Persons undergoing organ or bone marrow transplantation can benefit from pretransplant testing for *Toxoplasma*-specific IgG antibodies to determine immune status because they are at risk for either acute acquired infection if they are seronegative before transplantation, or at risk for reactivation if they are seropositive before transplantation (78). Those with acute acquired infection usually develop detectable *Toxoplasma*-specific IgG and IgM antibodies, while those with reactivation do not have a detectable *Toxoplasma*-specific IgM response. Seronegative transplant recipients of hearts from seropositive donors can develop toxoplasmic myocarditis that mimics organ rejection.

Toxoplasmic encephalitis is the most frequent CNS opportunistic infection of AIDS patients and is uniformly fatal if untreated. Among AIDS patients who died from 1992 through 1997 in the United States, 7.2% developed toxoplasmic encephalitis during the course of the syndrome (41). It is recommended that all HIV-infected persons be tested for *Toxoplasma*-specific IgG antibodies soon after the diagnosis of HIV infection to detect latent infection (4). If they are *Toxoplasma* seropositive, adult or adolescent patients who have a $CD4^+$ T-lymphocyte count of $<100/\mu l$ should be administered prophylaxis against toxoplasmic encephalitis with trimethoprim-sulfamethoxazole (TMP-SMZ). Most AIDS patients with toxoplasmic encephalitis have demonstrable IgG antibodies to *T. gondii*. However, approximately 3% of AIDS patients with toxoplasmic encephalitis do not have *Toxoplasma*-specific antibody in their serum. Local production of *Toxoplasma*-specific IgG antibody in CSF has been demonstrated for persons with AIDS and with toxoplasmic encephalitis (10). When the formula described above for toxoplasmosis in the newborn is used, a result of >1 corresponds to significant antibody production.

TREATMENT

In general, physicians treat *T. gondii* infection in four circumstances: (i) pregnant women with acute infection to prevent fetal infection (11, 17, 36); (ii) congenitally infected infants (31, 51); (iii) immunosuppressed persons, usually with reactivated disease (6, 7, 40, 49, 52); and (iv) acute and recurrent ocular disease (19, 37, 75, 76). Drugs are also prescribed for preventive or suppressive treatment in HIV-infected persons (4). The currently recommended drugs work primarily against the actively dividing tachyzoite form of *T. gondii* and do not eradicate encysted organisms (bradyzoites).

The most common drug combination used to treat congenital toxoplasmosis consists of pyrimethamine and a sulfonamide (sulfadiazine is recommended in the United States), plus folinic acid in the form of leucovorin calcium to protect the bone marrow from the toxic effects of pyrimethamine. Pyrimethamine inhibits dihydrofolate reductase, which is important in the synthesis of folic acid and produces a reversible depression of the bone marrow. Sulfonamines inhibit synthesis of dihydrofolic acid, also important in the synthesis of folic acid. The two drugs work synergistically against *T. gondii*. Due to toxicity, pyrimethamine and sulfadiazine therapy is generally recommended for use in pregnant women after the 17th week of gestation (55, 66). After the 18th week, pyrimethamine and sulfadiazine may be given if fetal infection is confirmed by amniocentesis or cordocentesis. Spiramycin (available through the FDA; phone: 301-796-1600) is recommended for pregnant women with acute toxoplasmosis when fetal infection has not been confirmed in an attempt to prevent transmission of *T. gondii* from the mother to the fetus (55, 66). Randomized prospective studies of treatment during acute infection in pregnant women have not been performed. Some researchers have questioned, or been unable to demonstrate, the effectiveness of treatment during pregnancy in preventing congenital infection (28, 84) or sequelae in infants (27). One hypothesis for the lack of effectiveness is that *T. gondii* tachyzoites transform into bradyzoites within days of infection, probably coinciding with the serological and cell-mediated responses (27). Therefore, by the time an infection is detected in a pregnant woman tachyzoites may have already been transmitted to the fetus, inflicted damage, and been converted to encysted bradyzoites that do not respond to therapy. Nevertheless, a multicenter observational study found that the treatment of acute *T. gondii* infection in pregnancy was associated with a reduction of sequelae in infants, but not a reduction in maternal-fetal transmission (24).

Pyrimethamine and sulfadiazine (plus leucovorin) are the drugs generally used to treat infants with congenital toxoplasmosis and have led to improved outcomes compared with historic controls (51, 66).

In immunosuppressed persons with toxoplasmosis, a regimen of pyrimethamine and sulfadiazine plus leucovorin is the preferred treatment (6, 7, 52, 55). Clindamycin is a second alternative for use in combination with pyrimethamine and leucovorin for those who cannot tolerate sulfonamides (6, 7, 12, 49, 55). Leucovorin prevents the hematologic toxicities associated with pyrimethamine therapy. Atovaquone in combination with either pyrimethamine or sulfadiazine has sufficient activity to be considered for treatment in some less severely affected adult patients (8, 55). The role of other drugs in the treatment of systemic toxoplasmosis has not been defined by controlled trials. In general, alternative drugs such as azithromycin, clarithromycin, and dapsone should be used in combination with another drug, preferably pyrimethamine (52).

