. Media are inoculated with the specimen from a swab and placed in an impermeable plastic bag with a bicarbonate-citric acid pellet. Contact of the pellet with moisture via evaporation from the medium during incubation or by crushing an ampoule of water adjacent to the pellet generates a CO_2-enriched environment within the bag. Organisms remain viable in the CO_2-enriched environment

TABLE 1 Body sites or specimens and culture media for the isolation of *N. gonorrhoeae* and *N. meningitidis*

Species	Syndrome	Gender	Site(s) or specimen(s)	Media
N. gonorrhoeae	Uncomplicated	Female	Endocervix (Bartholin's glands), rectum,[a] urethra, pharynx[a]	Selective
		Male, heterosexual	Urethra	Selective
		Male, homosexual, bisexual	Urethra, rectum,[a] pharynx[a]	Selective
	PID	Female	Endocervix endometrium,[b] fallopian tubes	Selective, nonselective
	DGI	Female/male	Endocervix, (urethra), urethra (male), skin lesions	Selective, nonselective
			Joint fluid	Nonselective, selective
			Blood	Blood culture medium
	Ophthalmia	Female/male	Conjunctivae	Nonselective
N. meningitidis	Meningitis	Female/male	CSF, skin lesions	Nonselective
			Blood	Blood culture medium
			Nasopharynx	Selective, nonselective

[a] If there is a history of oral-genital or anal-genital exposure.
[b] If a laparoscopic examination is performed.

during transport to a reference laboratory, but incubation for 18 to 24 h at 35°C prior to transport allows some initial outgrowth of the organisms and enhances survival.

Direct Examination of Clinical Specimens

Microscopy

The diagnosis of gonococcal urethritis in men can be made by observing gram-negative diplococci within or closely associated with polymorphonuclear leukocytes (PMNs) on a smear prepared from the urethral discharge (Fig. 1). When properly performed, the Gram stain has a sensitivity of 90 to 95% and a specificity of 95 to 100% for diagnosing genital gonorrhea in symptomatic men. For females, Gram stains of endocervical specimens collected under direct visualization of the cervix may also be helpful in diagnosis (see "Collection, Transport, and Storage of Specimens" above). Gram-stained smears of such specimens have a sensitivity of 50 to 70%, depending on the adequacy of the specimen and the patient population. An endocervical smear showing gram-negative intracellular diplococci, particularly from a woman with other signs and symptoms of gonococcal infection, is highly predictive. For patients with symptomatic proctitis, smears collected under direct visualization through an anoscope may provide a diagnosis for 70 to 80% of such patients, as opposed to blind collection, where Gram-stained smears have a sensitivity of only 40 to 60% (Fig. 2). Because of the presence of other gram-negative coccobacilli and bipolar staining bacilli in rectal and endocervical specimens contaminated with vaginal secretions, care must be taken not to overinterpret smears obtained from these sites. Gram-stained smears have no value in the diagnosis of pharyngeal gonococcal infection. Gram-stained smears should not be relied upon for diagnosis of gonorrhea and should be used adjunctively along with more specific tests.

Smears for Gram stain should be prepared from urethral and endocervical sites and should be collected with a swab other than that used for the collection of specimen for culture. The swab is rolled gently over the surface of a glass slide in one direction only to minimize distortion of PMNs and preserve the characteristic appearance of the microorganisms. Gram-stained smears from males with urethral discharge usually show moderate amounts to many PMNs with two or more gram-negative intracellular diplococci (Fig. 1). Smears prepared from specimens submitted in transport media may be difficult to interpret due to distortion of the PMNs or to interfering substances (e.g., charcoal). Smears from normally sterile or minimally contaminated sites (e.g., joint fluid) should also be prepared.

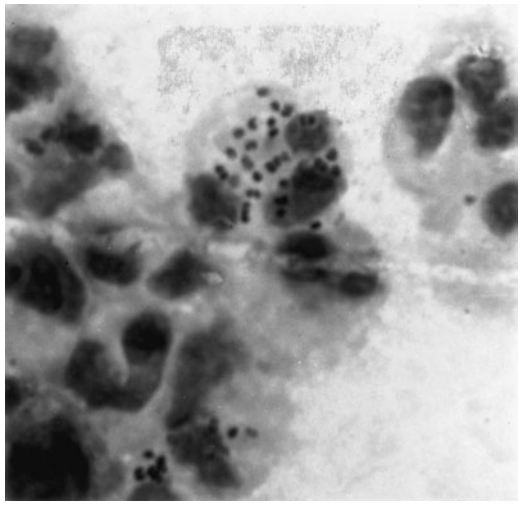

FIGURE 1 Gram stain of male urethral exudate. Some PMNs contain many diplococci; others contain none. Magnification, ×1,500.

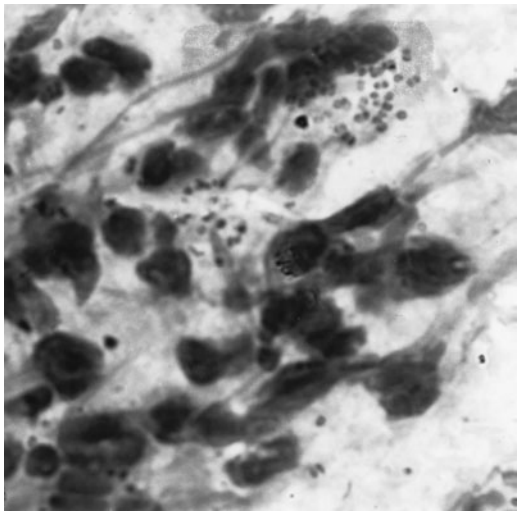

FIGURE 2 Gram stain of mucopurulent rectal exudate showing many diplococci inside PMNs. Magnification, ×1,500.

Antigen Detection

The only commercially available antigen detection test available for diagnosis of gonorrhea is the Binax NOW Gonorrhea Test (Binax, Inc., Portland, Maine). This immunochromatographic strip-based assay can be performed with male urine specimens and both vaginal and endocervical specimens. The test requires no additional materials and takes about 30 min to perform. In a comparative evaluation of the Binax NOW test performed on voided urine with conventional culture of urethral swab specimens from males, the NOW test had a sensitivity of 94.1% and a specificity of 95.8%, with corresponding positive and negative predictive values of 96.9% and 92.0%, respectively (92). The NOW test was shown to have a lower limit of detection of about 1×10^4 CFU of gonococci per ml of urine.

Nucleic Acid Detection Techniques

Nucleic acid detection techniques allow direct detection of *N. gonorrhoeae* in clinical samples and do not require viable organisms. Assays often allow the concurrent detection of *Chlamydia trachomatis*. For *N. gonorrhoeae,* these assays may be divided into three types: (i) direct probe hybridization to the target nucleic acid with direct detection of the hybrid; (ii) nucleic acid amplification tests (NAATs); and (iii) amplified-signal probe tests, which hybridize with nucleic acid and then amplify the signal of the probe. The direct probe tests only slightly increase the sensitivity of culture with a proficient specimen transport system, but the NAATs can appreciably increase sensitivity. The advantages of the tests are that specimens may be transported from geographically distant areas and stored for several days prior to testing in the laboratory. These samples can be maintained frozen prior to testing. The NAATs also allow use of noninvasive specimen types such as urine and vaginal swabs. The disadvantages of using nonculture nucleic

acid probe or amplification tests include unavailability of a viable isolate for antimicrobial susceptibility testing and the possibility of a positive test after treatment, since nucleic acids from organisms may persist for a period of time after successful therapy. One report noted that gonococcal DNA for the ligase chain reaction test remained for a mean of 1.7 days in male urine and 2.8 days in female urine, but 2.8 days in vaginal specimens (8). In contrast, chlamydia DNA may remain detectable for about 2 weeks and the recommended time for retesting is 3 weeks (43). Thus, amplification tests should not be used immediately to assess the success of therapy. Results of probe tests and NAATs may be used only to make a presumptive diagnosis of gonococcal infection and are inadmissible evidence in medicolegal cases in the United States at this time.

Direct Probe Hybridization

Two direct nucleic acid probe assays, the Gen-Probe PACE 2 and PACE 2C assays (Gen-Probe Inc., San Diego, Calif.), are approved by the Food and Drug Administration (FDA) for detecting *N. gonorrhoeae*. In the Gen-Probe tests, an acridinium ester-labeled DNA probe for a specific sequence of *N. gonorrhoeae* rRNA is allowed to hybridize with any complementary rRNA in the specimen (65). An acridinium ester hybridization protection assay detects any hybrids, and chemiluminescence generated by the acridinium ester in the hybrids is detected with a luminometer, resulting in a numerical readout. The PACE 2C test detects both *N. gonorrhoeae* and *C. trachomatis* in a single test. A probe competition assay may also be used to augment the specificity of the test. Compared to culture as the "gold standard," reported sensitivity ranged from 90.8 to 96.3% for women and 99.1 to 99.6% for men in the manufacturer's package insert, while specificity ranged from 97.5 to 100% for men and women. Evaluations of the assay in public health settings have supported the high sensitivity and specificity of the test (52).

NAATs

NAATs are designed to amplify *N. gonorrhoeae*-specific nucleic acid sequences from a particular gene target with up to a billion-fold amplification of as little as theoretically a single copy of the target nucleic acid, either DNA or RNA, depending on the specific assay. Currently, there are four commercially available NAATs for the detection of *N. gonorrhoeae:* one based on PCR, Roche AMPLICOR (Roche Molecular Diagnostics, Indianapolis, Ind.); one based on strand displacement amplification (BDProbeTec; Becton Dickinson); and two based on transcription-mediated amplification: APTIMA Combo2, which is for dual detection of gonorrhea and chlamydia, and APTIMA AGC, which is available for detection of only gonorrhea (both from GenProbe) (44, 70, 99). The AGC assay is presently available as an analyte-specific reagent.

The ligase chain reaction-based assay Abbott LCx (Abbott Laboratories Inc., Abbott Park, Ill.), which was commercially available and used by many laboratories, is no longer available due to manufacturing problems.

PCR for *N. gonorrhoeae* detects a 201-bp sequence in the cytosine methyltransferase gene. Although this assay has been used with sensitivity well above 90% for the detection of gonorrhea agents in cervical specimens, the clinical trial did not achieve a high enough sensitivity (64.8%) for the detection of gonorrhea in urine samples from women for FDA clearance, although it is highly accurate with male urine (Table 2) (70). PCR has been shown to detect gonorrhea in male urine with great accuracy with a sensitivity of 94.1% and a specificity of 99.9% in 1,291 symptomatic men, having a sensitivity which is somewhat lower (73.1%) in 721 asymptomatic men (70). It has also been used quite successfully in research settings with self-administered vaginal swabs from women, although it is not FDA cleared for use with vaginal swabs (101). Recently, this assay has been reported to have false-positive results caused by nonpathogenic *Neisseria* spp., such as *N. subflava*, *N. flavescens, N. lactamica,* and *N. cinerea* (77). These false-positive assays have been thought to be due to the interspecies genetic recombination potential that occurs among *Neisseria* spp., thus indicating the need for confirmation of positive PCR assays in extragenital specimens and those from low prevalence populations (77).

TABLE 2 Nucleic acid amplification tests for *Neisseria gonorrhoeae*[a]

Assay and specimen	Sensitivity (%)	Specificity (%)
PCR(COBAS)		
Cervical	92.4	99.5
Female urine	64.8	99.8
Male urine	94.1	99.9
Strand displacement amplification		
Cervical	96.6	98.9–99.8
Female urine	84.9	98.8–99.8
Male urine	98.1	96.8–98.7
Male urethral	98.1	96.8–98.7
Transcription-mediated amplification		
Cervical	99.2	98.7
Female urine	91.3	99.3
Male urine	97.1	99.2
Male urethral	98.8	98.2

[a] Percentages indicate comparisons with infected patient status; data from package inserts and clinical trials.

The strand displacement amplification assay (ProbeTec) is approved for detection of gonorrhea in cervical, male urethral, and female and male urine samples and has achieved widespread use in clinical laboratories throughout the United States and Europe (Table 2) (99). The BD ProbeTec ET system has very high sensitivities for gonorrhea in cervical and male urethral specimens and has demonstrated a sensitivity of 97.9% for the detection of gonorrhea in male urine in 680 patients, but it has a somewhat lower sensitivity in female urine (84.9%) (99). This assay has also been demonstrated to produce false positives with nonpathogenic *Neisseria* spp. (77).

TMA (APTIMA Combo2) has been shown to be perhaps the most sensitive assay for gonorrhea (44). It has sensitivities uniformly above 97% for cervical and male urine and urethral samples and well above 91% for female urine (Table 2). This assay has not been shown to produce false-positive results with nonpathogenic neisseriae (49).

Amplified-Signal Probe Test

The amplified-signal probe test employs hybridization of a probe with nucleic acid of the organism and then amplifies the signal of the probe. It is represented by the Digene Hybrid Capture II test (Digene, Silver Spring, Md.), which employs RNA hybridization probes which are specific for both genomic DNA and cryptic plasmid DNA sequences of *N. gonorrhoeae* and *C. trachomatis* (72). The RNA-DNA hybrids are captured in microtiter plate wells by specific antibodies, which are detected by alkaline phosphatase-labeled anti-RNA-DNA

hybrid antibodies. The signal is amplified using a chemiluminescent substrate detected by a luminometer. The test is positive if either chlamydia or gonorrhea is present, and then an organism-specific test is performed. It is approved only for cervical samples.

One study reported that the Digene assay was 92.2% sensitive and that the specificity was greater than 99% compared to culture adjudicated by direct fluorescent-antibody (DFA) staining and PCR (32). In another evaluation, compared to *N. gonorrhoeae* culture, it had a sensitivity of 93% (87/94) and a specificity of 98.5% (1,244/1,263) (87).

Additional Considerations for NAATs

Confirmation Tests for NAATs

Because of the potential for false-positive tests in low-prevalence populations, the Centers for Disease Control and Prevention (CDC) has suggested that confirmatory tests should be performed for patients testing positive from populations with a positive predictive value of <90% (26). Suggestions for confirmation include testing a second specimen with a different test using a different target; testing the original specimen with a different test that uses a different target or format; repeating the original test on the original specimen with a blocking antibody or competitive probe; or repeating the original test on the original specimen (26). The requirement for confirmatory testing for positive NAAT results is controversial, and analysis of the particular population under study will influence the decision by a laboratory as to whether to confirm these assays (86). The particular assay in use also plays a role in this decision (49, 86). At present, the only commercial assay with the capability to confirm a positive test with another gene target using the same platform is the Gen-Probe APTIMA assay, with the ACT and AGC stand-alone assays, which can be used to confirm either chlamydia or gonorrhea tests, respectively. These assays are also the only NAATs that are FDA cleared for use with vaginal swabs at present.

Noninvasive Sample Collection and Inhibitors

The ability to detect *N. gonorrhoeae* in noninvasive urine and vaginal samples, avoiding the necessity to obtain an endocervical specimen from women or a urethral swab from men, is an important advantage of NAATs over tests which require invasive specimen collection procedures. However, some specimens contain inherent inhibitors which may result in false-negative results by NAATs. The use of amplification controls in commercial NAATs can indicate when a specimen contains inhibitors by failure of the nonspecific amplification control to be amplified. When inhibition occurs, steps such as heating or dilution can be performed and the test can then be repeated. A discussion of inhibitors in amplification assays can be found on the Association of Public Health Laboratories website (http://www.aphl.org/chlamydia_lab.cfm).

Choice of NAAT and Cost Considerations

Amplified assays are more costly than culture and other detection methods. They have become widely used in clinical microbiology laboratories because of the ability to also test the sample for chlamydia and the ability to test "noninvasive" samples such as urine, as well as the convenience of transport of the sample. Factors that influence whether to choose to perform amplified testing for *N. gonorrhoeae,* as well as which test to choose, include the level of expertise in the laboratory, consideration of costs, training and equipment issues, the population being served, and whether transportation of specimens for culture is a problem. Also a consideration is whether isolates are required for susceptibility testing. The choice of which NAAT to use will also be based on sensitivity and specificity estimates, specimen types being tested (i.e., vaginal, urethral, cervical, or urine), testing that also includes chlamydia, and whether the laboratory wishes to confirm positive NAAT samples (45, 86).

Isolation Procedures

Various selective media allow recovery of *N. gonorrhoeae* from body sites harboring an endogenous bacterial flora. Enriched selective media include modified Thayer-Martin (MTM) medium, Martin-Lewis (ML) medium, GC-Lect medium (BD Biosciences), and New York City (NYC) medium. MTM, ML, and GC-Lect are chocolate agar-based media that are supplemented with additional growth factors, whereas NYC medium is a clear peptone-corn starch agar-based medium containing yeast dialysate, citrated horse plasma, and lysed horse erythrocytes. These media contain antimicrobial agents that inhibit other microorganisms and allow the selective recovery of *N. gonorrhoeae*, *N. meningitidis*, and *N. lactamica*. Vancomycin and colistin, antimicrobials present in all four formulations, inhibit gram-positive and gram-negative bacteria (including saprophytic *Neisseria* species), respectively. Trimethoprim is added to inhibit the swarming of *Proteus* spp. present in rectal and, occasionally, in cervicovaginal specimens. Nystatin (MTM medium), amphotericin B (NYC and GC-Lect media), or anisomycin (ML medium) is added to inhibit yeasts and molds. NYC medium also supports the growth of rapidly growing genital mycoplasmas and ureaplasmas. Media are available in either petri dishes or JEMBEC plates.

Media for the pathogenic *Neisseria* should be at room temperature before inoculation and should not be excessively dry or moist. Swab specimens are rolled in a "Z" pattern on selective medium and cross-streaked with a bacteriologic loop. If nonselective chocolate agar is also inoculated, these plates are streaked for isolation. Plates are incubated in a CO_2 incubator or a candle extinction jar at 35 to 37°C. The CO_2 level of the incubator should be 3 to 7%; higher CO_2 concentrations may inhibit growth of some strains. The atmosphere should be moist; with candle jars, moisture evaporating from the medium during incubation is usually sufficient for organism growth. If candle jars are used, candles should be made of white wax or beeswax; scented or colored candles release volatile products that may inhibit organism growth. CO_2 incubators that are not equipped with humidifiers can be kept moist by placing a pan of water on the lower shelf. Plates are inspected at 24, 48, and 72 h before a final report of "no growth" is issued. Suspect colonies are subcultured to chocolate agar, incubated, and used as inocula for identification procedures.

Presumptive Identification

Colony Morphology

Gonococci produce several colony types that are related to piliation of organisms in the colony. Typical colonies tend to be small (about 0.5 mm in diameter), glistening, and raised. With subculture of individual piliated colonies, the culture can be maintained in this colonial type. With nonselective subculture (i.e., a "sweep" of growth), the other colony types become evident, with all colonies eventually becoming the nonpiliated varieties. These colonies are larger (about 1 mm in diameter) and flatter and do not have the high profile and glistening highlights of piliated colony types. The presence of multiple colony types on a subculture from a primary plate may give the appearance of a mixed culture. Careful scrutiny and subculture with the use of a dissecting microscope (10×)

enable one to become familiar with these colony types. Some *N. gonorrhoeae* strains grow on commercially available sheep blood agar, although growth takes longer and is not as luxuriant as on chocolate agar. However, other strains do not grow on sheep blood agar at all.

Gram Stain and Oxidase Test

Smears prepared from suspicious colonies should be examined with the Gram stain. The Gram stain of organisms from colonial growth should show uniform, characteristic gram-negative diplococci. Some of the organisms may appear as tetrads, particularly on smears prepared from young colonies. Organisms on smears prepared from older cultures may appear swollen and variable in counterstaining intensity, while smears prepared from partially autolyzed colonies may be uninterpretable. Examination by Gram stain is essential for presumptive identification because other organisms may occasionally grow on selective media, particularly when oropharyngeal specimens are cultured (discussed below).

Oxidase test results are obtained with the tetramethyl derivative of the oxidase reagent (*N,N,N,N*-tetramethyl-1,4-phenylenediamine, 1% aqueous solution). A drop of this reagent is placed on a piece of filter paper and a portion of colonial growth is rubbed onto the reagent with a platinum loop, a cotton swab, or a wooden applicator stick. With fresh cultures, a dark purple color will appear on the filter paper within 10 s. Excellent results are obtained with the oxidase reagents that are packaged in crushable glass ampoules (e.g., BACTIDROP Oxidase; Remel, Inc.).

Superoxol Test

Superoxol (30% hydrogen peroxide) is another helpful test for rapid presumptive identification of *N. gonorrhoeae* (84). *N. gonorrhoeae* strains produce immediate, brisk bubbling when the colony material is emulsified with the reagent on a glass slide. Both *N. meningitidis* and *N. lactamica*, the other species that grow on selective media, generally produce weak, delayed bubbling, although some isolates of *N. meningitidis* may also produce immediate, brisk bubbling similar to the gonococcus in this test. Isolates of oxidase-positive, gram-negative diplococci that are recovered from urogenital sites and that grow on selective media may be presumptively identified as *N. gonorrhoeae*. The superoxol test provides an additional presumptive test for identifying these isolates. Confirmatory identification tests are recommended for all isolates and are required for identification of isolates from extragenital sites (i.e., throat, rectum, blood, joint fluid, and cerebrospinal fluid [CSF]).

Differentiation of Other Organisms on Selective Media

Presumptive and confirmatory identification of *N. gonorrhoeae* depends on the ability to differentiate this organism from others that may also grow on selective media. These organisms include *Kingella denitrificans*, *Moraxella catarrhalis*, other *Moraxella* species, *Acinetobacter* species, and *Capnocytophaga* species. *K. denitrificans* grows on MTM medium and produces colony types resembling those of *N. gonorrhoeae*. Whereas gonococci produce vigorous bubbling when colonial growth is immersed in 3% H_2O_2 or in superoxol, *K. denitrificans* produces a negative catalase reaction. *Moraxella* species are both oxidase positive and catalase positive; these organisms can be differentiated from *Neisseria* by the penicillin disk test (21). The organism is subcultured to a Trypticase-soy blood agar plate and streaked to obtain confluent growth. A penicillin susceptibility disk (10 U) is placed on the inoculum, and after overnight incubation in CO_2, a Gram stain is prepared from growth at the edge of the zone of inhibition. *Neisseria* species and *M. catarrhalis* retain their diplococcal morphology, although the cells may appear to be swollen (Fig. 3). Coccobacillary *Moraxella* species and *K. denitrificans* form filaments or spindle-shaped cells under the influence of subinhibitory concentrations of penicillin. *Acinetobacter* spp. can exhibit diplococcal morphology, but these organisms are oxidase negative. *Capnocytophaga* species appear as gram-negative, slightly curved, fusiform bacteria and are oxidase negative and catalase negative. *Capnocytophaga* spp. tend to spread over the agar surface due to gliding motility and may impede recovery of gonococci from oropharyngeal specimens incubated longer than 48 h.

Confirmatory Identification Tests for *Neisseria* Species

Confirmatory tests for *N. gonorrhoeae*, *N. meningitidis*, and other *Neisseria* species include carbohydrate acidification

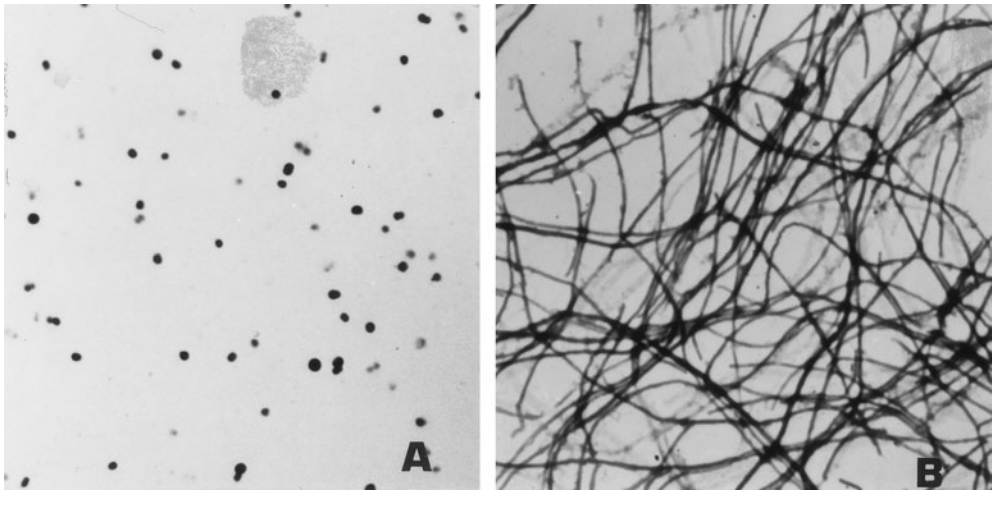

FIGURE 3 Cocci (A) and bacilli (B) exposed to subinhibitory concentrations of penicillin. Some cocci are swollen but still coccoid; bacilli form long strings. Magnification, ×1,000.

tests, chromogenic enzyme substrate tests, immunologic tests (e.g., fluorescent antibody or staphylococcal coagglutination), multitest identification systems, and DNA probe tests. Carbohydrate acidification tests and the multitest identification systems can be used to identify *N. gonorrhoeae*, *N. meningitidis*, and other *Neisseria* species (Table 3). Chromogenic substrate identification procedures are limited to those isolates that grow on selective media (i.e., *N. gonorrhoeae*, *N. meningitidis*, *N. lactamica*, and some strains of *M. catarrhalis*). Fluorescent-antibody, coagglutination, and other immunologic tests and the DNA probe culture confirmation test are available for identification of *N. gonorrhoeae* only. Most nucleic acid hybridization and NAAT procedures are approved for direct detection of *N. gonorrhoeae* in genital tract and urine specimens only.

Acid Production from Carbohydrates

Conventional CTA Carbohydrates

The traditional technique for identification of *Neisseria* species employs cystine-tryptic digest semisolid agar-base (CTA) medium containing 1% carbohydrate and a phenol red pH indicator (2). The usual test battery includes CTA-glucose, -maltose, -sucrose, and -lactose, plus a carbohydrate-free CTA control. The lactose structural analogue, *o*-nitrophenyl-β-D-galactopyranoside (ONPG), may be substituted for the lactose tube, and the addition of CTA-fructose is helpful for identifying the *N. subflava* biovars. Some CTA formulations may be supplemented with ascitic fluid to support growth of more fastidious strains. CTA media are inoculated with a dense suspension of the organism from a pure 18- to 24-h culture on chocolate agar. Either the inoculum is prepared in 0.5 ml of saline and divided among the tubes, or each tube is individually inoculated with a loopful of the organism. The inoculum is restricted to the top 0.5 in. of the agar-deep tubes. The tubes are incubated in a non-CO_2 incubator at 35°C with the caps tightened firmly. With a heavy inoculum, many isolates produce changes in the color of the phenol red indicator within 24 h. Some strains may change the indicator within 4 h, while other gonococcal strains may require 24 to 72 h to produce sufficient acid to change the indicator. Because CTA media containing 1% carbohydrate are used primarily for detection of acid by fermentative organisms, the small amounts of acid produced oxidatively by some strains of *Neisseria* species may not be detected. This method may be problematic for differentiating *N. gonorrhoeae* and *N. cinerea*. Consequently, it is no longer favored for the detection of acid production from carbohydrates. Table 3 shows the carbohydrate acidification profiles and other useful tests for the identification of *Neisseria* spp. recovered from humans.

Rapid Carbohydrate Tests

The rapid carbohydrate test is a non-growth-dependent method for detection of acid production from carbohydrates by *Neisseria* species. Small volumes (0.10 ml) of a balanced salts solution (0.04 g of K_2HPO_4 per liter, 0.01 g of KH_2PO_4 per liter, and 0.80 g of KCl per liter, pH 7.0) with phenol red indicator (0.5 ml of a 1% aqueous solution/liter) are dispensed in nonsterile tubes to which single drops of 20% filter-sterilized aqueous carbohydrates are added. A dense suspension of the organism is prepared in balanced salts solution, and 1 drop of this suspension is added to each of the carbohydrate-containing tubes. Tubes are incubated for 4 h at 35°C in a non-CO_2 incubator or a water bath. This method is economical, the reagents are easy to prepare and inoculate, and the results are clear-cut. The key to this technique is the use of reagent grade carbohydrates. Maltose from some bacteriologic media companies may produce positive or equivocal results for *N. gonorrhoeae* in this procedure, presumably due to the presence of contaminant glucose. Inocula may be obtained from the primary culture if sufficient colonies are present and if the growth is less than 24 h old. Since growth does not occur in the test medium, small numbers of contaminants do not interfere with the 4-h result. However, incubation cannot be continued overnight. The RIM-*Neisseria* Test (Rapid Identification Method-Neisseria; Remel, Inc.), the Gonobio-Test (I.A.F. Production, Inc., Laval, Quebec, Canada), and the Neisseria-Kwik test (MicroBio Logics, St. Cloud, Minn.) are commercial modifications of the rapid carbohydrate utilization test, and evaluations have reported good agreement with conventional methods, although these tests may not provide adequate differentiation between *N. gonorrhoeae* and *N. cinerea* (35, 36).

Chromogenic Enzyme Substrate Tests

Enzymatic identification systems use specific substrates that, after hydrolysis by bacterial enzymes, yield a colored end product that is detected directly or after the addition of a diazo dye-coupling reagent. These tests are used to identify species that are able to grow on selective media—*N. gonorrhoeae*, *N. meningitidis*, and *N. lactamica*. Because some *M. catarrhalis* strains grow on selective media, these systems also provide a presumptive identification of this organism as well. Chromogenic substrate identification tests should not be used to identify organisms recovered on blood and/or chocolate agar without prior subculture of the isolate to selective media. Enzymatic activities that are detected in these systems include β-galactosidase, γ-glutamylaminopeptidase, and prolyl-hydroxyprolyl aminopeptidase. β-Galactosidase and γ-glutamylaminopeptidase are specific for *N. lactamica* and *N. meningitidis*, respectively. The absence of these activities and the presence of prolyl-hydroxyprolyl aminopeptidase identify an organism as *N. gonorrhoeae*. Some *N. meningitidis* strains produce both γ-glutamyl aminopeptidase and prolyl-hydroxyprolyl aminopeptidase. *M. catarrhalis* lacks all three of these enzymatic activities. The Gonochek II (EY Labs, San Mateo, Calif.) is a commercial system that detects all three enzyme activities in a single tube (35). The BactiCard *Neisseria* (Remel, Inc.) uses filter paper pads that are impregnated with substrates for the three enzymes, plus an indoxyl butyrate substrate for identification of *M. catarrhalis* (62). The interpretive guidelines for these tests do not allow for the fact that some nongonococcal neisseria isolates (e.g., *N. subflava* bv. perflava) may be isolated on gonococcal selective media. These species are also prolyl-hydroxyprolyl aminopeptidase positive and may be misidentified as *N. gonorrhoeae* if additional tests are not performed. Recently, gonococcal strains lacking prolyl-hydroxyprolyl aminopeptidase have been isolated in Denmark and the United Kingdom (2, 42).

Immunologic Methods for Culture Confirmation

Direct Fluorescent Monoclonal Antibody Test

The DFA culture confirmation procedure uses monoclonal antibodies that recognize epitopes on the PorI (Protein I) outer membrane protein (OMP) of *N. gonorrhoeae*. The DFA test (*Neisseria gonorrhoeae* Culture Confirmation Test; Trinity Biotech, Wicklow, Ireland) is performed by preparing a smear on a DFA slide, overlaying the smear with DFA reagent, and incubating the smear for 15 min. After rinsing and mounting, the slide is examined with a fluorescence microscope. Gonococci appear as apple-green fluorescent

TABLE 3 Characteristics of *Neisseria* species of human origin[a]

Species	Colony morphology on chocolate agar	Growth on:			Acid from:					Reduction of NO_3	Polysaccharide from SUC
		MTM, ML, and NYC media (35°C)	Chocolate or blood agar (22°C)	Nutrient agar (35°C)	GLU	MAL	LAC	SUC	FRU		
N. gonorrhoeae[b]	Beige to gray-brown, translucent, smooth, 0.5–1 mm in diameter	+	0	0	+	0	0	0	0	0	0
N. meningitidis	Beige to gray-brown, translucent, smooth, 1–3 mm in diameter	+	0	V	+	+	0	0	0	0	0
N. lactamica	Beige to gray-brown, translucent, smooth, 1–2 mm in diameter	+	V	+	+	+	+	0	0	0	0
N. cinerea[c]	Beige to gray-brown to yellowish, translucent, smooth, 1–2 mm in diameter	V	0	+	0	0	0	0	0	0	0
N. polysaccharea	Beige to gray-brown to yellow, translucent, smooth, 1–2 mm in diameter	V	+	+	+	+	0	V	0	0	+
N. subflava[d]	Greenish, yellow, opaque, 1–3 mm in diameter, smooth to rough, sometimes adherent	V	+	+	+	+	0	V	V	0	V
N. sicca	White, opaque, 1–3 mm in diameter, adherent, wrinkled with age	0	+	+	+	+	0	+	+	0	+
N. mucosa	Greenish yellow, opaque, 1–3 mm in diameter	0	+	+	+	+	0	+	+	+	+
N. flavescens	Yellow, opaque, 1–2 mm in diameter	0	+	+	0	0	0	0	0	0	+
N. elongata[e]	Gray-brown, translucent, smooth, 1–2 mm in diameter, glistening, dry, claylike consistency	0	+	+	0	0	0	0	0	0	0

[a] Symbols and abbreviations: +, strains typically positive but genetic mutants may be negative; V, strain dependent; 0, negative; GLU, glucose; MAL, maltose; LAC, lactose; SUC, sucrose; FRU, fructose.

[b] *N. kochii* is considered to be a subspecies of *N. gonorrhoeae;* isolates of *N. kochii* exhibit characteristics of both *N. gonorrhoeae* and *N. meningitidis*, but are identified as *N. gonorrhoeae* by tests routinely used for identification of *Neisseria* spp.

[c] Some strains grow on selective media.

[d] Includes biovars subflava, flava, and perflava. *N. subflava* bv. perflava strains produce acid from sucrose and fructose and produce polysaccharide from sucrose; *N. subflava* bv. flava strains produce acid from fructose; *N. subflava* bv. subflava strains do not produce polysaccharide from sucrose.

[e] Rod-shaped organism. The catalase test is weakly positive or negative compared with those of other *Neisseria* spp. (catalase positive). Results in the table are for *N. elongata* subsp. *elongata*. Strains of *N. elongata* subsp. *glycolytica* may produce a weak acid reaction from D-glucose, are catalase positive, and do not reduce nitrate but do reduce nitrite. Strains of *N. elongata* subsp. *nitroreducens* (formerly CDC group M-6) may produce a weak acid reaction from D-glucose, are catalase negative, and reduce both nitrate and nitrite.

diplococci. The currently available kit is the same product that was developed and marketed by Syva in 1986. At that time, the DFA reagent was highly sensitive and specific; however, at present, many strains of *N. gonorrhoeae* fail to stain with this reagent (63). Serotyping and pulsed-field gel electrophoresis (PFGE) data indicate that gonococcal strains that are negative with the DFA reagent belong to a variety of serovars (17, 63). Since the monoclonal antibody cocktail used in this product has not been modified since 1986, package insert claims of 99.6% sensitivity and 100% specificity are no longer valid. Therefore, isolates that do not stain with the DFA reagent must be identified by another method. This limits the advantages of the DFA procedure, which included its rapidity, ability to test colonies directly from primary cultures, and the small amount of growth required for test performance. The DFA test is not intended for direct identification of organisms in smears from patient specimens.

Coagglutination Tests

Two coagglutination tests for the identification of *N. gonorrhoeae* are currently available: the Phadebact Monoclonal GC test (Boule Diagnostics AB, Huddinge, Sweden) and the GonoGen I (New Horizons Diagnostics, Columbia, Md.). The Phadebact Monoclonal GC test uses anti-PorI monoclonal antibodies bound to staphylococcal cells. Unlike the GC OMNI test previously marketed by Boule Diagnostics, this monoclonal GC test contains one reagent that reacts with serogroup WI *N. gonorrhoeae* strains and a second reagent that reacts with serogroup WII/WIII strains. Since a negative control reagent is not included, gonococcal isolates react with either the WI or the WII/WIII reagent, depending on the PorI epitopes expressed by an individual isolate. A suspension (0.5 McFarland standard) prepared in buffered saline (pH 7.2 to 7.4) is boiled and mixed with the two test reagents on a cardboard slide. Agglutination within 1 min is a positive test. Freshly subcultured serogroup WI (ATCC 19424) and serogroup WII/III (ATCC 23051) strains are recommended for quality control but are not provided with the kit. The GonoGen I coagglutination test also uses staphylococcal cells coated with anti-PorI monoclonal antibodies. This test kit contains test and control coagglutination reagents, and positive and negative test control suspensions are also included. GonoGen I also uses a boiled organism suspension (McFarland standard of 3) for testing, and agglutination with the test but not the control reagent constitutes a positive test. Attention to procedural details is necessary to prevent false-positive and false-negative results with these coagglutination tests. Some gonococci may not react with these reagents, and cross-reactions with other *Neisseria* species (i.e., *N. meningitidis*, *N. lactamica*, and *N. cinerea*) and *K. denitrificans* have been reported (2, 35, 63).

GonoGen II

GonoGen II (New Horizons Diagnostics) uses anti-PorI monoclonal antibodies conjugated to red-colored metal sol particles as the detection reagent. Colonies from agar medium are suspended in a solubilizing buffer that releases PorI-antigen-containing complexes from the cell wall. A drop of the antibody-sol particles is added, and the PorI antigen binds to the antibody-sol particles. After 5 min, 2 drops of this mixture are passed through a membrane filter that retains antigen-antibody complexes. Concentration of these complexes on the filter turns the filter red, identifying the organism as *N. gonorrhoeae*. Nongonococcal isolates do not produce these, so the entire suspension passes through the filter, resulting in the filter remaining white or pale pink. *N. gonorrhoeae* strains that do not react with the conjugate are not identified, and false-positive reactions have been noted with some *N. meningitidis* and *N. lactamica* strains (3, 63).

Multitest Identification Systems

Kit systems that identify *Neisseria* spp., *Haemophilus* spp., and other fastidious gram-negative organisms are available. These systems are the RapID NH *(Neisseria-Haemophilus)* (Remel, Inc.), the Vitek NHI (*Neisseria-Haemophilus* Identification) card (bioMerieux, Inc., Hazelwood, Mo.), the *Haemophilus-Neisseria* identification (HNID) panel (Dade Behring, Sacramento, Calif.), and the API NH (bioMerieux, Inc., La Balme-les-Grottes, France) (2, 10, 60, 61). These kits use modified conventional tests and chromogenic substrates to provide identifications within 2 to 4 h. The NHI card identifies the pathogenic *Neisseria* spp., *N. lactamica*, and *N. cinerea* (61). At present, a new NHI card is being developed for use with the Vitek-2 instrument. *N. cinerea* is not included in the database of the MicroScan HNID panel, resulting in misidentifications as *N. gonorrhoeae* or *M. catarrhalis*, and some *N. meningitidis* strains do not produce clear-cut reactions with key tests (60). RapID NH includes tests that enable identification of the pathogenic *Neisseria* and *N. cinerea* (2). The API NH system identifies gonococci, meningococci, and *N. lactamica* within 2 h; other *Neisseria* species required additional tests for correct species identification (2, 10).

DNA Probe Test for Culture Confirmation

The Accuprobe *Neisseria gonorrhoeae* Culture Confirmation Test (Gen Probe) identifies *N. gonorrhoeae* by the detection of species-specific rRNA sequences. Organisms from agar medium are lysed and mixed with a chemiluminescent acridinium ester-labeled single-stranded DNA probe that is complementary to gonococcal rRNA. DNA probe/rRNA hybrids are selected by a chemical process, and the presence of the probe is detected by hydrolysis of the acridinium ester and the consequent release of light energy. This energy is detected by a chemiluminometer and reported in relative light units. The Accuprobe test is more sensitive and specific than biochemical or immunologic culture confirmation tests and is particularly useful for confirming problem isolates (63).

NAATs

Theoretically, any of the FDA-cleared NAATs could be used to confirm the identification of an isolate from a culture. However, this particular use of the tests is not cleared by the FDA.

Typing Systems

Phenotypic and genotypic typing methods are used to differentiate between strains of *N. gonorrhoeae*. The specific characteristics chosen depend on the question(s) being asked. Antimicrobial resistance is frequently the subject of investigation or surveillance. Using the CLSI-approved method, susceptibilities to several agents are determined (i.e., penicillin, tetracycline, spectinomycin, an extended-spectrum cephalosporin [ceftriaxone or cefixime], a fluoroquinolone [ciprofloxacin or ofloxacin], and a macrolide [erythromycin or azithromycin]), and results are interpreted according to CLSI breakpoints (31, 73). Gonococcal strains are usually described by their pattern of penicillin-tetracycline susceptibilities (penicillin-tetracycline resistance phenotype) (79). Penicillin-tetracycline resistance phenotypes include penicillin resistant (PenR), tetracycline resistant (TetR), chromosomally mediated resistance to penicillin and tetracycline (CMRNG), β-lactamase-positive (PPNG), plasmid-mediated resistance to

tetracycline (TRNG), strains with plasmid-mediated resistance to both penicillin and tetracycline (PP/TR), and isolates susceptible to both penicillin and tetracycline (Susc.) (104). PPNG and TRNG isolates may exhibit chromosomally mediated resistance to tetracycline (PPNG, TetR) and penicillin (TRNG, PenR), respectively. Intermediate resistance or resistance to other antimicrobial agents is appended to the penicillin-tetracycline resistance phenotype. For example, a PPNG isolate exhibiting resistance to ciprofloxacin (CipR) would be designated PPNG, CipR.

Phenotypic characterization also includes the determination of requirements for growth using a chemically defined medium (auxotyping) and serotyping with a panel of 12 monoclonal antibodies in coagglutination tests to define serovars (85). Strains have been classified with a dual auxotype-serovar system to provide greater discrimination among strains than is possible with either typing system alone. Auxotyping involves determining growth requirements of individual strains for discrete metabolites on a chemically defined medium. For example, if a strain does not grow on a medium from which arginine has been omitted, the strain is recorded as requiring arginine. Strains with single or multiple growth requirements may be identified. Serotyping is performed with a panel of monoclonal antibody coagglutination reagents directed against epitopes on the PorI (protein I) molecule in the gonococcal outer membrane (85). Strains are divided into two major serogroups, serogroups IA and IB, based on the protein I species expressed by the strain; subdivision into serovars is then made according to the reactions observed with a panel of six protein IA- and six protein IB-specific antibody reagents. These typing methods are used to compare isolates in epidemiologic investigations, including studies on the dynamics of gonococcal strains in communities and the geographic spread of resistant strains, and for comparisons between strains for medicolegal investigations (85).

Gonococcal isolates may also be characterized by additional characteristics related to antimicrobial resistance. At least six different β-lactamase plasmids have been described in the gonococcus; these as well as two conjugative plasmids (one possessing a *tet*M determinant) have also been used to study the distribution of gonococcal strains (85). Strains possessing the *tet*M determinant may, with PCR-based tests, be assigned to one of two types: American or Dutch (58). Mutations in the *gyr*A and *par*C genes in strains exhibiting decreased susceptibilities to fluoroquinolones may also be characterized (33).

Molecular typing methods that characterize either specific genes or the entire chromosome have been used more recently to differentiate gonococcal isolates. With older methods, such as PFGE and restriction endonuclease analysis, the chromosome is digested into fragments with restriction enzymes that are resolved in polyacrylamide gels. Restriction endonuclease typing permitted differentiation among isolates belonging to the same serovar; however, restriction patterns are complex and are sometimes difficult to interpret. PFGE is tedious to perform and results in large fragments of DNA that are difficult to separate on conventional gels.

Recently developed typing methods involve amplification and restriction typing of individual genes or gene clusters. The Lip typing system permits the grouping of gonococcal isolates based on the number and sequence of pentamer amino acid repeats within the *lip* gene (94). Opa typing is based on identifying the restriction patterns of a family of 11 distinct and highly variable *opa* genes to give an *opa*-type (75). One disadvantage of the Opa typing system is that new types may evolve very rapidly, resulting in every isolate having a different type unless it is from a sexual partner or a short chain of sexual partners (75). A system for typing the variable regions of the *porB* gene using oligonucleotide probes has also been developed (93). This system can detect differences in *porB* among isolates belonging to the same serovar; however, this method requires the use of different hybridization conditions for individual probes. Real-time PCR amplification of the *porB* gene followed by pyrosequence analysis of highly polymorphic segments of the *porB1a* or *porB1b* alleles has been reported to provide a rapid, highly discriminatory approach to typing gonococcal isolates (96). *PorB* genotyping using probes or sequencing has been used along with amplification and sequence analysis of other genes (e.g., *gyr*A and *par*C) to characterize isolates with acquired resistance to antimicrobial agents used for the treatment of gonococcal infections (47). Use of molecular methods for detection of antimicrobial resistance may provide a molecular approach to surveillance whereby strain variation and dissemination of antimicrobial resistance can be monitored.