Because relapse often occurs after toxoplasmosis in HIV-infected patients, maintenance therapy (secondary prophylaxis) with pyrimethamine plus sulfadiazine (first choice) or pyrimethamine plus clindamycin (alternative) is recommended for the patient (4). Secondary prophylaxis for toxoplasmosis may be discontinued in patients with a sustained increase in $CD4^+$ counts (e.g., 6 months) to >200 cells/μl in response to highly active antiretroviral therapy if the patient has completed the initial therapy and has no symptoms or signs attributable to toxoplasmosis. For prophylaxis to prevent an initial episode of *T. gondii* in *Toxoplasma*-seropositive persons with a $CD4^+$ T-lymphocyte counts less than 100 cells/μl, trimethoprim-sulfamethoxazole is recommended as the first choice with alternatives consisting of dapsone plus pyrimethamine, or atovaquone with or without pyrimethamine. Leucovorin is given with all regimens including pyrimethamine (4).

Pyrimethamine and sulfadiazine are often used for persons with ocular disease (38). Clindamycin, in combination with other antiparasitic medications, is also frequently prescribed for ocular disease (19). A variety of newer agents have been tried in the treatment of ocular toxoplasmosis including atovaquone (61), rifabutin, trovafloxacin, azithromycin, and clarithromycin (39). In addition to antiparasitic drugs, physicians may add corticosteroids to reduce ocular inflammation. However, the optimal treatment for ocular toxoplasmosis remains to be defined by controlled trials.

Pathogenic and Opportunistic Free-Living Amebae

GOVINDA S. VISVESVARA

139

BACKGROUND

Small, free-living amebae belonging to the genera *Naegleria, Acanthamoeba,* and *Balamuthia* have been identified as agents of central nervous system (CNS) infections of humans and other animals (6, 8, 10, 13, 17, 19, 23, 24, 26–31, 36, 43, 52, 53, 55). Only one species of *Naegleria (Naegleria fowleri)*, several species of *Acanthamoeba* (e.g., *Acanthamoeba castellanii, A. culbertsoni, A. hatchetti, A. healyi, A. polyphaga, A. rhysodes, A. astronyxis,* and *A. divionensis*), and the only known species of *Balamuthia, Balamuthia mandrillaris,* are known to cause disease. *Acanthamoeba* spp. also cause infection of the human cornea, *Acanthamoeba* keratitis (4, 11, 21, 35, 47, 48, 54, 56). Additionally, both *Acanthamoeba* spp. and *B. mandrillaris* have been identified as agents of cutaneous infections in humans (5, 32, 45, 46). According to a recent report, *Sappinia diploidea,* a free-living ameba normally found in soil contaminated with the feces of elk and buffalo, was identified in an excised brain lesion from a 38-year-old immunocompetent man who developed a bifrontal headache, blurry vision, and loss of consciousness following a sinus infection. This finding clearly indicates that there are probably other small amebae that may also cause encephalitis in humans (15).

N. fowleri and *Acanthamoeba* spp. are commonly found in soil, freshwater, sewage and sludge, and even dust in air. Several species of *Acanthamoeba* have also been isolated from brackish water and seawater and from ear discharges, pulmonary secretions, nasopharyngeal mucosa samples, maxillary sinus samples, mandibular autografts, and stool samples (9, 17, 24, 27, 28, 38, 42, 44, 54). These amebae normally feed on bacteria and multiply in their environmental niche as free-living organisms. *Acanthamoeba* spp. have also been known to harbor *Legionella* spp., *Mycobacterium avium,* and other bacterial pathogens such as *Listeria monocytogenes, Burkholderia pseudomallei, Vibrio cholerae,* and *Escherichia coli* serotype O157, which signifies a potential expansion of public health importance of these organisms (14, 17, 24, 54). Additionally, pure cultures of *A. polyphaga* have been used to isolate *Legionella pneumophila* (37), *Legionella anisa* (22), and recently *Mycobacterium massiliense* (1) from human clinical specimens such as sputa, liver and lung abscess specimens, and even human feces. Obligate intracellular pathogens such as *Chlamydia, Chlamydophila,* and *Chlamydia*-like bacteria have been found in ~5% of *Acanthamoeba* isolates, and *Chlamydophila pneumophila,* a respiratory pathogen, can survive and grow within *Acanthamoeba* (14). Whether endosymbiont-bearing *Acanthamoeba* strains serve as reservoirs for these bacteria, some of which are potential pathogens for humans, is unknown.

Although *B. mandrillaris* has been recently isolated from soil (12, 39), not much is known about the environmental niche of *B. mandrillaris* and its feeding habits. It is, however, believed that its habitat is similar to those of *Acanthamoeba* and *Naegleria.* Excellent reviews (17, 24, 28, 42, 54) and books (27, 44) have been published on the biology, disease potential, pathology, pathogenicity, and epidemiology of these amebae.

The concept that these small, free-living amebae may occur as human pathogens was proposed by Culbertson and colleagues, who isolated *Acanthamoeba* sp. strain A-1 (now designated *A. culbertsoni*) from tissue culture medium thought to contain an unknown virus (7). They also demonstrated the presence of amebae in brain lesions of mice and monkeys that died within a week after intracerebral inoculation with *A. culbertsoni.* Culbertson hypothesized that similar infections might exist in nature in humans. In 1965, Fowler and Carter were the first to describe a fatal infection due to free-living amebae in the brain of an Australian patient (6). The infection is now believed to have been due to *N. fowleri* (6).

NAEGLERIA MENINGOENCEPHALITIS

In 1966, Butt et al. (6, 27) described the first case of CNS infection caused by *N. fowleri* in the United States and coined the term "primary amebic meningoencephalitis" (PAM). PAM is an acute fulminating disease with an abrupt onset that occurs generally in previously healthy children and young adults who have had contact with freshwater about 7 to 10 days before the onset of symptoms. It is characterized by a severe headache, spiking fever, a stiff neck, photophobia, and a coma leading to death within 3 to 10 days after the onset of symptoms (6, 27, 28, 43). The portal of entry of the *N. fowleri* amebae is the nasal passages. When people swim in lakes and other bodies of freshwater that harbor these amebae, the amebae may enter the nostrils of the swimmers, make their way into the olfactory lobes via the cribriform plate, and cause acute hemorrhagic necrosis leading to destruction of the olfactory bulbs and the cerebral cortex. Only a few patients have survived. Upon autopsy, large numbers of amebic trophozoites, many with ingested erythrocytes and brain tissue, are usually seen interspersed with brain tissue (Fig. 1). It is believed that *N. fowleri* directly ingests brain tissue by

producing food cups, or amebostomes, as well as exerting contact-dependent cytolysis, possibly mediated by a multicomponent system consisting of a heat-stable hemolytic protein, a heat-labile cytolysin, and/or phospholipase enzymes (17, 25). Cysts of *N. fowleri* are not usually seen in brain tissue. It was believed until recently that *N. fowleri* infects only humans. In March 1997, however, a report of the first case of PAM in a South American tapir was published, indicating that PAM can occur in animals other than humans (23). A recent report of PAM in Holstein cattle, associated with drinking of surface waters, indicates that this disease is probably more common than is currently appreciated (51).

ACANTHAMOEBA ENCEPHALITIS

Several species of *Acanthamoeba (A. culbertsoni, A. castellanii, A. polyphaga, A. astronyxis, A. healyi,* and *A. divionensis)* have been known to cause a chronic granulomatous amebic encephalitis (GAE), primarily in immunosuppressed (either because of iatrogenic suppression or because of human immunodeficiency virus infection or AIDS), chronically ill, or otherwise debilitated persons with no previous history of exposure to recreational freshwater (27, 28, 31, 54). GAE has an insidious onset and is usually chronic, lasting for more than a week and sometimes even for months (10, 26–28, 30, 55). It is characterized by a headache, confusion, dizziness, drowsiness, seizures, and sometimes hemiparesis. Cerebral hemispheres are usually the most heavily affected CNS tissue. They are often edematous, with extensive hemorrhagic necrosis involving the temporal, parietal, and occipital lobes. Amebic trophozoites and cysts are usually scattered throughout the tissue. Many blood vessels are thrombotic with fibrinoid necrosis and cuffed by polymorphonuclear leukocytes, amebic trophozoites, and cysts (Fig. 2). Multinucleated giant cells forming granulomas may be seen in immunocompetent patients. Some patients, especially those with human immunodeficiency virus infection or AIDS, develop chronic ulcerative skin lesions, abscesses, or erythematous nodules (26–28, 32, 45, 46, 55). It is believed that the route of invasion of and penetration into the CNS is hematogenous, probably from a primary focus in the lower respiratory tract or the skin (26–28). *Acanthamoeba* spp. also cause infections of the CNSs of animals besides humans. Such infections have been recorded in gorillas, monkeys, dogs, ovines, bovines, horses, and kangaroos (28, 36).

Because of the confusion that existed in the earlier literature with regard to the nomenclature of *Acanthamoeba* and *Hartmannella* spp., some workers in the field referred to these amebae as members of the *Hartmannella-Acanthamoeba* group or simply as "*H-A* amebae." Since no true *Hartmannella* species has been found to be pathogenic to humans, all references in the literature to *Hartmannella* in human tissues should be corrected to read *Acanthamoeba* or *Balamuthia.*

BALAMUTHIA (LEPTOMYXID) ENCEPHALITIS

It was believed that all cases of GAE were caused by *Acanthamoeba* spp. Although a number of these cases were confirmed by serologic techniques as being caused by *Acanthamoeba* spp., the causative organisms in a few cases could not be definitively identified. Since cysts were found in the brain tissues of the patients, it was believed that the infections were caused by some other species of *Acanthamoeba* that did not cross-react with the anti-*Acanthamoeba* sera used in the serologic test (28, 54). *B. mandrillaris* (leptomyxid ameba) was definitively identified by an indirect immunofluorescence test as the causal agent in these cases (5, 8, 13, 19, 28, 36, 52, 53). The rabbit anti-*B. mandrillaris* serum used in the indirect immunofluorescence test was made by using culture-derived *Balamuthia* organisms that were isolated from the CNS tissue of a baboon (52). It is now known that a number of primates, including gorillas, gibbons, baboons, orangutans, and monkeys, as well as dogs, sheep, and horses, have died of CNS infections caused by *B. mandrillaris* (13, 28, 29, 36, 52). According to a recent report, Hispanic Americans have a high incidence of *B. mandrillaris* infection. It is not clearly known whether this is due to environmental factors, genetic predisposition, limited access to medical care, or other socioeconomic factors and pressures (40).