In addition, two typing methods that characterize the entire chromosome are based on amplification fragment length polymorphism analysis. These methods use different restriction enzymes to digest the DNA (76, 91). The fluorescent amplification fragment length polymorphism approach has the same discriminatory power as the Opa typing system but is more stable than the latter system (76).

Antimicrobial Susceptibilities

Resistance of *N. gonorrhoeae* to antimicrobial agents is a major problem in the control of gonorrhea. Resistance occurs both as chromosomally mediated resistance to a variety of antibiotics and plasmid-mediated resistance to penicillins (penicillinase [β-lactamase]-producing) and to tetracycline (tetracycline-resistant *N. gonorrhoeae*). The Centers for Disease Control and Prevention (CDC) recommended the use of fluoroquinolones or broad-spectrum cephalosporins for the treatment of gonorrhea (28). Now, however, because of the emergence of resistance to fluoroquinolones (primarily ciprofloxacin and ofloxacin) (66), the CDC now recommends that if symptoms persist after treatment with one of the recommended therapies, patients should be reevaluated for *N. gonorrhoeae* infection by culture and the susceptibilities of any resulting gonococcal isolate should be determined (27). Strains with clinically significant resistance to fluoroquinolones, failure to respond to 500 mg of ciprofloxacin or 400 mg of ofloxacin, or MIC of ciprofloxacin $\geq$1.0 μg/ml or MIC of ofloxacin $\geq$2.0 μg/ml are now widespread in the Far East and have been isolated from a number of cities in the United States, the United Kingdom, Australia, and Canada (23, 24, 66).

The Gonococcal Isolate Surveillance Project (GISP) in 24 to 26 sentinel sites in the United States was implemented by the CDC to monitor changes in antimicrobial susceptibilities in *N. gonorrhoeae* on a monthly basis, but this project monitors only males and only approximately 3% of gonococcal isolates (24). A similar program was established by the World Health Organization and is called GASP (Gonococcal Antimicrobial Surveillance Program) (104). The GISP tests susceptibility to penicillin, tetracycline, spectinomycin, ceftriaxone, cefixime, ciprofloxacin, and azithromycin, and the results are published annually (24). Antimicrobial resistance patterns for *N. gonorrhoeae* vary geographically within the United States, and conducting local antimicrobial susceptibility studies can provide a more accurate assessment with which to judge appropriate treatment recommendations.

Susceptibilities of gonococcal isolates can be determined by an agar dilution method, either on antibiotic-containing media, the E test, or by a disk diffusion method recommended

by the Clinical Laboratory Standards Institute (CLSI), formerly NCCLS (73). Susceptibilities to penicillin, tetracycline, spectinomycin, an extended-spectrum cephalosporin, a fluoroquinolone, and azithromycin should be determined for surveillance purposes.

Azithromycin is not presently recommended for the routine treatment of uncomplicated gonococcal infections, although it may be used for the treatment of gonorrhea in geographic areas where fluoroquinolone-resistant isolates are prevalent and if spectinomycin is not available. The 2-g dose as cleared by the FDA should be used and not the 1-g dose recommended for the primary treatment of chlamydial infections (53). However, one recent report that studied the efficacy of a 1-g dose found only one failure of the 1-g therapy among 226 gonorrhea-infected patients in the United Kingdom (50).

With increasing testing for gonorrhea being performed by NAATs, monitoring of resistance has become more difficult. However, as understanding of molecular mechanisms of resistance increases, it may be possible in the future to determine antimicrobial resistance by using molecular techniques on specimens submitted for NAATs (47, 98, 106). Since worldwide resistance to fluoroquinolones (QRNG) has increased dramatically, there is an increased need to monitor susceptibility trends in different geographical areas and for different population types; and there is a great need for additional single-dose antibiotic regimes in order to control gonorrhea (46). Resistance in *N. gonorrhoeae* and QRNG has been reviewed (46, 106). Data from California indicated that as of 2003, the rate of QRNG had risen from <1% in 1999 to 20.2% in the last half of 2003 (14). The emergence and spread of QRNG seemingly has evolved from sporadic cases to endemic transmission among heterosexuals and particularly among MSM (14).

Culture remains the only test that can be used to identify *N. gonorrhoeae* for legal purposes and for the performance of susceptibility tests. As such, maintaining the ability to perform culture in local areas is an essential component of gonorrhea control programs.

Evaluation, Interpretation, and Reporting of Results

The level of testing and the format for reporting of results should be directed by the sociodemographic characteristics (e.g., age and gender) of the patient clientele served and a knowledge of the incidence and prevalence of clinically significant disease caused by *Neisseria* species, e.g., gonorrhea, in that population. When specimens are collected from patients at high risk for gonorrhea and there are no sociologic or medicolegal implications of a diagnosis of gonorrhea, a presumptive identification of *N. gonorrhoeae* may be sufficient if the diagnosis is intended to facilitate prompt and effective treatment. However, when specimens are collected to confirm a clinical diagnosis for patients such as women and children at low risk for gonorrhea, special concerns apply to laboratory processing and retention of specimens because of the medicolegal consequences that may ensue if an organism is identified as *N. gonorrhoeae*.

Special protocols should be developed for processing specimens from alleged victims of sexual abuse and assault. Suspect gonococci isolated from children must be confirmed by at least two different methods that involve different principles (3). Tests may include carbohydrate utilization, immunologic methods, enzymatic procedures, or the DNA probe culture confirmation test (see below). Of these, tests which detect acid production from glucose and the probe confirmation test provide the least equivocal results. Nongonococcal isolates may cross-react in coagglutination tests, and gonococcal isolates may not react in the monoclonal immunofluorescence test (63). Nongonococcal isolates may produce positive prolyl-hydroxyprolyl aminopeptidase reactions in enzyme substrate tests, as do gonococcal isolates. Therefore, communication between the clinician and the laboratory is essential to ensure that specimens of medicolegal importance are processed according to these criteria.

In general, with the exception of high-risk patients for whom presumptive identifications may suffice, similar principles apply to the identification of all gram-negative, oxidase-positive diplococci. Although many tests for identification of *Neisseria* and related species are marketed as confirmatory tests, most do not provide sufficient data to accurately identify an isolate to the species level without additional tests. Some different isolates may produce identical reactions with some tests, e.g., maltose-negative *N. meningitidis* and *K. denitrificans* may give reactions identical to those of *N. gonorrhoeae* in acid production tests. In addition, problems have been identified with most tests for the identification of *N. gonorrhoeae* and related species, e.g., false-negative acid production reactions from glucose with *N. gonorrhoeae* or false-positive reactions for glucose acidification with *N. cinerea*.

Culture confirmation tests are preferred for the identification of *Neisseria* and related species because they require the isolation of an organism which can be examined by multiple tests if the results of the primary tests are equivocal. Multitest identification systems provide the most information about biochemical characteristics that may, in some cases, allow the identification of an isolate. Rapid identification tests, including serologic and nucleic acid probe or amplification tests, that provide a "yes-no" answer, i.e., an isolate either is or is not *N. gonorrhoeae*, may be adequate if it is necessary only to eliminate *N. gonorrhoeae* as the causative agent; these tests are of limited usefulness when identification to the species level is required.

Because of the consequences of misdiagnosing gonorrhea or misidentifying strains of *N. gonorrhoeae*, three levels are recommended for reporting diagnoses of gonorrhea. These levels are "suggestive," which is defined on the basis of clinical findings, "presumptive," and "definitive," with the last two levels including the results of laboratory tests. A suggestive diagnosis is defined by (i) the presence of a mucopurulent endocervical or urethral exudate on physical examination and (ii) sexual exposure to a person infected with *N. gonorrhoeae*. A presumptive diagnosis of gonorrhea is made on the basis of two of the following three criteria: (i) typical gram-negative intracellular diplococci on microscopic examination of a smear of urethral exudate (men) or endocervical secretions (women); (ii) growth of *N. gonorrhoeae* from the urethra (men) or endocervix (women) on culture media and demonstration of typical colonial morphology, positive oxidase reaction, and typical gram-negative morphology; and/or (iii) detection of *N. gonorrhoeae* by nonculture tests (e.g., antigen detection, nucleic acid probe tests, or NAATs). Definitive diagnosis requires (i) isolation of *N. gonorrhoeae* from sites of exposure (e.g., urethra, endocervix, throat, or rectum) by culture (usually on a selective medium) and demonstration of typical colonial morphology, positive oxidase reaction, and typical gram-negative morphology; and (ii) confirmation by biochemical, enzymatic, serologic, or nucleic acid tests, e.g., carbohydrate utilization, rapid enzyme substrate tests, serologic methods, or the DNA probe culture confirmation test.

For reporting purposes, the laboratory should perform species level identification and confirmation with appropriate tests in order to report a definitive result of "*N. gonorrhoeae* confirmed" for the clinician unless otherwise requested. If an

organism suspected to be *N. gonorrhoeae* is tested by rapid tests but not by additional confirmatory tests that compensate for problems associated with the primary test and is reported as "presumptive *N. gonorrhoeae*," it is important that the clinician understands that additional tests may be required to confirm this identification. Ideally, to avoid confusion, an organism should be reported only as "gram-negative, oxidase-positive diplococcus isolated" unless it has been identified to the species level with sufficient tests to ensure the accuracy of the identification.

NEISSERIA MENINGITIDIS

Collection, Transport, and Storage of Specimens

Specimens helpful in the diagnosis of meningococcal disease include CSF, blood, aspirates, biopsy specimens, and nasopharyngeal and oropharyngeal swabs (Table 1). Occasionally, meningococci may be sought in sputum and bronchoalveolar lavage specimens. Genital, rectal, and oropharyngeal isolates of *N. meningitidis* may be recovered using the collection and inoculation procedures described for *N. gonorrhoeae*. Incubation conditions for inoculated media are the same as those described for *N. gonorrhoeae*. Meningococci grow well on all selective media for the pathogenic neisseriae, and vancomycin-susceptible strains have not been described. Recovery of both gonococci and meningococci from blood cultures may be adversely affected by the anticoagulant sodium polyanethol sulfonate that is present in blood culture media. This effect may be neutralized by addition of sterile gelatin (1% final concentration) to the media or by processing the blood specimen by lysis-centrifugation (i.e., Isolator, Wampole Laboratories, Cranbury, N.J.).

Laboratory Safety

N. meningitidis is classified as a biosafety level 2 organism, which means that a biological safety cabinet should be used for the manipulation of specimens that have a substantial risk for the generation of aerosols (e.g., centrifuging, grinding, and blending). Reports of laboratory-acquired meningococcal infections suggest, however, that manipulation of cultures, rather than patient specimens, increases the risk of infection for microbiology laboratory technologists (22, 25). Such manipulations may include the preparation of heavy organism suspensions for inoculation of identification systems and for serogrouping of isolates. Use of a biological safety cabinet when manipulating cultures for these purposes helps to provide protection of the laboratorian from aerosolized organisms. Alternative measures for protection from droplet aerosols, such as the use of splash guards and masks, are currently being assessed. Education and adherence to established laboratory safety precautions should minimize the risk of meningococcal infection for workers in the clinical microbiology laboratory. Laboratory policies should also be developed for situations that may require administration of chemoprophylaxis to employees who are exposed to meningococci. Laboratories may also consider offering the quadrivalent meningococcal vaccine (which includes serogroups A, C, Y, and W135) to microbiology laboratory staff. Vaccination would decrease, but not eliminate, the potential risk of laboratory-acquired infections.

Direct Examination

Microscopy

A presumptive diagnosis of meningococcal meningitis can be made by direct examination of CSF, using the Gram stain. If sufficient (i.e., more than 1 to 2 ml) CSF is received, the specimen should be centrifuged to obtain a pellet of material for examination and culture. Cytocentrifugation of CSF specimens enhances detection of small numbers of organisms and increases the sensitivity of the Gram stain in comparison with conventionally centrifuged or uncentrifuged specimens. On Gram-stained smears prepared from clinical specimens, meningococci appear as Gram-negative diplococci both inside and outside PMNs. Organisms may display considerable size variation and tend to resist decolorization. Heavily encapsulated strains may have a distinct pink halo around the cells. Because the presence of inflammatory cells has prognostic value (e.g., with fulminant, rapidly fatal disease, many organisms and few inflammatory cells are present), the Gram stain report to the physician should include quantitation of both organisms and PMNs.

Antigen Detection

Direct tests for detection of meningococcal capsular polysaccharides in CSF, serum, and urine are also available. Direct antigen tests use antibody-sensitized latex agglutination or coagglutination to detect capsular antigens of meningococcal serogroups A, B, C, Y, and W135. The serogroup B reagent also detects the cross-reacting *Escherichia coli* K1 antigen. These reagents are available from several vendors (BD Biosciences for latex tests; Boule Diagnostics AB for coagglutination tests). A negative test does not rule out meningitis, and false-positive latex agglutination tests may occur, particularly with urine specimens. Due to the enhanced sensitivity of the Gram stain provided by specimen cytocentrifugation and the problems with the specificity of the antigen detection assays, most laboratories in the United States no longer perform these tests routinely and they are not recommended.

Nucleic Acid Detection Techniques

Molecular methods for direct detection of *N. meningitidis* in clinical specimens are not currently available.

Isolation Procedures

For recovery of *N. meningitidis*, CSF specimens should be inoculated onto nonselective chocolate agar and sheep blood agar. Specimens that may harbor other organisms (e.g., oropharyngeal and nasopharyngeal swab specimens) should be inoculated onto both selective and nonselective media. Plates are incubated in 5 to 7% CO_2 at 35°C (CO_2 incubator or candle extinction jar) and inspected after 24, 48, and 72 h before a final report of "no growth" is issued. Suspicious colonies are subcultured to blood and chocolate agar for further identification.

Identification

Colony Morphology

Colonies of *N. meningitidis* are larger than gonococcal colonies, usually attaining a diameter of about 1 mm or more after 18 to 24 h of incubation. Colonies are low and convex, with a smooth, moist entire edge and a glistening surface. On sheep blood agar, colonies are usually gray; heavily encapsulated strains may be mucoid. The medium beneath and adjacent to the colonies may exhibit a gray-green cast, particularly in areas of confluent growth. Young cultures have a smooth consistency, while older cultures become gummy due to autolysis.

Identification Procedures

N. meningitidis is identified by acid production tests or by chromogenic enzyme substrate tests. Identification procedures

for meningococci produce the best results when inoculated from fresh 18- to 24-h subcultures on chocolate or blood agar. *N. meningitidis* acidifies glucose and maltose, but not sucrose, fructose, or lactose (Table 3). Isolates recovered on selective media can be identified with chromogenic enzyme substrate tests. *N. meningitidis* strains produce γ-glutamyl aminopeptidase; some strains also produce prolyl-hydroxyprolyl aminopeptidase. Glucose-negative, maltose-negative, and asaccharolytic *N. meningitidis* strains may also be isolated occasionally. For these isolates, chromogenic substrate confirmatory tests or serogrouping should be performed.

Serogrouping and Typing

Slide agglutination is commonly used for serogrouping meningococci. A dense suspension of the organism is prepared in 0.5 to 1.0 ml of phosphate-buffered saline (pH 7.2) from a 12- to 18-h subculture on Trypticase-soy blood agar. One drop of this suspension is mixed with 1 drop of meningococcal antisera on a sectored slide, and the slide is rotated for 2 to 4 min. Groupable strains agglutinate strongly within this time. Although isolates from systemic infections usually agglutinate rapidly, those from carriers may fail to agglutinate (nongroupable strains) or may autoagglutinate in saline. Use of younger cultures from blood agar (6 to 8 h) or use of a serum-enriched medium, such as Trypticase-soy agar containing 10% decomplemented horse serum, may resolve these problems. Antisera for the major meningococcal serogroups are available from BD Biosciences. Some nongroupable strains may actually be *N. polysaccharea;* testing for production of polysaccharide from sucrose helps identify this species (see below) (18).

N. meningitidis isolates may be serotyped and subserotyped based on OMP and lipooligosaccharide antigens (95). Meningococcal isolates can be subdivided into 20 serotypes based on class 2 and 3 OMP or PorB antigens, 10 serosubtypes based on class 1 OMP (PorA) antigens, and 13 immunotypes based on lipooligosaccharide antigens. Multilocus isoenzyme electrophoresis typing and multilocus sequence typing have been used to identify genetically defined clonal groups responsible for both epidemic and sporadic, endemic disease. Meningococcal serogroup antigen gene sequencing by sialytransferase gene PCR can be used to confirm serologic grouping results and to determine the genetic grouping of serologically "nongroupable" strains (19). Other molecular methods, including DNA fingerprinting, restriction fragment length polymorphisms, PFGE, ribotyping, repetitive element-based PCR, random-amplified PCR, *por*A gene sequencing, and PCR-amplicon endonuclease analysis, have also been developed for monitoring the epidemiology of pathogenic *N. meningitidis* locally and globally (13, 80, 103).

Antimicrobial Susceptibilities

Despite the occasional recovery of *N. meningitidis* strains with decreased susceptibility to penicillin, penicillin G remains the drug of choice for treatment of meningococcal meningitis. Several broad-spectrum cephalosporins reach therapeutic levels in CSF and are also recommended treatment options. Patients may also require intensive supportive care and monitoring for detection of complications and disease progression (100). Other biological agents (e.g., antiendotoxin and anticytokine monoclonal antibodies) may also play important roles as adjunctive therapies in the management of meningococcal septic shock.

As in the gonococcus, the antimicrobial susceptibility of *N. meningitidis* strains is also evolving (83). Historically, penicillin-susceptible strains of *N. meningitidis* have penicillin MICs of ≤0.06 μg/ml. Rare β-lactamase-producing meningococcal isolates have been encountered sporadically since 1983 in Canada, South Africa, and Spain; these isolates have penicillin MICs of >256 μg/ml. Since 1987, β-lactamase-negative *N. meningitidis* strains with penicillin MICs of >0.06 μ/ml have been isolated in the United Kingdom, Europe, Greece, South America, South Africa, Asia, and the United States (83). These strains are referred to as being relatively resistant to penicillin, being moderately susceptible to penicillin, and having diminished susceptibility to penicillin. Strains with decreased susceptibility to penicillin have MICs ranging from 0.10 to 1.0 μg/ml, and resistant strains are defined as having penicillin MICs of ≥2 μg/ml. Diminished penicillin susceptibility is due to decreased binding of penicillin by altered meningococcal cell wall penicillin-binding proteins (PBP 2 and PBP 3). In the case of the PBP 2 proteins, decreased binding of penicillin to the altered binding protein results from a mutation in the nucleotide sequence of the PBP 2 gene, *pen*A. Similar low-affinity forms of PBP 2 are found in penicillin-resistant strains of *N. lactamica*, *N. flavescens*, *N. polysaccharea*, and *N. gonorrhoeae* (20). The altered PBP 2 found in these *N. meningitidis* strains apparently arose from recombinational events that resulted in replacement of nucleotide sequences in the native meningococcal *penA* gene with corresponding genetic material from the commensal *Neisseria* species.

The clinical significance of diminished penicillin susceptibility in *N. meningitidis* is unclear at present. Although both treatment failures and higher rates of complications have been observed in patients infected with relatively resistant strains, the administration of higher doses of penicillin has been clinically effective. Broad-spectrum cephalosporins, such as ceftriaxone and cefotaxime, are active against both susceptible and moderately susceptible *N. meningitidis* strains, but MICs for some agents (e.g., cefuroxime, aztreonam, and imipenem) may be significantly higher than those of susceptible strains (78).

N. meningitidis strains may also demonstrate resistance to other antimicrobial agents (64). High-level chloramphenicol resistance due to production of chloramphenicol acetyltransferase has been reported in isolates from France and Vietnam. High-level resistance to sulfonamides, including trimethoprim-sulfamethoxazole, is widespread. Rifampin resistance has also emerged, even during the administration of rifampin prophylaxis, and is due to alterations in cell membrane permeability or to mutations in the *rpoB* gene coding for the β-subunit of the meningococcal RNA polymerase. In 2000, an *N. meningitidis* strain with decreased susceptibility to ciprofloxacin (MIC of 0.25 μg/ml) was isolated from a patient with invasive meningococcal disease in Australia (88). Susceptible strains have ciprofloxacin MICs of ≤0.03 μg/ml. Finally, some *N. meningitidis* strains have acquired the *tet*M tetracycline resistance determinant. Resistance to the extended-spectrum cephalosporins that may be used for treatment in developed countries has not been described.

For antimicrobial susceptibility testing of *N. meningitidis* isolates, MIC determinations are the methods of choice. Disk diffusion tests with penicillin, ampicillin, and rifampin for *N. meningitidis* are unreliable. The CLSI recommends either broth microdilution or agar dilution MIC testing of *N. meningitidis* using cation-adjusted Mueller-Hinton broth supplemented with 2 to 5% lysed horse blood or Mueller-Hinton agar with 5% (vol/vol) defibrinated sheep blood, respectively (31). For optimal growth of some *N. meningitidis* strains, this medium may require supplementation with IsoVitalex (1%) (BD Biosciences) or GCHI enrichment (Remel, Inc.). The E test may also be valuable for determining the antimicrobial

susceptibility of individual meningococcal isolates. Since most clinical microbiology laboratories are not equipped to perform agar dilution tests, isolates from patients who are not responding to appropriate antimicrobial chemotherapy and any presumptively penicillin-resistant isolates should be tested for β-lactamase production with the chromogenic cephalosporin test (Cefinase nitrocefin disks; BD Biosciences) and forwarded to a reference laboratory for agar or broth dilution susceptibility testing.

Evaluation, Interpretation, and Reporting

Meningococci are isolated most frequently from the oro- or nasopharynges of asymptomatic carriers along with other normal flora. *N. meningitidis* isolated from throat cultures should not be reported, since reporting implies that the organism is behaving as a pathogen and requires treatment. Meningococci from oropharyngeal cultures represent carriage strains. Meningococcal carriage may be transient, intermittent, or chronic, and carriage alone is not predictive of the development of life-threatening disease (105). While chemoprophylaxis with rifampin, ciprofloxacin, or ceftriaxone is recommended for close contacts of individuals with severe disease, treatment of meningococcal carriers is not recommended. Unless selective media are employed, colonies of *N. meningitidis* may not be noticed among the other members of the resident flora. *N. meningitidis* recovered from CSF, blood, and other normally sterile sites should be identified and reported. Isolates from sputum cultures must be interpreted with regard to clinical presentation and in consultation with clinicians caring for the patient. Because meningococci may be isolated from anogenital sites infected by gonococci, it is necessary to identify neisserial isolates from these sites to the species level by using confirmatory tests.

OTHER *NEISSERIA* SPECIES

Neisseria lactamica

N. lactamica resembles *N. meningitidis* in colony morphology and was initially thought to be a lactose-positive variant of *N. meningitidis*. This species is found in the throat and is isolated more frequently from children than from adults (48). *N. lactamica* grows on all types of selective media and produces acid from glucose, maltose, and lactose (Table 3). ONPG is also hydrolyzed and can be used as a substitute for lactose. Some strains may cause false-positive reactions with commercial coagglutination tests.

N. cinerea

N. cinerea is part of the commensal flora of the upper respiratory tract and has been isolated from other sites, including the cervix, rectum, conjunctivae, blood, and CSF (37, 38, 67). *N. cinerea* grows on both blood and chocolate agar. On chocolate agar after 24 h of incubation, colonies of *N. cinerea* resemble the large-colony types of *N. gonorrhoeae*, are about 1 mm in diameter, and are smooth with entire edges. The organism does not produce acid from carbohydrates in either CTA-based media or the rapid acid production test (Table 3). Weak positive reactions with glucose after overnight incubation have been reported with some identification systems, and its positive prolyl-hydroxyprolyl aminopeptidase reaction may also result in misidentifications of *N. cinerea* as *N. gonorrhoeae* (45, 79). Most *N. cinerea* isolates, however, do not grow well on MTM or other selective media, which precludes testing using chromogenic substrate tests such as the BactiCard-*Neisseria* (Remel, Inc.). *N. cinerea* can be differentiated from the asaccharolytic species *N. flavescens* by its inability to produce polysaccharide from sucrose (see below) and the lack of a discernible yellow pigment. This species is differentiated from the asaccharolytic diplococcal species *M. catarrhalis* by its negative nitrate reduction, DNase, and tributyrin hydrolysis reactions.

The colistin susceptibility test is helpful for differentiating *N. cinerea* from *N. gonorrhoeae*. A suspension of the organism (0.5 McFarland turbidity standard) is prepared in broth and is swabbed onto a chocolate or blood agar plate as for a disk diffusion susceptibility test. A 10-μg colistin disk is placed on the inoculum, and the plate is incubated in CO_2 for 18 to 24 h. *N. cinerea* is colistin susceptible and has a zone that is larger than or equal to 10 mm around the disk. Generally, *N. gonorrhoeae* grows up to the edge of the disk.

Neisseria flavescens

N. flavescens is found in the upper respiratory tract and is rarely associated with infectious processes. This organism forms smooth, yellowish colonies on blood, chocolate, and nutrient agar at 35°C. Most strains also grow at room temperature on chocolate or blood agar. This organism synthesizes iodine-positive polysaccharide from sucrose (see discussion below) and can be differentiated from *M. catarrhalis* by its yellow pigmentation, inability to reduce nitrate, and negative DNase and tributyrin hydrolysis reactions.

Neisseria subflava Biovars, *Neisseria mucosa*, and *Neisseria sicca*

N. subflava, *N. mucosa*, and *N. sicca* make up part of the normal human upper respiratory tract flora and are occasional isolates from infectious processes, including endocarditis, bacteremia, meningitis, empyema, pericarditis, and pneumonia. Identification of the "nonpathogenic" *Neisseria* species is not generally necessary unless the organism is determined to be clinically significant or is isolated from a systemic site (e.g., blood or CSF) or in pure culture. Identification is based on colony morphology, growth on simple nutrient media, inability to grow on selective media, acid production from carbohydrates, reduction of nitrate and nitrite, and synthesis of a starch-like, iodine-staining polysaccharide from sucrose. Nitrate reduction and nitrite reduction are determined in tryptic-soy or heart infusion broth containing 0.1% (wt/vol) KNO_3 or 0.01% (wt/vol) KNO_2, respectively. Polysaccharide synthesis is determined by inoculating the organism onto brain heart infusion agar containing 1% sucrose. Medium lacking sucrose is inoculated as a negative control. After incubation at 35°C for 48 h, the plates are flooded with Gram's or Lugol's iodine (1:4 dilution). A positive test is indicated by the development of a deep blue color in and around the colonies synthesizing the polysaccharide.

N. subflava strains can be subdivided into three biovars (biovars subflava, flava, and perflava) based on acid production from fructose and sucrose, synthesis of iodine-positive polysaccharide from sucrose, and reduction of nitrate and nitrite (Table 3). All three biovars reduce nitrite but not nitrate. *N. mucosa* has a carbohydrate utilization pattern similar to that of *N. subflava* bv. perflava and also produces the iodine-positive polysaccharide, but *N. mucosa* is able to reduce both nitrate and nitrite to nitrogen gas. All of these organisms display varying degrees of yellow pigmentation. *N. sicca* strains are biochemically identical to *N. subflava* bv. perflava, but they grow as dry, adherent, leathery colonies on agar media.

Neisseria polysaccharea

N. polysaccharea is found in the human oropharynx. This organism is an oxidase-positive, catalase-positive, gram-negative

diplococcus that forms smooth yellow colonies (81). Growth on selective media for the pathogenic *Neisseria* is a variable characteristic of *N. polysaccharea* due to the colistin susceptibility of some strains (4). The organisms are resistant to vancomycin. After 24 h of growth, *N. polysaccharea* forms colonies of about 2 mm in diameter on chocolate or blood agar. Acid is produced from glucose and maltose but not from fructose or lactose. Acid production from sucrose is variable and appears to depend on the types of media used to determine this characteristic. *N. polysaccharea* produces an amylosucrase enzyme that synthesizes amylopectin, an extracellular polysaccharide from sucrose. Nitrate is not reduced, whereas nitrite frequently is reduced. *N. polysaccharea* can be differentiated from *N. meningitidis* by polysaccharide synthesis and the γ-glutamylaminopeptidase test. *N. polysaccharea* produces iodine-positive polysaccharide from sucrose and is γ-glutamyl aminopeptidase negative, whereas *N. meningitidis* does not produce iodine-positive polysaccharide from sucrose and is γ-glutamyl aminopeptidase positive. Like *N. gonorrhoeae*, *N. lactamica*, and some *N. meningitidis* strains, *N. polysaccharea* is L-hydroxyprolyl aminopeptidase positive (4). The organism requires cysteine for growth and does not grow on nutrient agar or on chocolate agar at 22°C.

Neisseria elongata Subspecies

N. elongata subspecies *elongata*, *glycolytica*, and *nitroreducens* are rod-shaped members of the genus *Neisseria*. All subspecies are members of the human upper respiratory tract flora, and all have been isolated from infectious processes, including endocarditis (51). These subspecies can be differentiated on the basis of catalase reactivity, acid production from glucose, and reduction of nitrate (Table 3).

Actinobacillus, Capnocytophaga, Eikenella, Kingella, Pasteurella, and Other Fastidious or Rarely Encountered Gram-Negative Rods

ALEXANDER VON GRAEVENITZ, REINHARD ZBINDEN, AND REINIER MUTTERS

40

The bacterial genera covered in this chapter are taxonomically diverse, but common traits justify their discussion as a group. They are facultatively anaerobic gram-negative rods that belong neither to the families *Enterobacteriaceae, Vibrionaceae,* and *Aeromonadaceae* nor to the *Rickettsiales;* they are rather part of the families *Pasteurellaceae, Neisseriaceae, Cardiobacteriaceae, Flavobacteriaceae, Porphyromonadaceae,* and *Fusobacteriaceae* (51).

These bacteria grow aerobically but require, with the exception of *Chromobactrium* and some *Pasteurella* species, supplemented media for growth, grow slowly, often requiring 48 h at 37°C, and do not grow on enteric media such as MacConkey or desoxycholate agar. A 5 to 10% CO_2 atmosphere may be necessary for initial growth and improves growth on subcultures. Some isolates may be gram-variable; many species show limited viability. With the exception of *Chromobacterium*, they do not possess flagella but may show gliding or twitching motility, resulting in limited spreading of colonies and pitting of the agar (66).

Most species may be part of the flora of the nasopharynx and/or the oral cavity of animals and/or humans and, thus, are parasitic, in contrast to the environmental *Chromobacterium*. Only those isolated from humans are covered in this chapter. Transmission from animals to humans occurs by contact (e.g., bites or licking of wounds for *Pasteurella*), and from human to human by droplets (e.g., directly for *Kingella* or via paraphernalia or human bites for *Eikenella*); only *Chromobacterium* is transmitted by soil. Endogenous infections may occur as well (e.g., endocarditis).

The collection of specimens should follow the guidelines described in chapters 5 and 20. The low viability of many species makes use of transport media mandatory. Serological tests have not been tried on large numbers of cases.

The use of blood or chocolate agar and, wherever no normal flora is present, of enriched liquid media is mandatory. Selective media are mentioned below for each organism.

Phenotypic identification may present numerous difficulties. Identification to the species level often requires the use of multiple substrates not altogether available in many automated systems (17, 36, 60); databases of the latter also may not contain all relevant species. Similar biochemical characteristics, e.g., in *Actinobacillus* spp., may call for species confirmation by molecular methods (44, 52, 90). Triple-sugar iron or Kligler's agar may not support growth, e.g., of *Eikenella*. Gas formation, if present, is generally scant and may not be seen in these media. Media used to check acid formation from carbohydrates should be rich in peptones (e.g., cystine-trypticase agar), but serum should not be used, if at all possible, because it may split maltose. An alternative would be the use of Trypticase agar with 1% carbohydrate and a large inoculum (cell paste or agar block). Indole formation may take 2 days and may require extraction with xylene. The indole spot test is reliable only for *Pasteurella multocida* (103). Oxidase must be tested from colonies on blood-containing media with tetramethyl-*p*-phenylenediamine dihydrochloride (57). Catalase should preferably be checked in a liquid medium in order to avoid false-positive reactions on slides due to transfer of blood and false negatives due to weak reactions.

Except for a very recent report on *Pasteurella* spp. (30), there are no Clinical and Laboratory Standards Institute (CLSI) (formerly NCCLS) data for disk susceptibility testing of members of the group. MIC determinations require either dilution systems or E tests (55–56, 74, 80, 94). Most species are susceptible to many antimicrobials. There may even be small zones around 5-μg vancomycin disks (42).

Members of the group may cause infections anywhere in the human body. Those present in the oropharynx of animals often cause bite infections which may develop into systemic disease, particularly in immunosuppressed individuals. A disease particular to members of the group is HACEK endocarditis, named after the bacteria involved (*Haemophilus parainfluenzae*, *Haemophilus aphrophilus*, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium*, *Eikenella*, and *Kingella* spp.) (19). It is characterized by a long interval between first symptoms and diagnosis (2 weeks to 6 months), frequent embolization, and large vegetations on left-side valves. Native and prosthetic valves may be affected. Prognosis is good with appropriate antibiotic treatment. In modern automated blood culture systems, HACEK organisms grow within 5 days (35, 62). In a few instances, blood cultures were negative but microscopy of the resected valve and/or broad-range PCR of valve or emboli led to the diagnosis (98, 101). *Cardiobacterium*, *Capnocytophaga*, and *Eikenella* may also participate in noma lesions (108), whereas the latter two genera and *Actinobacillus actinomycetemcomitans* (as the predominant agent) participate in periodontal lesions (102).

PASTEURELLA

The genus *Pasteurella* belongs, together with the genera *Haemophilus* and *Actinobacillus* and several nonhuman ones, to the family *Pasteurellaceae* (51). These genera have identical cellular fatty acid composition, with C16:1ω7c, C16:0, and C14:0 as the principal components. There is no single phenotypic feature that distinguishes the genera *Pasteurella* and *Actinobacillus*. The guanine-plus-cytosine (G+C) content of the DNA for *Pasteurella* is between 37.7 and 45.9 mol%. Members of one group of pasteurellae, however, are by DNA-DNA hybridization more closely related to the other two genera and have been marked *[P.]* (5), whereas the other group are called *Pasteurella* sensu stricto.

Pasteurellae are coccoid to small, nonmotile, facultatively anaerobic gram-negative rods that occur singly, in pairs, or in short chains. Bipolar staining is frequent. The "related" species generally have a more pronounced rod-like morphology and may even grow on MacConkey agar. All pasteurellae are hemin and CO_2 independent, but a few strains require factor V (nicotine adenine dinucleotide) (80). Colonies are 1 to 2 mm in diameter after 24 h of growth on blood agar at 37°C and opaque-grayish. Encapsulated strains tend to be mucoid. A slight greening underneath them may be observed. The indole-positive species exhibit a mouse-like odor.

Pasteurellae are widespread in healthy and diseased wild and domestic animals. Their habitats are the nasopharynx and the gingiva. Those occurring in animals only (particularly in birds and mammals) (25) are not covered here. *P. multocida*, the species most frequently isolated from humans, also occurs in many animals including dogs and cats. In spite of the genotypical homogeneity of *P. multocida*, phenotypically diverse lineages have been observed, e.g., infections of wounds from bites by large cats may be due to sucrose-negative variants (27). Virulence factors (capsule serotypes A to F, a cytotoxin, filamentous hemagglutinins, and iron acquisition proteins) have been identified in animal models (63), but their role in human pathology remains to be elucidated. Most human cases are due to serotypes A, D, and F (37).

Human infections are predominantly those of wounds or soft tissues following bites, scratches, or licking of skin lesions by carnivores. Of 159 human isolates of *Pasteurella* sensu stricto, 60% were *P. multocida* subsp. *multocida*, 18% were *P. canis,* 13% were *P. multocida* subsp. *septica*, 5% were *P. stomatis,* and 3% were *P. dagmatis* (all except *P. canis* are associated with both dogs and cats) (68). Infected cat bite wounds contain pasteurellae (mostly subsp. *multocida* and *septica*) significantly more often than infected dog bite wounds, reflecting a higher oropharyngeal colonization rate in cats (50 to 90% versus 55 to 60%) (24). Two species may even be encountered in one sample (142). The second most common site not only of infection but also of colonization is the respiratory tract, where pasteurellae sensu stricto may also cause sinusitis and bronchitis as well as pneumonia and empyema (with a poor prognosis), mostly in patients with underlying disease (24, 141). Finally, systemic diseases (meningitis, peritonitis, septicemia, arthritis, endocarditis, and osteomyelitis) have also been reported, with underlying medical conditions, particularly liver cirrhosis, present in many individuals affected (8, 143). An association exists between subspecies and clinical presentation: subsp. *septica* is more often associated with wounds than with respiratory and systemic infections, whereas subsp. *multocida* predominates in respiratory infections and bacteremias (24, 37). Cases of human infection with *P. gallinarum* (3, 6) (now *Avibacterium gallinarum*) (13) have to be regarded with circumspection (45); nevertheless, a case of neonatal meningitis (1) seems to be beyond reproach.

Of the "related" species, *[P.] caballi* has primarily been isolated from horses (120) and also from horse bite wounds in humans (41). *[P.] bettyae* (formerly HB-5), of uncertain habitat, has been isolated from infections of the male and female genital tracts and of newborns (15, 33). *[P.] aerogenes* has been detected primarily in pigs and hamsters and was isolated from bite wounds from those animals (39, 46). *[P.] pneumotropica* corresponds in habitat and transmission to *P. multocida,* but human infections (bites, systemic disease) are rare (44). The former *[P.] haemolytica*, also of animal origin, has now been subdivided into trehalose-positive strains, named *[P.] trehalosi,* and trehalose-negative strains, named *Mannheimia haemolytica* (5). Cases of human infection are somewhat doubtful (89, 111, 141); one case of endocarditis (132) seems to conform to the former description of the *[P.] haemolytica* complex.

Media containing vancomycin, clindamycin, and/or amikacin have been used to select pasteurellae (9). Biochemical reactions of species isolated from humans are listed in Table 1. In view of the phenotypic similarity of some species and the presence of some unclassified taxa (12, 25), species identification requires tests that may not be included in automated diagnostic systems (61). Beta-hemolysis is observed only in the former *[P.] haemolytica* complex. PCR (71), repetitive extragenic palindromic PCR (24), and 16S rRNA gene sequencing (44) have been used for diagnostic confirmation. Typing of pasteurellae has employed multilocus enzyme electrophoresis, PCR profiling, restriction endonuclease analysis, pulsed-field gel electrophoresis, and ribotyping (27, 71).

Pasteurellae are generally susceptible to β-lactam antibiotics including penicillin, cephalosporins (except oral narrow-spectrum agents), tetracyclines, quinolones, and trimethoprim-sulfamethoxazole and are generally resistant to macrolides and amikacin; other aminoglycosides are only moderately active (54, 55, 56, 57, 143). A few β-lactamase-positive strains of *P. multocida* (100) and *[P.] bettyae* (15) have been reported; they were susceptible to a combination of penicillin and clavulanic acid.

ACTINOBACILLUS

The genus *Actinobacillus,* in the family *Pasteurellaceae* (51), resembles *Pasteurella* in the composition of cellular fatty acids but has a narrower G+C content of the DNA (between 40 and 43%).

Actinobacilli are nonmotile, facultatively anaerobic coccoid to small gram-negative rods on solid media but are longer in liquid media or in those containing glucose or maltose and show a tendency to bipolar staining. Arrangement is single, in pairs, and (rarely) in short chains. Growth requires enriched media but not necessarily hemin and is improved by a 5 to 10% CO_2 atmosphere.

Many species have been isolated only from animals and are not discussed here. Species isolated from humans belong either to *Actinobacillus* sensu stricto (26) or to *A. actinomycetemcomitans*. The former include *A. lignieresii* (primary habitat in the oral cavity of sheep and cattle), *A. equuli* subsp. *equuli* (oral cavity of horses and pigs), *A. equuli* subsp. *haemolyticus* and *A. suis* (oral cavity of pigs), and the exclusively human species *A. ureae* (formerly *Pasteurella ureae*) and *A. hominis.* The species *A. actinomycetemcomitans* is of uncertain taxonomic status because 16S rRNA gene sequencing and DNA-DNA hybridization place it more

[b] +, ≥90% of strains positive; −, ≤90% of strains negative; v, variable; w, weak; ND, no data available.
[c] All species reduce nitrate to nitrite and are negative for arginine dihydrolase and esculin hydrolysis.
[d] The three subspecies *multocida, septica,* and *gallicida* can be separated on the basis of sorbitol and dulcitol fermentation (+/− in subsp. *multocida*, −/− in subsp. *septica,* and −/+ in the mostly avian subsp. *gallicida*); weakly sorbitol-positive strains of subsp. *multocida* can be recognized by a negative α-glucosidase test and a specific PCR profile (52).
[e] Beta-hemolytic; *[P.] trehalosi* is trehalose positive; *Mannheimia haemolytica* is trehalose negative.

closely to the genus *Haemophilus* than to *Actinobacillus* (105). Its transfer to the genus *Haemophilus* (110), however, was not favored by the International Committee on Systematic Bacteriology Subcommittee on *Pasteurellaceae* and Related Organisms (72). Its habitat is the oral cavity of humans and of some primates (65).

Colonies of actinobacilli sensu stricto are approximately 2 mm in diameter after 24 h of growth at 37°C, are smooth or rough, are viscous, and often adhere to the agar surface. Smooth colonies are dome-shaped and have a bluish hue when viewed by transmitted light. *A. actinomycetemcomitans* colonies initially show a central dot and a slightly irregular edge, which, on further incubation, develops into a star-like configuration resembling "crossed cigars," and pit the agar (Fig. 1). After several subcultures, this rough morphology may give way to smooth and opaque, nonpitting colonies, reflecting loss of fimbriae. In liquid media, the bacterium forms granules which adhere to the sides and to the bottom of the tube.

A. lignieresii causes actinobacillosis, a granulomatous disease in cattle and sheep in which, in a fashion similar to actinomycosis, sulfur granules are formed in tissues (116). A few human soft tissue infections, originating from cattle or sheep bite wounds or contact, have been reported (109). The *A. equuli* subspecies and *A. suis* cause a variety of diseases in horses and pigs (25); human infections are mostly due to horse or pig bites or contact (7, 40). Both species have also been isolated from the human upper respiratory tract (117, 135). *A. ureae* has been isolated most often as a commensal from the human respiratory tract but also from meningitis patients following trauma or surgery (137) and other infections in immunocompromised patients (77). *A. hominis* was also encountered in such patients, as well as a commensal, albeit rarely (48).

A. actinomycetemcomitans is one of the major agents of adult and juvenile periodontitis (102). Furthermore, it has caused endocarditis (HACEK) (19) and soft tissue and other infections (75, 107). In sulfur granules, it may occur in combination with *Actinomyces* spp. (75).

Virulence factors of actinobacilli belong to the RTX (repeats-in-toxin) family, i.e., poreforming (hemolytic or cohemolytic) and cytolytic proteins (47). *A. actinomycetemcomitans* forms an RTX toxin termed leukotoxin, an epithelial distending toxin, some less well characterized immunomodulatory toxins, and fimbriae responsible for adherence (65).

Selective media have been devised for isolation of *A. actinomycetemcomitans* from dental samples. The clear Tryptic soy-serum-bacitracin-vancomycin medium allows observation of colonial morphology and catalase activity (127). It was recently modified (4). PCR has been used for detection, targeting the leukotoxin gene or specific 16S rRNA sequences (50).

Biochemical reactions are listed in Table 2. Species of *Actinobacillus* sensu stricto are easily separated from *A. actinomycetemcomitans* by urease production and sucrose fermentation. The latter and catalase and ONPG (*o*-nitrophenyl-β-D-galactopyranoside) reactions separate *A. actinomycetemcomitans* from *Haemophilus aphrophilus*, an important differentiation in the clinical laboratory which cannot always be accomplished if commercial systems are employed (17, 36). Separation of *A. equuli* subsp. *equuli* and *A. suis* may be impossible by phenotypic tests; the organisms share the same 16S rRNA gene sequence (26) but have different RTX toxin profiles (83).