The pathology and pathogenesis of *B. mandrillaris*-induced GAE are similar to those of *Acanthamoeba*-induced GAE. Both trophozoites and cysts are found in CNS tissue (Fig. 3), and their sizes overlap those of *Acanthamoeba* trophozoites and cysts (13, 28, 29, 36, 52, 53). Hence, it is difficult to differentiate *Balamuthia* from *Acanthamoeba* spp. in tissue sections under the light microscope. In some cases, *Balamuthia* trophozoites in tissue sections appear to have more than one nucleolus in the nucleus (Fig. 3). In such cases, it may be possible to distinguish *Balamuthia* amebae from *Acanthamoeba* organisms on the basis of nuclear morphology, since *Acanthamoeba* trophozoites have only one nucleolus. In most cases, electron microscopy, immunohistochemical techniques, or both are necessary to identify *Balamuthia* organisms. Ultrastructurally, the cysts are characterized by three layers in the cyst wall: an outer wrinkled ectocyst, a middle structureless mesocyst, and an inner thin endocyst (52, 53). *Balamuthia* amebae are antigenically distinct from *Acanthamoeba* organisms; they can easily be distinguished by immunofluorescence or other immunochemical assays (Fig. 4) (8, 13, 19, 28, 29, 36, 52, 53).

ACANTHAMOEBA KERATITIS

Acanthamoeba spp. also cause a painful vision-threatening disease of the human cornea, *Acanthamoeba* keratitis. If the infection is not treated promptly, it may lead to ulceration of the cornea, loss of visual acuity, and eventually blindness and enucleation (4, 11, 18, 23, 35, 47, 48, 56). The first case of *Acanthamoeba* keratitis in the United States was reported in 1973 in a south Texas rancher with a history of trauma to his right eye (18). Both trophozoite and cyst stages of *A. polyphaga* were demonstrated to be present in corneal sections and were repeatedly cultured from corneal scrapings and biopsy specimens. Between 1973 and July 1986, 208 cases were diagnosed and reported to the Centers for Disease Control (47, 48, 54). The numbers of cases increased gradually between 1973 and 1984, and a dramatic increase began in 1985. An in-depth epidemiologic and case control study (47, 48) revealed that a major risk factor was the use of contact lenses, predominantly daily-wear or extended-wear soft lenses, and that patients with *Acanthamoeba* keratitis were significantly more likely than controls to use homemade saline solution instead of commercially prepared saline (78 and 30%, respectively), to disinfect their lenses less frequently than recommended by the lens manufacturers (72 and 32%), and to wear their lenses while swimming (63 and 30%). *Acanthamoeba* keratitis is characterized by severe ocular pain, a 360° or partial paracentral stromal ring infiltrate, recurrent corneal epithelial breakdown, and a corneal lesion refractory to the commonly used ophthalmic antibacterial medications. *Acanthamoeba* keratitis in the early stages is frequently misdiagnosed as herpes simplex virus keratitis because of the irregular epithelial lesions, stromal infiltrative keratitis, and edema

that are commonly seen in herpes simplex virus keratitis (18, 56). A nonhealing corneal ulcer is often the first clue that *Acanthamoeba* keratitis may be the problem. It is estimated that as of August 2005, more than 4,000 cases of *Acanthamoeba* keratitis have occurred in the United States. Since the diseases caused by *Acanthamoeba* are not reportable in the United States, the actual number may be much higher.

MORPHOLOGY

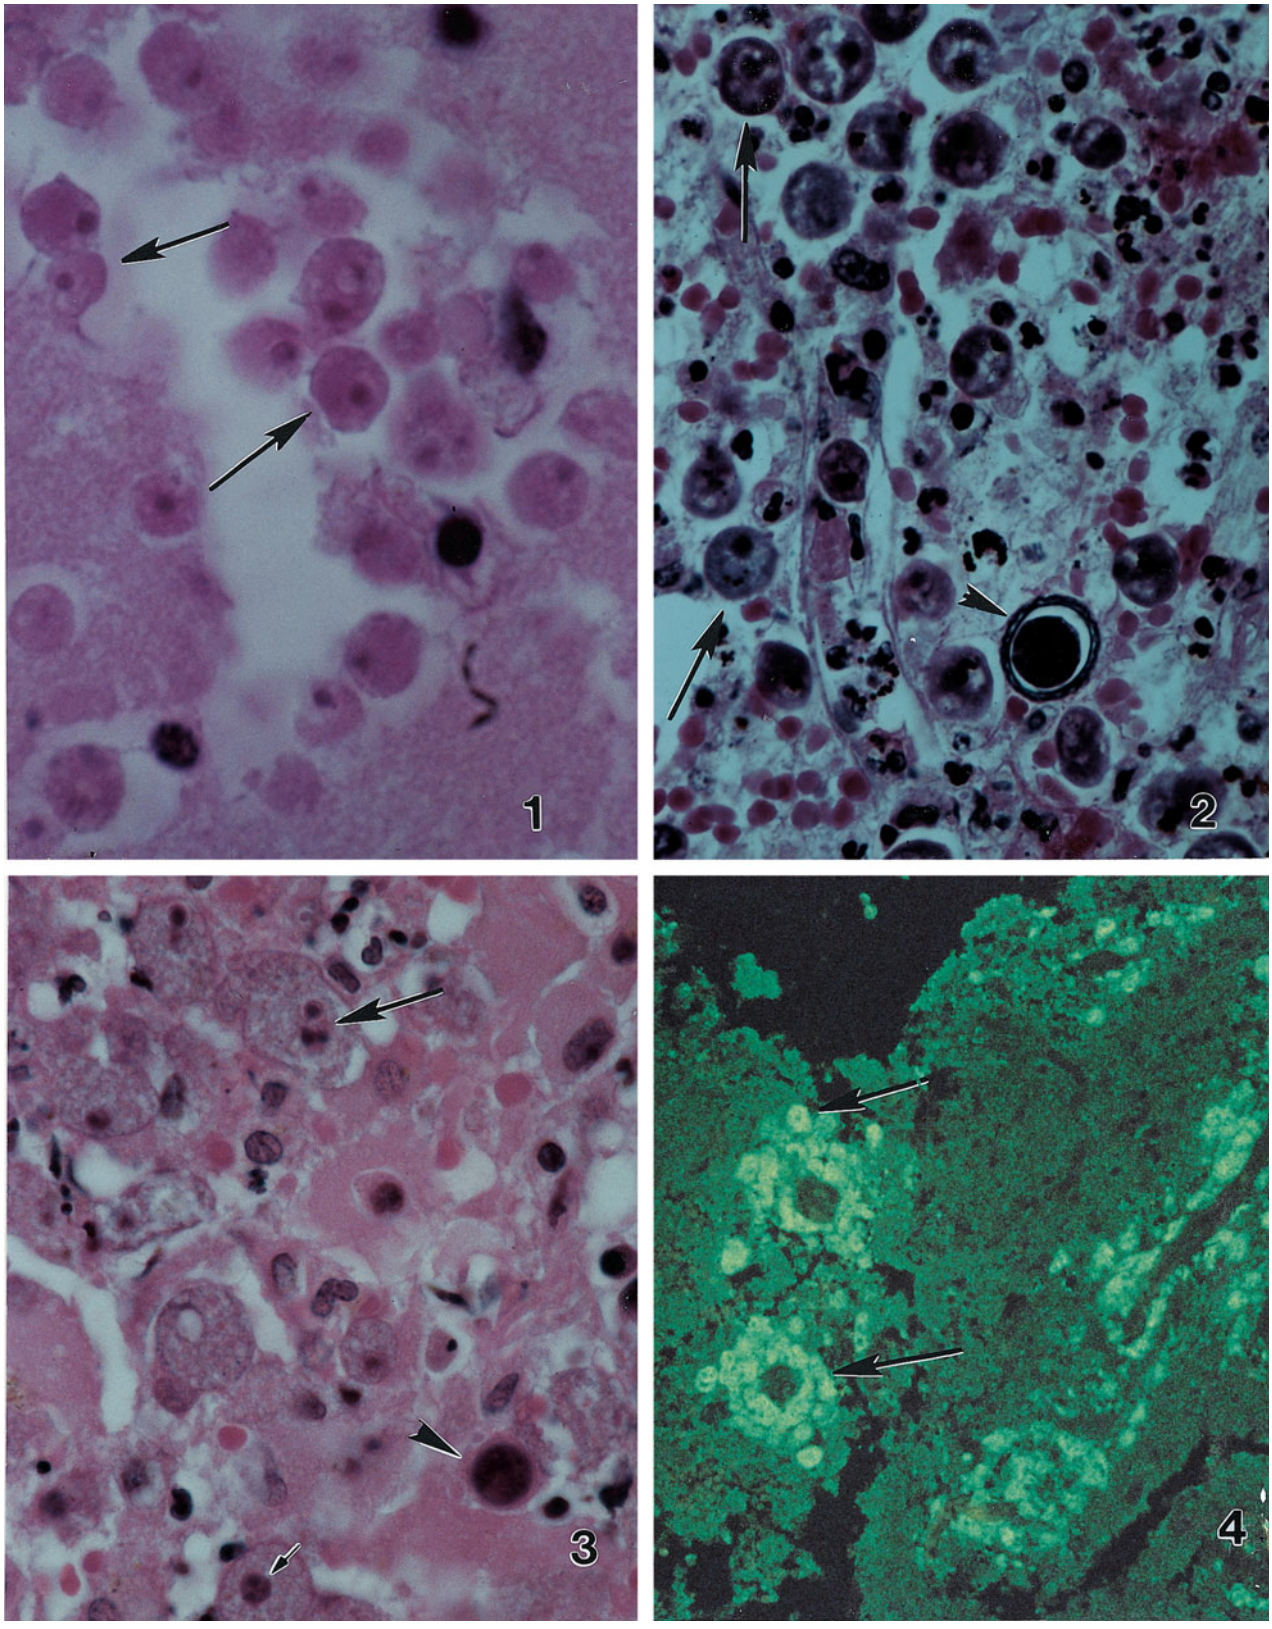
N. fowleri in its trophic form is a small, slug-like ameba measuring 10 to 35 μm long that exhibits an eruptive locomotion by producing smooth hemispherical bulges. The posterior end, termed the uroid, appears to be sticky and often has several trailing filaments. During its life cycle, this ameba produces a transient pear-shaped biflagellate stage, resulting from altered environmental conditions, and smooth-walled cysts (Fig. 5 to 8). The flagellates do not have cytostomes (mouths). Cysts are usually spherical and measure 7 to 15 μm, and the cyst wall may have one or more pores plugged with a mucoid material (34).