On the basis of surface polysaccharides determined by tube agglutination or multiplex PCR (131), six serotypes of

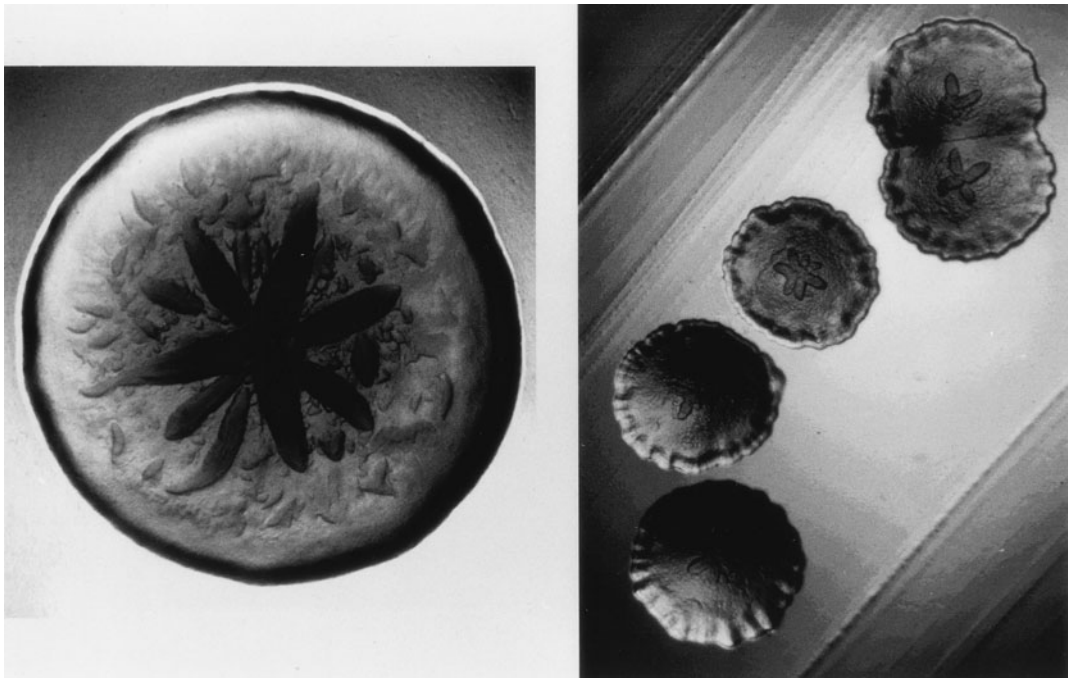

FIGURE 1 Star-shaped colonies of *Actinobacillus actinomycetemcomitans*.

A. actinomycetemcomitans can be distinguished, of which a, b, and c are most common. Serotype b is associated with periodontitis, penicillin resistance, and endocarditis, whereas serotype c is associated with other extraoral infections but also with periodontal health (106). Other typing systems (65, 107), also used on strains of *A. suis* and *A. equuli* (26), have been of less clinical relevance.

Susceptibility studies are extant for a few isolates of *A. ureae* and *A. hominis* that are susceptible to many antimicrobials including penicillin (48, 77). *A. actinomycetemcomitans* is usually susceptible to cephalosporins, ampicillin, doxycycline, and aminoglycosides; resistance to penicillin and macrolides is not uncommon (75, 80, 94, 107, 128). Penicillinase, however, has not been detected (94, 128).

CHROMOBACTERIUM

The genus *Chromobacterium,* in the *Neisseriaceae* family, contains one species, *C. violaceum* (51). It is a facultatively anaerobic, straight gram-negative rod which differs from all

TABLE 2 Biochemical reactions of *Actinobacillus* spp. and *Haemophilus aphrophilus*[a,b,c]

[c] All species are indole and ornithine decarboxylase negative and reduce nitrate to nitrite.

other species covered in this chapter by being motile by one polar and one to four lateral flagella, by growth on most enteric media, by an optimal growth temperature below 37°C, and an environmental origin. Colonies are 1 to 2 mm in diameter after 24 h of growth at 30 to 35°C, are round and smooth, have an almond-like smell, and may be beta-hemolytic. Most colonies produce a violet pigment called violacein, which is soluble in ethanol but not in water. Nonpigmented strains are known, however. The G+C value of the DNA is between 65 and 68 mol%.

C. violaceum inhabits soil and water in tropical and subtropical climates between latitudes of 35°N and 35°S (South Africa, Southeast Asia, Australia, southeastern United States). Human infections are rare. The portal of entry is usually the skin, but oral intake has also been reported. Wound infections, abscesses, and septicemia may develop. Infections are significantly associated with neutrophil dysfunction (glucose-6-phosphate dehydrogenase deficiency, chronic granulomatous disease [CGD]). Children without CGD and children with bacteremia show a high fatality rate (88, 123). A number of virulence factors other than endotoxin (adhesions, invasins, and cytolytic proteins) have been described (18).

Biochemical reactions are listed in Table 3. Identification of *C. violaceum* is easy if violacein is produced, although in those cases the oxidase reaction may be difficult to detect. Nonpigmented strains may be confused with *Aeromonas* spp. but are lysine, maltose, and mannitol negative. The principal cellular fatty acids do not differentiate between these genera.

C. violaceum is usually resistant to many antimicrobials but is often susceptible to imipenem, fluoroquinolones, gentamicin, tetracycline, and trimethoprim-sulfamethoxazole (2, 88).

EIKENELLA

The genus *Eikenella* belongs to the family *Neisseriaceae* (51). Thus far, only one species, *E. corrodens*, has been recognized, but DNA-DNA hybridization, composition of cellular carbohydrates, and the occurrence of biochemically aberrant (among them, catalase-positive) isolates suggest that there may be more than one genomospecies (76). The G+C content is between 56 and 58 mol%.

Eikenellae are slender, straight, small, nonmotile, facultatively anaerobic gram-negative rods (Fig. 2A). With a few exceptions, they require hemin for growth unless 5 to 10% CO_2 is present (53) and, therefore, grow poorly or not at all on triple-sugar iron or Kligler's agar. Colonies are 1 to 2 mm in diameter after 48 h of growth and show clear centers that are often surrounded by spreading growth, and they may pit the agar. They smell of hypochlorite and assume a slightly yellow hue after several days. In liquid media, granules are formed.

The habitat of *E. corrodens* is the oral cavity and perhaps the gastrointestinal tract of humans and some mammals from whom it can be transmitted via saliva (bites, syringes) to other individuals. The organism is associated with adult and juvenile periodontitis (102) and is also an agent of oral, pleuropulmonary, abdominal, joint, bone, and wound (e.g., human bite) infections (108, 122). These are often indolent and mixed with other members of the oropharyngeal flora. Risk factors are dental manipulations and intravenous drug abuse. Endocarditis is of the HACEK type if monomicrobial; polymicrobial cases, however, are known (19).

Detection is improved by use of a selective medium containing clindamycin (124) and by PCR (50). Biochemical reactions are recorded in Table 3. A typical isolate fails to form acid from carbohydrates and is ornithine decarboxylase and nitratase positive. Typing has been done by arbitrarily primed PCR (49) and restriction endonuclease analysis (23), demonstrating unstable polyclonality in the oral cavity.

E. corrodens is susceptible to many antimicrobials including penicillin, expanded- and broad-spectrum cephalosporins, carbapenems, doxycycline, and fluoroquinolones and is often resistant to macrolides (54, 55, 56). β-Lactamase-positive strains have become more frequent, but their resistance can be overcome by β-lactamase inhibitors (85).

KINGELLA

The genus *Kingella*, consisting of the species *K. kingae*, *K. denitrificans*, *K. oralis*, and *K. potus,* also belongs to the family *Neisseriaceae* (51). The G+C content of the DNA is between 47 and 58 mol%.

Its members are short, nonmotile, facultatively anaerobic gram-negative rods with square ends which lie together in pairs or clusters (Fig. 2B) and tend to decolorize unevenly on Gram stain. Colonies develop to 1- to 2-mm diameter in 48 h of growth, one type being smooth with a central papilla, the other showing spreading edges and pitting of the medium. *K. kingae*, as the only species, shows a small but distinct zone of hemolysis on blood agar. CO_2 (5 to 10%) enhances growth. Viability is limited.

K. kingae colonizes the throat but not the nasopharynx of many children aged 6 months to 4 years (139). The natural habitats of *K. denitrificans* and *K. potus* are unknown. *K. oralis* has been isolated from the healthy human mouth (22).

Infections with *K. kingae* show a predilection for bones and joints of previously healthy children under 4 years of age (139). Septic arthritis, diskitis, and osteomyelitis of the lower extremities but also occult bacteremia are conspicuous. Stomatitis and/or upper respiratory tract infections may precede systemic disease, which suggests possible interaction with viral disease(s) (139). Infections in adults occur more commonly in immunocompromised individuals (139) or may present as endocarditis (HACEK) (19). Ribotyping and pulsed-field gel electrophoresis have shown that person-to-person transmission via respiratory droplets may occur (125). *K. denitrificans* has been reported mostly as an agent of endocarditis (96). *K. oralis* has been isolated from patients with periodontitis, but its relationship to the disease is unclear (22). *K. potus* has caused a wound infection following a bite of a kinkajou (87).

Recovery of *K. kingae* from body fluids and pus can be difficult because these specimens seem to be inhibitory to the bacteria. The use of various blood culture media has significantly improved the detection rate (139). In a study using blood culture media for simulated synovial fluids, BacT/Alert (BioMérieux, Inc., Durham, N.C.) proved to be superior to BACTEC (Becton Dickinson, Cockeysville, Md.) blood cultures with regard to sensitivity and detection time (70), but comparative studies with clinical samples are not extant. Broad-range PCR has even detected *K. kingae*-specific sequences in synovial fluids that did not show growth in blood culture media (97). For isolation from areas with normal flora, solid media containing clindamycin (34) or vancomycin (140) as well as Thayer-Martin agar (140) have been recommended.

Biochemical test results are listed in Table 3. In addition to microscopic and colonial morphology, they serve to differentiate kingellae from rod-shaped members of the genus *Neisseria* (Table 4).

Kingellae are generally susceptible to β-lactam antibiotics, macrolides, doxycycline, trimethoprim-sulfamethoxazole, and quinolones (139). β-Lactamase-positive isolates exist; they are susceptible to the combination with β-lactamase inhibitors (96, 129).

SIMONSIELLA

The genus *Simonsiella* also belongs to the family *Neisseriaceae* and has a G+C content of the DNA of 40.3 to 50.1 mol% (51). Its members are strictly aerobic gram-negative, nonmotile, crescent-shaped rods. They are arranged in multicellular filaments, 10 to 50 μm by 2 to 8 μm, which are segmented into groups of mostly eight cells, resulting in a caterpillar-like appearance (Fig. 3). The long axis of each cell is perpendicular to the long axis of the filament, representing the width of the latter. Gliding motility and incomplete decolorization with Gram stain are usually observed. Simonsiellae grow well on blood agar but not on enteric media. Colonies are 1 to 2 mm in diameter after 24 h at 37°C and produce a pale yellow pigment.

FIGURE 3 Scanning electron micrograph of *Simonsiella* sp. with two multicellular filaments giving the appearance of caterpillars. (Courtesy of L. Corboz, Zürich, Switzerland.)

Three species which can be separated by biochemical tests (81) have been described. Their natural habitat is the oral cavity of sheep *(S. crassa)*, dogs *(S. steedae)*, and humans *(S. muelleri)*; simonsiellae from cats remain unnamed. *S. muelleri* has not been associated with human disease (20, 136).

An optimal medium for microscopic recognition is BSTSY agar, which contains bovine serum, glucose, tryptic soy broth, and yeast extract (82). *S. muelleri* (Table 3) is beta-hemolytic. The long axis of the cells measures 2.1 to 3.5 μm, and the short axis measures 0.5 to 0.9 μm.

One strain recovered from the gastric aspirate of a newborn was susceptible to β-lactam antibiotics, tetracycline, and gentamicin (136).

GROUP EF-4a

Groups EF-4a and EF-4b (EF, eugonic fermenter) also belong to the family *Neisseriaceae* (114), although they are not listed in the taxonomic outline of the bacteria (51). Group EF-4a consists of facultatively anaerobic, nonmotile, coccoid to short gram-negative rods (Fig. 2C) with a G+C content of 49.3 to 50.9 mol% (114). Colonies are slightly yellow or nonpigmented and often smell of popcorn.

The organisms are part of the normal flora of dogs, cats, and rodents, in whom they may cause pulmonary infection. Human infections are associated with cat or dog bite or contact (112, 133).

The two groups have identical habitats, microscopic and colony morphology, and fatty acid composition and cause the same infections in humans, but they differ biochemically. EF-4a (Table 3) is fermentative and arginine dihydrolase variable and reduces nitrate with or without gas formation (135). EF-4b is oxidative and arginine dihydrolase negative and always reduces nitrate without gas formation. Trimethoprim has been used in a selective medium (112). EF-4a organisms are susceptible to aminopenicillins, expanded- and broad-spectrum cephalosporins, fluoroquinolones, and trimethoprim-sulfamethoxazole and variably susceptible to penicillin, aminoglycosides, and macrolides (55, 92). β-Lactamases have not been found in any strain (92).

CARDIOBACTERIUM

The genus *Cardiobacterium*, which belongs to the family *Cardiobacteriaceae* (51), consists of *C. hominis* and a newly

described species, provisionally named *C. valvarum*, until now represented by five (61) and possibly another (69) isolate from which it differs in nitrate reduction but with whom it shares similar cellular fatty acids and a 99.4% 16S rRNA sequence similarity. The G+C content of the DNA is 59 to 60 mol%.

C. hominis occurs in short chains, pairs, or rosettes, showing bulbous ends and staining irregularly. Addition of yeast extract to the medium (e.g., in chocolate agar) seems to abolish this pleomorphism. Initial growth requires 5 to 10% CO_2. Colonies on blood agar attain a diameter of approximately 1 mm after 48 h at 37°C, are circular, smooth, and opaque, and may pit the agar. Colonies of *C. valvarum* are of the same or a smaller size (0.2-mm diameter), barely grow on chocolate agar, and show pleomorphism and sometimes pitting on that medium.

The normal habitat of *C. hominis* is the human upper respiratory tract and possibly also the gastrointestinal and genitourinary tracts (126). Human disease is mainly endocarditis (HACEK) (19, 31); on rare occasions, *C. hominis* has been isolated from other body sites (84, 108). In blood culture-negative cases, the diagnosis has been made by broad-range PCR and stains from heart valve or embolic tissue (98, 101).

Biochemical tests are recorded in Table 3. The indole test is weakly positive for *C. hominis* and was strongly positive for only one *C. valvarum* isolate (61). A positive indole reaction may initially suggest *Pasteurella* or *Suttonella;* identification must, therefore, include tests for catalase and mannitol fermentation.

C. hominis and *C. valvarum* are susceptible to many antimicrobials (30) including penicillin. β-Lactamase production is very rare and can be inhibited by clavulanic acid (93).

SUTTONELLA

The genus *Suttonella* is the second one in the family *Cardiobacteriaceae* (51). It contains one species, *S. indologenes* (formerly *Kingella indologenes*), a plump, irregularly staining, nonmotile, facultatively anaerobic gram-negative rod whose colonies may show spreading and/or pitting (135). The G+C value is 49 mol%. Characteristics differentiating *Suttonella* from morphologically and biochemically similar species are listed in Table 3. The organism, whose natural habitat is unknown, has only rarely been isolated from human sources, e.g., from diseased eyes (130, 135) and from blood cultures of patients with endocarditis (73, 135). Its susceptibility resembles that of *C. hominis.*

CAPNOCYTOPHAGA

The genus *Capnocytophaga,* in the family *Flavobacteriaceae* (51), consists of seven species. The G+C content of the DNA is 34 to 40 mol%.

Cells are mainly fusiform, medium to long, with tapered ends (Fig. 2D). Primary isolation requires 5 to 10% CO_2 and enriched media. Growth may differ depending on the composition of the blood agar base (38). Colonies are very small after 24 h at 37°C, reach 2 to 4 mm in diameter after 2 to 4 days, are convex or flat and often slightly yellow when scraped off the agar, show regular or spreading edges, and adhere to the agar surface.

The oxidase- and catalase-negative species *C. ochracea*, *C. gingivalis*, *C. sputigena*, *C. haemolytica*, and *C. granulosa* are normal inhabitants of the human mouth. The first three are also associated with juvenile and adult periodontitis (66, 102), whereas the latter two have been isolated from supragingival plaque of healthy adults as well as from subgingival plaque in adult periodontitis (28). All five species may cause septicemia and other infections (endocarditis, endometritis, osteomyelitis, abscesses, peritonitis, and keratitis) in immunocompetent and immunosuppressed (mainly neutropenic) patients (16, 108). They produce an immunosuppressive factor (104).

The oxidase- and catalase-positive species *C. canimorsus* and *C. cynodegmi* reside in the oral cavity of healthy dogs and cats (*C. canimorsus* is found in approximately 25% of dogs and 15% of cats) (14). Infections are associated mainly with dog and cat bites or contact. Patients infected with *C. canimorsus* most often present with septicemia and have been splenectomized or are alcoholics. In fulminant cases with a poor prognosis, disseminated intravascular coagulation, acute renal failure, respiratory distress syndrome, and shock may develop (91). Hemolytic-uremic syndrome and thrombotic thrombocytopenic purpura are other possible sequelae (78, 99). Meningitis, arthritis, eye infections (91), and endocarditis (118) have been reported as well. *C. cynodegmi* has rarely been isolated from localized and systemic infections (119). Both organisms are able to multiply intracellularly in mouse macrophages; *C. canimorsus* also produces a cytotoxin (43).

For detection of *Capnocytophaga* spp. in mixed cultures, various selective media containing bacitracin, polymyxin B, vancomycin, and trimethoprim (29) have been used, as has PCR (64). The organisms also grow on Thayer-Martin and Martin-Lewis agar. Inhibition by sodium polyanethol sulfonate has been reported (121).

Biochemical test results are listed in Table 5. Phenotypic species differentiation in the oxidase-negative group may be inconclusive (28), which has frequently resulted in the identification of the organism as "*Capnocytophaga* sp." 16S rRNA PCR-restriction fragment length polymorphism backed up by 16S rRNA gene sequencing has proven to be a reliable method for identification (28). Typing by restriction fragment length polymorphism has been undertaken (16).

Capnocytophaga spp. are usually susceptible to broad-spectrum β-lactams, macrolides, doxycycline, and fluoroquinolones but are resistant to aminoglycosides and to colistin (115). β-Lactamase-positive isolates have occasionally been found; they were susceptible to combinations with β-lactam inhibitors (74).

DYSGONOMONAS AND RELATED BACTERIA

In the genus *Dysgonomonas* of the family *Porphyromonadaceae*, three species have been recognized: *D. capnocytophagoides* (formerly CDC group DF-3), *D. gadei* (so far represented by one strain only) (68), and *D. mossii* (three strains) (86). The G+C content of the DNA has been approximately 38 mol%. The related DF-3-like bacteria have not been investigated further since their first description (32).

All resemble *Capnocytophaga* spp. in their growth characteristics; *D. mossii* has been reported to be dependent on heme (86). They are coccoid to small, nonmotile gram-negative rods (Fig. 2E). Colonies are entire, measure 1 to 2 mm in diameter after 24 h of growth, have a strawberry-like odor, and are neither adherent nor spreading.

Most *D. capnocytophagoides* strains have been isolated from stools of immunocompromised patients, and a few strains were from other sources (95). Diarrhea was reported to occur for one-half of 20 patients with fecal isolates, whereas routine stool cultures yielded the organism for 1.1 to 2.3% of individuals (95). One blood isolate was found by

[c] All species are negative for urease and ornithine decarboxylase and form acid from glucose.
[d] The isolate of *D. gadei* was catalase and indole positive (67).

ribotyping to be identical to one in the stool of the same patient (58). The natural habitat of the other species is unknown.

A selective medium containing cefoperazone, vancomycin, and amphotericin B has been used for stool cultures (58). The species show few biochemical differences (Table 5). Aerobically growing isolates of *Leptotrichia buccalis* may be confused with *Dysgonomonas;* however, the former have a different cellular fatty acid profile (mainly C16:0 and C11/t9/t6C18:1) and produce lactic acid from glucose whereas *Dysgonomonas* produces propionic and succinic acid (11).

Only *D. capnocytophagoides* strains have been checked for antimicrobial susceptibility, and they were found to be mostly susceptible to doxycycline, clindamycin, erythromycin, and trimethoprim-sulfamethoxazole, resistant to cephalosporins, aminoglycosides, and fluoroquinolones, and variably susceptible to other β-lactam antibiotics and imipenem (58, 95).

STREPTOBACILLUS

The genus *Streptobacillus,* in the family *Fusobacteriaceae,* consists of one species, *S. moniliformis,* with a G+C content of the DNA of 24 to 26 mol%.

The species is a facultatively anaerobic, nonmotile gram-negative rod with a pleomorphic appearance. For culture, media enriched with sheep or rabbit blood (15% seems to be optimal), serum, or ascitic fluid and a 5 to 10% CO_2 atmosphere are required. As a culture consisting of small- to medium-size rods ages, some organisms develop into 100- to 150-μm-long filaments which contain granules, bulbs (often in series), and bands (Fig. 2F). Coccal forms and Gram variability may also be observed. Eubacterial and L-phase colonies may be present in the same culture. The former are 1 to 3 mm in diameter after 48 h of growth on blood agar, are round and smooth, and develop optimally after approximately 72 h in 10% CO_2 at 37°C. L-phase colonies develop better on clear, serum-supplemented media and yield the characteristic "fried egg" appearance with irregular outlines and coarse granular lipid globules. In liquid media, growth occurs mainly in the form of "puff balls" at the bottom of the tube. The organism dies quickly unless subcultured.

S. moniliformis occurs naturally in the nasopharynx of wild and laboratory rats and other rodents (mice, squirrels, ferrets, weasels, and gerbils) and occasionally of dogs and cats that prey on rodents. Human infections result either from bites of those animals or from consumption of contaminated food or water. The former infection is called rat-bite fever, and the latter is called Haverhill fever. The characteristic picture of irregular fever, chills, myalgias, and arthralgias is followed in a few days by a maculopapular rash on the extremities and, sometimes, polyarthritis. Complications such as endocarditis (113), myocarditis, pericarditis, meningitis, pneumonia, amnionitis, and abscesses may develop (59).

The organism is best isolated from blood, joint fluid, or abscess material, which has to be collected and transported in the usual way (see chapters 5 and 20). It is inhibited by sodium polyanethol sulfonate present in blood culture media (138). Nalidixic acid has been used in selective media (138). In culture-negative cases, broad-range PCR of fluids has been employed (10, 134). Serological tests are unreliable (21).

S. moniliformis is biochemically inert (Table 5). Glucose is acidified weakly and in a delayed fashion (135). Identification may be confirmed by 16S rRNA gene sequencing (10) or by fatty acid analysis.

S. moniliformis is susceptible to many antimicrobials, particularly to penicillin and doxycycline, the mainstays of treatment (59). It is resistant to trimethoprim-sulfamethoxazole, nalidixic acid, and colistin. The MICs of aminoglycosides and ciprofloxacin are near breakpoint levels (138).

Haemophilus

MOGENS KILIAN

41

TAXONOMY AND DESCRIPTION OF THE GENUS

Members of the genus *Haemophilus* are gram-negative, non-acid-fast, nonmotile, and non-spore-forming rods that may range from small coccobacilli to filamentous rods. They are obligate parasites that, with a few misclassified exceptions (e.g., *Haemophilus ducreyi*), are exclusively adapted to human mucosal membranes in the respiratory tract. Most species of animal origin originally included in the genus *Haemophilus* have been transferred to the genus *Pasteurella* or the genus *Actinobacillus,* which together with the genus *Haemophilus* and several newly described genera of bacteria from animals constitute the family *Pasteurellaceae* (62).

The currently recognized *Haemophilus* species associated with humans are *H. influenzae, H. aegyptius, H. haemolyticus, H. parainfluenzae, H. parahaemolyticus, H. ducreyi, H. aphrophilus, H. paraphrophilus, H. segnis*, *H. pittmaniae*, and the poorly defined species *H. paraphrohaemolyticus* (36, 60).

All *Haemophilus* species are facultatively anaerobic. The genus name refers to the fact that in vitro growth requires accessory growth factors contained in blood: X factor (hemin; "X" for unknown) and V factor (NAD; "V" for vitamin). *H. influenzae* requires both of these compounds, whereas most other species require only one of them (Table 1). Strains of a few species grow better in a humid atmosphere with added 5 to 10% CO_2. The optimal temperature is about 33 to 37°C (see below).

Haemophilus species ferment a characteristic range of carbohydrates; end products from the fermentation of glucose are succinic, lactic, and acetic acids. Strains of some species (e.g., *H. aphrophilus*) produce gas in fermentation media. All *Haemophilus* strains reduce nitrate and produce alkaline phosphatase (35). The G+C content of DNA of *Haemophilus* species ranges from 37 to 44 mol% (35). Predominant cell wall fatty acids are *n*-tetradecanoate (14:0), 3-hydroxy-tetradecanoate (3-OH-14:0), hexadecanoate (16:1), and *n*-hexadecanoate (16:0) (36).

Separate subpopulations of *H. influenzae* express polysaccharide capsules, of which six different serotypes, termed serotypes a through f, have been described.

By traditional taxonomic criteria, it is unjustified to maintain the recognition of *H. influenzae* and *H. aegyptius* as separate species (10). However, one formal obstacle to combining the two is that the name *H. aegyptius* has priority over *H. influenzae*. Moreover, population genetic analyses reveal that they do constitute distinct populations of bacteria, and clinical experience indicates that they have distinct pathogenic potentials. This is even truer for the so-called *H. influenzae* biogroup aegyptius, which is the closest relative of *H. aegyptius* (7, 37). Likewise, several studies have questioned the validity of *H. paraphrophilus* as a species separate from *H. aphrophilus* (37).

According to nucleic acid hybridization studies and 16S rRNA sequence homologies, the species *H. ducreyi* does not belong in the genus *Haemophilus*, although it is a valid member of the family *Pasteurellaceae* (37, 62). *Actinobacillus actinomycetemcomitans* is closely related to *H. aphrophilus, H. paraphrophilus,* and *H. segnis* (62, 71). However, as *A. actinomycetemcomitans* lacks significant homology to the type species *H. influenzae*, the proposal to transfer *A. actinomycetemcomitans* to the genus *Haemophilus* has gained limited support (71). Rather, *A. actinomycetemcomitans* and its close relatives among the *Haemophilus* species warrant recognition as a separate genus in the family *Pasteurellaceae.*

EPIDEMIOLOGY AND TRANSMISSION

Haemophilus bacteria constitute approximately 10% of the normal bacterial flora of the healthy upper respiratory tract. The predominant species is *H. parainfluenzae*, which accounts for three-fourths of the *Haemophilus* flora both in the oral cavity and in the pharynx but is absent in the nasal cavity. Noncapsulate *H. influenzae* strains, predominantly of biotypes II or III, are present in the pharynx of most healthy children but normally constitute less than 2% of the total bacterial flora (19, 37).

Nasopharyngeal colonization by *H. influenzae* is a dynamic phenomenon characterized by constant turnover of a mixture of clones, with a mean duration of carriage of 1.4 to 2 months (19, 74, 80). During local infection a single clone of *H. influenzae* usually dominates the bacterial flora in the pharynx and nasal cavity. With increasing age of the individual, carriage of *H. influenzae* in the upper respiratory tract becomes less frequent (37). In contrast to the situation in the upper respiratory tract, patients with chronic obstructive pulmonary disease are often persistently colonized by a single or multiple clones of noncapsulate *H. influenzae* (54). In most populations without vaccination, *H. influenzae* serotype b carriage by

[i] For further characteristics, see Table 3.

healthy individuals is below 1% during the first 6 months of life but averages 3 to 5% throughout the rest of childhood, although it may be considerably higher in selected populations (74, 86). Crowding seems to be a factor contributing to a higher carriage rate (33, 74). In most populations, vaccination of children resulted in a significantly reduced carriage of *H. influenzae* serotype b as a result of antibodies induced by the conjugate vaccine (81), but there are unexplained exceptions to this pattern (3, 33).

The association between pharyngeal colonization with *H. influenzae* type b and the occurrence and transmission of disease remains poorly understood. Factors that seem to contribute to the lack of direct association are differences in virulence of individual clones of *H. influenzae* type b (56, 57) and in the disease susceptibility of individuals (33, 66). Carriage in healthy individuals of *H. aegyptius* and *H. influenzae* biogroup aegyptius has not been demonstrated.

The species *H. parainfluenzae, H. pittmaniae, H. aphrophilus, H. paraphrophilus,* and *H. segnis,* but not *H. influenzae,* are part of the normal microflora of the oral cavity in front of the palatinal arches. The species *H. aphrophilus, H. paraphrophilus,* and *H. segnis* occur predominantly on tooth surfaces in the biofilm known as dental plaque. Carriage of *H. parahaemolyticus* and *H. haemolyticus* in healthy individuals appears to be rare. Human saliva contains a mean number of more than 10^7 haemophili per ml (36). Symptomless cervical carriage of the venereal pathogen *H. ducreyi* may occur (29, 85). Spread of the *Haemophilus* species that colonize the upper respiratory tract typically occurs by respiratory droplets, and spread of *H. ducreyi* is by sexual intercourse.

CLINICAL SIGNIFICANCE

H. influenzae

Until the implementation of vaccination in many countries, *H. influenzae* was one of the three leading causes of bacterial meningitis worldwide. Most of these cases were in young children between the ages of 3 months and 3 years, with a peak incidence of infection at 6 to 7 months of age. Virtually all were caused by serotype b, and the majority belonged to biotype I. Both characteristics make them distinct from commensal strains. Strains with the same characteristics were also a major etiological agent of acute epiglottitis (obstructive laryngitis) associated with septicemia. The annual number of invasive *H. influenzae* serotype b infections in the United States is now below 100, most of which occur in unvaccinated or incompletely vaccinated children (1, 11). However, disease still occurs in selected vaccinated populations (27, 28, 43) and *H. influenzae* type b remains a leading cause of meningitis among unvaccinated children in many Asian and developing countries. It is estimated that at least 3 million cases of serious disease and 400,000 to 700,000 deaths occur in young children per year worldwide (66). Occasional cases of invasive infection caused by noncapsulate strains or strains possessing a capsule, primarily of serotype f, occur, mostly in patients with significant underlying disease, such as malignancy, chronic obstructive pulmonary disease, alcoholism, and human immunodeficiency virus infection (22). In children, underlying diseases are less common (26% of cases), and pneumonia and meningitis are equally represented (88). Strains that carry a capsule of serotype a, c, d, or e are occasionally isolated from patients with infections as well as from the healthy respiratory tract (38, 51, 86, 92). Among Navajo and White Mountain Apache children a relatively high incidence (20.2 cases per 100,000 population aged <5 years) of invasive disease with serotype a

strains is observed, but with no absolute increase in numbers in the period after vaccination against *H. influenzae* type b (51).

Invasion of the bloodstream by encapsulated strains of *H. influenzae* may also result in septic arthritis, osteomyelitis, cellulitis, and pericarditis (66, 86). Primary *H. influenzae* pneumonia is being recognized with increasing frequency in both children and adults and is sometimes complicated by bacteremia (44, 53, 58). A recent literature review revealed that *H. influenzae* accounted for 7% of identified etiologic agents of childhood community-acquired pneumonia in North America and Europe and for 21% of such agents in Africa and South America (58). Most isolates from patients with pneumonia are non-type b strains. Pneumonia was the predominant clinical syndrome in patients with *H. influenzae* serotype f disease (88).

Noncapsulate *H. influenzae* strains (often collectively referred to by the misnomer "nontypeable"), indistinguishable from strains found in the healthy respiratory tract (predominantly biotypes II and III), are frequent causes of infections in children. Infections with noncapsulate *H. influenzae* usually occur at sites contiguous with the upper respiratory tract (21, 53) and typically do not include bacteremia, although occasional cases are reported (21, 63). Noncapsulate *H. influenzae* is, after *Streptococcus pneumoniae*, the second most frequent cause of otitis media, the most common cause of purulent bacterial conjunctivitis, and an important cause of sinusitis and chronic or acute exacerbations of lower respiratory tract infections in patients with and without cystic fibrosis (21, 24, 53, 86). *H. influenzae* otitis media is usually associated with significantly increased proportions (>50% of total bacterial flora) of the same clone in the nasopharynx (18, 42). *H. influenzae* occasionally causes obstetric and neonatal infections, and in some countries these are predominantly due to biotype IV strains that are genetically distinct from other *H. influenzae* (73, 93). Both *H. influenzae* and *H. parainfluenzae* have been implicated in urinary tract infections and peritonitis (2, 73, 86, 93). Occasional cases of meningitis caused by noncapsulate *H. influenzae* are often associated with underlying medical problems including ventriculoperitoneal shunts (21, 63).

H. aegyptius

H. aegyptius (Koch-Weeks bacillus) is associated with an acute purulent and contagious form of conjunctivitis ("pink eye") that occurs in seasonal endemics, especially in hot climates (69, 86). In the mid-1980s and early 1990s bacteria that share many of the properties of *H. aegyptius* caused small epidemics of a fulminant pediatric disease known as Brazilian purpuric fever (BPF), manifested by high fever, hemorrhagic skin lesions, septicemia, vascular collapse, hypotensive shock, and death, usually within 48 h of onset (7). The disease is characteristically preceded by purulent conjunctivitis that has resolved before the onset of fever. Although invasive, these bacteria are noncapsulate and have been designated *H. influenzae* biogroup aegyptius (7), a term sometimes erroneously also applied to strains of *H. aegyptius*. Cases clinically similar to BPF were observed in Australia and in the United States, but these were caused by strains genetically related to but distinct from Brazilian BPF isolates (7, 37).

H. ducreyi

H. ducreyi causes the venereal disease soft chancre or chancroid. The genital lesion begins as a tender papule that becomes pustular and then ulcerated over the course of 2 days. Lesions may merge to form larger ulcers that may be accompanied by unilateral inguinal lymphadenitis (bubo formation). *H. ducreyi* infection is an important cause of genital ulcers in Asia, Africa, and Latin America, but is a less important cause of such infections in North America and most parts of Europe. However, PCR detection of *H. ducreyi* suggests that the prevalence of chancroid is underreported (64, 88). The disease has received renewed attention because it facilitates the transmission of human immunodeficiency virus in populations in which it is endemic. Extragenital lesions may occur but are rare (39, 70, 88).

Other Species

In my experience *H. parahaemolyticus* is often isolated from patients with pharyngitis in whom no other bacterial pathogen is detected, from patients with lower respiratory tract infections, and from patients with local abscesses in the oral cavity. Some *Haemophilus* isolates from lower respiratory tract samples from patients with chronic obstructive pulmonary disease are *H. haemolyticus*, some of which, disturbingly, are nonhemolytic and impossible to distinguish from *H. influenzae* by phenotypic analysis (55). Further studies on the clinical significance of these species in causing respiratory tract infections are needed.

Some of the oral *Haemophilus* species *(H. parainfluenzae, H. pittmaniae, H. aphrophilus, H. paraphrophilus*, and *H. segnis)* are occasionally implicated in subacute endocarditis, brain abscesses, sinusitis, arthritis, and osteomyelitis (2, 15, 76), which may follow a temporary bacteremic condition in association with dental treatments that cause a break of the oral mucosal barrier. Reported cases of meningitis ascribed to *H. parainfluenzae* can probably be explained by misidentification of *H. influenzae* isolates as described below.

COLLECTION, TRANSPORT, AND STORAGE

Specimens of patient blood and cerebrospinal fluid (CSF) are obtained and processed as described in chapters 5 and 20. Prompt transport of these samples to the laboratory is mandatory to ensure the fastest possible diagnosis and survival of microorganisms in the sample. Additional specimens from which *Haemophilus* organisms may be isolated include aspirated synovial fluid, pericardial fluid, pleural fluid, pus, nasopharyngeal or throat swabs, sputum, purulent discharge from infected eyes, urine, and occasionally vaginal swabs. It is important that samples taken from the respiratory tract remain representative of the infecting flora by avoidance of contamination with commensals as far as possible. Thus, throat swabs must be collected from the pharynx and not surfaces in front of the palatinal arches. Because most children carry *H. influenzae* in the upper respiratory tract, its mere detection is of no value for establishment of the etiology of otitis media (18).

Samples must be transported to the laboratory in a suitable transport medium or should be spread directly onto appropriate agar media whenever possible (especially conjunctival specimens). The viability of most *Haemophilus* organisms is readily lost as a result of drying out, and they do not survive more than a few days in clinical samples. This is particularly true for the more fastidious species such as *H. aegyptius*.

Genital specimens for *H. ducreyi* culture should be collected from the base and the undermined margins of the chancroid lesion with a saline- or broth-moistened swab. Cultivation may be supplemented by aspiration of pus from infected bubonic lymph nodes, but isolation of *H. ducreyi* from pus is usually less successful than isolation from ulcer material (17, 85). Direct plating on selective media is preferable as it results in the highest recovery. The use of transport media is a viable alternative only if a reliable source of refrigeration is

available, as the viability of *H. ducreyi* in various transport media is completely lost within 1 day at room temperature. Best results were obtained by using thioglycolate-hemin-based transport media containing various combinations of selenium dioxide, albumin, and glutamine (14). After storage at 4°C for up to 4 days, 71% of samples from patients clinically diagnosed with chancroid yielded growth of *H. ducreyi*.

Haemophilus isolates may be stored for many years at room temperature after lyophilization in skim milk or at −135°C on dry cotton swabs heavily inoculated with bacteria from an agar culture transferred to a sterile empty vial. An alternative method of storage is freezing below −60°C of 24-h broth cultures or suspensions of freshly grown cells in broth medium containing 10% glycerol. Biweekly transfers on agar media can also maintain most strains. However, strains of *H. aegyptius* and *H. ducreyi* will rapidly die out.

DIRECT EXAMINATION

Microscopic Examination

CSF

A smear of CSF previously concentrated by centrifugation at 10,000 × *g* or by filtration is stained by Gram's method or with methylene blue. Cytocentrifugation of CSF significantly increases the sensitivity of the Gram stain (79). Care should be exercised in destaining because the coccobacillary form of *H. influenzae* may morphologically resemble pneumococci. However, in CSF the organism may be relatively pleomorphic, with coccoid, coccobacillary, short-rod, long-rod, and filamentous forms. The bacteria may be few in number but are usually detected along with granulocytes by careful examination.

Capsules present on bacteria in CSF can be demonstrated by several techniques, provided that a sufficient number of bacteria are present. The simplest method is by demonstration of the capsular swelling reaction (Quellung reaction). A drop of CSF is mixed on a slide with a drop of an antiserum against each of the capsular serotypes (Becton Dickinson Diagnostic Systems, Sparks, Md.). When mixed with the relevant antiserum, the capsule will appear swollen and sharply delineated by phase-contrast microscopy when it is compared with a control smear without added antiserum. Immunofluorescence staining achieved by addition of a secondary layer of fluorescein-conjugated anti-rabbit immunoglobulins (DAKO, Carpinteria, Calif.) provides another excellent means of identifying and serotyping encapsulated strains of *H. influenzae* in clinical samples. It is important to include controls that rule out direct binding of the fluorescent-labeled secondary antibodies to the bacteria.

Respiratory Tract Specimens

The presence of small, pleomorphic gram-negative rods in sputum samples in areas of the sample that contain polymorphonuclear leukocytes and no squamous epithelial cells strongly suggests that a *Haemophilus* species is etiologically involved, but the final diagnosis must be established by cultivation. Due to their small size and staining reaction, *Haemophilus* bacteria may easily be missed in Gram-stained smears of sputa. Direct microscopy is also an important tool in cases in which fluid is collected by bronchoalveolar lavage or transthoracic needle aspiration.

Other Specimens

Due to the fastidious nature of *H. aegyptius,* microscopic examination of Gram-stained smears of conjunctival scrapings, particularly from patients with seasonal conjunctivitis, is a useful supplement to cultivation. *H. aegyptius* organisms appear as long, slender gram-negative rods (Fig. 1).

There is some doubt about the value of direct examination of Gram-stained smears or dark-field microscopy as an aid in the diagnosis of chancroid. Most genital ulcers have a polymicrobial flora, and the arrangements of *H. ducreyi* cells as long chains or "schools of fish," previously considered typical, appear to be more characteristic of smears prepared from cells grown in vitro (85). The sensitivity of Gram staining does not exceed 50% (85). The development of assays for the direct detection of *H. ducreyi* in smears by immunofluorescence has been hindered, in part, by the poor specificities of polyclonal antisera. Monoclonal antibodies against various surface epitopes on *H. ducreyi* have been developed and used in field studies. Many show satisfactory specificities and sensitivities compared with the results of culture techniques (85), but none appear to be commercially available.

Antigen Detection

Various immunochemical techniques for detection of capsular antigen of serotype b in CSF and other body fluids have been developed, but with the rarity of this serotype in many countries and the limited sensitivity that these tests offer over microscopy of Gram-stained smears, they are now of limited clinical value (49).

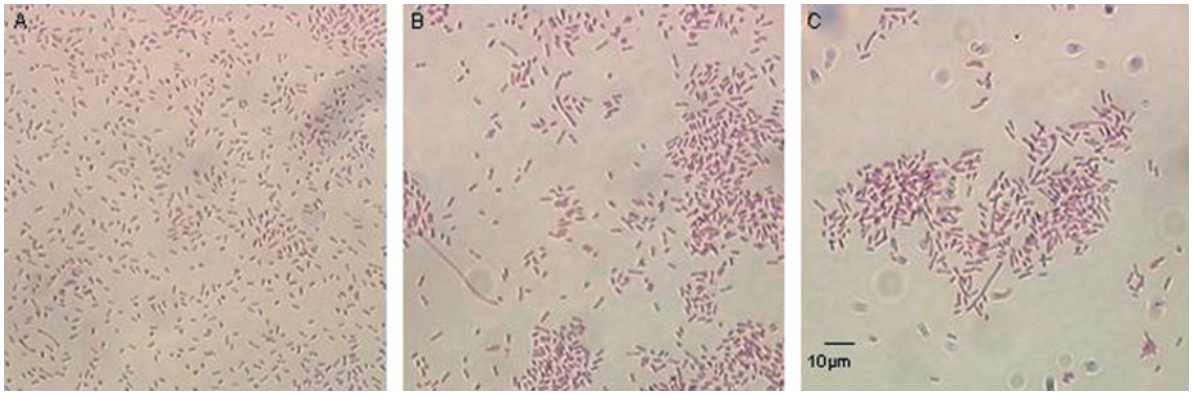

FIGURE 1 Gram-stained smears of *H. influenzae* (A), *H. aegyptius* (B), and *H. influenzae* biogroup aegyptius (C) showing the elongated slender rod morphology of the last two.

Nucleic Acid Detection Techniques

Real-time PCR-based technology for simultaneous detection of *H. influenzae* (serotypes b and c), *Neisseria meningitidis* (multiple serogroups), and *S. pneumoniae* (multiple serotypes) or for specific detection of *H. influenzae* type b in clinical samples of CSF, plasma, serum, and whole blood has been described (12, 47). Multiplex PCR may also be used for simultaneous detection of the four principal middle-ear pathogens *H. influenzae, S. pneumoniae, Moraxella catarrhalis*, and *Alloiococcus otitis* and of the major etiologic agents of genital ulcer disease, *H. ducreyi, Treponema pallidum*, and herpes simplex virus types 1 and 2. The sensitivity of these methods exceeds that of standard culture techniques, and their specificity is generally high (6, 12, 30, 47, 50, 64, 82). None of the methods are commercially available.

ISOLATION TECHNIQUES

Media

Attempts to isolate *Haemophilus* species must take into account the particular growth requirements of this group of bacteria (Table 1). The two growth factors hemin (X factor) and NAD (V factor) are contained in blood cells, but only X factor is directly available in conventional blood agar. To release V factor, the blood cells must be broken up by brief heating as in chocolate agar and in Levinthal's medium. In addition to liberating V factor, heat treatment inactivates V factor-destroying enzymes (NADase) present in blood. The heat treatment is obtained by adding the blood (5% sheep, bovine, or horse blood) to the medium base when its temperature is reduced to approximately 80°C immediately after autoclaving. A comparison of six medium bases showed that a medium consisting of GC agar base plus 5% chocolatized sheep blood and 1% yeast autolysate promoted the best growth of *H. influenzae, H. parainfluenzae,* and most other species that may be isolated from humans, excluding *H. ducreyi* (75).

For *H. aegyptius*, which is particularly fastidious, chocolate agar supplemented with 1% growth factor supplements (IsoVitaleX [Becton Dickinson Diagnostic Systems]; Vitox [Oxoid, Basingstoke, United Kingdom]; or cofactors-vitamin-amino acids [CVA; Gibco Diagnostics, Grand Island, N.Y.]) provides a good medium for isolation, although primary growth from clinical samples is never luxuriant (13, 91).

Growth on conventional blood agar may be achieved by adding a source of V factor, traditionally done by cross-streaking the inoculated plate with a staphylococcus or enterococcus strain. These bacteria excrete V factor and allow detection of *Haemophilus* species that grow as satellite colonies (Fig. 2). Alternatively, V factor may be supplied by applying a filter paper disk or a strip saturated with V factor (BD Diagnostic Systems, Franklin Lakes, N.J.; or Rosco A/S, Taastrup, Denmark) to the surface of the medium.