An *Acanthamoeba* organism is a slightly larger ameba (15 to 45 μm) that produces from the surface of its body fine, tapering, hyaline projections called acanthopodia (Fig. 9). It has no flagellate stage but produces a double-walled cyst (10 to 25 μm) (Fig. 10) with a wrinkled outer wall (the ectocyst) and a stellate, polygonal, or even round inner wall (the endocyst) (34).

Balamuthia trophozoites are in general irregular in shape; a few, however, may be slug-like. Actively feeding amebae may be 12 to 60 μm long, with a mean length of 30 μm (Fig. 11). The trophic forms, while feeding on tissue culture cells, produce broad pseudopodia without any clearly discernible movement. However, when tissue culture cells are destroyed, the trophozoites resort to a spider-like walking movement by producing finger-like determinate pseudopodia (53). Like *Acanthamoeba, Balamuthia* does not have a flagellate stage. Cysts are generally spherical and measure 6 to 30 μm in diameter (Fig. 12). Under the light microscope, each cyst appears to have an irregular and slightly wavy outer wall and a round inner wall. A layer of refractile granules immediately below the inner cyst wall is often seen in mature cysts. Under the electron microscope, the cyst wall can be seen to consist of three walls: a thin, irregular outer ectocyst; a thick, electron-dense inner endocyst; and a middle amorphous layer, the mesocyst (52, 53).

Acanthamoeba, Balamuthia, and *Naegleria* are predominantly uninucleate, although binucleate forms are occasionally seen. The nucleus is characterized by a large, dense, centrally located nucleolus. *Naegleria* amebae exhibit a promitotic pattern of cell division wherein the nucleolus and the nuclear membrane persist during nuclear division. *Acanthamoeba* spp., however, divide by conventional mitosis, in which the nucleolus and the nuclear membrane disappear during cell division. The pattern of nuclear division in *Balamuthia* is termed metamitosis: the nuclear membrane breaks down, and the nucleolus eventually disappears (53).

CLINICAL AND LABORATORY DIAGNOSIS



No distinctive clinical features differentiate PAM from pyogenic or bacterial meningitis. In PAM the cerebrospinal fluid (CSF) is usually pleocytotic, with a preponderance of polymorphonuclear leukocytes and no bacteria. The CSF pressure may be elevated. The CSF glucose level may be normal or slightly reduced, but the CSF protein level is increased, ranging from 1 to 10 mg/ml. Microscopic detection of amebic organisms in the CSF is the only means of diagnosing PAM. CSF should be examined in situ microscopically for the presence of *N. fowleri* amebae with directional movement. Giemsa or trichrome staining should be performed on CSF smears to visualize the nuclear morphology of the amebae. Gram staining is not useful in the detection of amebae. Further, a false-positive Gram stain may lead to inaccurate diagnosis and hence to inappropriate therapy, which will result in death. A recent report describing the transplantation of kidneys and a liver from a donor infected with *N. fowleri* (20) underscores the importance of a correct and timely diagnosis. Sequencing of the 5.8S rRNA gene and the internal transcribed spacers 1 and 2 (ITS1 and ITS2) of *N. fowleri* can not only differentiate *N. fowleri* from other *Naegleria* spp. but can also be used in the genotypic analysis of *N. fowleri* strains (58). However, this methodology has not been used to identify *N. fowleri* infections in clinical cases. *Acanthamoeba* trophozoites can be identified, although rarely, in the CSF, but *Balamuthia* organisms have never been seen in the CSF. They have, however, been identified in stained brain and/or skin biopsy specimens and also have been isolated in culture (5, 10, 19, 28, 36, 52, 53). *Acanthamoeba* organisms have also been recovered and identified from corneal scrapings as well as biopsy samples. Recently, direct examination of a patient's cornea with the confocal microscope has been used to diagnose *Acanthamoeba* keratitis (35). A large number of studies have sequenced the 18S rRNA gene to understand the phylogeny of *Acanthamoeba*. However, only a few studies have used this technique to identify *Acanthamoeba* keratitis or *Acanthamoeba* GAE by using patient specimens (3, 49). Similarly, molecular techniques have rarely been used to diagnose *B. mandrillaris* infections, although PCR technology is available to specifically identify *Balamuthia* DNA from cultured organisms as well as from tissue specimens (2, 13, 57). Efforts are, however, under way to develop real-time PCR protocols to simultaneously identify *Acanthamoeba, Balamuthia,* and *N. fowleri* in CSF specimens (35a; Y. Qvarnstrom, G. S. Visvesvara, R. Sriram, B. Barnes, and A. J. da Silva, *Proc. XIth Int. Meet. Biol. Pathog. Free-Living Amoebae*, České Budějovice, Czeck Republic, 2005).

COLLECTION, HANDLING, AND STORAGE OF SPECIMENS

For isolation of the etiologic agent, CSF, small pieces of tissue (brain, lung, skin, or corneal biopsy material), or corneal scrapings from the affected area must be obtained aseptically. The specimens should be kept at room temperature (24 to 28°C) and should never be frozen. The specimens may be kept at 4°C for short periods but never for more than 24 h. Personnel handling the specimens must take appropriate precautions, such as wearing surgical masks and gloves and

working in a biological safety cabinet. Remaining tissues must be preserved in 10% neutral buffered Formalin so that they can be examined histologically for amebae (50).

METHODS OF EXAMINATION

Direct Examination

Direct examination of the sample as a wet mount preparation is of paramount importance in the diagnosis of PAM and other diseases caused by these amebae. Since the amebae tend to attach to the surface of the container, the container should be shaken gently; then, a small drop of fluid is placed on a clean microscope slide and covered with a no. 1 coverslip. The CSF may have to be centrifuged at 500 × *g* for 5 min to concentrate the amebae. After the specimen has been centrifuged, most of the supernatant is carefully aspirated and the sediment is gently suspended in the remaining fluid. A drop of this suspension is prepared as described above for microscopic observation.

The slide preparation should be examined under a compound microscope with 10× and 40× lens objectives. Phase-contrast optics are preferable. If regular bright-field illumination is used, the slide should be examined under diminished light. The slide may be warmed to 35°C (to promote amebic movement), and amebae, especially *N. fowleri,* if present, can easily be detected by their active directional movements. Rarely, flagellates with two flagella may be seen. Currently, this is the most sensitive method available for the diagnosis of PAM.

Permanently Stained Preparations

A small drop of the sedimented CSF or other sample is placed in the middle of a slide, which is allowed to stand in a moist chamber for 5 to 10 min at 37°C. This will allow any amebae to attach to the surface of the slide. Several drops of warm (37°C) Schaudinn's fixative are dropped directly onto the sample, which is allowed to stand for 1 min. The slide is then transferred for 1 h to a Coplin jar containing the fixative. It may be stained with Wheatley's trichrome or Heidenhain's iron hematoxylin stain. Corneal scrapings smeared onto microscope slides may be fixed with methanol and stained with Hemacolor stain (Harleco, a division of EM Industries, Inc.) (28, 54).

ISOLATION

The recommended procedure for isolating free-living pathogenic amebae from biological specimens is as follows.

Materials

1. Page's ameba saline (17, 34). Physiological saline or phosphate-buffered saline solutions that are normally available in the clinical laboratories are not suitable, as the sodium chloride concentrations in these solutions will prevent the growth of amebae, especially *N. fowleri.*

2. Petri dishes containing 1.5% Difco agar made with Page's ameba saline (nonnutrient agar plate) (50). These plates can be stored at 4°C for up to 3 months. Chocolate agar with blood, Trypticase soy agar, and Lowenstein-Jensen agar have been used sometimes. These are not suitable because bacteria that coat the plates or bacteria from the clinical sample may overgrow and either prevent the growth of amebae, especially when they are in small numbers, or obscure their presence.

3. 18- to 24-h-old culture of *E. coli* or *Enterobacter aerogenes*
4. Sterile distilled water
5. Bacteriologic loop
6. Fine spatula made of nichrome wire
7. Sterile Pasteur pipettes with rubber bulbs
8. Sterile 1-ml serologic pipettes
9. Sterile screw-cap test tubes, 100 by 13 or 125 by 16 mm
10. Moist chamber
11. Vaspar (1:1 petrolatum-paraffin), melted
12. Microscope slides, 3 by 1 or 3 by 2 in. (7.6 by 2.5 or 7.6 by 5 cm)
13. Coverslips, 22 mm square, no. 1 thickness

Preparation of Agar Plates

1. Remove plates from the refrigerator, and place them in a 37°C incubator for 30 min.

2. Add 0.5 ml of ameba saline to a slant culture of *E. coli* or *Enterobacter aerogenes.* Gently scrape the surface of the slant with a sterile bacteriologic loop (do not break the agar surface). Using a sterile Pasteur pipette, gently and uniformly suspend the bacteria. Add 2 or 3 drops of this suspension to the middle of a warmed (37°C) agar plate, and spread the bacteria over the surface of the agar with a bacteriologic loop. The plate is then ready for inoculation.

Inoculation of Plates with Specimens

1. For CSF samples, centrifuge the CSF at 500 × *g* for 5 to 8 min. With a sterile serologic pipette, carefully transfer all but 0.5 ml of the supernatant to a sterile tube, and store the tube at 4°C for possible future use. Mix the sediment with the remaining fluid. With a sterile Pasteur pipette, place 2 or 3 drops in the center of the agar plate precoated with bacteria, and incubate in room air at 37°C.

2. For tissue samples, triturate a small piece of the tissue in a small amount of ameba saline. With a sterile Pasteur pipette, place 2 or 3 drops of the mixture in the center of the agar plate. Incubate the plate in room air at 37°C for CNS and lung tissues and at 30°C for tissues from other sites (skin, cornea).