Due to the relatively slow growth and small size of *Haemophilus* colonies, their presence in cultures from sites with a mixed flora may easily be overlooked. When necessary, this problem may be solved by including selective agents or by a special incubation procedure. This is particularly important for attempts to detect *H. ducreyi.* GC-HgS agar, which consists of GC agar (GIBCO Laboratories) supplemented with 3 mg of vancomycin per liter, 1% hemoglobin, 5% fetal bovine serum, 1% IsoVitaleX (Becton Dickinson Diagnostics), or some other comparable enrichment, has a high sensitivity for isolation of *H. ducreyi* from clinical specimens, as does Mueller-Hinton agar (BBL) supplemented with 5% chocolatized horse blood, 1% IsoVitaleX, and 3 mg of vancomycin per liter (MH-HB agar) (14). Strains of *H. ducreyi* that are inhibited by 3 mg of vancomycin per liter have been reported (32). However, this observation needs to be confirmed in other laboratories. It is generally accepted that the combined use of two media, e.g., GC-HgS and MH-HB, is optimal for the detection and isolation of *H. ducreyi,* possibly because of differences in nutritional requirements between strains (85), but the sensitivity of culture techniques for *H. ducreyi* is never 100% (14, 17, 85). Some lots of fetal calf serum inhibit growth of *H. ducreyi*. Fetal calf serum can be replaced by either activated charcoal or bovine albumin, but not by newborn calf serum (84).

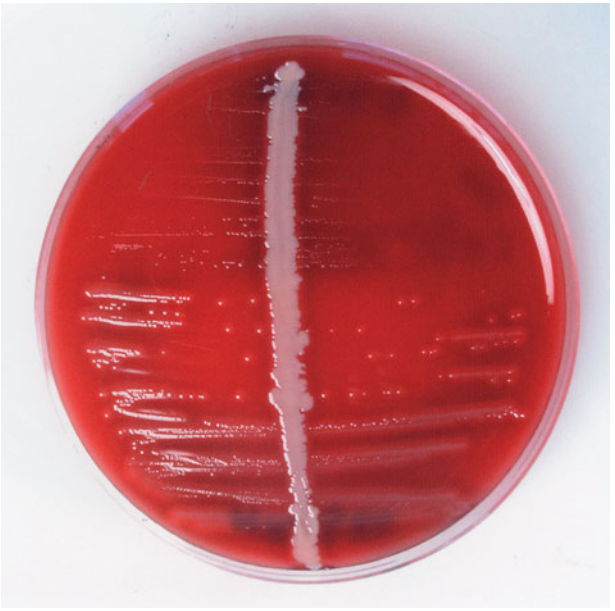

FIGURE 2 Growth of *Haemophilus* isolates on horse blood agar around a streak of *Staphylococcus aureus*. The upper half shows typical satellite growth characteristic of most *Haemophilus* species. The lower part shows characteristic lack of satellite growth of a strain of *H. parahaemolyticus* in spite of its requirement for V factor. Note that the colonies of *H. parahaemolyticus* resemble those of pyogenic streptococci on blood agar.

The problem of overgrowth of *H. influenzae* by *Pseudomonas aeruginosa* in cultures of sputa from patients with cystic fibrosis has been solved with some success by anaerobic incubation of inoculated chocolate agar plates containing 300 mg of bacitracin per liter. Detection of *Haemophilus* bacteria in cultures from the upper respiratory tract is also considerably improved by use of the latter medium (36). However, to be able to evaluate the relative proportion of haemophili in the microflora, a nonselective medium must be included.

Lower respiratory tract secretions and aspirates or swabs of pus from localized infections should be inoculated both on 5% blood agar cross-inoculated with a feeder strain and on chocolate agar.

Cultures of all *Haemophilus* organisms except *H. ducreyi* should be incubated at 35 to 37°C. *H. ducreyi* grows significantly better at 33°C. A moist atmosphere supplemented with 5 to 10% CO_2 is preferred by most strains and is mandatory for the isolation of *H. ducreyi* and many strains of *H. aphrophilus* and *H. paraphrophilus*. Given optimal conditions, most *Haemophilus* species grow to colonies of at least 1 to 2 mm in diameter after incubation for 18 to 24 h. Fresh isolates of *H. aegyptius* and *H. ducreyi* require incubation for 3 to 4 days.

Modern commercial blood culture systems show excellent recovery of *Haemophilus* species from blood samples. However, the same systems fail to recover *Haemophilus* species from normally sterile body fluids like pleural fluids, joint fluids, ascitic fluid, or dialysates unless blood (e.g., human blood, 1:8, vol/vol) or X- and V-factor enrichments are added (26, 67). Cultivation of spinal fluid or subcultivation from blood cultures should be performed on both chocolate agar and blood agar.

Appearance of Growth

With the exception of *H. aphrophilus* and *H. ducreyi,* all *Haemophilus* species that may be isolated from humans require V factor. Therefore, on blood agar these species will grow as satellite colonies around the staphylococcus streak. Colonies of *H. parahaemolyticus* and some strains of *H. haemolyticus* are surrounded by strong beta-hemolytic zones on horse, bovine, and rabbit blood agar. In contrast, *Haemophilus* species are nonhemolytic on sheep blood agar. Colonies of the three hemolytic species *H. parahaemolyticus*, *H. haemolyticus*, and *H. pittmaniae* usually do not show satellite growth on agar media with blood that they are capable of lysing and may be mistaken for pyogenic streptococci (Fig. 2).

H. influenzae colonies on chocolate agar are grayish, semiopaque, smooth, and flat convex and reach a diameter of 1 to 2 mm after incubation for 24 h. In dense areas of the plate, encapsulated strains tend to grow confluently, in contrast to colonies of noncapsulate strains, which remain separate. On clear agar media such as Levinthal's agar, colonies of encapsulated strains show a bright iridescence (red, blue, green, and yellow) when light is obliquely transmitted from behind. The phenomenon is most clearly detected in young (10- to 18-h) cultures and gradually disappears during prolonged incubation. In some strains with capsules of serotypes other than type b, iridescence is not always clear-cut. Noncapsulate strains examined in the same way show a more uniform bluish green color. Strains from cases of meningitis and epiglottitis virtually always produce indole, and so do many noncapsulate isolates (e.g., biovar II). Release of indole gives the growth on agar media a characteristic pungent smell similar to that of *Escherichia coli*. Otherwise, *Haemophilus* strains emit a "mouse-nest" smell.

Colonies of *H. parainfluenzae* may be up to 2 mm in diameter after incubation for 24 h and appear either smooth or rough and wrinkled. Most colonies are flat, grayish, and semiopaque. *H. aphrophilus* and *H. paraphrophilus* grow as rough, raised colonies that rarely attain a diameter exceeding 1 mm. When incubated in air without extra CO_2, these species grow, if at all, in colonies of varying sizes; the growth mimics that of a mixed culture. Fresh isolates of *H. aegyptius* and *H. segnis* grow as small (<1 mm), smooth colonies. Colonies of *H. ducreyi* are smooth and semitranslucently gray and attain a diameter of 0.1 to 0.5 mm on enriched chocolate agar after incubation for 3 days. They are characteristically cohesive and can be pushed intact across the surface of the agar.

Microscopy of Cultures

Gram-stained smears of *Haemophilus* isolates show small gram-negative rods with varying degrees of polymorphism (Fig. 1). The most extensive polymorphism, which may include long filamentous forms, is observed with the X-factor-independent species. *H. ducreyi* often appears as parallel rows of small rods in chains with a "school of fish," "railroad track," or "fingerprint" appearance.

IDENTIFICATION

X- and V-Factor Requirement

The satellite phenomenon, which may be detected in primary blood agar plate cultures, provides a convenient means for a tentative genus identification of all of the V-factor-requiring species that are regularly isolated from humans. However, other bacteria, such as occasional strains of *Pasteurella multocida,* some animal-pathogenic *Actinobacillus* and *Pasteurella* species (59, 62), and some streptococci may also show satellite growth, although it is not always due to V-factor requirement.

A small 5.25-kb plasmid that is normally present in *H. ducreyi* has been found to confer independence of V factor in occasional isolates of *H. parainfluenzae* (46, 94). How widespread such V-factor-independent strains of *H. parainfluenzae* are is not known.

A prerequisite for detection of the satellite phenomenon is an agar medium that lacks V factor. Since ordinary blood agar contains various amounts of free V factor, depending on the method of preparation and length of storage, it is sometimes difficult to achieve convincing satellite growth on this medium. The special problem associated with hemolytic strains has already been mentioned. In case of doubtful reactions, far better results are obtained on a blood agar medium to which the blood (5 to 10%) is added before autoclaving. Since NAD is heat labile, this medium is completely devoid of V factor but otherwise satisfies all growth requirements of *Haemophilus* species, including X factor.

Determination of a requirement for X factor is done in some laboratories by demonstrating growth around an X-factor-containing paper disk (Becton Dickinson Diagnostic Systems) on an agar medium or by comparing growth on medium with blood to growth on medium without blood. However, even when particular care is being exercised to avoid carrying over X factor with the inoculum, this method results in erroneous results in up to 20% of cases (M. Kilian, unpublished observations). If the identity is not confirmed by biochemical tests, *H. influenzae* strains are often misidentified as *H. parainfluenzae* and occasionally vice versa. This undoubtedly explains some of the reported cases of meningitis ascribed to *H. parainfluenzae.* The porphyrin test (34) provides a more accurate and rapid means of determining the X-factor requirement.

Porphyrin Test

The porphyrin test is based on the observation that hemin-independent *Haemophilus* strains excrete porphobilinogen and porphyrins, both of which are intermediates in the hemin biosynthetic pathway (Fig. 3), when supplied with δ-aminolevulinic acid. X-factor-requiring strains do not excrete these compounds because of a lack of enzymes involved in the biosynthesis of heme (36).

The substrate consists of 2 mM δ-aminolevulinic acid hydrochloride (Sigma Chemical Co., St. Louis, Mo.) and 0.8 mM $MgSO_4$ in 0.1 M phosphate buffer at pH 6.9. It is distributed in 0.5-ml quantities in small glass tubes and may be stored for several months in a refrigerator. Sterility is not required. The substrate is inoculated by suspending a heavy loopful of bacteria from an agar plate culture. After incubation for 4 h at 37°C, the mixture is exposed to UV light (wavelength, approximately 360 nm), preferably in a dark room. A red fluorescence from the bacterial cells or from the fluid indicates the presence of porphyrins; i.e., growth of the strain is not dependent on X factor. In cases of doubtful

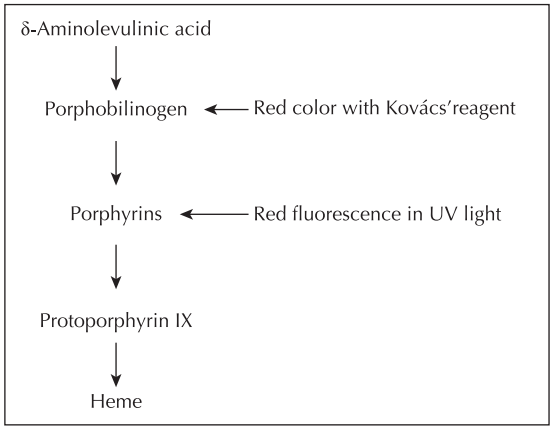

FIGURE 3 Principal steps of the heme biosynthetic pathway and methods for detection of intermediate compounds.

reactions, tubes may be reincubated for up to 24 h. An alternative way is to add 0.5 ml of Kovács' reagent (p-dimethylaminobenzaldehyde, 5 g; amyl alcohol, 75 ml; concentrated HCl, 25 ml), shake the mixture vigorously, and allow the phases to separate. A red color in the lower water phase is indicative of porphobilinogen. When this method of reading is used, it is advisable to include an inoculated tube without δ-aminolevulinic acid as a negative control. Kovács' reagent also gives a red color reaction with indole, which, however, will be present in the upper alcohol phase. Still, indole-positive strains of *H. influenzae* may erroneously be identified as X-factor independent in the absence of an appropriate control. Another disadvantage of this method of reading is that further incubation of samples with doubtful reactions is not possible.

Hemolysis

Hemolysis induced by isolates of *H. haemolyticus, H. parahaemolyticus,* and *H. pittmaniae* may be detected on agar plates with horse, bovine, or rabbit (quad plates) blood but not on sheep blood agar. Demonstration of the hemolytic activity of *H. ducreyi* requires specialized media. Reproducible results have been obtained with bilayer horse blood agar plates consisting of GC agar base, 1% X factor-V factor supplement, and 5% horse blood. All strains examined were less hemolytic on sheep blood agar (83).

Biochemical Tests, General

Table 1 shows key reactions for further differentiation of the *Haemophilus* species. Tests for fermentation of glucose, sucrose, and lactose are important for species identification. They are performed in 1% solutions of the respective carbohydrates in phenol red broth base (Becton Dickson Diagnostic Systems) supplemented with X and V factors (10 mg/liter each; Sigma Chemical Co.) after autoclaving (35). Reactions are usually clear-cut after 24 h of incubation, but some species such as *H. segnis* and *H. aegyptius* show weak reactions.

The ability to reduce nitrate, which is a characteristic of all *Haemophilus* species, can be demonstrated after 5 days of growth in Levinthal's broth with 0.1% (wt/vol) of potassium nitrate. Strains of *H. aphrophilus* and *H. paraphrophilus* may, however, reduce nitrate beyond nitrite, which may result in a negative reaction for nitrite (35).

Direct Enzyme Tests

Three biochemical reactions are important tools in the differentiation of some of the *Haemophilus* species and for differentiation from species of other *Pasteurellaceae* genera: indole production, urease, and ornithine decarboxylase activities (Table 2). The three biochemical reactions used in identification and in biotyping (see below) of *H. influenzae* and *H. parainfluenzae* may preferably be performed as rapid tests that bypass the problems of special growth requirements (35). All three test media (0.3- to 0.5-ml quantities) are inoculated with a heavy loopful of bacteria from an agar culture, and the results are read after incubation for 4 h. (The test for ornithine decarboxylase may in some cases require additional incubation for 18 to 20 h.)

Indole Test

The substrate for the indole test is 1% L-tryptophan in 0.05 M phosphate buffer at pH 6.8. After inoculation and incubation for 4 h, 1 volume of Kovács' reagent is added and the mixture is shaken. A red color in the upper alcohol phase indicates the presence of indole.

Urease Test

The substrate for the urease test is 0.1 g of KH_2PO_4, 0.1 g of K_2HPO_4, 0.5 g of NaCl, and 0.5 ml of 1:500 phenol red in 100 ml of distilled water. The pH is adjusted to 7.0 with NaOH, and 10.4 ml of a 20% (wt/vol) aqueous solution of urea is added (for 1:500 phenol red, dissolve 0.2 g of phenol red in NaOH and add distilled water to 100 ml). The development of a red color within 4 h after inoculation indicates urease activity.

TABLE 2 Differential tests for *H. influenzae, H. parainfluenzae, H. aegyptius*, *H. parahaemolyticus,* and *H. segnis* and for biotyping of *H. influenzae* and *H. parainfluenzae*

Species and biotype	Indole	Urease	Ornithine decarboxylase

H. segnis	−	−	−

[a] For differentiation of *H. aegyptius, H. influenzae* biotype III, and *H. influenzae* biogroup aegyptius, see text for further information.

Ornithine Decarboxylase Test

The substrate for ornithine decarboxylase is the medium used regularly for other bacteria (see chapter 21). For *Haemophilus* organisms it is to be inoculated with a heavy loopful of bacteria from an agar plate culture. A purple color developing within 4 to 24 h indicates ornithine decarboxylase activity.

Alternative Methods

Several commercial kits are available for identification of *Haemophilus* species once the V-factor requirement has been determined; e.g., API NH (bioMérieux Inc., Hazelwood, Mo.), Vitek NHI Card V1308 (bioMérieux), the Haemophilus ID Test kit (Remel, Lenexa, Kans.), the RIM-H system (Austin Biological Laboratories, Austin, Tex.), and RapidID NF (Innovative Diagnostics, Norcross, Ga.) (65, 72). However, most of these kits do not provide sufficient information to accurately identify an isolate to the species level without additional tests. Therefore, it is advisable that more unusual findings be confirmed with traditional tests.

DNA-Based Identification

If the technology is available, isolates of most *Haemophilus* species and related genera may easily be identified by determining a partial 16S rRNA gene sequence and comparing it with sequences of type strains available in databases accessible on the Internet (e.g., http://www.ncbi.nlm.nih.gov/BLAST/ or http://rdp.cme.msu.edu/index.jsp, which allows a BLAST search against only type strains). Because of their close similarities, the technique does not differentiate between *H. influenzae, H. aegyptius*, and *H. influenzae* biogroup aegyptius and between *H. aphrophilus* and *H. paraphrophilus*.

A review of various published methods for identification of virulence-associated properties and identification probes and a comprehensive compilation of primer and probe sequences have been prepared by Van Belkum and van Alphen (89).

Particular Identification Problems

The differentiation of *H. influenzae, H. aegyptius,* and *H. influenzae* biogroup aegyptius by standard laboratory techniques is impossible at present. The three taxa form distinct clusters by phylogenetic analysis based on multiple genetic and phenotypic traits including electrophoretic mobility of selected housekeeping enzymes (as determined by multilocus enzyme electrophoresis) (37). Both *H. aegyptius* and *H. influenzae* biogroup aegyptius have the same key biochemical characteristics as *H. influenzae* biotype III (Table 2). Since the latter does not possess the invasive potential of BPF strains or the ability to cause serious endemic conjunctivitis, as *H. aegyptius* strains do, it is important to develop means for exact identification. *H. aegyptius* and *H. influenzae* biogroup aegyptius lack the ability to ferment xylose, in contrast to the vast majority of *H. influenzae* strains (7, 35). Additional characteristics that may be of use in the separation of *H. aegyptius* from *H. influenzae* are its poorer in vitro growth, its more slender and rod-like shape (Fig. 1), and its ability to agglutinate human erythrocytes as a result of more stable pilus expression (36). It has been reported that the distinct outer membrane protein profiles of *H. aegyptius* and *H. influenzae* biotype III may be used as an adjunct to differentiate the two species (9).

Recently it has become clear that identification of *H. haemolyticus* poses special problems. Some strains of *H. haemolyticus* are clearly nonhemolytic and cannot be distinguished from *H. influenzae* by phenotypic analysis (55). The prevalence and clinical significance of *H. haemolyticus* are therefore not clear.

Isolates of *H. ducreyi* may be presumptively identified by their adherent colony characteristics, by their appearance in Gram-stained smears, and by a positive oxidase and negative catalase reaction. Confirmation can be achieved by demonstrating a negative porphyrin test result, the inability to ferment carbohydrates, and a positive reaction for nitrate reduction. However, commercial identification systems fail to reveal the ability to reduce nitrate, and a positive oxidase reaction is obtained only with tetramethyl-*p*-phenylenediamine (36, 52).

H. aphrophilus and *A. actinomycetemcomitans* are not easily distinguished from certain *Pasteurella* species, which potentially may explain two reports of the isolation of *Pasteurella gallinarum* from human cases of endocarditis and bacteremia (25). Criteria for the identification of such bacteria may be found elsewhere (62; see also chapter 40).

Biochemical reactions that are valuable in separating *H. aphrophilus* and *H. paraphrophilus* from the closely related *A. actinomycetemcomitans* and other resembling species are provided in Table 3.

TYPING SYSTEMS

Capsular Serotyping

Due to significant differences in pathogenic potentials of noncapsulate and individual serotypes of encapsulated strains of *H. influenzae,* capsule detection and serotyping have been important in the analysis of clinical isolates. The separation of the six serotypes of *H. influenzae* is based on structurally distinct capsular polysaccharides. Until vaccination against *H. influenzae* type b was introduced, identification of serotype b strains was of particular practical significance, as invasive pathogenicity was almost exclusively associated with that serotype. There is no doubt that the exclusive focus on serotype b in many laboratories has resulted in an underestimation of infections caused by other serotypes.

The evaluation of cases of apparent vaccine failure necessitates definitive serotyping. Furthermore, the decline of *H. influenzae* serotype b carriage raised concerns about an increase of *H. influenzae* carriage and disease caused by other serotypes and by noncapsulate strains. A study of Alaskan residents aged 10 years and older suggests such an increase (from 0.5 to 1.1 per 100.000 per year) (68).

Capsular serotyping may be carried out by slide agglutination, by coagglutination with staphylococci or latex particles coated with type-specific antibodies, by a capsular swelling test, and by immunofluorescence microscopy. A recent multicenter comparison of the outcome of slide agglutination serotyping with PCR-based detection of capsule biosynthesis genes in 141 invasive *H.* influenzae isolates showed discrepancies in 40% of the isolates characterized. Discrepancies were due mainly to false-positive reactions obtained with isolates that were noncapsulate. An overall 94% agreement was achieved when the slide agglutination method was performed correctly (38). It is therefore advisable that laboratories that are unable to perform appropriate serotyping of isolates refer these to reference laboratories.

Bacterial suspensions used for serological typing of isolates must be prepared from a young (12- to 18-h) agar culture, since the capsular structure tends to deteriorate in older cultures. A smooth suspension of bacteria is made in normal saline containing formalin (0.5%, vol/vol) and must be of sufficient density to permit the antigen-antibody reaction to proceed to completion within 1 min. In a strong positive slide

agglutination reaction, all bacteria are agglutinated, and the fluid between the clusters is clear.

As polyclonal antisera contain various proportions of antibodies to somatic antigens, agglutination may occur as a result of reaction with somatic antigens. This problem may result in simultaneous agglutination in antisera against several serotypes. Only strong reactions occurring within 1 min should be taken as a positive reaction. Antisera for serotyping of encapsulated *H. influenzae* isolates are available from Becton Dickinson Diagnostic Systems and from some state laboratories. A coagglutination test for detection of serotype b is available under the product name Phadebact (Boule Diagnostics AB, Huddinge, Sweden).

PCR-Based Capsule Typing

While traditional serotyping in inexperienced hands is liable to frequent misinterpretations, the capsule serotype of an isolate may be unequivocally determined by detection of serotype-specific gene sequences. The most attractive method is PCR capsular genotyping, which is easier to perform than probe analysis as there is no need for lengthy DNA extractions, Southern blotting, and hybridization. This PCR methodology may also be used to detect deletion mutants and the amplification pattern of the *capB* locus (21, 90), which differentiates two distinct evolutionary divisions (divisions I and II) of *H. influenzae* type b with different pathogenic potentials (56). Primers specific for the *bex*A gene, which is required for capsule transport and present in strains of all six serotypes, can be used to differentiate between noncapsulate and capsulate isolates (90). Primers for the *bex*A gene (Primers HI-1 and HI-2) and three-primer sets for amplification of each of the six serotype-specific gene sequences are shown in Table 4.

[a] The data are from references 20 and 31.

[b] Primers labeled "3" represent sequences between primers labeled "1" and "2" and may, in combination with one of the primary primers, be used for confirmation in second rounds of PCR using the first-round PCR product as a template.

Occasional strains that have lost the ability to produce a serotype b capsule (b⁻ mutants) are identified by a positive result in the type-b-specific PCR and a negative result with the *bexA* gene primers (21).

Other Typing Methods

H. influenzae and *H. parainfluenzae* may be subdivided into eight biotypes or biovars each (35, 36) on the basis of indole production, urease, and ornithine decarboxylase activities (Table 2). Biotypes of *H. influenzae* show a relationship to source of isolation (35, 61) and to capsular serotype (35) in agreement with the fact that the serotypes constitute separate evolutionary lineages, in contrast to serotypes of *S. pneumoniae* (48, 56, 57). The vast majority of serotype a, b, and f strains belong to biotype I, serotype c strains are usually biotype II, and strains with serotype d or e capsules are biotype IV (35). Subtyping on the basis of outer membrane proteins, lipopolysaccharides, or isoenzymes has also been done. However, for epidemiological purposes, typing by DNA-based techniques (DNA fingerprinting, ribotyping, pulsed-field gel electrophoresis, and multilocus sequence typing [MLST]) is preferred because of their superior discriminatory power (41, 48, 77). The optimal typing method is MLST, which is based on sequencing of parts of seven selected housekeeping genes (*adk, atpG, frdB, fucK, mdh, pgi,* and *recA*) (48). The method has the advantage that results are electronically portable and easily comparable between laboratories. In addition, by taking advantage of the MLST database (http://haemophilus.mlst.net/) it is possible to see one's own observations in a global context.

ANTIBIOTIC SUSCEPTIBILITY

Wild-type strains of the *Haemophilus* species are susceptible to ampicillin, cephalosporins, chloramphenicol, sulfonamides, tetracycline, and the macrolide-azalide-ketolide group of antimicrobials. However, mainly because of the spread of conjugative plasmids, a large proportion of clinical isolates are resistant to ampicillin and most other β-lactam antibiotics, to chloramphenicol, and to the tetracyclines (5, 8, 23, 45). The likelihood that an *H. influenzae* isolate will be resistant to ampicillin varies from 5 to 60% in different countries. This development has effectively removed the aminopenicillins (without the addition of a β-lactamase inhibitor) and certain cephalosporins as options for empirical treatment of infections in which *H. influenzae* is a suspected pathogen. Resistance to β-lactams is in most cases a result of a TEM-1 and, to a lesser extent, ROB-1-type β-lactamase production. There are also β-lactamase-negative strains for which ampicillin MICs are increased due to mutations in the penicillin-binding proteins (4, 5, 78, 87). Those strains are referred to as β-lactamase-negative, ampicillin resistant (BLNAR). The prevalence of BLNAR *H. influenzae* in the United States is still below 1%, but recent surveys from several European countries show prevalences from 2 to 20% among *H. influenzae* isolates (33). In contrast to other cephalosporins tested, cefixime is still fully active against *H. influenzae* with the BLNAR phenotype (31).

The rate of macrolide nonsusceptibility is about 1% for azithromycin and 10% for clarithromycin and is in most cases categorized as intermediate resistance. Resistance to fluoroquinolones is still rare (the reported rate in Spain is 0.1%) (16, 45).

Considerable geographical and temporal differences in the antimicrobial susceptibilities of *H. ducreyi* isolates have been recorded. There is very little information concerning chromosomally mediated resistance in *H. ducreyi*. However, most clinical isolates contain plasmids, which may encode resistance, either separately or in combination, to sulfonamides, aminoglycosides, tetracyclines, chloramphenicol, and β-lactam antibiotics. It is not unusual for a single isolate to contain multiple resistance plasmids. Both TEM-1 and ROB-1 β-lactamases have been identified in isolates from Thailand (85). Recommended drugs are azithromycin, ceftriaxone, ciprofloxacin, or erythromycin (95). Strains for which the erythromycin MIC is 4 mg/liter have been isolated in Thailand and Singapore (85). In general, the prevalence and spectrum of antimicrobial resistance make it important that clinical isolates of *H. ducreyi* be routinely monitored for resistance.

Comprehensive and up-to-date in vitro susceptibility data for other *Haemophilus* species are not available. However, there are indications that the prevalence of resistance in these species is higher than in *H. influenzae*. Both β-lactamase-mediated resistance and non-β-lactamase-mediated resistance to ampicillin have been observed in *H. parainfluenzae*. A PCR-based screening of nasopharyngeal haemophili of a group of individuals in the United Kingdom revealed that 59% carried plasmids encoding β-lactamase. Of these, 83% were in *H. parainfluenzae* and 17% were in *H. influenzae* (40). Transmissible resistance to chloramphenicol and aminoglycosides in *H. parainfluenzae, H. parahaemolyticus,* and *H. paraphrophilus* has been described (36).

EVALUATION, INTERPRETATION, AND REPORTING

Detection of *Haemophilus* species by culture is uncomplicated and reliable provided that correct media and incubation procedures are being applied. Only for *H. ducreyi* do isolation procedures show suboptimal sensitivity. Once they become commercially available, PCR methods will become important in the diagnosis of *H. ducreyi* infections.

Interpretation of laboratory findings is also, in most cases, uncomplicated. Isolation of *Haemophilus* species from sites other than the upper respiratory tract and from normally sterile sites is almost always clinically significant. The mere detection of *H. influenzae* in a sample from the nasopharynx is of no clinical significance. However, strong predominance in the flora suggests an impaired balance that may be associated with sinusitis, otitis media, or other local infection in the area. It is therefore important that findings be interpreted on this basis and that they be reported in semiquantitative terms. It is also unavoidable that sputum samples are contaminated with haemophili during passage through the pharynx and oral cavity. The sample must be evaluated by microscopy prior to culture to make sure that small gram-negative rods in the sample are associated with inflammatory cells and not with squamous epithelial cells from the upper respiratory tract. Even in samples that bypass the upper respiratory tract, a mixture of bacteria often renders the interpretation difficult.

Detection of *H. ducreyi* in samples from genital ulcers or in inguinal lymph node aspirates is always clinically relevant and should be followed by proper antibacterial therapy.

With the virtual elimination of *H. influenzae* serotype b disease in many countries, the demands on the clinical microbiology laboratory in this area have changed dramatically. Methods specifically designed to detect antigens of *H. influenzae* type b are of less importance, and more emphasis should be placed on other serotypes. In this context, it is important to realize that observations made for one human population do not necessarily apply to other populations. Population genetic analyses of *H. influenzae* suggest that individual clones of *H. influenzae* may be strictly adapted to

humans with a particular genetic background and do not spread freely among human populations (57). As there is significant coupling of gene loci (linkage disequilibrium) in the *H. influenzae* population, such differences may include antibiotic resistance markers as well as virulence traits.

Enterobacteriaceae: Introduction and Identification

J. J. FARMER III, K. D. BOATWRIGHT, AND J. MICHAEL JANDA

42

In the fifth edition of this Manual in 1991, Farmer and Kelly commented that it was becoming more difficult to cover the family *Enterobacteriaceae* in a single chapter. The family includes many important organisms (see Tables 1 to 7) such as the plague bacillus *Yersinia pestis,* the typhoid bacillus *Salmonella enterica* serotype Typhi *(Salmonella typhi),* four genera with species that often cause diarrhea and other intestinal infections, seven species that frequently cause nosocomial infections, many other organisms that occasionally cause human or animal infections, dozens of species that occasionally occur in human clinical specimens, and many other species that do not occur in human clinical specimens but can be confused with those that do. In the sixth edition, the material on *Enterobacteriaceae* was divided among three chapters: an introduction to the family that described the overall plan for isolation and identification; a chapter that covered *Salmonella, Shigella, Escherichia coli,* and *Yersinia,* the enteric pathogens; and a chapter that covered the remaining genera and species in the family. In the seventh edition, a fourth chapter was added that covered *Klebsiella, Enterobacter, Citrobacter,* and *Serratia.* In the eighth edition, there were also four chapters. However, *Yersinia* was assigned to its own chapter, and *Klebsiella, Enterobacter, Citrobacter, Serratia,* and *Plesiomonas* (see this chapter) and the remaining *Enterobacteriaceae* were grouped together. This organization has been maintained for the ninth edition.

Because of space limitations, many topics in the present chapter are discussed briefly and only a few primary literature citations are given. Several books, reviews, and chapters are recommended for more detailed information (5, 12–14, 16, 24, 32, 37, 38, 43, 45, 49, 55, 63, 68, 69, 82, 90, 92).

NOMENCLATURE AND CLASSIFICATION

The nomenclature and classification of the genera, species, subspecies, biogroups, and serotypes of *Enterobacteriaceae* have always been topics for heated debate and differing opinions (12–14, 24, 31–34, 37, 38, 55, 63). Until recently, genera and species were defined by biochemical and antigenic analysis. Today, newer techniques such as nucleic acid hybridization and nucleic acid sequencing, which measure evolutionary distance (see chapters 16 and 19 in this Manual), have made it possible to determine the evolutionary relationships among organisms in the family (12–16, 21, 37, 38, 55). The use of these molecular techniques has led to the discovery of many new species and has resulted in the proposed reclassification of others (12–14, 37).

This chapter includes the different names and classifications that clinical microbiologists are likely to encounter in the scientific literature and in material accompanying commercial products. The nomenclature and classification given in Tables 1 to 5 are a compromise based on all available evidence. They include most of the genera, species, subspecies, biogroups, and unnamed Enteric Groups included in the family. If two names are widely used for the same organism, both are mentioned in this chapter with one in parentheses. Many of the "nonclinical" organisms in the family are also included, because there is a possibility that they will be isolated from a human clinical specimen in the future (12–14, 16, 37, 55).

Most of the newly described organisms are very rarely found in clinical specimens (26, 32, 37). This is illustrated by the published listings of organisms that most often cause bacteremia, nosocomial infections, and infections of the gastrointestinal tract (see Tables 6 and 7). The National Library of Medicine's Internet taxonomy database has a useful list of organisms in the family *Enterobacteriaceae* and its relatives (http://www.ncbi.nlm.nih.gov/Taxonomy/Browser/wwwtax.cgi?id=543). This list may also be accessed through http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=Taxonomy by selecting "Taxonomy" in the "Search" field and typing "Enterobacteriaceae" in the adjacent "for" field. The Internet site of J. P. Euzéby (http://www.bacterio.cict.fr) gives nomenclature, classifications, original literature citations, and other information for all of the genera and species in the family *Enterobacteriaceae* and its relatives. Unfortunately, the Euzéby site has no alphabetical list of the genera included in the family.

New Species That Occur in Human Clinical Specimens

Names of several new organisms and several "proposed alternative classifications" have been published since the previous edition of this Manual (Table 2), and several of the new organisms occur in human clinical specimens. It is becoming more and more difficult to update the biochemical reaction table (Table 3) of clinically important *Enterobacteriaceae.* For example, *Klebsiella granulomatis (Calymmatobacterium granulomatis)* does not grow on most bacteriological media and lacks a type strain that can be grown and described based on

TABLE 1 Genera and species of *Enterobacteriaceae* that cause,[a] or are associated with, specific or unusual human diseases, syndromes, or conditions[b]

Disease, syndrome, or condition	Organism(s)	Comment
Brain abscesses	*Citrobacter diversus, Enterobacter sakazakii*	Severe, often fatal disease in neonates, survivors have severe mental impairment; cause outbreaks in hospital nurseries.
Dysentery[c]	*Shigella*	One the most important human diarrheal diseases ("invasive" strains of *Escherichia coli* cause a similar but often milder disease)
Granuloma inguinale	*Klebsiella granulomatis (Calymmatobacterium granulomatis)*	Chronic genital ulcerative disease; organism is difficult to demonstrate microbiologically because it does not grow on laboratory media (see text).
Hemorrhagic colitis[c]	*Escherichia coli* O157:H7	Other Shiga toxin-producing strains can also causes a similar, but often milder disease.[b]
Histamine poisoning (scombroid poisoning)	*Proteus morganii, Klebsiella=Raoultella,* others	Caused by bacteria that produce large amounts of histamine and histamine-like substances (scombrotoxin) when they multiply and spoil fish tissues (via bacterial histidine decarboxylase)
Intestinal infection preceded by *Entamoeba histolytica* infection	*Edwardsiella tarda*	Several interesting studies suggest that the protozoan infection must precede *Edwardsiella tarda* in order for it to cause infection.
Meningitis and sepsis in neonates caused by ingesting contaminated infant formula	*Enterobacter sakazakii*	Nursery outbreaks in which infants acquire the strain from dried infant formula that is contaminated with the bacterium; other coliform organisms have also been isolated from formula samples.
Neutropenic patients—initial fever and fever after empirical antibiotic treatment	*Escherichia coli, Klebsiella, Enterobacter*	
Ozena	*Klebsiella ozaenae*	Chronic atrophic rhinitis (ozena), foul smelling discharge from the nose: causative role is uncertain; it may be just colonization.
Paratyphoid fever	*Salmonella* serotypes Paratyphi A, B, C, and others	Causation: paratyphoid fever is an enteric fever that is similar to typhoid fever[b].
Plague (pneumonic and bubonic plague)	*Yersinia pestis*	One of the most important human diseases—the "Black Death" of the Middle Ages
Pneumonia associated with alcoholism—"Friedländer's pneumonia"	*Klebsiella pneumoniae*	Capsular types K1–K6 are most frequently isolated.
Pseudoappendicitis	*Yersinia enterocolitica*	The appendix is normal after surgical removal.
Rhinoscleroma	*Klebsiella rhinoscleromatis*	Chronic granulomatous infection of the nasal passages and respiratory tract; usually seen in the tropics
Reiters syndrome (reactive arthritis)	*Salmonella, Shigella,* enteropathogenic strains of *Yersinia enterocolitica*	Sometimes occurs after gastrointestinal infection; more common in patients with the HLA-B27 histocompatibility antigen
Salmonellosis[c]	*Salmonella*—any of the named or numbered serotypes	One of the most important human diarrheal diseases
Shigellosis[c]	*Shigella*—any of the named and provisional serotypes	One of the most important human diarrheal diseases
Tropical sprue/enteropathy	*Klebsiella, Enterobacter, Hafnia,* others	"Syndrome of enigmatic origin" characterized by prolonged diarrhea and malabsorption by certain residents of the tropics (68); strong presumption for causation (68)
Typhoid fever[c]	*Salmonella* serotype Typhi	One of the most important human diseases

[a] See reference 68 for more details and the evidence for causation versus association in each.

[b] "Adherent-invasive *Escherichia coli*–strains" have been isolated from some patients with Crohn's disease (10), and this organism is being investigated for a causal role (along with many other unrelated organisms).

[c] See reference 68 and chapter 43 for discussions.

TABLE 2 Newly proposed genera, species, and subspecies of *Enterobacteriaceae,*[a] including several "proposed alternative classifications" for previously described organisms

Organism	Occurrence in human clinical specimens	Proposed as: comments	Reference
Averyella dalhousiensis (formerly classified as Enteric Group 58)	Yes	New genus and new species that colonize or infect traumatic injuries; septicemia in a patient receiving total parenteral nutrition (TPN) through a subcutaneous port	56
Citrobacter Group 139	Yes	Proposed alternative classification[b] for Enteric Group 139, which caused a small hospital outbreak	94[b]
Enterobacter cloacae subsp. *dissolvens*	Yes	Proposed alternative classification for *Enterobacter dissolvens;* isolated from plants, blood, skin abscess, abdomen	51
Enterobacter ludwigii	Yes	New species, 16 clinical isolates from blood, urine, etc.; formerly included in *Enterobacter cloacae;* now part of this species complex	52
Enterobacter radicincitans	No	New species isolated from phyllosphere of winter wheat; fixes nitrogen, promotes plant growth	59
Escherichia albertii	Yes	New species; originally misidentified as "Shiga toxin-producing *Hafnia alvei*"	53
Klebsiella singaporensis	No	New species represented by a single isolate from soil	67
Klebsiella variicola	Yes	New species that is phenotypically almost identical to *Klebsiella pneumoniae;* isolated from plants but also from human blood	81
Kluyvera intermedia	No	Proposed alternative classification for *Enterobacter intermedius*	74
Photorhabdus asymbiotica subsp. *australis*	Yes	New subspecies isolated from blood and wounds of patients in Australia	2
Photorhabdus luminescens subsp. *kayaii* and subsp. *thracensis*	No	Two new subspecies isolated from nematodes in Turkey	48
Salmonella enterica	Yes	An old species, but newly made legitimate (see text)	58
Samsonia erythrinae	No	New species isolated from diseased erythrina trees (*Erythrina* sp.)	89
Serratia marcescens subsp. *sakuensis*	No	New subspecies; reported to produce endospores; isolated from wastewater	1
Serratia quinivorans	No	Proposed alternative classification of *Serratia proteamaculans* subsp. *quinivora;* isolated from plants and insects	3
Yersinia aleksiciae	Yes (feces only)	New species represented by only five strains, formerly included in *Yersinia kristensenii* serogroup O:16; isolated from human feces, pork products, and rats/moles	87
Yersinia enterocolitica subspecies *palearctica*	Yes	New subspecies that was proposed to include one of the three evolutionary groups in the species	72
Xenorhabdus budapestensis, X. ehlersii, X. inexii, X. szentirmaii	No	Four new species that are symbiotic in nematodes of the genus *Steinernema* (family *Steinernematidae*) and that are insect pathogens	65

[a] This table includes organisms that were not included in this chapter in the 8th edition of the Manual.
[b] This chapter should be cited as the reference for *Citrobacter* Group 139 as a proposed alternative classification for Enteric Group 139.

simple phenotypic methods. Another problem has been the unavailability of certain strains (62). Other new organisms are almost identical to older organisms in their phenotypic properties. For example, *Klebsiella variicola* will be very difficult to differentiate from *K. pneumoniae* and other *Klebsiella* species. All the newly described species of *Enterobacteriaceae* need to be characterized and added to Table 3.

Organisms That Do Not Occur in Human Clinical Specimens

New or unusual *Enterobacteriaceae* that do not occur in human clinical specimens are listed in Tables 1 to 5, and more information and literature citations can be found at the Internet sites previously cited and in the new edition of *Bergey's Manual of Systematic Bacteriology* (16). These new organisms should be characterized and added to Table 3.

The Expanding Number of *Enterobacteriaceae* Species

How many species of *Enterobacteriaceae* are there? There are probably many hundreds, if not thousands. This is becoming more apparent as methods such as DNA-DNA hybridization and 16S rRNA sequencing (14, 16) are being used to study strains isolated from human clinical specimens, plants, animals,

TABLE 3 Biochemical reactions[a] of the named species, subspecies, biogroups, and Enteric Groups of the family *Enterobacteriaceae*

Organism	Indole production	Methyl red	Voges-Proskauer	Citrate (Simmons)	Hydrogen sulfide (TSI)	Urea hydrolysis	Phenylalanine deaminase	Lysine decarboxylase	Arginine dihydrolase	Ornithine decarboxylase	Motility	Gelatin hydrolysis (22°C)	Growth in KCN	Malonate utilization	D-Glucose, acid	D-Glucose, gas	Lactose fermentation	Sucrose fermentation	D-Mannitol fermentation	Dulcitol fermentation	Salicin fermentation	Adonitol fermentation	*myo*-Inositol fermentation	D-Sorbitol fermentation	L-Arabinose fermentation	Raffinose fermentation	L-Rhamnose fermentation	Maltose fermentation	D-Xylose fermentation	Trehalose fermentation	Cellobiose fermentation	α-Methyl-D-glucoside fermentation	Erythritol fermentation	Esculin hydrolysis	Melibiose fermentation	D-Arabitol fermentation	Glycerol fermentation	Mucate fermentation	Tartrate, Jordan's	Acetate utilization	Lipase (corn oil)	DNase (25°C)	Nitrate → nitrite	Oxidase, Kovacs	ONPG test	Yellow pigment (25°C)	D-Mannose fermentation	Tyrosine hydrolysis

Matrix 1, Version 11, February 2006

[a] Each number is the percentage of positive reactions after 2 days of incubation at 36°C (unless a different temperature is indicated). The vast majority of these positive reactions occur within 24 h. Reactions that become positive after 2 days are not considered. Abbreviations: TSI, triple sugar iron agar; ONPG, *o*-nitrophenyl-β-D-galactopyranoside. Several "species" in the table are composed of two or more DNA-DNA hybridization groups, so the term "complex" should be understood to follow the species name (see text).

[b] An asterisk by the name of an organism indicates that it occurs in human clinical specimens.

[c] Species in the same genus are grouped with their closest phenotypic and evolutionary relatives (14, 16, 38) rather than being listed alphabetically. For example, the three "subgroups" of the genus *Citrobacter* are defined as "A," "B," and "C" and are listed together.

[d] The Roman numerals refer to the seven *Salmonella* groups that are also biochemically and genetically distinct (see text).

TABLE 4 New, unusual, fastidious, or unculturable genera and species that have been classified[a] (14) in the family *Enterobacteriaceae*

Human pathogen
Klebsiella granulomatis (Calymmatobacterium granulomatis)—causes donovanosis (granuloma inguinale) (see text)
Associated with plants, but some species may occasionally cause or be associated with human clinical infections (see text)
Pantoea, 7 species, 2 subspecies
Pathogenic for or associated with plants; not isolated from human clinical specimens
Brenneria, 6 species; causes a variety of diseases of deciduous trees and walnut trees
Dickeya, 6 species (4 new species plus 2 additional species from other genera) (83)
Erwinia, 9 to 28 species, several named subspecies; major plant pathogen, also exists as a saprophyte and epiphyte
Pectobacterium, 4 to 6 species, several named subspecies; causes soft rot and a variety of other plant diseases, including blights, cankers, die back, leaf spot, and wilts
Phlomobacter fragariae—unculturable species that occurs in the sieve tubes of phloem tissue of plants.
Pathogenic for or associated with insects; not isolated from human clinical specimens
Arsenophonus—2 species, *A. nasoniae,* which is culturable and was originally described as causing the "son-killer" trait in a parasitic wasp, and *A. tiatominarum,* which has not been cultured
Buchnera aphidicola—Cannot be cultivated outside of the aphid host; it is essential for the survival of the aphid.
Photorhabdus—3 species, 3 subspecies. Two species are found only in nematodes and insects that are infected by the nematode. One species, *P. asymbiotica,* causes bacteremia and wound infections in humans (see text).
Wigglesworthia glossinidia—Obligate intracellular endosymbiont of tsetse flies
Xenorhabdus—several species; found only in nematodes and the insects that the nematodes infect; insect pathogens
Associated with extreme environments, not isolated from human clinical specimens
Alterococcus agarolyticus—habitat is coastal hot springs

[a] The unculturable and extremely fastidious organisms have been classified in the family *Enterobacteriaceae* based mainly on 16S rRNA sequencing data. This table includes some organisms whose eventual classification may be as "relatives" of *Enterobacteriaceae*. For more information about each organism, see the Internet site of J. P. Euzéby at http://www.bacterio.cict.fr.

and the environment. One example is the study by Müller et al. (71), who found six new species of *Buttiauxella* and two new species of *Kluyvera* in a large collection of strains isolated from snails. Similarly, additional DNA-DNA hybridization subgroups, which are probably new species (sometimes called genomospecies), have been found in systematic studies of *Enterobacter cloacae* (12), *Proteus vulgaris* (73), *Rahnella aquatilis* (17), *Klebsiella* (67, 81), *Enterobacter* (48, 52, 54, 59), *Yersinia* (7, 8), and *Citrobacter* (15, 18, 94). Most of the *Enterobacteriaceae* that clinical microbiologists encounter every day belong to just a few of the many species described (32). However, the expanding number of *Enterobacteriaceae* species is becoming a serious problem for reference laboratories and for commercial identification systems, whose identification methods are becoming inadequate for complete and accurate identification. When a commercial identification system gives an unusual organism for a final identification, there are several possibilities to consider (56): the identification is correct, just unusual; the identification is incorrect because another aerobic or anaerobic organism is present (42) and the biochemical profile is the result of the metabolic activities of the mixture; or a handling or coding error was made somewhere along the way. Before a final report of an unusual organism is issued, it is advisable to do as much checking as possible. This checking could include repeating the biochemical tests with the same commercial system after confirming the absence of a contaminating aerobic or anaerobic organism (42), testing the isolate with another commercial identification system (56) or with tube tests, and comparing the strain's antibiogram with known patterns reported for this organism. If these steps do not resolve the problem, the state health department or a reference laboratory can be contacted for advice, and the culture will often be accepted for further study. Different commercial systems often give different identifications for the same strain. The "gold standard" for identification is DNA-DNA hybridization; however, it is unavailable except in a few research laboratories. A different standard is evolving that is based on 16S rRNA sequencing. Although less accurate, it is a readily available alternative, and unusual strains can be submitted to a commercial laboratory (Accugenix, Newark, Del. [http://www.accugenix.com] or Midi, Newark, Del. [http://www.midi-inc.com]) for a "fee-for-service" identification. Clinical isolates reported with results obtained with these commercial tests should be reported with a disclaimer to indicate their research ("non-Clinical Laboratory Improvement Amendment [CLIA]") status. We suspect that a reference laboratory's identification based on phenotypic characteristics will be the final result for most difficult strains and will be done at state or national health departments or commercial reference laboratories.

Changes in Classification: "Proposed Alternative Classifications"

Contrary to popular opinion, there is no designated international body that considers every proposed change in classification and then issues an official classification. For almost 75 years, the Subcommittee on *Enterobacteriaceae* (http://www.the-icsp.org/subcoms/Enterobacteriaceae.htm) of the International Committee on Prokaryotes (http://www.the-icsp.org/default.htm) has studied and discussed the nomenclature and classification of the family. When the *Enterobacteriaceae* Subcommittee studies a specific "proposed reclassification," it can only make a recommendation, which can then be accepted or rejected by individuals in the scientific community. It should be emphasized that changes in classification are decided by usage, not by a judicial decision or action (see chapter 19 for further discussion). Sometimes two classifications are widely used, and both can be "correct." Classifications are correct if they conform to all the

TABLE 5 *Enterobacteriaceae* that are difficult to differentiate and identify completely; use of the term "complex"[a] as a solution for reporting cultures[b]

Vernacular name	Organisms included, definition, and comment
Citrobacter freundii complex	In addition to *C. freundii,* this term includes *C. braakii, C. gillenii, C. murliniae, C. rodentium, C. sedlakii, C. werkmanii,* and *C. youngae,* which are difficult to differentiate (15, 18).
Enterobacter agglomerans complex	This term includes over 60 named organisms: over a dozen "*Enterobacter agglomerans* DNA-DNA hybridization groups,"[c] the species of *Brenneria, Dickeya, Erwinia, Pectobacterium, Pantoea,* and perhaps also *Enterobacter cowanii,* all of which are difficult or impossible to differentiate.
Enterobacter cloacae complex	*E. cloacae* is made up of at least five DNA-DNA hybridization groups (12). The definition of the complex would include *Enterobacter ludwigii* plus these unnamed groups. For practical identification schemes, the term includes *Enterobacter amnigenus* and *Enterobacter kobei,* which are difficult to differentiate.
Klebsiella pneumoniae complex	In addition to *K. pneumoniae,* the term includes the closely related species (subspecies) *K. ozaenae* and *K. rhinoscleromatis* and the new species *K. ludwigii.* For practical identification schemes, the term includes *Klebsiella (Raoultella) planticola* and *K. terrigena,* which are very difficult to differentiate. *Klebsiella (Raoultella) ornithinolytica* is ornithine$^+$ and thus phenotypically distinct.
Kluyvera-Buttiauxella complex	This complex includes two genera with almost a dozen species (Table 3) and now includes *Kluyvera intermedia,* formerly classified as *Enterobacter intermedium.*
Proteus vulgaris complex	*P. vulgaris* is made up of at least four DNA-DNA hybridization groups. The definition of the complex could be expanded to include the closely related species *P. penneri* and *P. hauseri,* which can often be differentiated.
Rahnella aquatilis complex	*R. aquatilis* is made up of at least three DNA-DNA hybridization groups.
Serratia liquefaciens complex	The term includes *S. liquefaciens* and three closely related species *S. grimesii, S. proteamaculans,* and S. *quinovorans,* which are difficult to differentiate.
Yersinia enterocolitica complex	In addition to *Y. enterocolitica,* the term includes the closely related species *Y. aldovae, Y. bercovieri, Y. frederiksenii, Y. intermedia, Y. kristensenii,* and *Y. mollaretii,* which are difficult to differentiate.

[a] The word "group" is an alternative term for complex; e.g., the *Enterobacter agglomerans* group, which is also a vernacular name.
[b] An alternative approach would be to report only the genus name (i.e., *Citrobacter* species, *Kluyvera* species, or *Kluyvera-Buttiauxella* species). However, the terms in this table have a narrower definition.
[c] Some of the *Enterobacter agglomerans* DNA-DNA hybridization groups can rarely occur in human clinical specimens.

rules in the *Bacteriological Code (International Code of Nomenclature of Bacteria).* However, classifications can be useful or not useful and can be frequently used in the literature or rarely used (14, 16, 38).

Proposed Changes in Classification and Other Changes in Table 3

Several "alternative classifications" have been proposed in the literature. Some of these appear to be totally justified and have been incorporated into Table 3. However, others have not been fully discussed or widely accepted by the scientific community (28). Table 3 gives the nomenclature and classification that one of us (J.J.F.) has incorporated into tables, data matrices, and computer programs used to identify clinical and nonclinical isolates of *Enterobacteriaceae.* It will differ from other nomenclatures and classifications.

In the seventh edition, the genus *Plesiomonas* was classified in the family *Vibrionaceae* along with *Aeromonas.* Because *Plesiomonas* is closer to *Enterobacteriaceae* than to *Vibrionaceae* based on 16S rRNA sequencing and because it contains the enterobacterial common antigen, it was included in the family *Enterobacteriaceae* in the eighth edition, and this classification has been maintained in the ninth edition. However, *Plesiomonas* is oxidase positive, a characteristic not shared with other species of *Enterobacteriaceae,* and is a distant relative of *E. coli,* the type species of the type genus of *Enterobacteriaceae* (14). Thus, the classification of *Plesiomonas* in the family *Enterobacteriaceae* might best be viewed as tentative.

In Table 3, the organism originally classified (9, 40) as *Xenorhabdus luminescens* DNA hybridization group 5 is now classified as *Photorhabdus asymbiotica* (44). It has caused rare cases of bacteremia and wound infection in the United States (40) and Australia (75). These Australian strains are distinct in some ways and have been proposed (Table 2) as *Photorhabdus asymbiotica* subspecies *australis* (2).

The names *Citrobacter diversus* and *Citrobacter koseri* have both been used in the literature for some time, but the name *Citrobacter diversus* has been used much more frequently. Many workers recognized the phenotypic similarity of these two organisms and thought that they might be the same. The species have different type strains, and so considering them to be the same will always be a subjective matter. They can be considered subjective synonyms but not objective synonyms (which must have the same type strain). The name *Citrobacter diversus* became the correct name for this organism on 1 January 1980, when the *Approved Lists of Bacterial Names* was issued, because under the laws of priority it was the older name. However, in 1993 the Judicial Commission of the International Committee on Systematic Bacteriology issued an Opinion (57) that the name *Citrobacter koseri* should be conserved over the name *Citrobacter diversus,* even though the name *Citrobacter diversus* was the older name, was on the

TABLE 6 *Salmonella* isolates in the United States for 1993 to 2003[a]

Rank for 2003	Serotype name (or formula[b])	No. of isolates: 1993–2002	No. of isolates: 2003
1	Typhimurium	83,873	6,631
2	Enteritidis	74,241	4,863
3	Newport	24,637	3,847
4	Heidelberg	19,837	1,810
5	Javiana	9,186	1,659
6	Montevideo	7,918	849
7	Saintpaul	4,838	823
8	Munchen	6,904	781
9	Oranienburg	6,093	554
10	Infantis	5,477	539
11	Branderup	4,824	530
12	Agona	6,068	510
13	1, 4, [5], 12:i:−[b]	628	498
14	Thompson	5,766	494
15	Mississippi	2,389	438
16	Typhi	3,979	359
17	Paratyphi B (L-tartrate$^+$)	3,014	331
18	Hadar	6,197	280
19	Bareilly	1,419	234
20	Stanley	2,157	224
	Paratyphi A	822	108
	Paratyphi C	9	0
	Choleraesuis	675	19
	Choleraesuis variety Kunzendorf		13
	Other serotypes		5,239
	Incomplete or no typing		2,105
	Total	354,093	33,589

[a] Surveillance data are from the Centers for Disease Control and Prevention. A free copy of the annual *Salmonella* surveillance reports can be obtained from the Centers for Disease Control and Prevention, Foodborne and Diarrheal Diseases Branch, Mail Stop A38, 1600 Clifton Rd., Atlanta, GA 30333. Recent surveillance reports can also be viewed on the Internet at http://www.cdc.gov/ncidod/dbmd/phlisdata/salmonella.htm. Note: the entire document for a given year can be very large, so it may be necessary to download individual tables to avoid time and computer data storage problems. A paper copy (619 pages in color) of CDC's very useful *Salmonella* atlas (22) is also available without charge (contact Richard Bishop at rqb7@cdc.gov).

[b] This serotype is referred to by its antigenic formula because it does not have a formal serotype name, unlike the other 19 serotypes. Its O antigens are 1, 4, [5], 12 ([5] indicates that serofactor 5 may or may not be present); its H antigen for phase one is "i," and it does not have a phase two H antigen.

Approved Lists of Bacterial Names, was the correct name under the rules of the *Bacteriological Code,* and was the name used most frequently in the literature. This opinion needs much more discussion by the scientific community, which is beyond the scope of this chapter; therefore, both names are included in Table 3.

Phenotypic and 16S rRNA sequencing data indicate that *Kluyvera cochleae* is almost identical to *Enterobacter intermedium,* and the proposed reclassification of this organism as *Kluyvera intermedia* (74) appears to solve several problems (Tables 2 and 3).

Another change in Table 3 is that species in the same genus are now grouped with their closest phenotypic and evolutionary relatives (14, 16, 38) rather than listed alphabetically. For example, three subgroups of the genus *Citrobacter* are defined as A, B, and C and listed together. In addition, we propose that Enteric Group 139 be reclassified as *Citrobacter* Group 139. A similar notation is used in Table 3 for other genera; Tables 2 and 4 and the text give explanations.

Other Proposed Changes in Nomenclature and Classification

Proposed Classification of Three *Klebsiella* Species in *Raoultella*

In 2001, Drancourt et al. (28) proposed that *Klebsiella planticola, K. ornithinolytica,* and *K. terrigena* be classified in a new genus, *Raoultella,* as *R. planticola, R. ornithinolytica,* and *R. terrigena.* These three species are extremely similar to *Klebsiella pneumoniae* in their phenotypic properties (37), making differentiation very difficult (Table 3). This proposed alternative classification needs further evaluation; however, we agree that these three species should be grouped together and have done this in Table 3.

Enterobacter agglomerans Group–*Pantoea*

The *Enterobacter agglomerans–Pantoea* complex is a confusing subject, and writers continue to make errors in the definition

TABLE 7 *Shigella* isolates in the United States for 2003[a]

Rank	Serotype	Isolates
1	*Shigella sonnei* (serogroup D)	9,263
2	*Shigella flexneri* (serogroup B)	1,660
3	*Shigella boydii* (serogroup C)	125
4	*Shigella dysenteriae* (serogroup A)	41
	Not (completely) serotyped	463
	Total *Shigella* isolates	11,552

[a] Data are from the Centers for Disease Control and Prevention at http://www.cdc.gov/ncidod/dbmd/phlisdata/shigella.htm. Surveillance reports for previous years are also at this Internet address. Note: the entire document for a given year is typically very large so it may be prudent to download individual tables to avoid time and computer data storage problems.

and circumscription (boundaries) of *Pantoea agglomerans.* In 1972, Ewing and Fife redefined the name *Enterobacter agglomerans* to include a wide variety of organisms known under many different names (32). These investigators also defined 11 different biogroups to recognize the phenotypic diversity of the many strains included in *Enterobacter agglomerans.* This name has become useful for clinical microbiologists, and it has been used extensively in the literature. Systematic analysis by Brenner and coworkers using DNA-DNA hybridization indicated that *Enterobacter agglomerans* is very heterogeneous, with at least 14 DNA hybridization groups (12). For this reason, the names "*Enterobacter agglomerans* complex" and "*Enterobacter agglomerans* group" (37) have been used to better indicate the heterogeneity of this "species" (Tables 3 and 5). However, it has been very difficult to find simple tests to differentiate and identify all of the DNA hybridization groups (37). For this reason, workers have been reluctant to subdivide the *Enterobacter agglomerans* group until a definitive classification could be proposed (37). Gavini et al. (46) took the first step toward more logical classification for this complex group by proposing that the group of six strains defined by Brenner et al. as "DNA hybridization group 13 of *Enterobacter agglomerans*" be classified in a new genus, *Pantoea,* as *P. agglomerans.* They also defined a new species in the genus, *Pantoea dispersa* (46), previously classified as *Enterobacter agglomerans* DNA hybridization group 3 by Brenner (12).

However, this new classification has caused communication problems. Some authors have broadened the original definition of Gavini et al. for *Pantoea agglomerans* to include organisms that are not phylogenetically related. Since DNA-DNA hybridization is not routinely done and since simple tests are not available to definitively identify strains to the level of DNA hybridization group, it seems prudent to retain the vernacular name "*Enterobacter agglomerans* complex" as a convenient name for clinical microbiologists to use in reporting clinical isolates (Tables 3 and 5). This term is defined biochemically in Table 3, and it should be emphasized that it is used merely for convenience because the name *Enterobacter agglomerans* is well understood and widely used in the literature. Eventually, this term will be replaced with a better classification. When definitive testing in a reference laboratory (usually including DNA hybridization) is done, more precise names can be used in reporting. Examples could include *Pantoea agglomerans* (limited to strains that fall into DNA hybridization group 13), *Pantoea dispersa* (limited to strains that fall into DNA hybridization group 3), and *Enterobacter agglomerans* DNA hybridization group 1, etc. Tables 3 and 5 use and define the vernacular name *Enterobacter agglomerans* complex, a term that may prove useful for reporting isolates in most microbiology laboratories because almost none can do DNA-DNA hybridization. A less desirable vernacular name for this group of organisms is the "*Pantoea agglomerans* complex."

Enterobacter taylorae–Enterobacter cancerogenus

Enterobacter taylorae and *Enterobacter cancerogenus* may be two names for the same organism (47). However, they have different type strains; therefore, they are not objective synonyms under the rules of the *Bacteriological Code.* Until the identity of these two organisms is universally accepted, both names will be used (Table 3).

Nomenclature, Classification, and Reporting of the Genus *Salmonella*

After much study and a lengthy judicial process (58), there is now good agreement on many issues in the nomenclature and classification of the genus *Salmonella* (32, 41, 58, 70, 76, 78, 79). The recent decision of the Judicial Commission on the International Committee on Systematics of Prokaryotes (58) to replace *Salmonella choleraesuis* with *Salmonella enterica* stabilizes this issue which has caused confusion and the use of illegitimate names in the literature for many years. In 2005 (58), *Salmonella enterica* finally became the legitimate species name to include most of the most important serotype names. Three 2005 references (58, 78, 91) and the Internet site of J. P. Euzéby (http://www.bacterio.cict.fr) provide additional historical insights and alternative perspectives on the issues.

Until the 1970s, the species concept in the genus *Salmonella* was based on epidemiology, host range, biochemical reactions, and antigenic structure (the O antigen, phases 1 and 2 of the H antigen, and the Vi antigen, if present), and strains that differed in one or all of these properties were given distinct names. Names such as *Salmonella typhi, Salmonella cholerae-suis* (originally some names such as this one were written with a hyphen, which was eventually dropped because of changes in the *Bacteriological Code*), *Salmonella paratyphi* A, *Salmonella paratyphi* A var. *durazzo, Salmonella typhimurium, Salmonella typhimurium* var. *copenhagen, Salmonella enteritidis,* and *Salmonella newport* began to appear, and the list rapidly expanded to include hundreds of names. Some workers believed that these names really represented biological species, but others thought that they were antigenic and biochemical varieties with an uncertain evolutionary relationship. However, there was universal agreement that the names were an extremely useful way to communicate about the particular serotypes and the diseases they caused. Most authors wrote the serotype names in italics as a species in the genus *Salmonella,* for example, *Salmonella typhimurium* (32, 41). Several proposals to the Judicial Commission of the International Committee on Systematic Bacteriology have requested that important serotype names be preserved (31, 33, 34) to preserve stability in nomenclature, but it is not clear whether this is a matter that will be decided by judicial action or by usage.

In 1973, Crosa et al. (25) used DNA-DNA hybridization to show that *Salmonella* strains could be grouped into five main evolutionary groups. Two (possibly three) additional groups are now known (11, 78, 79). The vast majority of strains that cause human infections occur in DNA hybridization group 1 (*Salmonella* group I). Strains isolated from animals and the environment clustered into the four other groups, designated DNA groups 2 (II), 3a (IIIa), 3b (IIIb), and 4 (IV). Over the

years, different authors have used different terms to refer to these evolutionary groups: DNA-DNA hybridization groups (25, 41), multilocus enzyme electrophoresis clusters (11, 79), subgenera, species (see the *Approved Lists of Bacterial Names* and http://www.bacterio.cict.fr), and subspecies (70, 76, 77). Crosa et al. (25) showed that all five groups of *Salmonella* were very highly related genetically. With the operational species definition usually used in DNA hybridization, these five groups were considered to belong to the same species. Under the rules of the *Bacteriological Code,* the name of this species had to be *Salmonella choleraesuis.* However, this species name is a cause of confusion, since *Salmonella choleraesuis* would have two totally different meanings, a broad one as a species and a narrow one as a serotype. There was support for making an exception to the rules of the *Bacteriological Code* and using a name that has never been used as a serotype name to avoid confusion. There was a formal proposal in 1999 to coin a new name, *Salmonella enterica* (31), which would replace the name *Salmonella choleraesuis* as the species name to represent most of the serotypes of *Salmonella.* However, the proposal to replace the name *Salmonella choleraesuis* with *Salmonella enterica* was denied by the Judicial Commission of the International Committee on Systematic Bacteriology. Thus, *Salmonella choleraesuis* remained the correct name until a variation of the original proposal to the Judicial Commission was approved in 2005 (58). Even though it was an illegitimate name, the name *Salmonella enterica* had already been used by the World Health Organization's International Center for *Salmonella* (76) and by many of the World Health Organization's national centers for *Salmonella.* The name had also been used widely in the literature. Fortunately, the 2005 decision of the Judicial Commission has made *Salmonella enterica* the correct name, which is gaining universal acceptance.

Another point of confusion concerns the method of writing serotype names. For almost 100 years, serotype names have been written as species (the serotype-as-species nomenclature), for example, *Salmonella enteritidis.* The World Health Organization's International Center for *Salmonella* at the Institut Pasteur, Paris, France, introduced a different nomenclature in which the serotype name is capitalized and not written in italics. In this nomenclature, the name *Salmonella enteritidis* would be written in one of the following ways: "*Salmonella enterica* serovar Enteritidis," "*Salmonella* serovar Enteritidis," "*Salmonella* ser. Enteritidis," or "*Salmonella* Enteritidis." The nomenclature described by McWhorter-Murlin and Hickman-Brenner (70) is similar, but these authors use the term "serotype" instead of "serovar." The main advantage of these nomenclatures is that they do not artificially treat the serotypes as species. The main disadvantage is that they create a new nomenclature that differs from one that has been widely accepted and used for more than 70 years. There have been literally hundreds of thousands of uses of the serotype-as-species nomenclature in the literature. The International Center for *Salmonella*'s nomenclature appears in the second edition of *Bergey's Manual* (78) and is being used (sometimes with modifications) by the national centers for *Salmonella* (19, 70). However, many published articles and books continue to use the nomenclature. Since *Salmonella* names are being written differently by different authors and different national centers for *Salmonella,* it is not surprising that the literature is beginning to reflect this confusion. Recent examples of the way "serotype Typhimurium" is being written include *Salmonella* serotype Typhimurium, *Salmonella* ser. Typhimurium, *Salmonella typhimurium, Salmonella* Typhimurium, *Salmonella* typhimurium, *Salmonella* serovar Typhimurium, and *Salmonella* serovar *Typhimurium* or simply Typhimurium (omitting the genus name *Salmonella* entirely) (88). When the variations are combined with the four species and subspecies possibilities, i.e., *Salmonella choleraesuis, Salmonella choleraesuis* subspecies *choleraesuis, Salmonella enterica,* and *Salmonella enterica* subspecies *enterica,* the number of possible variations is multiplied considerably. One example of the almost endless possibilities is *Salmonella enterica* subspecies *enterica* serovar Typhimurium.

The current disagreements in *Salmonella* nomenclature and classification include the use of the term "serotype" (19, 70) versus "serovar" (76, 77) (both terms are often abbreviated as "ser."); the best way to write the names of the serotypes; the use of names versus antigenic formulas for some of the serotypes; the argument over whether some well-known serotype names should be eliminated and combined with other serotypes (19, 70, 76, 77); and the question of how to name the distinct DNA hybridization groups.

Most clinical microbiology laboratories identify *Salmonella* isolates with a commercial identification system and then with commercial *Salmonella* "polyvalent grouping antisera," which will agglutinate only those strains with the O antigen groups contained in the polyvalent serum (often only groups A through E). These two methods usually give definitive results, and a simple report can be issued such as "*Salmonella* serogroup B," avoiding the problems described above. Abbreviating "serotype" and "serovar" as "ser." would be a further simplification and would avoid the disagreement over these two terms. Reference laboratories that do complete serotyping and biochemical testing can issue a definitive report such as "*Salmonella* serotype Typhimurium" or "*Salmonella enterica* serotype Typhimurium."

Nomenclature for Shiga Toxins/Verotoxins Produced by *E. coli* and *Shigella*

Several different names are being used in the literature for the cytotoxins produced by *E. coli* and *Shigella.* This topic is critical because of the importance of *E. coli* O157 and other strains that produce these toxins (see chapter 43 of this Manual). Several different commercial assays for these toxins are being marketed; therefore, it is essential to read the package insert carefully to determine exactly which toxin(s) the kit is detecting and to word laboratory reports accordingly.

For almost 100 years, it has been known that *Shigella dysenteriae* serogroup O1 produces a potent cytotoxin known as Shiga toxin. More recently, it has been shown that certain strains of *E. coli* that cause intestinal infections produce a similar toxin, which was first detected because it was cytotoxic for Vero cells in tissue culture. A number of recent studies have defined these proteins from *S. dysenteriae* O1 and *E. coli,* and there is agreement that they constitute a family of toxins. They are being referred to in the literature as Shiga toxin (ST), Shiga-like toxins (SLT), verocytotoxin(s), and verotoxin(s) (VT), and at least five different toxins are involved (20, 86). This complex subject was recently reviewed by Scheutz and Strockbine (86). The *E. coli* strains that produce these toxins are often referred to as STEC and VTEC. Calderwood et al. (20) summarized the data available and proposed that strains of *E. coli* that produce these toxins be called "Shiga toxin-producing" *E. coli,* which would replace the previous term, "Shiga-like toxin producing." They also recommended that the new toxin name be cross-referenced with the corresponding verotoxin name. With this nomenclature, a laboratory report for a stool culture might be worded, "Positive for *E. coli* O157:H7, which produces Shiga

toxins Stx1 (VT1) and Stx2 (VT2)." Hopefully, the differences between those using the two different nomenclatures will be resolved, resulting in a single nomenclature.

Proposed Reclassification of *Calymmatobacterium granulomatis* as *Klebsiella granulomatis*

Calymmatobacterium granulomatis has received little attention in industrialized countries. In the seventh edition of this Manual, *Calymmatobacterium* was mentioned only twice (pages 25 and 50). It was listed as an aerobic bacterium that can be found in the genital area, and under the topic "Specimen Management" it was mentioned under the disease granuloma inguinale, or ulcerative donovanosis, with the notes "mostly a tropical disease" and "culture is nonproductive." *Calymmatobacterium granulomatis* has been described as a highly pleomorphic gram-negative rod that does not grow on laboratory media. Diagnosis of granuloma inguinale has been based on showing the presence of "Donovan bodies" in Giemsa-stained smears of mononuclear cells or histiocytes from the patient's genital ulcers.

It had been assumed for almost a century that *Calymmatobacterium granulomatis* has no relationship to the "easy-to-culture" organisms of the family *Enterobacteriaceae.* However, Carter et al. (21) proposed that *Calymmatobacterium granulomatis* be reclassified in the genus *Klebsiella* as *Klebsiella granulomatis.* This proposal was based both on nucleotide sequence relatedness and on disease similarity. Granuloma inguinale is a disease similar to rhinoscleroma, also a tropical disease (nasal infection) caused by (or associated with) *Klebsiella rhinoscleromatis.* While this alternative classification is being evaluated and tested, it would be helpful to write both scientific names, with the writer's preference listed first: *"Klebsiella granulomatis (Calymmatobacterium granulomatis)"* (which we prefer) or *"Calymmatobacterium granulomatis (Klebsiella granulomatis)."* Other diseases of unknown etiology may be caused by unculturable *Enterobacteriaceae.*

DESCRIPTION OF THE FAMILY *ENTEROBACTERIACEAE*

Most genera and species in the family *Enterobacteriaceae* share the following properties: they are gram negative and rod shaped; do not form spores; are motile with peritrichous flagella or are nonmotile; grow on peptone or meat extract media without the addition of other supplements or sodium chloride; grow well on MacConkey agar; grow both aerobically and anaerobically; are often active biochemically; ferment (rather than oxidize) D-glucose and other sugars, often with gas production; are catalase positive and oxidase negative; reduce nitrate into nitrite; contain the enterobacterial common antigen; and have 39 to 59% guanine-plus-cytosine (G+C) contents in DNA (5, 12–14, 38, 55). Host-adapted species that are unculturable, difficult to culture, or slow growing appear to have evolved in some genera (14) (Table 4).

When techniques that measure evolutionary distance are used, genera and species in the family should also be more closely related to *E. coli,* the type species of the type genus of the family, than they are to organisms in other families (14, 38). Tables 1 to 5 expand on this definition and give most of the exceptions.

NATURAL HABITATS

Enterobacteriaceae are widely distributed on plants and in soil, water, and the intestines of humans and animals (5, 14, 43, 55). Some species occupy very limited ecological niches. *Salmonella* serotype Typhi causes typhoid fever and is found only in humans (50, 68). In contrast, strains of *Klebsiella pneumoniae* are distributed widely in the environment and contribute to biochemical and geochemical processes (63). However, strains of *K. pneumoniae* also cause human infections, ranging from asymptomatic colonization of the intestinal, urinary, and respiratory tracts to fatal pneumonia, septicemia, and meningitis.

CLINICAL SIGNIFICANCE

Some *Enterobacteriaceae* are associated with or cause specific humans diseases (Table 1) (14, 55, 68, 69, 82). Many cause, or are isolated from, abscesses, pneumonia, meningitis, septicemia, and infections of wounds, the urinary tract, and the intestine (68, 69). They are a major component of the normal intestinal flora of humans but are relatively uncommon as normal flora of other body sites. Several species of *Enterobacteriaceae* are very important causes of nosocomial infections (69). *Enterobacteriaceae* may account for 80% of clinically significant isolates of gram-negative bacilli and 50% of clinically significant bacteria in clinical microbiology laboratories (30). They account for nearly 50% of septicemia cases, more than 70% of urinary tract infections, and a significant percentage of intestinal infections (68, 69).

Human Extraintestinal Infections

Except for the species of *Shigella,* which rarely cause infections outside the gastrointestinal tract, many species of *Enterobacteriaceae* commonly cause extraintestinal infections. However, a small number of species, i.e., *E. coli, Klebsiella pneumoniae, Klebsiella oxytoca, Proteus mirabilis, Enterobacter aerogenes,* the *Enterobacter cloacae* complex, and *Serratia marcescens,* account for most of these infections. Urinary tract infections, primarily cystitis, are the most common (85), followed by respiratory, wound, bloodstream (27), and central nervous system infections. Many of these infections, especially sepsis and meningitis, are life threatening and are often hospital acquired. Because of the severity of these infections, prompt isolation, identification, and susceptibility testing of *Enterobacteriaceae* isolates are essential.

Human Intestinal Infections

Several organisms in the family *Enterobacteriaceae* are also important causes (Tables 6 and 7) of intestinal infections of humans and animals worldwide. Although other species in the family have been associated with diarrhea (93) or even implicated as causes of diarrhea, only organisms in four genera, *Escherichia* (29, 36, 55, 61), *Salmonella* (25, 41, 50, 78), *Shigella* (32, 68), and *Yersinia* (7, 60, 68, 80), have been clearly documented as enteric pathogens. These four genera are discussed in chapters 43 and 44 of this Manual. Other *Enterobacteriaceae* such as *Citrobacter, Edwardsiella, Hafnia, Morganella, Proteus, Klebsiella, Enterobacter,* and *Serratia* may have an association with diarrhea in certain studies (39, 93), and some authors have gone as far as to implicate them as actually causing diarrhea (5, 93). Strains of these *Enterobacteriaceae* that produce "biologically active" compounds (often vastly overstated as being "enterotoxin-producing strains") have been isolated from people with diarrhea (93), but the causal role of these strains in diarrhea is uncertain. One possible way to emphasize the drastic change in the stool flora would be to issue a report such as "*Klebsiella pneumoniae* isolated in essentially pure culture

(10 of 10 colonies tested); please consult the laboratory to discuss possible significance." The patient's antibody response, or lack of one, would be a helpful way to assess the particular organism's causative role. There is no evidence that strains of these other genera are important causes of diarrhea.

In contrast to the arguable role of the organisms listed above, the evidence for the causal role of *Plesiomonas shigelloides* (see chapter 45 in this Manual) in diarrhea is somewhat stronger. A safe generalization would be that "certain strains of *P. shigelloides* may cause diarrhea in certain people under certain conditions, but it is probably not an intrinsic pathogen." For an intrinsic pathogen, most strains would cause diarrhea in most people, under most conditions (39).

Surveillance at the National and International Levels

Many countries provide surveillance data on the Internet for plague, typhoid fever, salmonellosis, shigellosis, diarrheagenic *E. coli*, institutional infections, bacteremia, meningitis, antibiotic resistance, and other enteric and nonenteric infections. Often the word "infection" or a similar word is used when the term "clinical microbiology isolate" would be more appropriate. Care must be used in interpreting these data because "association" and "clinical microbiology isolate" do not equate with "causation" and "infection" in each instance (39). For example, few would argue with the use of the term "infection" for a clinical isolate of *Salmonella* serotype Typhi from the stool of a patient with typhoid fever. In contrast, the word "infection" would be an overstatement if used to describe a stool isolate of a nonenteropathogenic *Yersinia enterocolitica* serotype (such as O10) or one of the other six species of the *Y. enterocolitica* group (Table 3). Check to see if surveillance data make these important distinctions.

SPECIMEN COLLECTION, TRANSPORT, AND PROCESSING

Extraintestinal Specimens

Enterobacteriaceae are recovered from infections at many different body sites, and normal practices (see chapters 5 and 20 of this Manual) for collecting blood, respiratory, wound, urine, and other specimens should be followed.

Intestinal Specimens

Stool cultures are usually submitted to the laboratory with a request to isolate and identify the cause of a possible intestinal infection, usually manifested as diarrhea (see chapter 20). The groups of *Enterobacteriaceae* usually associated with diarrhea in the United States are *Salmonella* (22), *Shigella* (23), and certain pathogenic strains of *E. coli* and *Yersinia enterocolitica.*

Stool specimens require special attention to both collection and transportation and should be obtained early in the course of illness, when the causative agent is likely to be present in the largest numbers in feces. At this stage, the use of enrichment broths should be unnecessary. If rapid processing (within 2 h of collection) is not possible, a small portion of feces or a swab coated with feces should be placed in transport medium, such as Stuart, Amies, Cary-Blair, or buffered glycerol saline. Cary-Blair is probably the best overall transport medium for diarrheal stools. In cases of diarrhea that do not yield a causative agent, a tube of frozen stool can be invaluable for looking for new causative agents or for testing against the patient's convalescent serum. More information about the isolation, identification, typing, and virulence testing of isolates of *Salmonella, Shigella, E. coli,* and *Y. enterocolitica* is given in chapters 43 and 44.

Macroscopic and Microscopic Examination

Stool specimens should be examined visually for the presence of blood or mucus, but microscopic examination is less helpful because of its lack of specificity (84). Although identification by fluorescent-antibody staining is theoretically possible for all enteric pathogens, it has been of limited success because the method is difficult and there are many serological cross-reactions among the species of *Enterobacteriaceae* (32). This technique was most often used to detect *Salmonella* strains (primarily in the food industry) and certain serogroups of *E. coli* and to aid in outbreak investigations.

ISOLATION

Extraintestinal Specimens

Most strains of *Enterobacteriaceae* grow readily on the plating media commonly used in clinical microbiology laboratories (see chapter 20). MacConkey agar, generally interchangeable with eosin methylene blue agar, is usually used, because it allows a preliminary grouping of enteric and other gram-negative bacteria. The most common isolates of *Enterobacteriaceae* have a characteristic appearance on blood agar and MacConkey agar that is useful for preliminary identification (Table 8). Broth enrichment can increase the isolation rate if small numbers of *Enterobacteriaceae* are present, but this step is not normally required.

Intestinal Specimens

Media that can be used routinely for intestinal specimens include a nonselective medium such as blood agar, a differential medium of low to moderate selectivity such as MacConkey agar, and a more selective differential medium such as xylose-lysine-deoxycholate (XLD) agar or Hektoen enteric agar (HE). A broth enrichment substance such as selenite (or GN [gram-negative broth] or tetrathionate) can be included, particularly if the specimen is not optimal. A highly selective medium such as brilliant green agar, bismuth sulfite, Rambach, or CHROM agar *Salmonella* (BD Diagnostics, Sparks, Md.) can also be included for isolating strains of *Salmonella.* A special plate, such as sorbitol-MacConkey agar (or one of its modifications), can be added to enhance the isolation of Shiga toxin-producing strains of *E. coli* O157:H7. This medium should be used if the stool is frankly bloody or if the patient has a diagnosis of hemolytic-uremic syndrome, and it can be used for all fecal specimens if resources permit (see chapter 42). When the presence of *Yersinia enterocolitica* is suspected, a selective-differential medium, such as CIN (cefsulodin-Irgasan-novobiocin) agar (also called *Yersinia* selective agar), can be added (see chapter 44). A complete stool culture procedure should also include media for isolation of *Campylobacter* and possibly *Vibrio* strains in areas where cholera and other *Vibrio* infections are common. Several new plating media appear to be more sensitive or specific and are gaining in popularity (see chapters 43 and 44).

IDENTIFICATION

There are many different approaches to identifying strains of *Enterobacteriaceae* (14, 37, 38).

TABLE 8 Colonial appearance of the most common *Enterobacteriaceae* on MacConkey agar and sheep blood agar[a]

Genus or species	Appearance and typical colony diameter on:	
	MacConkey agar	Sheep blood agar[b]
Salmonella and *Shigella*	Colorless, flat, 2–3 mm	Smooth, 2–3 mm
Escherichia coli (lactose positive)	Red, usually surrounded by precipitated bile, 2–3 mm	Smooth, 2–3 mm
Escherichia coli (lactose negative)	Colorless, 2–3 mm	Smooth, 2–3 mm
Yersinia enterocolitica	Colorless, less than 1 mm	Smooth, less than 1 mm
Klebsiella pneumoniae	Pink, mucoid, 3–4 mm	Mucoid, 3–4 mm
Enterobacter	Pink, not as mucoid as *Klebsiella*, 2–4 mm	Smooth, 3–4 mm
Proteus vulgaris and *Proteus mirabilis*	Colorless, flat, often swarm slightly, 2–3 mm	Swarm in waves to cover plate
Other *Proteus*, *Providencia*, and *Morganella* species	Colorless, flat, no swarming, 2–3 mm	Flat, 2–3 mm, no swarming

[a] Most strains appear this way, but there are exceptions.
[b] Most strains of *Enterobacteriaceae* are nonhemolytic, which is in contrast to many strains of *Aeromonas* and *Vibrio,* which are hemolytic. A few strains of *E. coli* are strongly hemolytic, as are occasional strains of other *Enterobacteriaceae*.

Conventional Biochemical Tests in Tubes

Tube testing was once used by all clinical microbiology laboratories, and it is still widely used in reference and public health laboratories (32, 37). Although some laboratories prepare their own media from commercial dehydrated powders, most of the common media are also available commercially in glass tubes that are ready to use. Growth from a single colony is inoculated into each tube, and the tests are read at 24 h and usually also at 48 h. In many reference laboratories, most tests are often kept for 7 days to detect delayed reactions. Unfortunately, the media and tests are not completely standardized, and few laboratories use exactly the same formulations or procedures. Even with these variables, this approach usually results in correct identifications of the common species of *Enterobacteriaceae.* Table 3 gives the results for *Enterobacteriaceae* in 48 tests (for the media and methods used to generate the data in this table, see references 32, 35, and 37).

Computer Analysis To Assist in Identification

Two microcomputer programs were developed in the 1980s at the Centers for Disease Control and Prevention (CDC)'s Enteric Reference Laboratories to assist with the identification of *Enterobacteriaceae* cultures. "George" and "Strain Matcher" were described in the 1985 review of the family (37). One of us (J.J.F.) plans to revise and update these programs to run on current operating systems and make them more available. These plans include modifying the *Enterobacteriaceae* data matrix in Table 3 and other data matrices to be compatible with the probabilistic identification program *PIBWin* that is free and can be downloaded from the Internet (http://www.som.soton.ac.uk/staff/tnb/pib.htm).

Screening Tests, Using All Information Available

Over the years, the Enteric Reference Laboratories at CDC have found that many genera, species, and serotypes can be tentatively identified with a number of screening tests (Table 9). More precise identification can be made by using a complete set of tests or commercial identification systems. Because of the limited availability of certain reagents (bacteriophage O1 and *Yersinia* typing sera, etc.), these screening tests may be more useful in a reference or research laboratory.

Example 1. A urine isolate has the following properties: colonies on MacConkey agar are 2 to 3 mm in diameter, are bright red and nonmucoid, and have precipitated bile around them; it is indole positive and 4-methylumbelliferyl-β-D-glucuronidase (MUG) positive; it grows at 44.5°C; and it is antibiotic resistant. These results are completely compatible with *E. coli.*

Example 2. An isolate from the feces of a diarrhea patient has the following properties: colonies on MacConkey agar are 2 to 3 mm in diameter and colorless; colonies on XLD agar are 2 to 3 mm and black; the isolate agglutinates in *Salmonella* polyvalent O serum and in O-group B serum; the MUCAP test (hydrolysis of 4-methylumbelliferyl caprylate; Biolife, Milan, Italy) and lysis by bacteriophage O1 are positive; and it is antibiotic resistant. All these results are compatible with *Salmonella* serogroup B.

Commercial "Kits" for Identification

A commercial kit is defined as a panel of miniaturized or standardized tests that are available commercially. The tests incorporated in the kits are often a subset of those given in Table 3. The approach for using kits is similar to the conventional tube method, with the main differences being in the miniaturization, the number of tests available, the suspending medium, and the method of reading and interpreting results (sometimes by machine). Kits are now used by most American laboratories and are discussed in chapter 15. Kits often give the correct identification for the most common species of *Enterobacteriaceae,* but they may not be as accurate for some of the new species. It is important to check the instruction manual to determine which organisms have been included in the database and the number of strains that were used to define each organism. The main problem with kit-based identification is that the tests used (usually about 20 tests) are becoming inadequate to differentiate all of the current species of *Enterobacteriaceae* given in Tables 1 to 5. This is also becoming a problem with conventional tube tests, even when the 48 tests listed in Table 3 are used. Unusual identifications or "no identification" obtained with a kit could be verified by other methods or approaches (56), but referral to a reference laboratory may be the best alternative. Other methods might

TABLE 9 Screening test for the enteric pathogens *Salmonella, Shigella, Escherichia coli, Yersinia,* and for the other important *Enterobacteriaceae* and those most frequently isolated from human clinical specimens[a]

Organism (genus, species, or serotype)	Test or property[b]
Salmonella	Lactose$^-$, sucrose$^-$, H_2S^+, O1 phage$^+$[c], MUCAP$^+$[d], agglutinates in polyvalent serum,[b] typical colonies on media selective/differential for *Salmonella* (brilliant green agar, SS agar, Rambach agar, CHROM agar, etc.), lysed by the *Salmonella*-specific "bacteriophage O1"[c], often antibiotic resistant
Salmonella typhi	Ornithine$^-$, H_2S^+ (trace amount only), L-rhamnose$^-$, no gas produced during fermentation, agglutinates in group D serum, Vi serum, and flagella "d" serum
Shigella	Nonmotile, lysine$^-$, gas$^-$, agglutinates in polyvalent serum, biochemically inactive, often antibiotic resistant, PhoE$^+$ (molecular test)[d]
Shigella dysenteriae	Agglutinates in group A serum, D-mannitol$^-$
Shigella dysenteriae O1	Catalase$^-$, agglutinates in O1 serum, Shiga toxin$^+$
Shigella flexneri	Agglutinates in group B serum, D-mannitol$^+$
Shigella boydii	Agglutinates in group C serum, D-mannitol$^+$
Shigella sonnei	Agglutinates in group D serum, D-mannitol$^+$, ornithine decarboxylase$^+$, lactose$^+$ (delayed), characteristic colony variation from smooth to rough
Escherichia coli	Extremely variable biochemically, indole$^+$, MUG$^+$, grows at 44.5°C, sometimes antibiotic resistant, PhoE$^+$ (molecular test)[d]
Escherichia coli O157:H7	Colorless colonies on sorbitol-MacConkey agar (SMAC), red colonies on MacConkey agar, MUG$^-$, D-sorbitol$^-$ (or delayed), agglutinates in O157 serum and H7 serum; many commercial media and tests are available (95)
Escherichia coli—invasive strains	Many strains resemble *Shigella* because they are "inactive" biochemically: lactose$^-$, nonmotile, lysine$^-$; O antigen groups O28, O29, O112, O124, O136, O143, O144, O152, O164, O167, and others; no commercial assay or simple way to isolate and identify
Yersinia	Grows on CIN agar, often more active biochemically at 25 than 36°C ; motile at 25°C, nonmotile at 36°C, urea$^+$
Yersinia enterocolitica, pathogenic serotypes	Smaller colonies (often less than 1 mm) than other *Enterobacteriaceae* species on enteric plating media, CR-MOX$^+$, pyrazinamidase$^-$, salicin$^-$, esculin$^-$, agglutinate in O-typing sera for "enteric pathogenic" serotypes: 3; 4,32; 5,27; 8; 9; 13a,13b; 18; 20; or 21
Yersinia enterocolitica O3 (a pathogenic serotype)	D-Xylose$^-$, agglutinates in O3 serum, tiny colonies at 24 h on plating media; in most countries it is the most frequently isolated pathogenic serotype
Yersinia enterocolitica, nonpathogenic serotypes	CR-MOX$^-$, pyrazinamidase$^+$, salicin$^+$, esculin$^+$, do not agglutinate in O-typing sera for "enteric pathogenic" serotypes: 3; 4,32; 5,27; 8; 9; 13a,13b; 18; 20; or 21
Citrobacter	Citrate$^+$, lysine decarboxylase$^-$, often grows on CIN agar, strong characteristic odor
Enterobacter	Variable biochemically, citrate$^+$, VP$^+$, resistant to cephalothin
Enterobacter sakazakii	Yellow colonies (more pigmented at 25 than 36°C), often "tough as leather"; grows on several selective media designed for its isolation; D-sorbitol negative, delayed positive DNase at 36°C
Hafnia	Lysed by *Hafnia*-specific bacteriophage 1672,[c] often more active biochemically at 25 than 36°C
Klebsiella	Mucoid colonies, encapsulated cells, nonmotile, lysine$^+$, very active biochemically, ferment most sugars, VP$^+$, malonate$^+$, resistant to carbenicillin and ampicillin
Proteus-Providencia-Morganella	Phenylalanine$^+$, tyrosine hydrolysis$^+$, often urea$^+$, resistant to colistin
Proteus	Swarms on blood agar, pungent odor, H_2S^+, gelatin$^+$, lipase$^+$
Proteus mirabilis	Urea$^+$, indole$^-$, ornithine$^+$, maltose$^-$
Proteus vulgaris	Urea$^+$, indole$^+$, ornithine$^-$, maltose$^+$
Providencia	No swarming, H_2S^-, ornithine$^-$, gelatin$^-$, lipase$^-$
Morganella	Very inactive biochemically, no swarming, citrate$^-$, H_2S^-, ornithine$^+$, gelatin$^-$, lipase$^-$, urea$^+$
Plesiomonas shigelloides	Oxidase$^+$, lysine$^+$, arginine$^+$, ornithine$^+$, *myo*-inositol$^+$
Serratia	DNase$^+$, gelatinase$^+$, lipase$^+$, resistant to colistin and cephalothin
Serratia marcescens	L-Arabinose$^-$
Serratia, other species	L-Arabinose$^+$

[a] This table gives only the general properties of the genera, species, and serogroups, so there will be exceptions. See Table 3 in this chapter and following chapters for more details and more precise data. The properties listed for a genus or group of genera generally apply to each of its species, and the properties listed for a species generally apply to each of its serotypes.

[b] See Table 3 for biochemical test results given as percentages. The serological tests refer to slide agglutination in group or individual antisera (O1, O3, etc.) for *Salmonella, Shigella, Escherichia coli,* or *Yersinia,* respectively.

[c] These are two bacteriophage tests useful for identification. The *Hafnia*-specific bacteriophage 1672 (HER 272) is available from the American Type Culture Collection (ATCC 51873-B1).

[d] Abbreviations: CIN, cefsulodin-Irgasan-novobiocin agar (a plating medium selective for *Yersinia*); CR-MOX, Congo red, magnesium oxalate agar (a differential medium useful for distinguishing pathogenic from nonpathogenic strains of *Yersinia*); MUCAP, 4-methylumbelliferyl caprylate (a genus-specific test for *Salmonella*); MUG, 4-methylumbelliferyl-β-D-glucuronidase; ONPG, *o*-nitrophenyl-β-D-galactopyranoside; PhoE, a research test done by PCR that is sensitive and specific for *E. coli*/*Shigella* (57); VP, Voges Proskauer.

include a different kit (which will have similar limitations), a kit that contains more tests (such as those in 96-well plastic plates), or more expensive research techniques such as molecular tests or 16S rRNA sequencing (56).

Molecular Methods of Identification

Molecular methods have proved extremely useful for identification to the level of family, genus, species, serotype, clone, and strain and for differentiating pathogenic from nonpathogenic strains (see chapter 16 of this Manual). For example, a PCR test for the *phoE* gene appears to be a sensitive and specific test for determining if a strain belongs to the *Escherichia-Shigella* group (88). However, few if any of these molecular methods are commercially available. In the United States, commercial diagnostic tests must often be approved by the Food and Drug Administration if they are used on human clinical specimens. Regulatory and cost limitations have greatly restricted the use of molecular methods in clinical microbiology laboratories. However, they have proved extremely useful in a research setting. In the United States, to conform to the CLIA regulations of 1988, also called CLIA '88, it is necessary to report these research results with a disclaimer unless all the CLIA requirements have been met.

Problem Strains

Most strains of *Enterobacteriaceae* grow rapidly on plating media and on media used for biochemical identification, but occasionally a slow-growing or fastidious strain is encountered. Some strains grow poorly on blood agar but much better on chocolate agar incubated in a candle jar. This characteristic suggests a possible nutritional requirement or a mutation involving respiration. There are slow-growing strains of *E. coli, Klebsiella pneumoniae,* and *Serratia marcescens,* and typical biochemical reactions of these strains usually require extended incubation. Another type of problem organism is sometimes isolated from patients being treated with antimicrobial agents. Li et al. described such "pleiotropic" (having multiple phenotypic expression) mutants of *S. marcescens* (66) and *Salmonella* after exposure to gentamicin. These strains react atypically in many of the standard biochemical tests and are difficult to identify. A different type of pleiotropic mutant induced by chemical exposure was reported by Lannigan and Hussian (64). A *Salmonella* strain lost the ability to produce hydrogen sulfide, reduce nitrate to nitrite, and produce gas from glucose because of chlorate resistance acquired after exposure to Dakin's solution (a solution that contains chlorate and is found in hospitals). Similarly, "dwarf" colony forms of *Salmonella* serotype Typhi have been known for many years. They are only 0.2 to 0.3 mm in diameter after 24 h of incubation but are normal size if the medium is supplemented with sulfite or thiosulfate. Some atypical and slowly growing strains become more typical and grow better after they have been transferred several times. Laboratories occasionally isolate strains that grow rapidly but have a biochemical reaction profile that does not fit (Table 3) any of the described species, biogroups, or Enteric Groups of *Enterobacteriaceae* (56). At present, this type of culture can be reported only as "unidentified." It may be an atypical strain of one of the organisms listed in Tables 1 to 5, or it may belong to a new species that has not been described (37, 56, 94). Additional testing at a state, national, or international reference laboratory can often answer the question about the culture's identity and has led to the discovery of new causes of human infections (12–18, 37, 55, 56, 71, 94).

Commercial Products and Services

A wide variety of commercial products and diagnostic services are available for *Enterobacteriaceae,* but availability is constantly changing. The best approach is to go to a suppliers' Internet site to check availability, technical information, and price. Products include routine and reference identification products and kits (with or without antimicrobial susceptibility tests), combination isolation-identification products, dehydrated media, ready-to-use media in tubes and plates, antisera, reagents, antibiotic products, cultures, and bacteriophages. Services include serodiagnosis, isolation, identification, antimicrobial susceptibility testing, molecular testing, serotyping, and subtyping. For more information, see chapters 15 and 16 of this Manual, the U. S. Food and Drug Administration's *BAM Manual Online* (http://www.cfsan.fda.gov/~ebam/bam-toc.html), and references 55 and 92.

ANTIBIOTIC SUSCEPTIBILITY

Several methods are available for testing the antibiotic susceptibility of *Enterobacteriaceae,* but the most popular are disk diffusion (6) and broth dilution (see chapters 17 and 70 to 78). Several textbook and infectious disease reviews describe antibiotic usage in clinical practice (4, 68, 69, 82).

When antibiotics were first introduced, there was only slight resistance among the species of *Enterobacteriaceae.* Today, antibiotic resistance is much more common among strains isolated from humans and animals. Resistance patterns vary depending on the organism and its origin (4, 68, 69, 82).

Intrinsic Resistance

Intrinsic resistance is a genetic property of most strains of a species and evolved long before the clinical use of antibiotics. For example, essentially all strains of *Serratia marcescens* have intrinsic resistance to penicillin G, colistin, and cephalothin. This evolution of resistance can best be shown by studying strains isolated and stored before the antibiotic era or by studying a large collection of strains from a wide variety of sources including strains that have had little or no exposure to antibiotics. Table 10 lists some common *Enterobacteriaceae* and their intrinsic resistance patterns.

The Antibiogram as a Marker in Epidemiological Studies

Antibiotic susceptibility testing is usually done on isolates that are clinically significant and provides an antibiogram that is useful for comparing isolates in epidemiologic studies. When the selective ecological pressure of antibiotics is changed, the resistance patterns of epidemic (or endemic) strains may also change (4, 68, 69, 82). These changes have been documented in outbreaks that have lasted for several months or longer. Even with these limitations in stability, the antibiogram is probably the most useful and practical laboratory marker for comparing strains and can be extremely helpful in recognizing and analyzing infection problems.

Use of Antibiograms for Identification

The antibiogram of a culture can be compared with those of known isolates (Table 10) to provide a different approach to identification. When the antibiogram and identification are incompatible (for example, a strain of *Klebsiella* that is susceptible to ampicillin and carbenicillin or a culture of *Enterobacter* that is susceptible to cephalothin), the culture should be streaked and checked for purity. In addition, both the identification and the antibiogram may have to be repeated.

TABLE 10 Intrinsic antimicrobial resistance in some common *Enterobacteriaceae* species

Genus/species	Most strains are resistant to:
Buttiauxella species	Cephalothin
Cedecea species	Polymyxins, ampicillin, cephalothin
Citrobacter amalonaticus	Ampicillin
Citrobacter freundii	Cephalothin
Citrobacter diversus (*C. koseri*)	Cephalothin, carbenicillin
Edwardsiella tarda	Colistin
Enterobacter cloacae	Cephalothin
Enterobacter aerogenes	Cephalothin
Many other *Enterobacter* species	Cephalothin
Escherichia hermannii	Ampicillin, carbenicillin
Ewingella americana	Cephalothin
Hafnia alvei	Cephalothin
Klebsiella pneumoniae	Ampicillin, carbenicillin
Kluyvera ascorbata	Ampicillin
Kluyvera cryocrescens	Ampicillin
Proteus mirabilis	Polymyxins, tetracycline, nitrofurantoin
Proteus vulgaris	Polymyxins, ampicillin, nitrofurantoin, tetracycline
Morganella morganii	Polymyxins, ampicillin, cephalothin
Providencia rettgeri	Polymyxins, cephalothin, nitrofurantoin, tetracycline
Other *Providencia*[a] species	Polymyxins, nitrofurantoin
Serratia marcescens[b]	Polymyxins, cephalothin, nitrofurantoin
Serratia fonticola	Ampicillin, carbenicillin, cephalothin
Other *Serratia* species	Polymyxins,[c] cephalothin

[a] Most strains of *Providencia stuartii* are also resistant to cephalothin and tetracycline.
[b] *Serratia marcescens* can also be resistant to ampicillin, carbenicillin, streptomycin, and tetracycline.
[c] Most *Serratia* species are resistant to polymyxins, but some strains have unusual zones of inhibition from 10 to 12 mm or larger, even though they are resistant when tested by other methods.

Some of the material in this chapter was taken from or adapted from chapters and reviews of the family Enterobacteriaceae *that J.J.F. wrote while an employee or "guest researcher" of the U.S. Government. Under U.S. copyright law, these publications are defined to be "works of the U.S. Government" and thus are not subject to copyright under the U.S. Code.*

Special thanks are expressed to the many people who did biochemical testing at CDC of over 10,000 cultures whose results are tabulated in Table 3.

Escherichia, Shigella, and *Salmonella**

JAMES P. NATARO, CHERYL A. BOPP, PATRICIA I. FIELDS,
JAMES B. KAPER, AND NANCY A. STROCKBINE

43

TAXONOMY

Escherichia, Shigella, and *Salmonella* are classified in the family *Enterobacteriaceae,* which is addressed in chapter 42 of this Manual (35). Species in these three genera are gram-negative rods that grow well on MacConkey agar (MAC). When these organisms are motile, it is by peritrichous flagella; however, all strains of *Shigella* spp. and some strains of *Escherichia* and *Salmonella* are nonmotile. All ferment D-glucose; *Escherichia* and *Salmonella* strains usually produce gas. *Shigella* is phenotypically similar to *Escherichia coli* and, with the exception of *Shigella boydii* serotype 13, would be considered the same species by DNA-DNA hybridization analysis (16). Findings from recent phylogenetic studies with nucleotide sequences of internal fragments from 14 housekeeping genes show that *S. boydii* 13 strains cluster in a neighbor-joining tree with *Escherichia albertii*, a newly described species of *Escherichia* associated with diarrheal disease in Bangladeshi children (48, 49).

NATURAL HABITATS

Escherichia, Shigella, and *Salmonella* are most frequently isolated from the intestines of humans and animals. Because *E. coli* is ubiquitous in human and animal feces, the presence of this species in water is considered to be an indicator of fecal contamination. Some species or serotypes are isolated primarily from humans (e.g., all species of *Shigella* and *Salmonella* serotype Typhi), while others (e.g., *Salmonella* serotype Gallinarum and *Salmonella* serotype Marina) are strongly associated with certain animal hosts. These genera can be isolated from fecally contaminated foods or water but probably do not occur as free-living organisms in the environment. *Salmonella* strains can, however, survive for long periods of time, perhaps years, in the environment (58).

COLLECTION, TRANSPORT, AND STORAGE OF FECAL SPECIMENS

Information on the collection, transport, and storage of specimens from extraintestinal sites is provided in chapters 5 and 20 of this Manual. Fecal specimens can include whole stools, swabs prepared from whole stools, or rectal swabs with visible fecal staining. Transport of fecal specimens to the laboratory in a timely fashion is critical, particularly for more delicate organisms such as *Shigella* (119). Ideally, fecal specimens should be examined as soon as they are received in the laboratory, but if not processed immediately, they should be either refrigerated or frozen at −70°C. Fecal specimens that will not be examined within 1 to 2 h after collection and all rectal swabs should be immediately placed in chilled transport medium and stored refrigerated. If specimens in transport medium are not to be examined within 3 days, they should be frozen immediately at −70°C.

Many of the commercially available transport media (e.g., Cary-Blair, Stuart's, and Amies transport media) are satisfactory for these organisms. Although acceptable for the transport of *E. coli, Salmonella,* and *Shigella,* buffered glycerol saline should not be used for specimens that must also be tested for *Campylobacter* and *Vibrio*.

ESCHERICHIA

Description of the Genus

The genus *Escherichia* is composed of motile or nonmotile bacteria that conform to the definitions of the family *Enterobacteriaceae* (35). There are six species in this genus: *Escherichia albertii, E. blattae, E. coli, E. fergusonii, E. hermannii,* and *E. vulneris*. The type species is *E. coli*. Typical biochemical reactions are listed in Table 1.

Clinical Significance

Of the six *Escherichia* species, *E. coli* is the species usually isolated from human specimens. It is a nearly ubiquitous constituent of the bowel flora of healthy individuals; however, certain strains may cause extraintestinal and intestinal infections in healthy as well as immunocompromised individuals. Urinary tract infections, bacteremia, meningitis, and diarrheal disease are the most frequent clinical syndromes, caused primarily by a limited number of pathogenic clones of *E. coli* (53). In particular, *E. coli* organisms bearing the K1 capsule are isolated with high frequency from cases of neonatal sepsis and meningitis. Uropathogenic *E. coli* strains are not easily identified by conventional microbiologic methods. *E. hermannii* and *E. vulneris* are most often obtained from

* This chapter contains information presented in chapter 42 by Cheryl A. Bopp, Frances W. Brenner, Patricia I. Fields, Joy G. Wells, and Nancy A. Strockbine in the eighth edition of this Manual.

[a] Values are percentages of isolates tested with positive test results within 1 or 2 days of incubation at 35 to 37°C. Reactions for isolates that become positive after 2 days are not considered. Data were compiled from findings published by Ewing (34), Wathen-Grady et al. (117, 118), Ansaruzzaman et al. (5), Pryamukhina and Khomenko (88), and Farmer (37) and from unpublished findings from the reference laboratory at the CDC, 1972 to 2005.

[b] Excludes strains previously identified as *S. boydii* 13.

wound infections but have also been isolated from infections at other body sites, while *E. fergusonii* is most frequently identified from human feces (9). *E. albertii* has recently been implicated as a possible diarrheal pathogen in humans (see below) (104). *E. blattae,* which is a commensal organism of cockroaches, is not recovered from human specimens.

Diarrheagenic *E. coli*

There are at least five categories of recognized diarrheagenic *E. coli:* Shiga toxin (ST)-producing *E. coli* (STEC) (also referred to as enterohemorrhagic *E. coli* [EHEC]), enterotoxigenic *E. coli* (ETEC), enteropathogenic *E. coli* (EPEC), enteroaggregative *E. coli* (EAEC), and enteroinvasive *E. coli* (EIEC) (53, 72). The clinical significance of several other groups of putative diarrheagenic *E. coli*, particularly diffusely adherent *E. coli* (DAEC), is unclear.

STEC: O157 and Other STEC Serogroups

We refer to the STEC category of diarrheagenic *E. coli* according to the toxins that these organisms produce, e.g., STEC rather than EHEC, because the essential genetic features that define organisms capable of causing hemorrhagic colitis and hemolytic-uremic syndrome (HUS) are not clear. *E. coli* serotypes O157:H7 and O157:nonmotile (NM) (O157 STEC) produce one or more Shiga toxins, also called verocytotoxins, and are the most frequently identified diarrheagenic *E. coli* serotypes in North America and Europe. Each year an estimated 73,000 cases of illness and 60 deaths are caused by O157 STEC in the United States (69).

E. coli O157:H7 and other STEC serotypes cause illness that can present as mild nonbloody diarrhea, severe bloody diarrhea (hemorrhagic colitis), and HUS (reviewed in reference 42). Additional symptoms of *E. coli* O157:H7 infection include abdominal cramps and lack of a high fever. Of patients with O157 STEC diarrhea, 4% or more develop HUS (90), a condition characterized by microangiopathic hemolytic anemia, thrombocytopenia, and acute renal failure. The fatality rate of HUS has declined in recent years due to improvements in case management.

O157 STEC is thought to cause at least 80% of cases of HUS in North America and is recognized as a common cause of bloody diarrhea in developed countries (90). In the United States, the rate of isolation of O157 STEC from fecal specimens is highest in the Northern tier states, where it may approach the rates of common diarrheal pathogens. Many U.S. clinical laboratories do not routinely culture stools for O157 STEC; as a result, many illnesses are not detected (24).

O157 STEC colonizes dairy and beef cattle and, therefore, ground beef has caused more O157 STEC outbreaks than any other vehicle of transmission (101). Other known vehicles of transmission include raw milk, sausage, roast beef, unchlorinated municipal water, apple cider, raw vegetables, and sprouts; these vehicles are typically exposed to water contaminated by bovine manure. O157 STEC spreads easily from person to person because the infectious dose is low (<200 CFU); outbreaks associated with person-to-person spread have occurred in schools, long-term-care institutions, families, and day-care facilities.

More than 150 non-O157 STEC serotypes have been isolated from persons with diarrhea or HUS (http://www.microbionet.com.au/frames/feature/vtec/brief01.html). In some countries, non-O157 STEC strains, particularly *E. coli* serotypes O111:NM and O26:H11, are more commonly isolated than O157 STEC, although most outbreaks and cases of HUS are attributed to the latter (serotypes characteristic of diarrheagenic *E. coli* pathotypes are presented in Table 2). In the United States, *E. coli* O157:H7 is the most frequently isolated STEC but increasingly non-O157 STEC are identified as causes of outbreaks and sporadic illness (23). At the CDC's *E. coli* Reference Laboratory, 72% of all non-O157 STEC isolates received between 1983 and 2000 belonged to eight serogroups (O26, O111, O103, O121, O45, O145, O165, and O113) (N. A. Strockbine, unpublished data). Because most laboratory methods for the detection of O157 STEC do not detect non-O157 STEC, the numbers of infections with serotypes other than O157:H7 or O157:NM are probably underestimated.

ETEC

ETEC, which produces heat-labile *E. coli* enterotoxin (LT) and/or heat-stable *E. coli* enterotoxin (ST), is an important cause of diarrhea in developing countries, particularly among young children (72). ETEC also is a frequent cause of traveler's diarrhea. Ten U.S. outbreaks were reported to the CDC from 1995 to 2001, whereas only 15 outbreaks occurred during the preceding 25 years (C. A. Bopp, unpublished data) (30). ETEC is infrequently identified in the United States, but this may be attributable in part to the fact that few laboratories are capable of identifying this pathogen. ETEC strains, particularly those associated with outbreaks, tend to cluster in a few serotypes (Table 2).

The most prominent symptoms of ETEC illness are diarrhea and abdominal cramps, sometimes accompanied by nausea and headache, but usually with little vomiting or fever (30). Although ETEC is usually associated with relatively mild watery diarrhea, illness in some recent ETEC outbreaks has been notable for its prolonged duration.

EPEC

In the past, EPEC strains were defined as certain *E. coli* serotypes that were epidemiologically associated with infantile diarrhea but did not produce enterotoxins or Shiga toxins and were not invasive. The traditional EPEC serotypes are listed in Table 2; typically these serotypes show a distinct pattern of localized adherence to HeLa and HEp-2 cells (115). These serotypes usually also demonstrate actin aggregation in the fluorescent actin stain test, which correlates with the attaching-and-effacing lesion in vivo (72). Because of the lack of simple diagnostic methods for EPEC, few laboratories attempt to identify these organisms. Full EPEC pathogenicity requires two genetic elements: the EPEC adherence factor (EAF) plasmid, which encodes most importantly the bundle-forming pilus, and the chromosomal locus of enterocyte effacement (LEE), which mediates the attaching-and-effacing phenotype. The term "typical EPEC" has been suggested for those organisms harboring both the EAF plasmid and the LEE pathogenicity island (see below). Typical

	O157:H45				

[a] Outbreak-related serotypes are shown in bold type. NM, nonmotile; NT, not typeable.

EPEC correspond to EPEC of the classical serotypes and are important causes of diarrhea in developing countries (32, 72); these organisms were implicated in highly lethal nursery outbreaks in the United States and the United Kingdom before 1970. The infection is currently rare in the industrialized world. More recently, atypical EPEC have been implicated as enteric pathogens in the United States, including in several outbreaks of diarrheal disease (113). These strains possess a functional LEE apparatus but do not carry the EAF plasmid. The full role of these pathogens has yet to be elucidated, but they may be considered as potential causes of diarrheal outbreaks when no other pathogens are identified.

The symptoms of often severe, prolonged, and nonbloody diarrhea, vomiting, and fever in infants or young toddlers are characteristic of EPEC illness (72). Infection with EPEC has been associated with chronic diarrhea; sequelae may include malabsorption, malnutrition, weight loss, and growth retardation.

EIEC

EIEC strains invade cells of the colon and produce a generally watery, but occasionally bloody, diarrhea by a pathogenic mechanism similar to that of *Shigella*. EIEC is rare in the United States and is less common than ETEC or EPEC in the developing world (72). EIEC strains, like ETEC and EPEC, are associated with a few characteristic serotypes (Table 2). Three large outbreaks of diarrhea caused by EIEC have been reported in the United States (72).

EAEC

EAEC, as originally defined by its specific pattern of aggregative adherence to HEp-2 cells in culture, has been associated with diarrhea in a variety of clinical settings, including endemic diarrhea in children of both impoverished and industrialized countries, epidemic diarrhea, diarrhea of travelers to developing countries, and persistent diarrhea among patients with human immunodeficiency virus/AIDS infection (47). The pathogenicity of EAEC has been confirmed in volunteer studies (73) and by implication of EAEC in diarrhea outbreaks (28). Early studies frequently failed to find an association of EAEC with pediatric diarrhea, but this association has been strengthened by the use of molecular techniques, which discriminate the true pathogens exhibiting the aggregative pattern (29, 95). The term "typical EAEC" describes organisms harboring virulence genes under the control of the global EAEC regulator AggR (95). Typical EAEC may be a common cause of pediatric diarrhea in U.S. infants (29) and should be considered as a potential cause of foodborne outbreaks and diarrhea in human immunodeficiency virus/AIDS patients (47). EAEC diarrhea is accompanied by signs and symptoms of mild inflammation (abdominal pain and fever), but stools usually do not contain blood or fecal leukocytes (47).

Putative Diarrheagenic *E. coli*

Several putative pathotypes have been described. For none of these types has virulence clearly been demonstrated in volunteer strudies or outbreak investigations. DAEC strains, which exhibit a characteristic diffuse pattern of adherence to HEp-2 cells, have been implicated as causes of diarrhea in some epidemiologic studies but not others (72), and a prototype DAEC strain did not elicit diarrhea in adult volunteers (109). In several studies, DAEC infections have been significantly associated with watery diarrhea among children 1 to 5 years of age but were not associated with illness among infants (59). DAEC may occur in industrialized countries (72). A complex signal transduction cascade has been suggested as the mechanism of DAEC pathogenesis (99).

Cytotoxic necrotizing factor (CNF)-producing *E. coli* strains produce a toxin that induces morphological alterations (multinucleation) and death in tissue cultures (20). Two forms have been described: CNF1 and CNF2. CNF1-producing strains were originally detected in infants with enteritis and later from humans with extraintestinal infections (13, 20). Most CNF1-producing strains are also hemolytic, although the toxin is distinct from hemolysin. CNF2-producing strains have been isolated from animals with diarrhea (31, 80, 102). The role of these strains in human diarrheal disease has not been definitively determined (72).

Cytolethal distending toxin-producing *E. coli* strains produce a heat-labile factor that induces cytotonic and cytotoxic changes in Chinese hamster ovary cells similar to those caused by LT (51). This factor does not affect Y-1 cells. The results of one study in Bangladesh suggested that cytolethal distending toxin-producing *E. coli* strains are associated with diarrhea (3), but other studies are needed to establish their status as etiologic agents.

Several diarrheal outbreaks have been linked to *E. coli* strains that do not belong to any of the established pathotypes. Some of these strains carry the gene encoding the enteroaggregative ST-like toxin (EAST1), which is related to the ETEC ST enterotoxin. Further studies are needed to prove the pathogenicity of these strains, but the EAST1 gene can be identified using molecular techniques (68).

Isolation Procedures

Isolation procedures for extraintestinal infections are covered in chapter 20.

Isolation Procedures for STEC

All fecal specimens submitted for culture of bacterial enteric pathogens in areas of high endemicity or from patients with bloody diarrhea should be examined for O157 STEC (106). Culture for non-O157 STEC is indicated for patients with HUS and/or bloody diarrhea and should be considered for other patients with diarrhea based on severity of illness, age, and epidemiologic or exposure information.

Because there is no selective isolation medium for non-O157 STEC, testing for the presence of Shiga toxin in fecal specimens is the best approach for detecting these organisms. Commercial enzyme-linked immunoassays are a sensitive means of detecting Shiga toxin (33, 63). Isolation and serotyping of STEC from fecal specimens that are positive by nonculture assays should always be attempted because serotype information is important for public health purposes and may also help in clinical decisions.

Enrichment

Although broth enrichment is widely used for the recovery of O157 STEC from foods, there is little evidence that it enhances isolation from human fecal specimens. However, immunomagnetic separation (IMS), a technique shown to increase the rate of isolation of O157 STEC from food specimens, has been adapted to culture of fecal specimens (54). IMS enhances the detection of O157 STEC from patients with HUS, patients presenting an extended period of time after the onset of illness, asymptomatic carriers, or specimens that have been stored or transported improperly. IMS beads for O157, O111, and O26 are available commercially (Table 3), or laboratories may produce beads with other O-specific antibodies (81).

TABLE 3 Partial listing of commercial suppliers of reagents for detection of STEC[a]

Antisera for tube agglutination
Difco Laboratories (Division of Becton Dickinson and Co., Sparks, Md.)
O157 and H7 antisera
SA Scientific, San Antonio, Tex.
O157 and H7 antisera
Denka Seiken Co., Ltd., Tokyo, Japan
O157, H7, O145, O128, O111, O103, O91, O26, and other *E. coli* O antisera
Latex slide agglutination reagents
Denka Seiken Co., Ltd., Tokyo, Japan
O157, O111, and O26 reagents
Oxoid Inc., Ogdensburg, N.Y.
O157, O145, O128, O111, O103, O91, and O26 reagents
ProLab Diagnostics, Inc., Ontario, Canada
O157 and H7 reagents
Remel, Inc., Lenexa, Kans.
O157 and H7 reagents
Immunomagnetic beads
Dynal Biotech Inc., Lake Success, N.Y.
Anti-O157 labeled beads
Denka Seiken Co., Ltd., Tokyo, Japan
Anti-O157, anti-O111, and anti-O26 labeled beads
O157 immunoassays
Meridian Diagnostics Inc., Cincinnati, Ohio
For testing stool specimens or enrichment broths for O157 antigen
Denka Seiken Co., Ltd., Tokyo, Japan
For testing colony sweeps or individual colonies for O157, O111, or O26 antigens
Shiga toxin immunoassays
Meridian Diagnostics Inc., Cincinnati, Ohio
For testing stool specimens, enrichment broths, colony sweeps, or individual colonies for Shiga toxin
Remel, Inc., Lenexa, Kans.
For testing stool specimens or enrichment broths for Shiga toxin
Denka Seiken Co., Ltd., Tokyo, Japan
For testing colony sweeps or individual colonies for Shiga toxin
Oxoid Inc., Ogdensburg, N.Y.
For testing individual colonies for Shiga toxin
Chromogenic agars (for visual detection of O157:H7 colonies upon direct inoculation of agar plates)
Merck KGaA, Darmstadt, Germany
Biomerieux Inc., Hazelwood, Mo.
Biosynth International, Inc., Naperville, Il.
Biolog, Inc., Hayward, Calif.
CHROMagar; available under license to Becton Dickinson and Co., Franklin Lakes, N.J.

[a] Not intended to be a comprehensive listing. The U.S. Food and Drug Administration has not approved all of these reagents for use with clinical specimens. This table does not include reagents or tests specifically intended for examination of food, water, or environmental specimens. The online version of the *Bacteriological Analytical Manual* lists many tests for food specimens (http://www.fda.gov). Inclusion does not constitute endorsement by the CDC or ASM.

Plating Media

Because O157 STEC strains ferment lactose, they are impossible to differentiate from other lactose-fermenting organisms on lactose-containing media. Most O157 STEC strains do not ferment the carbohydrate D-sorbitol overnight, in contrast to the approximately 80% of other *E. coli* strains that ferment sorbitol rapidly. Thus, sorbitol-containing MacConkey agar (SMAC) is used for isolation of O157 STEC. Sorbitol-nonfermenting colonies are suspected (but not definitively) to be O157:H7 (67). In some areas of central Europe, sorbitol-fermenting O157 STEC strains are commonly isolated from patients with HUS (12); these organisms are very rare in North America (Strockbine, unpublished).

Specific culture media have been developed to exploit biochemical and antibiotic resistance traits that are characteristic of STEC strains. Several chromogenic agar media are available commercially to assist in rapid identification (Table 3); these media generally perform well for O157:H7 and for some non-O157 STEC (10, 65, 77) Cefixime-tellurite SMAC (CT-SMAC) has also proved to be a useful selective medium for O157:H7. It has been used mainly for culture of animal and food specimens because of its selectivity, but it has also been applied to culture of human fecal specimens (25, 124). It has been reported that some O157:NM strains fail to grow on CT-SMAC (54).

As noted above, *E. coli* strains with particular virulence in the urinary tract cannot be easily distinguished from organisms of lower virulence, and any *E. coli* isolated in high numbers (particularly $>10^5$ CFU/ml of urine) should be considered a potential pathogen. *E. coli* with increased virulence in the urinary tract is commonly hemolytic on sheep blood agar and expresses one or more of several urinary tract adhesins. Several chromogenic media have been proposed for use in detecting uropathogenic *E. coli;* these have been compared in published studies (6, 26).

Commercial Rapid Diagnostic Methods

A number of commercial immunoassays (Table 3) are now available for detecting Shiga toxin or O157 antigen in fecal specimens, enrichment broth cultures, colony sweeps, or individual colonies. Isolation of STEC from fecal specimens that are positive by one of these rapid diagnostic methods is important for public health purposes. Determination of the subtype of O157 STEC and the serotype of a non-O157 STEC isolate is valuable for outbreak investigations and surveillance purposes (see "Subtyping" and "Identification" below).

Screening Procedures for STEC Strains

For the isolation of O157 STEC from SMAC, colorless (nonfermenting) colonies are tested with O157 antiserum or latex reagent (103) (Table 3). If the O157 latex reagent is used, it is important to test positive colonies with the latex control reagent to rule out nonspecific reactions. The manufacturers of these kits recommend that strains reacting with both the antigen-specific and control latex reagents be heated and retested. However, in a study that followed this procedure, none of the nonspecifically reacting strains were subsequently identified as O157 STEC (14).

Unlike most other *E. coli* strains, O157 STEC do not express beta-glucuronidase; therefore, the MUG reaction (4-methylumbelliferryl-beta-D-glucuronide for detection of beta-glucuronidase activity) is helpful for screening for

O157 STEC (98). MUG-positive, urease-positive O157 STEC strains have been isolated in the United States but are still rare (45) (Strockbine, unpublished).

For the recovery of STEC from stool specimens which test positive for Shiga toxin, either SMAC or MacConkey agar should be inoculated. It is advantageous to use SMAC because O157 STEC can be quickly and easily identified. If sorbitol-nonfermenting colonies are negative with O157 latex, then sorbitol-fermenting colonies (because most non-O157 STEC ferment sorbitol) and a representative sample of sorbitol-nonfermenting colonies may be selected for Shiga toxin testing. Latex reagents and antisera (Table 3) for detecting certain non-O157 STEC serotypes are now available and could also be used to test colonies from Shiga toxin-positive specimens or to serogroup Shiga toxin-positive isolates.

Virtually all O157 STEC and 60 to 80% of non-O157 STEC produce a characteristic *E. coli* hemolysin, referred to as enterohemolysin (Ehly), which is distinct from the α-hemolysin, produced by other *E. coli* strains (11). A special medium, washed sheep blood agar supplemented with calcium (WSBA-Ca), is used as a differential medium for the detection of enterohemolytic activity (11). Ehly-producing colonies can be differentiated from α-hemolysin-producing colonies on WSBA-Ca because the latter are visible after 3 to 4 h of incubation. After 3 to 4 h, colonies are marked for the appearance of α-hemolysin, and the plates are examined again after 18 to 24 h. Incorporation of mitomycin C into the WSBA-Ca enhances the appearance of the Ehly hemolysis and increases the proportion of non-O157 STEC that exhibit this activity (107). Because many non-O157 STEC strains do not demonstrate the enterohemolytic phenotype and because enterohemolytic nontoxigenic strains have been reported, additional screening methods should be used in conjunction with WSBA-Ca medium (96).

Presumptive STEC isolates should be sent to a reference laboratory or a public health laboratory for further characterization.

Isolation Methods for Diarrheagenic *E. coli*

Methods for the identification of ETEC, EPEC, EIEC, EAEC, and the putative diarrheagenic *E. coli* are generally available only in reference or research settings. Public health and reference laboratories usually examine specimens for these pathogens only when an outbreak has occurred and specimens are negative for routine bacterial pathogens. EAEC should be considered as a possible etiologic agent of watery diarrhea for which no other pathogen has been identified (29), and ETEC should be considered for travelers. EPEC should be considered as a possible pathogen in outbreaks of severe nonbloody diarrhea occurring in infants or young toddlers, particularly in nursery or day care settings. EIEC and EAEC should be considered as possible etiologic agents in outbreaks of diarrhea, bloody or nonbloody.

To capture *E. coli* for further testing, fecal specimens should be plated on a differential medium of low selectivity (e.g., MAC). Five to 20 colonies, mostly lactose fermenting but with a representative sample of nonfermenting colonies, should be selected and inoculated to nonselective agar slants (such as L agar or nutrient agar). These colonies are then sent to a reference laboratory for testing or are screened for virulence-associated characteristics if assays are available. Strains can be kept frozen for long periods in L broth with 15 to 50% glycerol at −80°C. Arrangements for sending *E. coli* isolates from well-characterized outbreaks to the CDC for testing can be made through local and state health departments.

Screening Procedures for ETEC, EPEC, EAEC, and EIEC Strains

E. coli pathotypes other than STEC cannot be distinguished from other *E. coli* strains by biochemical screening techniques. Many EIEC strains are nonmotile and fail to decarboxylate lysine; however, some EIEC strains are motile or lysine positive. Use of commercial antisera to the classical EPEC somatic (O) and capsular (K) antigens is no longer recommended.

Identification

Biochemical Identification

Biochemical identification of presumptive O157 STEC isolates is necessary because other species may cross-react with O157 antiserum or latex reagents, including *Salmonella* O group N, *Yersinia enterocolitica* serotype O9, *Citrobacter freundii*, and *E. hermannii*. Special biochemical tests (cellobiose fermentation and growth in the presence of KCN) may be necessary to differentiate *E. hermannii* from *E. coli*, but because *E. hermannii* is rarely detected in stool specimens, use of these tests is not cost-effective for most laboratories.

Identification of *E. albertii* with commercial identification systems is problematic at present because representative strains of this species are not yet included in commercial databases (1). Abbott and colleagues, who extensively characterized five strains of *E. albertii* by conventional biochemical methods and by commercial identification panels, reported that *E. albertii* is an indole-negative species that ferments D-mannitol but not D-xylose (1). In their study, *E. albertii* strains were identified by commercial systems as *Hafnia alvei; Salmonella* or *S. enterica* serotype Cholerasuis; *E. coli*, inactive or serotype O157:H7; or *Yersinia ruckeri*. Although some strains would have been clearly misidentified, the majority of the strains generated probability scores for the final identification that were unacceptable or the identification was inconsistent with the source of the specimen (e.g., the fish pathogen *Y. ruckeri* from a human specimen), which should have triggered additional biochemical tests to establish a more reliable identification. The authors found that the most reliable clue to the possible presence of *E. albertii* was an unacceptable first-choice identification of *H. alvei* for an isolate that is both L-rhamnose and D-xylose negative.

Biochemical tests that can help discriminate *E. albertii* strains from selected members of the *Enterobacteriaceae* family with similar biochemical phenotypes are shown in Table 1. Two biogroups of *E. albertii* are listed in Table 1. These correlate with two of the distinct clusters of strains identified in the *E. albertii* lineage by phylogenetic studies (49). Biogroup 1 is comprised of the five strains isolated from Bangladeshi children with diarrhea, while biogroup 2 is comprised of strains formerly identified as *S. boydii* 13. The strains in the two biogroups differ from each other in their abilities to produce indole from tryptophane, decarboxylate lysine, and ferment D-sorbitol. Antigenic relationships between members of the *E. albertii* lineage and other members of the *Enterobacteriaceae* family have been observed (e.g., *S. boydii* 7 and *E. coli* O28). A diagnostic PCR assay using three housekeeping genes was described by Hyma et al. (49) for *E. albertii;* this assay is independent of biochemical or antigenic phenotypes and should facilitate studies to learn about the diversity within the lineage, their natural habitat, and their role in enteric disease.

Serotyping

The serologic classification of *E. coli* is generally based on the O antigen (somatic) and the H antigen (flagellar) (9).

The O and H antigens of *E. coli* are stable and reliable strain characteristics, and although 181 O antigens and 56 H antigens have been described (a few of which are no longer recognized), the actual number of serotype combinations associated with diarrheal disease is limited (Table 2). Determination of the O and H serotypes of *E. coli* strains implicated in diarrheal disease is particularly useful in epidemiologic investigations (Table 2). Even though antisera for the tube agglutination test are available from several manufacturers, most laboratories do not attempt to complete *E.* coli serotyping because it is costly. For well-characterized outbreaks with no identified etiologic agent, arrangements may be made through state health departments to send *E. coli* isolates to the CDC for virulence testing and serotyping.

Serologic Confirmation of O157 STEC

Confirmation of *E. coli* O157:H7 requires identification of the H7 flagellar antigen. H7-specific antisera and latex reagents are commercially available (Table 3), but detection of the H7 flagellar antigen often requires multiple passages (103). Isolates that are nonmotile or negative for the H7 antigen should be tested for the production of Shiga toxins or the presence of Shiga toxin gene sequences.

Approximately 85% of O157 isolates from humans received by the CDC are serotype O157:H7, 12% are nonmotile, and 3% are H types other than H7 (Strockbine, unpublished). *E. coli* O157:NM strains frequently produce Shiga toxin and are otherwise very similar to O157:H7, but no O157 strain from human illness with an H type other than H7 has been found to produce Shiga toxin (Strockbine, unpublished) (38).

Virulence Testing

Detection of diarrheagenic pathotypes is typically performed on *E. coli* colonies selected from selective or nonselective media. If PCR techniques are used, a sweep of confluent growth from a MAC plate may be screened; if the PCR assay is positive, isolated colonies may then be picked and screened individually. Multiplex PCR assays are capable of simultaneously detecting multiple *E. coli* pathotypes (75).

STEC

Two distinct Shiga toxins, Stx1 and Stx2, also referred to as verocytotoxins, have been described. In addition, there are several variant forms of Stx2, including Stx2c, Stx2d, Stx2e, and Stx2f, which in one study were more frequently identified from asymptomatic carriers than HUS (40). All of these toxins are similar to the Shiga toxin expressed by *Shigella dysenteriae* serotype 1, and the Stx1 toxins produced by O157 STEC and other STEC serotypes are virtually identical. STEC may produce either Stx1 or Stx2 or both toxins. The production of Stx or the genes encoding Stx can be detected by a variety of biologic, immunologic, or nucleic acid-based assays (72). Protocols for several of these tests (e.g., cell culture, DNA probing, and PCR) are available (79). Stx has also been directly detected in the blood of HUS patients by using flow cytometry even in the absence of serologic or microbiologic evidence of STEC infection (111).

STEC strains represent a spectrum of virulence potential ranging from the highly virulent O157:H7 serotype that has been responsible for the majority of outbreak cases to avirulent serotypes that have been isolated only from nonhuman sources. The presence of additional virulence factors other than Stx correlates with disease potential. The most important of these virulence factors are the intimin adhesin and the type III secretion system encoded on the LEE pathogenicity island (53). The *eae* gene probe for intimin and the *hly*A (*ehx*A) gene probe for a plasmid-encoded hemolysin have been the most frequently employed methods to determine virulence potential, but probes for at least 25 different virulence-associated genes have been employed to characterize STEC strains (86). STEC have been classified into five "seropathotypes" (A through E) based on the occurrence of serotypes in human disease, in outbreaks, and in severe disease (HUS or hemorrhagic colitis) and on possession of specific virulence genes (55).

ETEC

The ST and LT enterotoxins produced by ETEC may be detected by a variety of biologic, immunologic, and nucleic acid-based assays (72). Two distinct ST variants (STh and STp) have been identified in human strains. Strains that produce ST only or ST in combination with LT have caused most ETEC outbreaks in the United States (30).

Immunoassays for the identification of ST or LT from culture supernatants of ETEC strains are available from at least two commercial sources (Table 3). The ST EIA assay (Denka Seiken Co., Ltd., and Oxoid Ltd.) is a competitive enzyme immunoassay for the detection of ST only (97). A reversed passive latex agglutination assay (VET-RPLA; Oxoid; a similar kit is available from Denka Seiken) detects both cholera toxin and LT, which are highly related antigenically. The effectiveness of the VET-RPLA may be optimized by use of a culture medium designed for LT production such as Biken's medium rather than the medium recommended by the manufacturer (122).

EPEC

EPEC, EAEC, and DAEC can be detected by the characteristic patterns of adherence to HEp-2 or HeLa cells in culture (115). These patterns are also observed on formalin or glutaraldehyde-fixed cells, obviating the need to prepare cells expressly for the assay (70).

EPEC are defined on the basis of the attaching/effacing (A/E) histopathology produced on epithelial cells and the lack of Stx (reviewed in references 32 and 53). The A/E phenotype can be detected by tissue culture cell assays or by DNA probe or PCR tests for the *eae* gene encoding intimin or the LEE pathogenicity island. The EAF plasmid of typical EPEC (see above) is detected by fragment or oligonucleotide probes or PCR primers (72). Atypical EPEC possess only the A/E phenotype/LEE pathogenicity island but do not possess the EAF plasmid.

EAEC

Several simple assays have been described as surrogates to the cell adherence test for identification of EAEC. These include a simple biofilm formation assay on polystyrene (123) and screening for the presence of a pellicle at the surface of broth media (4). EAEC can be more definitively identified by a specific DNA probe (the AA or CVD432 probe) (7), which is superior to tissue culture adherence assays in identifying pathogenic strains of EAEC (29). More recent data suggest that the AA probe corresponds to a putative virulence gene called *aat*A (76), which is under the control of a regulator termed AggR. AggR in turn controls several other virulence factors (95). Thus, the *aggR* gene (which defines typical EAEC) may represent a superior diagnostic target.

EIEC

EIEC can be identified by various in vivo assays, immunoassays, and nucleic acid-based assays for invasiveness, but

no commercial kits or reagents are available. Cell culture invasion assays or DNA-based assays for the *ipa*C or *ipa*H invasion-related factors are, for the most part, practical only in research settings (72). Plasmid DNA electrophoresis may be used to detect the large 120- to 140-MDa plasmid associated with invasiveness, but this plasmid is easily lost when the isolate is subcultured. Because of shared invasiveness-related characteristics, these assays also detect *Shigella* strains.

DAEC

DAEC were initially defined on the basis of a diffuse adherence pattern to cultured epithelial cells, but this phenotype is not specific for enteric strains (99). Various DNA probes and PCR assays have been proposed for DAEC identification as reviewed (72).

Extraintestinal *E. coli*

The presence of any *E. coli* in urine specimens at 10^5 CFU/ml (or lower in some situations) or in cerebrospinal fluid or blood specimens in any amount is indicative of infection and the need for treatment. Numerous virulence factors have been identified for extraintestinal *E. coli* (53), particularly the K1 antigen, but these are usually identified only in epidemiological studies.

Subtyping

Several methods of subtyping have been used for *E. coli* O157:H7 isolates. In particular, pulsed-field gel electrophoresis (PFGE) methods are useful (72). A national molecular subtyping network, PulseNet, was established in 1996 by the CDC to facilitate subtyping of bacterial foodborne pathogens, including *E. coli* O157:H7, *Shigella,* nontyphoidal *Salmonella* serotypes, and *Listeria monocytogenes* (108). Successful detection of outbreaks by this network of state and local public health laboratories is dependent upon submission of isolates by clinical laboratories for confirmation and subtyping.

Determination of the serotype and the antimicrobial susceptibility pattern is usually adequate for defining outbreak strains of ETEC, EPEC, and EIEC. Plasmid typing or PFGE methods may also be helpful for distinguishing between sporadic isolates and outbreak strains, but neither method has been widely used for these groups of *E. coli*.

Serodiagnostic Tests

At the present time, serodiagnostic tests for diarrheagenic *E. coli* are valuable only for seroepidemiology surveys and are not useful for the diagnosis of sporadic infections. Assays that measure serum antibody response to lipopolysaccharide (LPS) have been used to detect STEC infection in culture-negative HUS patients (72). Enzyme-linked immunosorbent assays have been described to detect saliva antibodies to LPS (62) and serum antibodies to the secreted EspB protein in HUS patients (100).

Antimicrobial Susceptibilities

STEC

Antimicrobial therapy for O157 STEC diarrhea or HUS is controversial: some publications have suggested that antibiotics increase the risk of HUS (42, 121), while a meta-analysis of published reports found no significantly increased risk (94). Until recently, *E. coli* O157:H7 isolates were almost uniformly sensitive to antimicrobial agents. However, since the early 1990s, O157 and other STEC strains have demonstrated slowly increasing levels of resistance to certain antibiotics, particularly streptomycin, sulfonamides, and tetracycline (see http://www.cdc.gov/narms/).

ETEC, EPEC, EIEC, EAEC, and Other Diarrheagenic *E. coli* Strains

Treatment with an appropriate antibiotic can reduce the severity and duration of symptoms of ETEC infection (72). Antimicrobial resistance, particularly to tetracycline, is common among ETEC strains isolated from outbreaks in the United States (30). Antibiotic treatment may be helpful for diarrhea caused by EPEC (72). Most EPEC strains associated with outbreaks are resistant to multiple antimicrobial agents (32). EAEC are commonly resistant to most antibiotics, though these strains are typically sensitive to fluoroquinolones. Clinical studies have demonstrated the effectiveness of ciprofloxacin for travelers with diarrhea caused by EAEC (41). Little information about the efficacy of antimicrobial treatment or the prevalence of resistance is available for EIEC or other putative diarrheagenic *E. coli* strains, but determination of the antimicrobial susceptibility pattern may be helpful in establishing whether the isolates are associated with an outbreak.

Interpretation and Reporting of Results

STEC

A presumptive diagnosis of an O157 STEC (isolate positive for O157 antigen) or a non-O157 STEC (isolate positive for Shiga toxin) infection should be reported to the clinician as soon as the laboratory obtains this result. It is advisable to indicate on negative reports that non-O157 STEC strains can cause diarrhea and HUS. Clusters and outbreaks of STEC should be reported to public health authorities. Presumptive STEC isolates should be confirmed by demonstration of the O157 and H7 antigens or assay for Shiga toxin and should be identified biochemically as *E. coli*. STEC isolates should be forwarded to a local or state public health laboratory for serotyping and/or molecular subtyping.

ETEC, EPEC, EAEC, and EIEC

Generally, the ETEC, EPEC, EAEC, and EIEC classes of diarrheagenic *E. coli* are identified only during outbreak investigations. A laboratorian reporting these results, which usually will be a retrospective diagnosis obtained by a reference laboratory, should provide an explanation of the clinical significance of these organisms and may refer the clinician to the reference laboratory for further information. All suspected outbreaks should be reported to public health authorities.

SHIGELLA

Description of the Genus and Taxonomy

The genus *Shigella* is composed of nonmotile bacteria that conform to the definition of the family *Enterobacteriaceae* (35). There are four subgroups of *Shigella* that historically have been treated as species: subgroup A as *S. dysenteriae,* subgroup B as *Shigella flexneri,* subgroup C as *Shigella boydii,* and subgroup D as *Shigella sonnei*. From a genetic standpoint, the four species of *Shigella* and *E. coli* represent a single genomospecies (56). Using a genetic definition for species, the four species of *Shigella* would be regarded as serologically defined anaerogenic biotypes of *E. coli.* The current nomenclature of *Shigella* is maintained largely for medical purposes because of the useful association of the genus epithet with

TABLE 4 Differentiation of *E. coli* and *Shigella*

Test	Result[a] of test with:		
	Shigella	Inactive *E. coli*[b]	*E. coli*
Lysine decarboxylase	−	d	+

[b] Nonmotile, anaerogenic biotypes sometimes referred to as Alkalescens-Dispar bioserotypes.

the distinctive disease (shigellosis) caused by these organisms. The type species is *S. dysenteriae*. *Shigella* does not form gas from fermentable carbohydrates, with the exception of certain strains of *S. flexneri* serotype 6 and *S. boydii* serotype 14. Compared with *Escherichia, Shigella* strains are less active in their use of carbohydrates (Table 4). *S. sonnei* strains ferment lactose on extended incubation, but other species generally do not use this substrate in conventional medium.

Recent findings from phylogenetic studies show that *S. boydii* 13 strains, some of which can produce gas from glucose, are more appropriately regarded as *E. albertii* (49). *S. boydii* 13 strains were first described in 1952 and then added to the *Shigella* scheme in 1958 (36).

Epidemiology and Transmission

Humans and other large primates are the only natural reservoirs of *Shigella* bacteria. Most transmission is by person-to-person spread, but infection is also caused by ingestion of contaminated food or water. Shigellosis is most common in situations in which hygiene is compromised (e.g., child care centers and other institutional settings). In developing populations without running water and indoor plumbing, shigellosis can become endemic. Sexual transmission of *Shigella* among men who have sex with men also occurs.

In the United States, an estimated 450,000 cases of shigellosis occur each year, with 70 deaths (69). Up to 20% of all U.S. cases of shigellosis are related to international travel. Most infections in the United States and other developed countries are caused by *S. sonnei; S. flexneri* is the second most common serogroup (44). In the developing world, the most prevalent *Shigella* species are *S. flexneri* and *S. dysenteriae* 1, with the latter being the most frequent cause of epidemic dysentery. Infection with *S. dysenteriae* 1 is associated with high rates of morbidity and mortality in developing countries, particularly when antimicrobial resistance or its misdiagnosis delays appropriate treatment.

Clinical Significance

Members of the genus *Shigella* have been recognized since the late 19th century as causative agents of bacillary dysentery. *Shigella* causes bloody diarrhea (dysentery) and nonbloody diarrhea. Shigellosis often begins with watery diarrhea accompanied by fever and abdominal cramps but may progress to classic dysentery with scant stools containing blood, mucus, and pus. Ulcerations, which are restricted to the large intestine and rectum, typically do not penetrate beyond the lamina propria. Bloodstream infections can occur but are rare. All four subgroups of *Shigella* are capable of causing dysentery, but *S. dysenteriae* serotype 1 has been associated with a particularly severe form of illness thought to be related in part to its production of Shiga toxin. Infection can occasionally be asymptomatic, particularly infection with *S. sonnei* strains. Complications of shigellosis include HUS, which is associated with *S. dysenteriae* 1 infection, and Reiter chronic arthritis syndrome, which is associated with *S. flexneri* infection (2). The identification of *Shigella* species is important for both clinical and epidemiologic purposes.

Isolation Procedures

Enrichment and Plating Media

There is no reliable enrichment medium for all *Shigella* isolates, but gram-negative broth and Selenite broth are frequently used. For the optimal isolation of *Shigella,* two different selective media should be used: a general-purpose plating medium of low selectivity (e.g., MAC) and a more selective agar medium (e.g., xylose lysine desoxycholate agar [XLD]). Desoxycholate citrate agar (DCA) and Hektoen Enteric agar (HE) are suitable alternatives to XLD as media with moderate to high selectivities. Salmonella-Shigella agar (SS) should be used with caution because it inhibits the growth of some strains of *S. dysenteriae* 1.

Screening Procedures

Shigella strains appear as lactose- or xylose-nonfermenting colonies on the isolation media described above. *S. dysenteriae* 1 colonies may be smaller on all of these media, and these strains generally grow best on media with low selectivities (e.g., MAC). *S. dysenteriae* 1 colonies on XLD agar are frequently very tiny, unlike other *Shigella* species. *S. sonnei* colonies often appear flattened and spread out on blood agar plates.

Suspect colonies may be screened biochemically or serologically on Kligler iron agar [KIA] or triple sugar iron agar [TSI]. *Shigella* species characteristically produce an alkaline slant and an acid butt (K/A) but do not produce gas or H_2S. A few strains of *S. flexneri* 6 and a very few strains of *S. boydii* produce gas in KIA or TSI. The motility and the lysine decarboxylase tests are characteristically negative for *Shigella* and can be used to further screen isolates before serologic testing (Table 4). Isolates that react appropriately with the screening biochemicals should then be identified with a complete set of biochemical tests, with automated systems or self-contained commercial kits being satisfactory, and should be tested with grouping antisera. Confirmation requires both biochemical and serologic identification, and laboratories that do not perform both types of tests should send *Shigella* isolates to a reference laboratory for confirmation.

Identification

Biochemical

Because the somatic antigens of most serotypes of *Shigella* are either identical or related to those of *E. coli*, suspicious cultures that are serologically negative should be tested further biochemically (35). *Shigella* and inactive *E. coli* (anaerogenic or lactose nonfermenting) are frequently difficult to distinguish by routine biochemical tests. See Table 4 for the biochemical reactions characteristic of *Shigella* spp. Although *S. dysenteriae* and *S. sonnei* are biochemically distinct, *S. flexneri* and *S. boydii* are often biochemically indistinguishable, so that serologic grouping is essential.

Serotyping

Serologic testing is essential for the identification of *Shigella*. Three of the four subgroups, A (*S. dysenteriae*), B (*S. flexneri*), and C (*S. boydii*), are made up of a number of serotypes. Subgroup A has 15 serotypes; subgroup B has 8 serotypes (with serotypes 1 to 5 subdivided into 11 subserotypes); and subgroup C has 19 serotypes numbered 1 through 20, with *S. boydii* 13 reclassified as *E. albertii*. Subgroup D (*S. sonnei*) is made up of a single serotype. Subgroups A and C are rare. Several provisional *Shigella* serotypes have also been described, which are held sub judice until findings from the characterization of representative isolates show them to be unique. Antisera for the identification of provisional serotypes are typically available only at reference laboratories.

Serologic identification is typically performed by slide agglutination with polyvalent somatic (O) antigen grouping sera, followed, in some cases, by testing with monovalent antisera for specific serotype identification. Monovalent antiserum to *S. dysenteriae* 1 is required to identify this serotype and is not widely available. Because of the potentially serious nature of illness associated with this serotype, isolates that agglutinate in subgroup A reagent should be sent to a reference laboratory immediately for further serotyping.

Biochemically typical *Shigella* isolates that agglutinate poorly or that do not agglutinate at all should be suspended in saline and heated in a water bath at 100°C for 15 to 30 min. After cooling, the antigen suspension is tested in normal saline to determine if it is rough (agglutinates spontaneously). If the heated and cooled suspension is not rough, it may then be retested for agglutination in antisera.

Subtyping

A variety of methods have been used to subtype *Shigella,* including colicin typing (particularly for *S. sonnei*), plasmid profiling, restriction fragment length polymorphism analysis, PFGE, and ribotyping (105). For an overview of the epidemiologic use of typing methods, refer to chapter 12 in this Manual.

Serodiagnostic Tests

Several serodiagnostic assays based on different antigens possessed by *Shigella* have been described (61, 114). These assays are practical only in research settings for seroepidemiology surveys and are not currently used for the diagnosis of infection in individual patients.

Antimicrobial Susceptibilities

Shigella infections are often treated with antimicrobial agents. Because of the widespread antimicrobial resistance among *Shigella* strains, all isolates should undergo susceptibility testing (http://www.cdc.gov/narms/). Reporting of susceptibility results to the clinician is particularly important for *S. dysenteriae* 1 isolates. Infections caused by these strains are often acquired during international travel to areas where most strains are multidrug resistant (110). In many areas of Africa and Asia, *S. dysenteriae* 1 strains are resistant to all locally available antimicrobial agents, including nalidixic acid, but are still susceptible to the fluoroquinolones (93); however, fluoroquinolone-resistant strains have been reported in south Asia.

Interpretation and Reporting of Results

A preliminary report of suspected *Shigella* infection may be issued if biochemical or serologic screening tests are positive. If serotyping results are available, these should also be reported, particularly if the isolate is *S. dysenteriae* 1. All *Shigella* isolates should be tested for antimicrobial susceptibility. Before issuing a final report, isolates should be confirmed by both serologic and biochemical methods. Isolates, particularly those from individuals with dysentery-like illness, that are biochemically identified as *Shigella* but that are serologically negative may be new serotypes of *Shigella* and should be sent to a reference laboratory for further characterization. Isolates from sites other than the gastrointestinal tract and which resemble *Shigella* should be carefully scrutinized for gas production and other differentiating characteristics. These isolates should be sent to a reference laboratory for confirmation because they are more likely to be anaerogenic *E. coli,* certain strains of which may cross-react with *Shigella* antiserum.

SALMONELLA

Description of the Genus

The genus *Salmonella* is composed of motile bacteria that conform to the definition of the family *Enterobacteriaceae* (35). The nomenclature employed to describe the genus *Salmonella* had been problematic for many years, due to the use of multiple schemes in the literature and the historical practice of considering different serotypes of *Salmonella* to be different species. The publication of Judicial Opinion 80 in 2005 (112) will hopefully serve to clarify nomenclatural issues regarding the genus *Salmonella,* and the conventions set forth in that opinion are used here. *Salmonella* history and nomenclature are reviewed at the following website: http://www.bacterio.cict.fr/s/salmonella.html.

The genus *Salmonella* is composed of two species, *Salmonella enterica* and *Salmonella bongori* (formerly subspecies V) (91). *Salmonella enterica* has been subdivided into six subspecies: *S. enterica* subsp. *enterica*, designated subspecies I; *S. enterica* subsp. *salamae,* subspecies II; *S. enterica* subsp. *arizonae,* subspecies IIIa; *S. enterica* subsp. *diarizonae*, subspecies IIIb; *S. enterica* subsp. *houtenae,* subspecies IV; and *S. enterica* subsp. *indica,* subspecies VI. The type species is *S. enterica* subsp. *enterica*. Subspecies IIIa and IIIb represent organisms originally described in the genus "*Arizona*"; subspecies IIIa contains the monophasic strains and subspecies IIIb contains the diphasic strains of "*Arizona*" (92). Despite their common history, subspecies IIIa and IIIb are more closely related to some of the other subspecies of *Salmonella enterica* than they are to each other and thus should be considered separate entities (120).

Subspecies I strains are commonly isolated from humans and warm-blooded animals. Subspecies II, IIIa, IIIb, IV, and VI strains and *S. bongori* are usually isolated from cold-blooded animals and the environment. Non-subspecies I strains are typically considered rare human pathogens; they make up about 1 to 2% of *Salmonella* isolates reported to the U.S. National *Salmonella* surveillance system (22). The biochemical tests useful for identification of *Salmonella* and for subspecies differentiation are given in Table 5.

Salmonella Serotypes

Salmonella serotyping is a subtyping method based on the immunologic characterization of three surface structures: O antigen, which is the outermost portion of the LPS layer that covers the bacterial cell; H antigen, which is the filament portion of the bacterial flagella; and Vi antigen, which is a capsular polysaccharide present in specific serotypes. Serotyping of *Salmonella* is commonly performed to facilitate public health

TABLE 5 Biochemical reactions useful for differentiating *Salmonella* species and subspecies[a]

surveillance for *Salmonella* infection and to aid in the recognition of outbreaks. The serotype of an isolate often correlates with a particular disease syndrome or food vehicle, making serotype data particularly useful in identifying cases and defining outbreaks. For example, *Salmonella* serotype Typhi causes typhoid fever, a more severe disease syndrome than those caused by most other *Salmonella* serotypes. *Salmonella* serotype Enteritidis is associated with infections acquired from chicken or egg products (82). Further, *Salmonella* serotyping is performed worldwide and has aided in the recognition of international outbreaks (64). *Salmonella* serotypes Enteritidis and Typhimurium are the two most common serotypes in the United States, making up approximately 35 to 40% of all culture-confirmed infections (22).

Clinical Significance

Strains of *Salmonella* are categorized as typhoidal and nontyphoidal, corresponding to the disease syndrome with which they are associated. Strains of nontyphoidal *Salmonella* usually cause an intestinal infection (accompanied by diarrhea, fever, and abdominal cramps) that often lasts 1 week or longer (46). Less commonly, nontyphoidal *Salmonella* can cause extraintestinal infections (e.g., bacteremia, urinary tract infection, or osteomyelitis), especially in immunocompromised persons. Persons of all ages are affected; the incidence is highest in infants and young children. *Salmonella* is ubiquitous in animal populations, and human illness is usually linked to foods of animal origin. Salmonellosis also is transmitted by direct contact with animals, by nonanimal foods, by water, and occasionally, by human contact. Each year, an estimated 1.4 million cases of illness and 600 deaths are caused by nontyphoidal salmonellosis in the United States (69).

Typhoid fever, caused by *Salmonella* serotype Typhi, is a serious bloodstream infection common in the developing world. However, it is rare in the United States, where an estimated 800 cases, with fewer than 5 deaths, occur each year; >70% of U.S. cases are related to foreign travel (69). Typhoid fever typically presents with a sustained debilitating high fever and headache. Adults characteristically present without diarrhea. Illness is milder in young children, where it may manifest as nonspecific fever. Humans are the only reservoir for *Salmonella* serotype Typhi, indicating that this serotype is adapted to the human host; healthy carriers have been noted. Typhoid fever typically has a low infectious dose ($<10^3$) and a long, highly variable incubation period (1 to 6 weeks). It is transmitted through person-to-person contact or fecally contaminated food and water. Fatal complications of typhoid most commonly occur in the second or third week of illness.

A syndrome similar to typhoid fever is caused by "paratyphoidal" strains of *Salmonella, Salmonella* serotypes Paratyphi A, Paratyphi B, and Paratyphi C. Serotypes Paratyphi A and Paratyphi C are rare in the United States (22). Serotype Paratyphi B is a diverse serotype that is associated with both paratyphoid fever and gastroenteritis (87). The two pathovars are typically differentiated on the basis of the ability to ferment tartrate; isolates causing paratyphoid fever, the systemic pathovar, are tartrate negative. Isolates associated with gastroenteritis, the enteric pathovar, are typically tartrate positive and are referred to as *Salmonella* Paratyphi B var. L(+)-tartrate + or *Salmonella* Paratyphi B var. Java. The systemic pathovar of *Salmonella* Paratyphi B is considered to be rare in the United States; however, the tartrate reaction is often not reported, making it impossible to distinguish between the two pathovars (22).

Salmonella serotypes Choleraesuis and Dublin are host adapted to cattle and pigs, respectively, causing serious disease in these two animal species. They rarely cause human infection, but such infections are typically severe, with spread to extraintestinal sites (66, 116). *Salmonella* serotype

Dublin has been shown to share virulence traits with *Salmonella* serotype Typhi, which may contribute to its invasiveness in humans (71, 83).

Isolation Procedures

Enrichment

Maximal recovery of *Salmonella* from fecal specimens is obtained by using an enrichment broth, although isolation from acutely ill persons is usually possible by direct plating of specimens. Enrichment broths for *Salmonella* are usually highly selective and inhibit certain serotypes of *Salmonella,* particularly *Salmonella* serotype Typhi. The three selective enrichment media most widely used to isolate *Salmonella* from fecal specimens are tetrathionate broth, tetrathionate broth with brilliant green, and Selenite broth (SEL). SEL may also be used for the recovery of *Salmonella* serotype Typhi and *Shigella,* although its value as enrichment for the latter has not been clearly established. Specimens that might contain organisms inhibited by selective enrichment broths should be plated directly or cultured in a nonselective enrichment broth (e.g., gram-negative broth).

A number of commercial rapid diagnostic tests are available for the testing of foods, but to our knowledge, none has been evaluated in the literature for use with fecal specimens.

Plating Media

Many differential plating media, varying from slightly selective to highly selective, are available for isolation of *Salmonella* from fecal specimens. Media of low selectivity include MAC and eosin methylene blue. Media of intermediate selectivity include XLD, desoxycholate citrate agar, Salmonella-Shigella agar, and HE. Highly selective media include bismuth sulfite agar, the preferred medium for the isolation of *Salmonella* serotype Typhi, and brilliant green agar. Bismuth sulfite agar, XLD, and HE all have H_2S indicator systems, which are helpful for the detection of lactose-positive *Salmonella*. Most laboratories today use HE or XLD because these media may also be used for the isolation of *Shigella*.

In the developing world, typhoid fever is frequently diagnosed solely on clinical grounds, but isolation of the causative organism is necessary for a definitive diagnosis. *Salmonella* serotype Typhi is more frequently isolated from blood cultures than from fecal specimens. Blood cultures are positive for 80% of typhoid patients during the first week of fever but show decreasing positive results thereafter.

Screening Procedures

A latex agglutination kit has been described for screening for *Salmonella* from SEL enrichment broth (Wellcolex Color *Salmonella;* Remel Inc., Lenexa, Kans.) (15). This kit can also be used to screen individual colonies from primary plates. In using this kit, it should be kept in mind that it identifies only those *Salmonella* isolates belonging to the more common O serogroups and it does not differentiate between O groups C_1 and C_2.

Suspect colonies may be inoculated onto a screening medium such as KIA or TSI. On KIA or TSI, most *Salmonella* strains produce a K/AG + reaction, indicating that glucose is fermented with gas, and H_2S is produced. On these media, *Salmonella* serotype Typhi isolates are characteristically K/A but do not produce gas and only a small amount of H_2S is visible at the site of the stab and in the stab line. Lysine iron agar is also a useful screening medium because most *Salmonella* isolates, even those that ferment lactose, decarboxylate lysine and produce H_2S. Alternately, isolates may be identified by a battery of biochemical tests or by slide agglutination with antisera for *Salmonella* O groups. Isolates suspected of being *Salmonella* serotype Typhi should be tested serologically with *Salmonella* Vi and O group D antisera (see below).

If the biochemical reactions for a particular isolate are not characteristic but *Salmonella* antigens are found, the cultures should be plated on MAC or eosin methylene blue to obtain a pure culture, tested with a complete set of biochemical tests, or forwarded to a reference laboratory.

Identification

Clinical laboratories may issue a preliminary report of *Salmonella* when an isolate is positive either with *Salmonella* O group antisera or by biochemical identification methods. An isolate is confirmed as *Salmonella* when the specific O serogroup has been determined and biochemical identification has been completed.

Biochemical Identification

Suspect colonies from one of the differential plating media mentioned above can be identified biochemically as *Salmonella* spp. with traditional media in tubes or commercial biochemical systems. Methods of biochemical identification and specific commercial manual and automated identification systems are covered in chapter 15. The species and subspecies of *Salmonella* can be identified biochemically, as indicated in Table 5.

Serotyping

O serogroup determination is adequate for confirmation of isolates as *Salmonella.* Full serotype determination is useful for public health surveillance but is beyond the scope of most routine clinical laboratories. The methods described below for serotyping are intended primarily for reference laboratories. *Salmonella* isolates are serotyped based on the antigenic properties of their O (somatic) antigens, H (flagellar) antigens, and Vi (capsular) antigen (17). O antigen is a carbohydrate antigen and is the outermost component of LPS. It is a polymer of O subunits; each O subunit is typically composed of four to six sugars depending on the O antigen. O antigens are designated by numbers and are divided into O serogroups based on antigenic factors associated with the O subunit. Many of the common O groups were originally designated by letter and are still commonly referred to by letter (e.g., serotype Typhimurium belongs to group O:4 or group B, serotype Enteritidis belongs to group O:9 or group D1). Additional O antigenic factors have been identified for specific O groups. They are typically associated with a side sugar that is added to the basic O subunit structure, and they are often variably present or variably expressed within O groups or within serotypes.

H antigen is a protein antigen called flagellin; multiple flagellin subunits make up the flagellar filament. The ends of flagellin are conserved and give the flagellum its characteristic filament structure; the antigenically variable portion of flagellin is the middle region, which is surface exposed. Salmonellae are unique among the enteric bacteria in that they commonly express two different flagellin antigens, although specific serotypes such as Typhi and Enteritidis possess only one flagellar antigen. The two flagellar antigens are referred to as phase 1 and phase 2; monophasic and diphasic strains express one or two flagellar antigens, respectively. Individual flagellar antigens can be composed of multiple antigenic factors. For example, the phase 2 flagellar antigen of serotype Typhimurium is antigen 1,2, which is composed of two antigenic factors, 1 and 2.

Many of the O and H antigenic types are found in multiple subspecies, and isolates from different subspecies can have the same antigenic profile. Thus, subspecies determination is an integral component of serotype determination for *Salmonella*. The serotype for all *Salmonella* strains can be designated by an antigenic formula; additionally, serotypes belonging to subspecies I are given a name which is typically related to the geographical place where the serotype was first isolated (84). The antigenic formulae of *Salmonella* serotypes are listed in the Kauffmann-White scheme and are expressed as follows: O antigen(s), Vi (when present): phase 1 H antigen(s): phase 2 H antigen(s) (when present). For example, the antigenic formula for *Salmonella* serotype Typhimurium is 4,5,12:i:1,2. Serotype names for subspecies I serotypes are written in roman (not italicized) letters, and the first letter is a capital letter (for example, *Salmonella* serotype [ser.] Typhimurium or *Salmonella* Typhimurium [19]). Serotypes belonging to other subspecies are designated by their antigenic formulae following the subspecies name (for example, *S. enterica* subsp. *salamae* ser. 50:z:e,n,x or *Salmonella* serotype II 50:z:e,n,x).

The WHO Collaborating Centre for Reference and Research on *Salmonella,* which is located at the Pasteur Institute in Paris, France, maintains the Kauffmann-White Scheme for the designation of *Salmonella* serotypes (84). The Kauffmann-White scheme is updated annually with a listing of new serotypes (85). Currently, there are 2,541 recognized *Salmonella* serotypes; the majority belong to subspecies I (1,504 serotypes [85]). Most common serotypes belong to O groups A, B, C_1, C_2, D_1, and E_1 (also known as groups O:2, O:4, O:7; O:8; O:9, and O:3,10, respectively). Serotypes belonging to subspecies II (502 serotypes), IIIa (95 serotypes), IIIb (333 serotypes), IV (72 serotypes), VI (13 serotypes), and *S. bongori* (22 serotypes) are primarily found in O groups O:11 (F) through O:67 (commonly referred to as the higher O groups).

Determination of O Antigens

O (heat-stable, somatic) antigens are identified by first testing the isolate in antisera that detects one or multiple antigenic factors corresponding to the O groups (O grouping antisera). Once the O group is determined, antisera that recognize single antigenic factors are used to confirm the O group and identify any additional antigenic factors that are associated with that O group (O single-factor antisera) (18). The approach most commonly used for determining O antigens is to initially test the isolates by slide agglutination in antisera against O groups A to E_1 because approximately 95% of *Salmonella* isolates belong to one of these O groups. If no agglutination occurs in antisera for these O groups, the isolate is tested in pools containing the remaining *Salmonella* O antisera, O:11 through O:67.

Determination of H Antigens

H (flagellar) antigens are typically determined by tube agglutination tests using broth cultures. Isolates are initially tested with H typing antisera, which recognize individual or multiple antigenic factors, and then with H single-factor antisera, which recognize individual antigenic factors. Typically, the flagellar antigens in a diphasic strain are coordinately regulated so that only one is expressed at time in a single bacterial cell; however, both phases may be detected in the whole culture, particular with a fresh clinical isolate. When only one phase is detected (either phase 1 or phase 2), the strain should be inoculated into a semisolid medium to which sterile antiserum to the detected flagellar antigen has aseptically been added. Growth of the strain in this semisolid agar immobilizes cells expressing the detected antigen and allows the growth of bacteria expressing the antigen in the other phase. After phase reversal, the strain is tested in appropriate H typing and single-factor antisera to complete the serotyping. A strain must be actively motile to ensure the good expression of H antigens; sometimes it must be passed through one or more tall tubes of semisolid agar to enhance motility before H antigens can be detected.

Detection of the Vi Antigen and Identification of *Salmonella* Serotype Typhi (9,12,[Vi]:d:-)

The Vi antigen, a heat-labile capsular polysaccharide, is useful for the identification of *Salmonella* serotype Typhi. It is also occasionally detected in *Salmonella* serotype Dublin, *Salmonella* serotype Paratyphi C, and some *Citrobacter* strains, so its detection does not constitute definitive evidence of *Salmonella* serotype Typhi. Vi antigen is identified by slide agglutination with specific antiserum.

If *Salmonella* serotype Typhi is suspected, the culture is first tested live (unheated) in O group D antiserum (which contains antibodies to O antigens 9 and 12) and Vi antiserum on a slide. The Vi capsular polysaccharide can mask the O antigens, blocking their reactivity with the O grouping antiserum. If only the Vi antiserum is positive, the bacterial suspension is heated in boiling water for 15 min to remove the capsule, cooled, and tested again in the same antisera. After heating, *Salmonella* serotype Typhi isolates will be negative in the Vi antiserum but positive in the O group D antiserum. Expression of the Vi antigen by *Salmonella* serotype Typhi is variable but tends to occur more frequently in freshly isolated cultures than in cultures that have been subcultured. If the strain is typical for *Salmonella* serotype Typhi on TSI or KIA (see "Screening Procedures" above), is urease negative, and reacts in O group D or Vi antiserum, a presumptive report is made. The identity of the isolate is confirmed by biochemical testing (Table 5) and determination of the H (flagellar) antigen (see below) before a final report is issued. *Salmonella* serotype Typhi strains typically express only one flagellar antigen, Hd.

Identification Problems

Several potential problems may prevent accurate serotype determination. The strain may express the Vi capsular antigen, which can block the binding of antibodies against the O antigens. The strain may be rough, i.e., fails to make complete O antigens. Rough strains have a tendency to weakly agglutinate in multiple O grouping antisera. The strain may be mucoid and not agglutinate in any O antisera, or isolates can be nonmotile and not express any flagellar antigens. Among isolates submitted to the National *Salmonella* Reference Laboratory at the CDC, isolates from urine are frequently rough, mucoid, and/or nonmotile. When O antigen and/or H antigens are not detected, a strain is confirmed as a *Salmonella* species by characterization of any antigens that are expressed and by biochemical testing (Table 5).

Many laboratories are likely to overlook *Salmonella* serotype Paratyphi A because they do not screen with O group A antiserum or because it is H_2S negative, lysine negative, and citrate negative. *Salmonella* serotypes Paratyphi B and Paratyphi B var. L(+)-tartrate + (var. Java) can be confused because they have an identical antigenic formula (4,5,12:b:1,2), but they are distinguished biochemically by their tartrate reaction. Similarly, *Salmonella* serotype Choleraesuis and *Salmonella* serotype Paratyphi C have the same antigenic formula (6,7:c:1,5) but are differentiated biochemically. *Salmonella* serotype Paratyphi C may express the

Vi antigen. *Citrobacter* and *E. coli* strains may possess O, H, or Vi antigens that are related to those of *Salmonella;* biochemical identification may be necessary to confirm that an isolate is *Salmonella* (see Table 5 in this chapter and Table 1 in chapter 42).

Subtyping

For rarer serotypes, serotype identification may be all that is necessary to identify clusters of temporally related isolates. However, additional subtyping methods are typically required for more common serotypes (e.g., Typhimurium, Enteritidis, and Newport). A variety of phenotypic (e.g., phage typing, antimicrobial susceptibility pattern determination, and biotyping) and genotyping methods (e.g., plasmid fingerprinting, PFGE, IS*200* profiling, and random amplified polymorphic DNA analysis) have been developed for subtyping within serotypes of *Salmonella* (74, 108). PFGE is the current method of choice for the subtyping of most *Salmonella* serotypes since it is universally applicable and provides good strain discrimination for most serotypes. PulseNet, an international subtyping network that tracks *Salmonella,* is based on PFGE (108). *Salmonella* serotype Enteritidis has limited diversity in PFGE analysis; as a result, phage typing is still commonly used to characterize strains, particularly in an outbreak setting (39, 82).

Serodiagnostic Tests

The Widal test, which measures agglutinating antibodies to the O and H antigens of *Salmonella* serotype Typhi, produces false-negative and false-positive reactions and does not provide a definitive diagnosis of individual cases of infection. Two other rapid serodiagnostic tests have proved more useful than the Widal test for the serodiagnosis of typhoid fever (78) (Tubex; IDL Biotech, Sollentuna, Sweden; and TyphiDot; Malaysian Biodiagnostic Research SDN BHD, Kuala Lumpur, Malaysia).

Antimicrobial Susceptibilities

Antimicrobial therapy is not recommended for uncomplicated *Salmonella* gastroenteritis, and routine susceptibility testing of fecal isolates is not warranted for treatment purposes. However, determination of antimicrobial resistance patterns is often valuable for surveillance purposes and may be performed periodically to monitor the development and spread of antimicrobial resistance among *Salmonella* isolates.

In contrast to uncomplicated salmonellosis, treatment with the appropriate antimicrobial agent can be crucial for patients with invasive *Salmonella* and typhoidal infections, and the susceptibilities of these isolates should be reported as soon as possible (57). Testing methods are detailed in chapter 73. The untreated case mortality rate for typhoid fever is >10%; when patients with typhoid fever are treated with appropriate antibiotics, the rate should be <1%. However, increasing levels of resistance to one or more antimicrobial agents in *Salmonella* isolates, particularly in *Salmonella* serotype Typhi, make selection of an appropriate antibiotic problematic. In particular, reduced susceptibility to ciprofloxacin among *Salmonella* serotype Typhi isolates and increasing numbers of treatment failures are of concern (52, 89).

Antimicrobial resistance, particularly multiple drug resistance, has been noted in several nontyphoidal serotypes of *Salmonella*. A strain of *Salmonella* serotype Typhimurium phage type DT104 resistant to five antimicrobials (ampicillin, chloramphenicol, streptomycin, sulfonamides, and tetracycline, or ACSSuT) emerged in the late 1990s and is now recognized worldwide. In 2002, 21% of *Salmonella* serotype Typhimurium isolates in the United States had the ACSSuT resistance profile (21). The ACSSuT resistance determinant has been found in *Salmonella* serotype Agona strains (27). The genomic element that carries this ACSSuT determinant has been found to harbor these and other resistance determinants in a variety of serotypes, indicating that the element may spread horizontally to other serotypes and acquire additional resistance determinants (60).

The emergence of a clone of *Salmonella* serotype Newport resistant to at least nine antimicrobials, including expanded-spectrum cephalosporins, was first noted in 2000 in the northeastern United States (43) and has now been found in many regions of the United States (8). In 2002, this strain made up 22% of all serotype Newport strains in the United States. Similarly resistant strains of *Salmonella* serotype Newport were recently reported in Japan, documenting the potential for worldwide spread of multiply resistant strains (50). Additional information regarding these and other antimicrobial resistant strains can be found at the CDC's NARMS website (http://www.cdc.gov/narms/).

Interpretation and Reporting of Results

A preliminary report can be issued as soon as a presumptive identification of *Salmonella* is obtained. In most situations, a presumptive identification would be based on biochemical findings obtained either by traditional or commercial systems or by a serologic reaction in *Salmonella* O grouping antisera. A confirmed identification requires both biochemical and serologic identification methods. Because the National *Salmonella* Surveillance System depends on the receipt of serotype information for *Salmonella* strains isolated in the United States for the tracking of outbreaks of infection, laboratories should follow the procedures recommended by their state health departments for submitting isolates for further characterization, including complete serotyping. The antimicrobial susceptibility of typhoidal *Salmonella* strains and strains from normally sterile sites should be determined, and the strains should be forwarded to a reference or public health laboratory for complete biochemical and serologic characterization.

*Yersinia**

AUDREY WANGER

44

TAXONOMY AND HISTORY OF THE GENUS

Yersinia pseudotuberculosis and *Y. pestis* were included in the genus *Pasteurella* until 1944, when van Loghem suggested that a new genus be formed due to the significant phenotypic and genotypic differences among the organisms. It was not until 1964 that *Y. enterocolitica* was renamed by Frederiksen from the previous name of *Bacterium enterocolitica* assigned in 1939 following a report of several cases of gastrointestinal disease. This diverse group of organisms was further divided into a subgroup initially designated *Y. enterocolitica*-like organisms and later into an additional four species *(Y. intermedia*, *Y. frederiksenii*, *Y. kristensenii,* and *Y. aldovae)* based on sugar fermentation and DNA relatedness. Subsequent species designations included *Y. ruckeri*, *Y. rohdei*, *Y. mollaretii*, and *Y. bercovieri.* The newest member of the genus is *Y. aleksiciae,* named after the German scientist Stojanca Aleksic (54) and previously included in the species *Y. kristensenii*. Although phenotypically identical, the two species were differentiated by multilocus enzyme electrophoresis (MLEE) typing and 16S rRNA analysis. A further breakdown of *Y. enterocolitica* into subspecies *(enterocolitica* and *palearctica)* differentiable based only on 16S rRNA gene sequencing has been proposed (37).

Although most species of the genus have been isolated from humans, with the exception of *Y. aldovae*, the only species that are considered human pathogens are *Y. pestis*, *Y. pseudotuberculosis,* and *Y. enterocolitica.* These species, in addition to *Y. ruckeri* serogroup 01, which is the cause of enteric red mouth disease in rainbow trout, are the only members of the genus that are pathogenic for animals. All of the other species are considered to be nonpathogenic, environmental isolates.

As a group, members of the genus *Yersinia* have a G+C content of 46 to 50% and are related to the rest of the members of the family *Enterobacteriaceae* by 10 to 32%. Intraspecies relatedness is very variable, ranging from 55 to 74% with the exception of that of *Y. pestis* and *Y. pseudotuberculosis,* which demonstrate more than 90% relatedness. Based on multilocus sequence typing (MLST) of the housekeeping genes, the two species are very closely related. *Y. pestis* is believed to have evolved from *Y. pseudotuberculosis* prior to the first plague pandemic (1, 12, 64). Detailed analysis of genetic differences between the species was later described by Hinchliffe et al. using DNA microarrays (22). The entire genome of *Y. pestis* has recently been sequenced, and work is in progress to sequence the genome of *Y. pseudotuberculosis*. Data collected from these studies will likely provide definitive information regarding the ancestry of these organisms (42). However, despite the high degree of relatedness between the two species, they have not been combined due to the significant epidemiologic and clinical differences that exist between them.

DESCRIPTION OF THE AGENTS

As are all members of the family *Enterobacteriaceae*, *Yersinia* is a gram-negative, non-spore-forming bacillus that exhibits bipolar staining particularly when seen in primary specimens stained with Giemsa or Wayson's dye, although Wayson's dye is not readily available in most routine clinical laboratories. The bacilli are smaller than other members of their family (0.5 to 0.8 μm in diameter and 1 to 3 μm in length) and tend to grow more slowly as well. With the exception of *Y. pestis*, which is nonmotile, all of the members of the genus are motile at room temperature and nonmotile at 37°C due to the presence of peritrichous or paripolar flagella.

Yersinia species are facultative anaerobes that grow at a wide range of temperatures (4 to 43°C), but optimal growth conditions are 25 to 28°C. *Yersinia* ferments glucose with the production of acid and no gas. Most strains will grow on MacConkey agar as well as various selective media; however, most exhibit poor growth in liquid media and do not form a turbid suspension (62). *Yersinia* is catalase positive and oxidase negative.

The cell walls and antigenic structures of *Yersinia* species are also very similar to those of other members of the *Enterobacteriaceae* family, with an O-specific side chain and only minor variations in the lipopolysaccharides of various serogroups. *Y. enterocolitica* has more than 70 serotypes, *Y. pseudotuberculosis* has 15 (7), and *Y. pestis* lacks the O antigen.

Although all three pathogenic *Yersinia* species, *Y. pestis*, *Y. enterocolitica,* and *Y. pseudotuberculosis*, are associated with different clinical entities, they all have in common the possession of a 70- to 75-kb virulence plasmid that contains the major virulence factors, including the *Yersinia* outer membrane proteins (Yops) and the processing and regulatory proteins for the Yops: Ysc (*Yersinia* secretion) and Lcr (low-calcium response) (6).

The gene for enterotoxin production in *Y. enterocolitica* and *Y. pseudotuberculosis* as well as those for other invasion factors such as invasin is located on the chromosome. *Y. pestis* has two

*This chapter contains information presented in chapter 43 by Jochen Bockemühl and Jane D. Wong in the eigth edition of this Manual.

plasmids that carry the genes for plasminogen activator (Pla), the bacteriocin pesticin (Pst), murine toxin (Ymr), and fraction 1 protein capsule (F1). *Y. pestis*, *Y. pseudotuberculosis,* and some strains of *Y. enterocolitica* also have a chromosomally located high-pathogenicity island that carries the genes for yersiniabactin, a siderophore that provides the organisms with iron. Additionally, *Y. pestis* contains the gene *hsm*, responsible for a hemin storage system. A comprehensive review of the virulence mechanisms and pathogenesis of *Yersinia* species has been recently published (61).

EPIDEMIOLOGY AND TRANSMISSION

The natural reservoir for *Y. pestis* is rodents, which have an inapparent infection and are not a common source of infection for humans. Although many different species of fleas infect more than 100 rodent species that can be specific to geographic locations, transmission of plague is classically associated with the rat flea *(Xenopsylla cheopis)* (18). Approximately 3,000 human cases of plague are identified every year in the world, and about 12 to 15 are identified in the United States (35), where 90% of cases occur in New Mexico, Arizona, Colorado, and California. Transmission to humans is usually through the bite of an infected rodent flea and regurgitation by the flea during a blood meal. *Yersinia* can survive in the stomach and proventriculus of the flea and actually multiply there and block the proventriculus, causing the flea to bite its host mammal repeatedly, thereby increasing chances for disease transmission (43). Interestingly, when the environmental temperature is above 80°F, *Y. pestis* does not produce coagulase, so blockage of the proventriculus is unlikely to occur in the flea, which makes transmission to humans less likely to occur (51). The most common reservoir in the United States for plague transmission is the squirrel. A secondary mode of transmission of disease to humans is through contact with infected cats, either by scratches, bites, or inhalation of aerosolized organisms. Cats become infected by ingestion of contaminated rodents. Human-to-human transmission is very rare and occurs only with the pneumonic form by inhalation of aerosolized particles, which might occur in a bioterrorism attack (see chapter 9). Death can occur within 2 to 4 days. Pneumonic plague is a very rare sequela in patients appropriately treated with antibiotics (<5%) (29). Rare cases of person-to-person transmission from patients with pneumonic plague have been documented. Several of the virulence factors of *Y. pestis* aid in dissemination, including plasminogen activator (Pla), the Yops, and pH 6 antigen. These virulence factors are involved in cell lysis, suppression of the immune system, and survival of the organisms within macrophages. Once *Y. pestis* enters the human host, other virulence factors such as F1 capsular antigen and the yersiniabactin iron scavenging system aid the organism in survival within phagocytes. Endotoxin produced by the organism is associated with the subsequent septic shock and systemic response. *Y. pestis* has been known to survive for days to weeks outside of the vector or mammalian host (in flea feces, dead rodents, or soil), which allows for further transmission.

Plague Pandemics

There have been three plague pandemics, each in different parts of the world and all believed to have been due to one of three biovars of *Y. pestis* differentiated by their abilities to ferment glycerol and to reduce nitrate (see "Identification"). The earliest pandemic, called the Justinian plague, in the fifth through seventh centuries in Africa was associated with biovar Antiqua. Biovar Medievalis, which was identified in Central Asia, was associated with the pandemic known as the Black Death during the 13th to 15th centuries. Modern plague, which originally was identified in southern China and is now worldwide, is associated with biovar Orientalis (29). Using microarray analysis, Zhou et al. (63) proposed a new, fourth biovar, Microtus, which includes strains previously part of the biovar Medievalis but separated based on biochemical, molecular, and pathogenicity differences. Biovar Microtus is pathogenic to the rodent genus *Microtus* (voles), mice, and other small rodents but not to large mammals, including humans (65).

There are more than 70 serotypes of *Y. enterocolitica,* and only a few are associated with disease in animals or humans, five of which are associated with human disease. Serotypes seem to be location specific. *Y. enterocolitica* organisms are widely distributed in nature and are found in the gastrointestinal tracts of many animal species, most commonly swine, rodents, and dogs. Due to their enhanced growth in cold temperatures, geographic distribution is mostly in the northern portions of the United States and in colder portions of Europe. Food products, particularly raw and poorly cooked meats, are frequently found to contain these organisms, although the majority of them are of nonpathogenic serotypes.

Y. pseudotuberculosis is also found in the environment (soil and water) and in a diverse group of wild and domesticated animal species. The main reservoirs for the organism are rodents, rabbits, and wild birds. The mode of transmission of *Y. pseudotuberculosis* is unknown, although due to its similarity to *Y. enterocolitica* (both are found in the environment), it has been speculated that transmission is via contaminated food or water.

CLINICAL SIGNIFICANCE

There are three forms of plague: pneumonic, septicemic, and bubonic. Bubonic plague is the most common clinical presentation. Following the bite of an infected flea, *Y. pestis* migrates through the blood and proliferates in the regional lymph nodes. Following a 2- to 8-day incubation period, the patient develops a fever and a painful swelling (bubo) in the area of the affected node.

Pneumonic plague can be a rare complication of bubonic plague or can be the primary infection following inhalation of aerosolized organisms either from contact with infected animals or from a bioterrorism event. After an incubation period of 1 to 6 days, symptoms include high fever and cough with hemoptysis and chest pain (24). An even higher mortality rate is associated with this form of plague than with bubonic plague.

Septicemic plague can occur when the organisms inoculated by the infected flea spread to the bloodstream without localizing in regional lymph nodes. This form of the disease is more common in children and is rapidly fatal. Septicemic plague can also occur following bubonic plague that is not adequately treated.

The most common form of disease due to *Y. enterocolitica* is gastroenteritis associated with consumption of contaminated food or water. It is not unusual to isolate *Y. enterocolitica* from raw meats including beef, lamb, pork, and chicken. The organism has also been found as a contaminant of cooked, prepackaged deli meat. The majority of strains isolated from human food sources are of the nonpathogenic serotypes. Carriage of the pathogenic serotypes of *Y. enterocolitica* is more common in swine; therefore, consumption of raw or poorly cooked pork, such as chitterlings, is the main risk factor for gastroenteritis (11, 26). Severity of disease is related to the serotype and can range from self-limited gastroenteritis to terminal ileitis and

mesenteric lymphadenitis, often misdiagnosed as appendicitis. Young children most commonly develop gastroenteritis and present with fever, diarrhea, and abdominal pain following consumption of food contaminated by *Yersinia.* Although symptoms typically resolve within approximately 7 days, patients can carry the organism in their gastrointestinal tracts for as long as several months. Organisms can migrate out of the gut via the lymphatics into local lymph nodes. An uncommon complication of gastroenteritis is septicemia, which is associated with the patient's HLA type. Persons at high risk for septicemia include the elderly and immunocompromised patients, particularly those with underlying metabolic diseases that are associated with iron overload (hemochromatosis), cancer, liver disease, and steroid therapy.

The production of urease allows the organism to survive in the stomach and colonize the small intestine of the human host. Pathogenic strains contain YoPs which allow them to resist the normal phagocytic and complement killing process that takes place in the Peyer's patches (58).

Y. enterocolitica is the most common cause of transfusion-related infections due to contaminated red blood cells. Since the organism is able to survive and multiply at refrigeration temperatures, donated blood contaminated with small numbers of organisms from an asymptomatic person can transmit infection to the transfused patient (31).

Reactive arthritis is an uncommon sequela of diarrhea due to *Y. enterocolitica*. Patients at increased risk include those who are carriers of the HLA-B27 allele and those with other immunologic disorders. Reactive arthritis is differentiated from rheumatoid arthritis by the asymmetrical involvement of multiple joints, most commonly the sacroiliac and the spine. Symptoms appear several days to months after the onset of diarrhea and may persist for months. Other, less common diseases associated with *Y. enterocolitica* infection include inflammatory bowel disease, most commonly associated with serotype O:3 (48), and autoimmune thyroid disorders such as Graves' disease and Hashimoto's thyroiditis (14). Both *Y. enterocolitica* and *Y. pseudotuberculosis* have been isolated from patients with Crohn's disease, although a causal relationship has not been proven (23).

Y. pseudotuberculosis usually produces a self-limiting disease, particularly in children and young adults. Rarely, *Y. pseudotuberculosis* can cause mesenteric lymphadenitis that clinically mimics appendicitis and septicemia and that occurs usually in immunocompromised patients (diabetics and those with liver cirrhosis or iron overload) (15). Long-term sequlae of *Y. pseudotuberculosis* infection include erythema nodosum, Reiter's syndrome, and nephritis. *Y. pseudotuberculosis* has also recently been implicated as a cause of foodborne illness following an outbreak of gastroenteritis-pseudoappendicitis associated with consumption of contaminated lettuce (40).

The other *Yersinia* species are not known to be human pathogens. Some of the other *Yersinia* species have also been shown to produce an enterotoxin and therefore may be associated with enteric disease in some patients (58). Elderly patients, more commonly women and those being treated with acid blockers, are more likely to develop gastroenteritis due to *Yersinia* species other than *Y. enterocolitica* and to have a prolonged course of disease related to these organisms (33).

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

Y. pestis is on the list of agents of bioterrorism (see chapter 9), and therefore all routine procedures performed with this organism should be done in a facility with a biosafety level of at least 2. Processes which are high risk for creating an aerosol should be performed under biosafety level 3 conditions. Routine clinical laboratories or sentinel laboratories should notify their local public health departments in the case of a presumptive diagnosis of plague. Clinical laboratories should be aware of the protocols as outlined by the American Society for Microbiology (http://www.asm.org/Policy/index.asp?bid=520).

Diagnosis of plague can be made by detection of *Y. pestis* in a bubo aspirate or by growth of *Y. pestis* from the blood. Patients with bubonic plague may shed organisms into the blood intermittently, so obtaining multiple sets of blood cultures over a 24-h period increases the sensitivity of detection. Blood cultures should be incubated at both 28 and 35°C to increase chances of recovery of the organism (3, 24). Other sources appropriate for culture include respiratory samples such as sputum, throat swabs, and throat washing specimens; however, due to contamination of these specimens with normal flora, a bronchial alveolar washing or lavage specimen would be preferable (3). Tissue samples should be collected in a sterile container with a small amount of sterile nonbactericidal saline to avoid drying of tiny pieces. Swab specimens are not recommended due to the poor recovery of the organisms. Blood or tissue specimens can also be collected from animals suspected to have died from *Y. pestis* infection for culture or direct fluorescent-antibody testing for the presence of the F1 antigen. Sera can also be collected from dead infected animals to test for antibody to *Y. pestis*. Material from fleas can be inoculated into mice for culture or direct fluorescent-antibody testing. If clinical suspicions are high and cultures of animal material fail to yield *Y. pestis,* PCR can be attempted. Specimens should be sent to the laboratory immediately, and if a delay in transit of more than 2 h is expected, the sample should be transported at 2 to 8°C, with the exception of blood, which should be transported under ambient conditions.

The appropriate specimen for culture of *Y. enterocolitica* and *Y. pseudotuberculosis* as well as other *Yersinia* species is stool, blood, or lymph nodes, depending on the disease form suspected. If food is suspected as the source of an outbreak, the local health department should be involved in processing of such specimens (see chapter 12). Maintain food at 4°C, and transport it as soon as possible. Swabs should be transported to the laboratory at 4°C in Cary-Blair, Amies, or Stuart's medium. Stool specimens can also be placed in transport media and should be maintained at 4°C if transport is expected to take longer than 2 to 4 h.

MICROSCOPY

Yersinia species are small (1 to 2 μm by 0.5 μm) gram-negative bacilli that appear either as single cells or as pairs or short chains, particularly when stains are prepared from liquid medium. Direct microscopy of a tissue specimen by using either Wright, Giemsa, Wayson's, or methylene blue stain may be helpful in presumptive identification of *Y. pestis* since the organisms appear to be safety pin shaped due to bipolar staining (Fig. 1). This morphology is not always evident following Gram staining or staining of colonies from culture media. Other, more specific direct staining methods include the use of fluorescently labeled antibody to the capsular F1 antigen, which is confirmatory for *Y. pestis*. However, rare strains of *Y. pestis* may lack the F1 antigen, and therefore the LcrV antigen, a key virulence factor that is secreted by the organism, has been used to develop a more sensitive diagnostic tool.

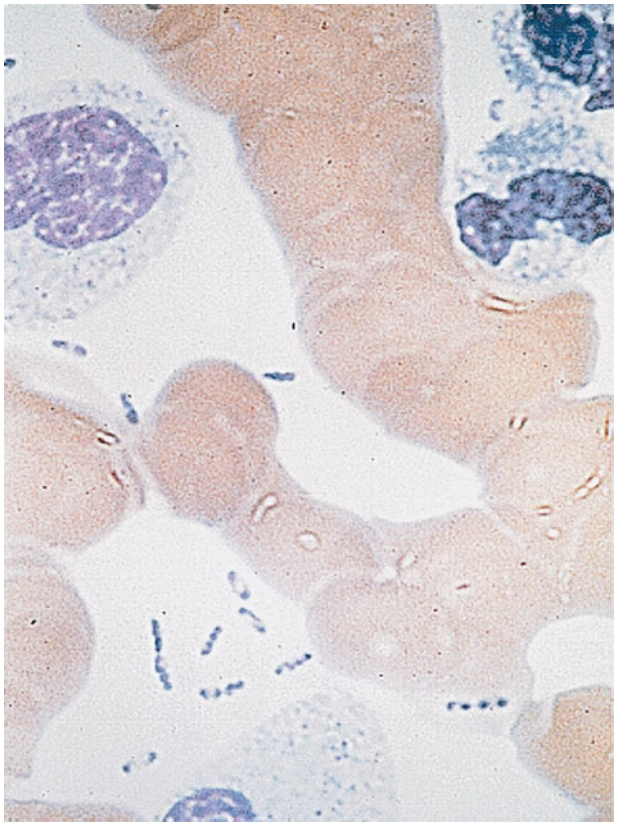

FIGURE 1 Giemsa stain of a blood smear from a patient with *Y. pestis* infection. Note the bipolar-staining "closed safety pin"-shaped cells. (Courtesy of the Centers for Disease Control and Prevention.)

DIRECT DETECTION

An antigen capture enzyme-linked immunosorbent assay (ELISA) using monoclonal antibody to the LcrV antigen detects as little as 0.5 ng of purified *Y. pestis* LcrV in blood or sputum (20). The only disadvantage is that the assay cannot distinguish *Y. pestis* from the other *Yersinia* species, although it would be less likely to find other species in respiratory specimens or blood cultures. A capture ELISA for detection of *Y. pestis* in bubo aspirates can also be applied to serum. This assay was tested on patients in Madagascar and was found to have a high sensitivity (100% with bubos and 90% with sera; limit of detection, 4 ng/ml) and specificity (approximately 99%) (52). Chanteau et al. modified the ELISA to use two different monoclonal antibodies, both directed at the F1 capsular antigen and designed in a dipstick format, to be used in the field for rapid diagnosis of plague in humans or animals (13). The only disadvantage of this assay is the inability to detect strains that lack the F1 capsule; however, this is a rare occurrence (53). Unfortunately, commercial sources for this antigen are not currently available.

Tissue biopsy specimens fixed in formalin can also be stained with an immunohistochemical stain that is based on a monoclonal antibody to the F1 capsular antigen of *Y. pestis*. This is a rapid method for diagnosis of plague that does not rely on having fresh tissue or live organisms (21).

Assays for the direct detection of nucleic acid in patient specimens have been developed to increase the sensitivity of detection of *Y. pestis*, especially in cases of suspected bioterrorism. Initial assays designed to detect the 16S rRNA gene were not found to be useful due to cross-reactivity with *Y. pseudotuberculosis* (45). The most sensitive assay at this time uses primers directed at the plasminogen activator gene (*pla*) that is located in a high copy number on a *Y. pestis*-specific plasmid. Development of a real-time PCR assay to detect the *pla* gene in sputum samples spiked with *Y. pestis* decreased the time to detection to 2 h and increased the sensitivity to 1.5 bacteria per ml (34). This assay also has the advantage of being useful for real-time diagnosis in the field in regions of the world where plague is endemic and culture methods are impractical (45). Following the sequencing of the entire genome of *Y. pestis* (42), so-called signature genes could be identified on the chromosome of *Y. pestis* that allow for its distinction from *Y. pseudotuberculosis* (63).

PCR has also been used as a sensitive method to detect small numbers of *Y. enterocolitica* in foodstuff (59), as well as in stored red blood cells to prevent transfusion reactions (49). Use of a multiplex PCR assay containing primer sets directed at four different virulence genes to test food samples allows for the distinction between pathogenic and nonpathogenic serotypes and specifically identifies the presence of *Y. enterocolitica* serotype O:3 (59).

ISOLATION PROCEDURES

Yersinia species grow on most routine media including blood, chocolate, and MacConkey agars incubated at 35°C in ambient air. Eosin-methylene blue, xylose-lysine-deoxycholate agar, and Hektoen enteric agars do not provide any advantage in the isolation of *Y. enterocolitica* and the differentiation of *Yersinia* species from other normal stool flora. Due to their ability to ferment sucrose and the fact that *Yersinia* species grow more slowly than most *Enterobacteriaceae*, a selective medium is recommended for specifically culturing for *Yersinia* from nonsterile sites. There are various selective media for the recovery of *Y. enterocolitica*, including cefsulodin-Irgasan-novobiocin (CIN) agar, which inhibits the growth of many other organisms from the family *Enterobacteriaceae*. Another selective medium is salmonella-shigella deoxycholate calcium chloride agar (17). CIN agar has been found to provide better recovery rates for *Yersinia* than either MacConkey or salmonella-shigella agar incubated at room temperature. Growth of many strains of *Y. pseudotuberculosis* can be inhibited on CIN agar, and therefore MacConkey agar is preferred for isolation.

Recovery of *Y. enterocolitica* from food is more difficult than recovery from human clinical specimens, and samples are usually referred to a public health laboratory (see chapter 12). Food must be enriched with saline (or a selective broth such as modified Rappaport broth containing magnesium chloride, malachite green, and carbenicillin [MRB]) at cold temperatures for approximately 21 days (2 to 4 days in MRB) (17).

Selective media are not commonly used for the isolation of *Y. pestis*, since when isolated from sterile sites organisms will grow on MacConkey agar and seem to be inhibited to some extent on CIN agar selective for *Y. enterocolitica*. Ber et al. developed a new medium, BIN (brain heart infusion supplemented with Irgasan, cholate salt, crystal violet, and nystatin), for the isolation of *Y. pestis* from specimens likely to be contaminated with normal flora, such as respiratory specimens (4), bubo aspirates, and stool specimens. Plates should be incubated at room temperature in 5% CO_2 for fastest growth. Cultures from suspected plague patients should be incubated for 5 days and up to 7 days if the patient has been treated for more than a few days with an appropriate antimicrobial.

Acute and convalescent serum samples should be collected for serologic testing from pretreated patients for whom cultures do not grow after this period of time.

Y. pestis colonies are slow growing and are only 1 to 2 mm in diameter after 48 h of incubation, with an irregular, "hammered copper" appearance. No hemolysis is seen on blood agar media. Viewed with a dissecting microscope, the colonies are raised with irregular edges, appearing as a "fried egg" (Fig. 2). Organisms growing in broth appear in clumps along the side of the tube in flocculant or stalactite-like formations if the tube is not shaken. After 24 h of incubation, the clumps settle to the bottom of the tube. Colonies of *Y. pestis* growing on BIN agar have a bluish color in the center and a transparent precipitate around the colony.

Colonies of *Y. enterocolitica* have a bull's eye appearance with a red center on CIN agar. Other members of the *Enterobacteriaceae* family, which grow on CIN agar, such as *Serratia*, *Morganella,* and *Citrobacter* spp., produce colonies similar in appearance to those of *Yersinia*, but larger. The use of pectin agar has also been described for isolation of *Y. enterocolitica* from stool and differentiation from other *Enterobacteriaceae*. Although the medium was more sensitive than other currently used selective media and the only other member of the family able to grow and demonstrate a similar colony morphology was *Klebsiella oxytoca,* the medium is not currently commercially available (9).

IDENTIFICATION

Yersinia are catalase positive and oxidase negative and ferment glucose, as do all other members of the family *Enterobacteriaceae*. *Y. enterocolitica* and *Y. pseudotuberculosis* can be presumptively identified by reactions on triple sugar iron (TSI) and lysine iron agar slants. *Y. enterocolitica* produces a yellow color in the entire TSI tube without gas production, and *Y. pseudotuberculosis* produces an alkaline slant and an acid butt, similar to *Shigella*. Both species are lysine decarboxylase negative and therefore produce a yellow butt in lysine iron agar slants. *Yersinia* species are included in the databases of some automated systems; however, most species have not been thoroughly evaluated due to the small number of *Yersinia* isolates tested. Although *Y. pestis* is included in the databases of many of the manual and automated systems (41), commercial systems may not adequately identify *Yersinia* species (particularly *Y. pestis*) due in part to their slow growth and biochemical inactivity. In addition, *Y. pestis* has been misidentified as *Y. pseudotuberculosis* and as *Shigella, Salmonella,* and *Acinetobacter* species. API 20E was shown to have the highest sensitivity and specificity for the identification of *Y. enterocolitica* and *Y. pseudotuberculosis* (39). A miniaturized, automated system (MICRONAUT; Merlin, Bornheim-Hersel, Germany) available only outside of the United States shows promise in the identification of *Yersinia* species based on enzyme reactivity (38).

Presumptive identification of *Y. pestis* is based on the detection of bipolar-staining, small gram-negative bacilli forming pinpoint colonies after 24 h on blood, with better growth at 28 than at 35°C, and non-lactose-fermenting colonies on MacConkey agar that are catalase positive and indole, oxidase, and urease negative. See "Basic Protocols for Sentinel Laboratories" on the American Society for Microbiology website for specific information, pictures, and flowcharts (http://www.asm.org/Policy/index.asp?bid=520). Following presumptive identification, routine clinical laboratories should notify the local public health laboratory and refer the isolate for confirmatory testing. *Y. pseudotuberculosis* can be differentiated from *Y. pestis* by negative urease activity.

Y. pestis can further be separated into biovars based on phenotypic methods. Biovars Antiqua and Medievalis are glycerol and arabinose positive, and biovar Antiqua is nitrate positive and biovar Medievalis is negative. Biovar Orientalis is glycerol negative and arabinose and nitrate positive, and the newest biovar, Microtus, is glycerol positive and arabinose and nitrate negative (65).

Presumptive identification of *Y. enterocolitica* can be made based on typical morphology on CIN agar, reactivity on TSI agar, and urease positivity. Identification of the other *Yersinia* species can be performed by biochemical analysis (Table 1).

Y. enterocolitica has six biogroups which can be differentiated based on reactivity to esculin, indole, D-xylose, trehalose, pyrazinamidase, β-D-glucosidase, and lipase. Although the issue is controversial, biogroup 1A is thought to be nonpathogenic and biotypes 1B and 2 through 5 are pathogenic. Strains belonging to biotype 1A can be differentiated from the

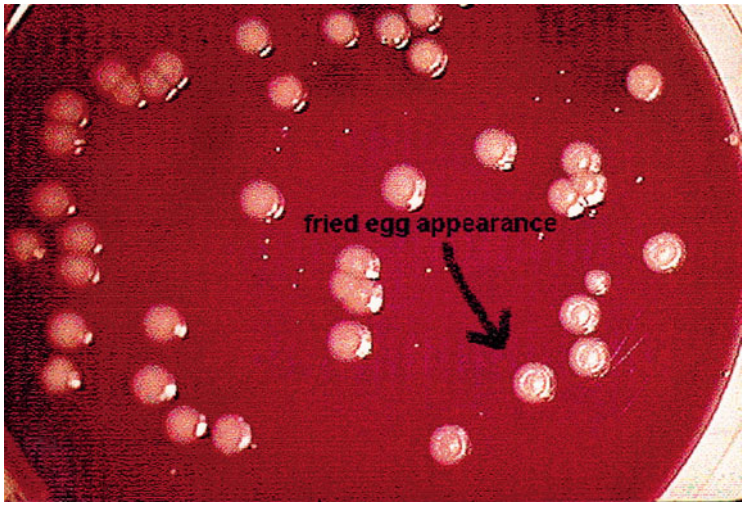

FIGURE 2 Typical fried egg-shaped colonies of *Y. pestis* on sheep blood agar. (Courtesy of the Centers for Disease Control and Prevention.)

TABLE 1 Biochemical reactivity of *Yersinia* species[a]

Yersinia species	Reaction or characteristic[b]

others by salicin and pyrazinamidase positivity (Table 2) (25). Serotyping could also help determine the pathogenicity of the isolate since only 11 of the 60 known serotypes are pathogenic; however, antisera are not readily available. Other methods that have been evaluated to determine the pathogenicity of *Y. enterocolitica* are based on the presence of the virulence plasmid and include autoagglutination, calcium dependency testing, and Congo red binding. Selective media containing Congo red as well as PCR assays have been evaluated for differentiation of virulent from avirulent strains but are currently being used only in research laboratories (5, 60).

TYPING SYSTEMS

Methods used for the evaluation of the relatedness of *Yersinia* species include serotyping, biotyping, antibiogram analysis, and bacteriophage typing as well as genetic methods. *Y. enterocolitica* can be divided into six biogroups, 1A, 1B, 2, 3, 4, and 5, by using biochemical analysis. These biogroups vary in geographic locations and pathogenic potentials (50). *Y. enterocolitica* also contains more than 70 serotypes, although serotyping is not often performed in routine clinical laboratories since the antisera are not readily available. Pulsed-field gel electrophoresis has long been considered the "gold standard" for typing of *Yersinia* species. Pulsed-field gel electrophoresis was found to be a more useful tool than ribotyping for typing of pathogenic isolates of *Y. enterocolitica* (59). Patterns generated by the restriction enzyme NotI alone or combined with ApaI and XhoI were highly discriminatory (36).

Recently, MLEE has been evaluated for its discriminatory power among *Yersinia* species. Sequencing of a single gene unique to an organism, such as 16S rRNA, has also been used for strain analysis of *Yersinia* species (30). An approach that combines the ease of MLEE testing with the specificity of genome sequencing is MLST. Comparing the sequences of multiple unique genes allows for better discrimination than comparing only 16S rRNA. This technique has recently been applied to *Yersinia* (2). MLST analysis of a large collection of *Yersinia* species was further studied by Kotetishvili et al. (30). With the use of six genes, all of the *Y. pestis* isolates appeared to be homogeneous and also were found to be identical to *Y. pseudotuberculosis*. Most of the other species of *Yersinia* tested also appeared to be homogeneous, with the exception of *Y. enterocolitica*, *Y. frederiksenii*, *Y. kristensenii,* and *Y. mollaretii,* which were more heterogeneous.

SEROLOGIC TESTS

The gold standard for the diagnosis of plague is isolation of the organism from blood or aspirate; however, serology can play a role, particularly for retrospective diagnostic and epidemiologic studies in areas where plague is endemic (46). Most patients with plague seroconvert 1 to 2 weeks following the onset of symptoms (47). Diagnosis can be made based only on a fourfold rise in antibody titers between acute and convalescent serum samples. Assay methods include passive hemagglutination, which is the method recommended by the World Health Organization due to its low cost and ease of performance. However, the assay lacks both sensitivity and specificity due to lack of standardization and lack of commercialization of reagents. The most commonly used antigen in serologic assays for *Y. pestis* is the capsular F1 antigen, which is a highly immunogenic, stable antigen and present in high concentrations in sera and bubo fluids of plague patients even after several days of appropriate antimicrobial therapy.

TABLE 2 Biotypes of *Y. enterocolitica*[a] after incubation at 25°C for 48 h

[b] +, ≥90% of strains positive; d, 11 to 89% of strains positive; −, ≥90% of strains negative; (+), weakly positive reaction.

[c] According to Kandolo and Wauters (27a).

Other assays include ELISA, which is not standardized either and must be confirmed by using a Western blot assay.

Serology can be used as an adjunct in the diagnosis of disease due to *Y. enterocolitica* or *Y. pseudotuberculosis*. Antibody is detectable within the first week of illness and returns to normal levels 3 to 6 months later. The specificity of serologic assays ranges from 82 to 95% due to cross-reactivity between the two species and also with *Brucella*, *Franciscella,* and *Vibrio* species, *Borrelia burgdorferi, Chlamydia pneumoniae,* and some *Escherichia coli* serogroups. Another disadvantage of using serology for diagnosis is that antibodies to *Y. enterocolitica* O antigens can be found in many normally healthy patients due to the frequency of exposure to nonpathogenic serotypes. Most human infections with *Y. enterocolitica* involve serotypes O:3, O:5, 27, O:8, and O:9. Serotype O:3 is the most common cause of gastroenteritis. However, as mentioned above, antisera are available only to public health and research laboratories.

Antibody to outer membrane proteins (Yops) that are present only in virulent strains of *Y. enterocolitica* may be more helpful. In a small study of normally healthy blood donors, immunoglobulin M (IgM) antibody to Yops was 97% specific for acute infection (57). Testing of blood donors for anti-Yop IgA in New Zealand, which has a high incidence of *Y. enterocolitica* gastroenteritis, showed promise in preventing transfusion-related infections (28). The presence of IgG and IgA antibodies to *Y. enterocolitica* Yops is also used as an aid in the diagnosis of autoimmune disorders that occur post-infection, such as reactive arthritis, erythema nodosum, Graves' disease, and Hashimoto's thyroiditis (14). Increased sensitivity and specificity are seen with the Western blot assay compared to complement fixation and ELISA; however, cross-reactivity is still seen, particularly with *B. burgdorferi*, which can be associated with arthritis that is clinically indistinguishable from that due to *Y. enterocolitica* (47).

ANTIMICROBIAL SUSCEPTIBILITIES

Pneumonic plague is nearly 100% fatal if not treated within the first 24 h of development of symptoms. The drug of choice for the treatment of plague, pneumonic, septicemic, or bubonic, is streptomycin. However, due to the lack of availability of streptomycin and the threats of *Y. pestis*'s being used as an agent of bioterrorism, other agents have been evaluated in vitro and in animal models. The only other antibiotic currently approved for treatment of plague is doxycycline; however, other alternatives would be gentamicin and a fluoroquinolone (8). Antibiotic resistance among isolates of *Y. pestis* has been described, but only in rare case reports of resistance to tetracycline or streptomycin. Fluoroquinolone resistance has been induced in vitro, but naturally occurring resistance has not been documented (16). Steward et al. documented the efficacy of fluoroquinolones in the mouse model of systemic and pneumonic plague (55). Rapid detection of ciprofloxacin-resistant strains of *Y. pestis* can be accomplished by using real-time PCR and assessing point mutations in the DNA gyrase gene (32). An isolate of *Y. pestis* from a single infected patient in Madagascar was found to be multidrug resistant, with resistance to streptomycin, sulfonamides, tetracycline, and chloramphenicol (19). The treatment of choice for plague meningitis is chloramphenicol.

Most cases of *Y. enterocolitica* gastroenteritis do not require treatment; however, treatment is necessary in cases of systemic disease, especially in immunosuppressed patients. Treatment options include trimethoprim-sulfamethoxazole and a fluoroquinolone. *Y. enterocolitica* produces two different β-lactamases, one of which is a class A constitutive enzyme and the other of which is an inducible class C enzyme that is not inhibited by β-lactamase inhibitors. The presence of one or both of these enzymes varies depending on the biogroup (10). Although the β-lactamase confers resistance to penicillin on *Y. enterocolitica,* the organism remains uniformly susceptible to the extended-spectrum cephalosporins (44). Resistance to fluoroquinolones is due to either a mutation in the *gyrA* gene or efflux mechanisms. In a study conducted in Spain, 23% of *Y. enterocolitica* strains isolated from patients with gastroenteritis were nalidixic acid resistant. All resistant isolates had a mutation in *gyrA,* and some were resistant based on an efflux mechanism as well (10). *Y. enterocolitica* strains are susceptible in vitro to aminoglycosides, chloramphenicol, tetracycline, trimethoprim-sulfamethoxazole, and extended-spectrum cephalosporins.

Y. pseudotuberculosis is susceptible to ampicillin, tetracycline, chloramphenicol, cephalosporins, and aminoglycosides. Although infections due to *Y. pseudotuberculosis* are not usually treated, patients with septicemia should be treated with ampicillin, streptomycin, or tetracycline.

Y. aldovae and *Y. ruckeri* are also susceptible to penicillin. *Y. frederiksenii*, *Y. intermedia,* and *Y. rhodei* produce a β-lactamase similar to that of *Y. enterocolitica*, which is expressed at different levels in different strains (56).

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

Y. pestis, *Y. enterocolitica,* and *Y. pseudotuberculosis* are the primary pathogens in the genus *Yersinia.* Isolation of *Y. pestis* from any body site warrants further investigation. Isolation of *Y. enterocolitica* or *Y. pseudotuberculosis* from stool culture is not sufficient for causal evidence of disease since nonpathogenic serotypes may be normal stool flora. However, no readily available methods except those using routine biochemicals, which are not usually maintained in routine clinical laboratories, are available for differentiation of pathogenic serotypes. Isolation of either species in pure culture from a symptomatic patient with no other diagnosis should be considered suspect. Isolation of either species from blood or other normally sterile sites should also be considered significant.

It has not been shown to be cost-effective to screen all stools for *Y. enterocolitica* by using CIN agar. Isolation rates vary based on geographic locations, with the highest incidence in the colder portions of the country (27), so the decision to routinely rule out these organisms in stool cultures should be evaluated in individual laboratories after consultation with the infectious disease physicians.

Although the other *Yersinia* species besides *Y. pestis*, *Y. enterocolitica,* and *Y. pseudotuberculosis* are not considered human pathogens, they have been isolated from the gastrointestinal tracts of symptomatic patients with no other diagnosis. It has been recommended that the presence of these *Yersinia* species in pure culture be reported and that antibiotic susceptibility testing be performed to assess these organisms' pathogenic potentials. These organisms may be underrecognized pathogens (33).

Due to the lack of accuracy of commercial systems for the identification of *Y. pestis* and the implications related to bioterrorism with its identification, isolates should be sent to a local public health laboratory for confirmation.

Klebsiella, Enterobacter, Citrobacter, Serratia, Plesiomonas, and Other *Enterobacteriaceae*

SHARON L. ABBOTT

45

TAXONOMY

Taxonomic changes within the *Enterobacteriaceae* have become commonplace and undoubtedly will continue at a rapid pace for the foreseeable future. Three major taxonomic changes in the *Enterobacteriaceae* included in the eighth edition of this Manual merit mention again. The oxidase-positive organism, *Plesiomonas shigelloides,* which clusters with *Proteus* in phylogenetic studies using 16S and 5S rRNA sequencing is now a member of the family *Enterobacteriaceae* (98, 99, 125). The *Enterobacteriaceae* will be redefined in the next edition of *Bergey's Manual* to accommodate an oxidase-positive organism and other organisms that defy the traditional definition of this family. Inclusion of *Calymmatobacterium granulomatis,* a nonculturable organism causing a sexually transmitted disease, in the genus *Klebsiella* as *K. granulomatis* was another major change (28, 85). This move was based on 16S rRNA and *phoE* gene sequencing. Lastly, it should be remembered that *Enterobacter agglomerans* now resides in the genus *Pantoea; P. agglomerans* remains heterogeneous at the DNA level (46). Members of the *Enterobacteriaceae* covered in this chapter, including new taxa or taxonomic changes, are listed in Tables 1 and 2. When laboratories adopt taxonomic changes, which are dictated by common usage in the literature, the older epithet should be included in parentheses following the new name.

Because of the genetic heterogeneity within the genus, taxonomic changes occur frequently in *Enterobacter*. To start, two new species, *E. radicincitans* and *E. ludwigii,* have been added to the genus (64, 81). *E. radicincitans* is a plant growth-promoting bacterium isolated from the phyllosphere of wheat, and *E. ludwigii,* which is isolated from human clinical specimens, was formerly a genomovar within the *E. cloacae* complex. Two other clusters of organisms previously included in the *E. cloacae* complex are now subspecies of *E. hormaechei*. Strains previously known as *E. hormaechei* are now subsp. *hormaechei,* and there are two newly created subspecies, subsp. *oharae* and subsp. *steigerwaltii;* all three subspecies are isolated from human clinical specimens from multiple sites and from plants (63). *Enterobacter intermedius,* which clustered with the type strain of *Kluyvera cochleae* by 16S rRNA sequencing, has been moved to the genus *Kluyvera* (118). The older legitimate epithet, *intermedius,* has replaced *cochleae* as the species name, resulting in the new designation *Kluyvera intermedia*. *E. dissolvens,* which was previously suspected to belong in *E. cloacae,* is now *E. cloacae* subsp. *dissolvens;* strains formerly known as *E. cloacae* are now *E. cloacae* subspecies *cloacae* (62). *E. cloacae* remains a heterogeneous species with several DNA groups residing within it, and as with *P. agglomerans* groups, these groups remain unnamed because they are not separable by phenotypic tests (61). *Hafnia alvei* is composed of two distinct DNA hybridization groups, and studies are in progress to name DNA hybrization group 2 (74).

Several additions have been proposed for the genus *Serratia*. *S. marcescens* subsp. *sakuensis* is a strain isolated from activated sludge from a wastewater treatment plant in Japan and reportedly is a spore former; strains known as *S. marcescens* assume subspecies status as subsp. *marcescens* (2). Of the two new species added to *Serratia,* one is a urea-utilizing organism isolated from water in India, named *S. ureilytica,* of which only a single strain is known, and the other is a nonculturable symbiont found in aphids and provisionally designated "*Candidatus* Serratia symbiotica" (17, 104).

In the genus *Klebsiella,* a group of nitrogen-fixing strains isolated from plants (banana, rice, sugar cane, and maize) and human clinical samples, primarily blood, have been named *K. variicola* (124). A second new species, *K. singaporensis,* has been proposed for a single strain isolated from soil collected from sugar cane roots in Singapore (93).

Two new species have been created within the genus *Photorhabdus, P. temperata* and *P. asymbiotica,* and three subspecies (*luminescens, laumondii,* and *akhurstii*) were described for the existing species, *P. luminescens* (43). *P. temperata,* like *P. luminescens,* is a symbiont of nematodes that causes disease in insects. However, *P. asymbiotica* contains only isolates from human infections and has two subspecies, *asymbiotica* and *australis,* isolated in the United States and Australia, respectively (3). Four new species, all symbionts in entomopathogenic nematodes, have been proposed for the genus *Xenorhabdus* including *X. budapestensis, X. ehlersii, X. innexi,* and *X. szentirmaii* (92).

Two new genera, *Averyella* and *Dickeya*, have been proposed for the *Enterobacteriaceae* (78, 127). *Averyella dalhousiensis* strains, previously known as enteric group 58, are isolated primarily from human wound specimens, although the organism was recently isolated from blood (78). The genus *Dickeya* includes two species transferred from *Pectobacterium (chrysanthemi)* and *Brenneria (paradisiaca)* as well as four novel species *(dadantii, dianthicola, dieffenbachiae,*

TABLE 1 Nomenclature, isolation source, and significance of selected genera of the family *Enterobacteriaceae*[a]

Current (previous) designation	Clinical data			Environmental data
	Frequency	Source	Significance	
Averyella dalhousiensis (enteric group 58)	Unk	Wound, blood	2	Unk
Citrobacter				
C. amalonaticus	++	**Feces,** blood, wound, UT, RT	2	Unk, one isolate from an animal
C. braakii	++	**Feces,** UT, wound	2	Similar to *C. freundii*
C. farmeri (*C. amalonaticus* biogroup 1)	++	**Feces,** UT, blood, wound, RT	2	Unk
C. freundii	++++	All sites, feces most common	1	Water, soil, fish, animals, food
C. koseri (*C. diversus*)	++	All sites, CSF most common	1	Unk
C. rodentium	−			Pathogenic for mice
C. sedlakii	+	Feces, UT, blood, wound	3	Same as for *C. braakii*
C. werkmanii	+	**Feces,** blood, wound	3	Same as for *C. braakii*
C. youngae	+++	**Feces,** UT, blood, wound	3	Same as for *C. braakii*
C. gillenii (*Citrobacter* DNA group 10)	+	**Feces,** UT, blood	3	Same as for *C. braakii*
C. murlinae (*Citrobacter* DNA group 11)	+	Feces, blood, UT, wound	3	Same as for *C. braakii*
Enterobacter				
E. aerogenes	++++	All sites	1	Water, soil, sewage, animals, dairy products
E. amnigenus biogroup 1	−			Plants
E. amnigenus biogroup 2	−			Water
E. asburiae	++	**UT,** RT, feces, wound, blood	2	Water
E. cancerogenus (*E. taylorae*)	++	**Wound,** RT, feces	2	Animals, water
E. cloacae subsp. *cloacae*	++++	All sites	1	Water, soil, sewage, meat
E. cloacae subsp. *dissolvens* (*Enterobacter dissolvens*)	−			Diseased corn stalks
E. cowanii (*P. agglomerans*/ Japanese NIH group 42)	Unk	UT, RT, blood, wound	3	Unk
E. gergoviae	++	RT, UT, blood	2	Water, cosmetics
E. hormaechei subsp. *hormaechei*	++	RT, wound, blood	1	Unk, one isolate from a frog
E. hormaechei subsp. *oharae*	++	All sites	1	Plants
E. hormaechei subsp. *steigerwaltii*	++	All sites	1	Plants
E. kobei	Unk	Unk	Unk	Food
E. ludwigii (*E. cloacae*)	Unk	UT, RT, blood, stool	2	Food
E. nimipressuralis (*Erwinia*)	−			Diseased elms
E. pyrinus (*Erwinia*)	−			Diseased pear trees
E. radicincitans	−			Phyllosphere of winter wheat
E. sakazakii	++	RT, wound, CSF	1	Unk
Hafnia alvei DNA Group 1 and DNA Group 2	++	**Feces,** blood, RT	2	Ubiquitous
Klebsiella				
K. pneumoniae	++++	All sites, RT and UT most common	1	Ubiquitous, including foods and water
K. granulomatis (*Calymmatobacterium*)	++	Genital tract	1	None
K. pneumoniae subsp. *ozaenae*	++	**Nasal discharge,** RT, UT, blood	1	Unk
K. pneumoniae subsp. *rhinoscleromatis*	++	Nasal discharge	2	Unk
K. oxytoca	++++	All sites	2	Ubiquitous, including foods and water
K. variicola	++	Blood	1	Plants
K. singaporensis	−			Soil

(Continued on next page)

TABLE 1 Nomenclature, isolation source, and significance of selected genera of the family *Enterobacteriaceae*[a] *(Continued)*

Current (previous) designation	Clinical data			Environmental data
	Frequency	Source	Significance	
Morganella morganii subsp. *morganii* and subsp. *sibonii*	++	All sites	1	Unk, isolations from mammalian and reptile gastrointestinal tracts
Pantoea agglomerans (*Enterobacter*)	+++	All sites	2	Plants
Photorhabdus	++	Wound	2	Unknown, possibly insects
P. asymbiotica subsp. *asymbiotica* and subsp. *australis*				
P. luminescens	−			Nematodes infecting insects
P. temperata	−			Nematodes infecting insects
Plesiomonas shigelloides	+++	**Feces,** blood	1	Aquatic habitats and animals
Proteus				
P. hauseri (*P. vulgaris* genomospecies 3)	+	Unk	Unk	Unk, probably like *P. mirabilis*
P. mirabilis	++++	**UT,** blood, CSF	1	Animals, birds, fish, foods
P. myxofaciens	−			Gypsy moth
P. penneri	++	**UT,** blood, wound, feces, eye	1	Probably similar to *P. mirabilis*
P. vulgaris	+++	**UT,** wound, stool, RT	1	Probably similar to *P. mirabilis*
Providencia				
P. alcalifaciens	+++	All sites, UT and feces common	1	Mammals, water
P. heimbachae	+	Feces	3	Penguins
P. rettgeri	+++	All sites, UT most common	1	Same as for *P. alcalifaciens*, insects
P. rustigianii	+	Feces	3	Unk
P. stuartii	+++	All sites, UT most common	1	Mammals
Raoultella				
R. ornithinolytica (*Klebsiella*)	+	Wound, UT, blood	2	Food
R. planticola (*Klebsiella*)	Unk	Similar to *K. pneumoniae*?	3	Plants, water
R. terrigena (*Klebsiella*)	Unk	Similar to *K. pneumoniae*?	3	Soil, water
Serratia				
S. entomophila	−			New Zealand grass grub, water
S. ficaria	+	RT, wound	3	Fig wasps, figs, plants
S. fonticola	+	**Wound,** RT	3	Water, birds
S. liquefaciens complex (*S. liquefaciens* sensu stricto, *S. proteamaculans*, *S. grimesii*)	+++	RT, wound	2	Plants, insects, mammals, birds, dairy products
S. marcescens subsp. *marcescens*	++++	All sites, RT most common	1	Water, soil, plants, vegetables, animals, insects
S. marcescens subsp. *marcescens* biogroup 1	+	**UT,** RT	2	Unk
S. marcescens subsp. *sakuensis*	−			Wastewater
S. odorifera biogroup 1 and biogroup 2	+	RT, wound, feces, blood, UT	2	Plants
S. plymuthica	+	RT	3	Water, plants, small mammals
S. rubidaea	+	RT, wound, blood, UT, feces	2	Water, plants
S. ureilytica	−			Water
"*Candidatus* Serratia symbiotica"	−			Aphid symbiont

[a] Abbreviations and symbols: ++++, frequent; +++, occasional; ++, rare; +, very rare; −, not yet isolated from humans; CSF, cerebral spinal fluid; RT, respiratory tract; Unk, unknown; UT, urinary tract; 1, major pathogenic species of humans; 2, proven cause of disease in rare instances; 3, isolated from humans, significance unknown. Bold denotes most common source. Data are from references 2, 3, 17, 21, 23, 37, 42, 46, 50, 51, 52, 68, 71, 74, 78, 89, 97, 104, 106, 111, 112, 113, 118, 130, and 133.

Cedecea genomospecies 5		"*Candidatus* Regiella insecticola"[e] (104)
Kluyvera ascorbata		"*Candidatus* Phlomobacter fragariae"[f] (147)
Kluyvera cryocrescens		*Dickeya* species[f] (127)
Kluyvera georgiana		*Erwinia* species[b,f] (79, 114, 129)
Leclercia adecarboxylata		*Edwardsiella ictaluri*[d] (58)
Leminorella grimontii		*Kluyvera intermedia*[f] (*Enterobacter intermedius* and *Kluyvera cochleae*) (105, 118)
Leminorella richardii		*Obesumbacterium proteus*[c] (71)
Leminorella genomospecies 3		*Pantoea* species[b,c,f] (33, 57 ,80)
Moellerella wisconsensis		*Pectobacterium* species[f] (57)
Rahnella aquatilis		*Samsonia erythrinae*[f] (134)
Rahnella genomospecies 2 (22)		*Sodalis glossinidius*[e] (32, 100)
Rahnella genomospecies 3		*Wigglesworthia glossinidia*[e] (4)
Tatumella ptyseos		*Xenorhabdus* species[e] (18, 92)
Yokenella regenburgei		

[a] References are given in parentheses. Genomospecies listed cannot be biochemically separated from other species within their genus and/or only a single strain exists.
[b] Rare human isolates of no, or questionable, significance.
[c] Environmental isolates.
[d] Fish, marine, animal, or bird isolates.
[e] Insect isolate or pathogen.
[f] Plant isolate or phytopathogens.

and *zeae); Dickeya* species are not isolated from human specimens (127).

Miscellaneous genera within the *Enterobacteriaceae* are given in Table 2. Numbered genomospecies designations within a genus are given when they are comprised of a single strain, if too few organisms exist to be named, or if they cannot be differentiated from other members of their genus with available phenotypic tests. The genera listed in the last two columns of Table 2 are not isolated from human clinical specimens or are isolated but may not be significant, and most of these taxa will be unfamiliar to clinical microbiologists. However, it should be noted that a *Pantoea dispersa*-like organism and a strain of *Pantoea ananatis* have been reported recently from bacteremic patients (33, 129). *Erwinia persicinus* and *Buttiauxella gaviniae* have been isolated from a urinary tract infection (UTI) and a spinal cord patient with urinary bladder pathology, respectively (34, 114). A number of the organisms in the third column cannot be grown on laboratory media, so they are unlikely to be confused with, or necessitate separation from, those genera seen in humans. References have been included for those organisms that are isolated only from nonhuman sources, and they will not be discussed further.

DESCRIPTION OF GENERA