3. Handle water and soil samples in the same manner as CSF and tissue specimens, respectively.

4. Control cultures are recommended for comparative purposes, although care should be exercised to prevent cross-contamination of patient cultures.

Examination of Plates

1. Using the low-power (10×) lens objective of a microscope, observe the plates daily for 7 days for amebae.

2. If you see amebae anywhere, circle that area with a wax pencil. With the fine spatula, cut a small piece of agar from the circled area, and place it face down on the surface of a fresh agar plate precoated with bacteria; incubate as described above. Both *N. fowleri* and *Acanthamoeba* spp. can easily be cultivated in this way and, with periodic transfers, maintained indefinitely. When the plate is examined under a microscope, the amebae will look like small blotches, and if they are observed carefully, their movement can be discerned. After 2 to 3 days of incubation, the amebae will start to encyst. If a plate is examined after 4 to 5 days of incubation, trophozoites as well as cysts will be visible. *B. mandrillaris,* however, will not grow on agar plates seeded with bacteria. While *B. mandrillaris* can be grown on monkey kidney or lung fibroblast cell lines and human brain microvascular endothelial cells and axenically in a complex medium (12, 16, 39, 42, 52, 53), such techniques are not routinely available.

Identification and Culture

Identification of living organisms to the genus level is based on characteristic patterns of locomotion, morphologic features of

the trophic and cyst forms, and results of enflagellation experiments. Immunofluorescence or immunoperoxidase tests using monoclonal or polyclonal antibodies (available at the Centers for Disease Control and Prevention) will be helpful in differentiating *Acanthamoeba* spp. from *B. mandrillaris* in fixed tissue and in identifying the species, especially *Acanthamoeba* spp., in fixed tissue (8, 13, 19, 28, 36, 52, 53).

Enflagellation Experiment

1. Mix 1 drop of the sedimented CSF containing amebae with about 1 ml of sterile distilled water in a sterile tube, or with a bacteriologic loop, scrape the surface of a plate that is positive for amebae, transferring a loopful of scraping to a sterile tube that contains approximately 1 ml of distilled water.

2. Gently shake the tube, and transfer a drop of this suspension to the center of a coverslip whose edges have been coated thinly with petroleum jelly. Place a microscope slide over the coverslip, and invert the slide. Seal the edges of the coverslip with Vaspar. Place the slide in a moist chamber, and incubate as before for 2 to 3 h. In addition, incubate the tube as described above.

3. Periodically examine the tube and the slide preparation microscopically for free-swimming flagellates. *N. fowleri* has a flagellate stage; *Acanthamoeba* spp. and *B. mandrillaris* do not. If the sample contains *N. fowleri,* about 30 to 50% of the amebae will have undergone transformation into pear-shaped biflagellate organisms (Fig. 7).

Other Culture Methods

Axenic Culture

Acanthamoeba spp. can easily be cultivated axenically, without the addition of serum or host tissue, in many different types of nutrient media, e.g., Proteose Peptone-yeast extract-glucose medium, Trypticase soy broth medium, and chemically defined medium (50). *N. fowleri,* however, requires media containing fetal calf serum or brain extract, e.g., Nelson's medium. A chemically defined medium has only recently been developed for *N. fowleri* (33). *B. mandrillaris* cannot be cultivated on agar plates with bacteria. It can, however, be cultivated on mammalian cell lines (12, 16, 39, 52, 53) or a complex axenic medium (41).

Axenic cultures of *Acanthamoeba* spp. and *N. fowleri* can be established as follows. An actively growing 24- to 36-h-old ameba culture is scraped from the surface of the plate, suspended in 50 ml of ameba saline, and centrifuged at 500 × *g* for 5 min. The supernatant is aspirated, and the sediment is inoculated into Proteose Peptone-yeast extract-glucose medium or Nelson's medium, depending on the ameba isolate, and incubated at 37°C. Gentamicin, to a final concentration of 50 μg/ml, is added aseptically to the medium before the amebae are inoculated. Three subcultures into the antibiotic-containing medium at weekly intervals are usually sufficient to eliminate the associated bacteria (*E. coli* or *Enterobacter aerogenes*).

Cell Culture

Acanthamoeba spp., *B. mandrillaris,* and *N. fowleri* can also be inoculated onto many types of mammalian cell cultures. Shell vial cultures normally used in the isolation of viruses are suitable for the isolation of the amebae provided that antifungal agents (amphotericin B) are not included in the antibiotic mix. The amebae grow vigorously in these cell cultures and produce cytopathic effects somewhat similar to those caused by viruses (17, 42, 52, 53). Because of such cytopathic effects, *Acanthamoeba* organisms were mistaken for transformed cell types presumed to contain viruses and were erroneously termed lipovirus and Ryan virus (27, 54).

Animal Inoculation

Two-week-old Swiss Webster mice weighing 12 to 15 g each can be infected with these amebae. The mice are anesthetized with ether, and a drop of ameba suspension is instilled into their nostrils. Mice infected with *N. fowleri* die within 5 to 7 days after developing characteristic signs such as ruffled fur, aimless wandering, partial paralysis, and finally coma and death. Mice infected with *Acanthamoeba* spp. and *B. mandrillaris* may die of acute disease within 5 to 7 days or may die of chronic disease after several weeks. In all cases, the presence of amebae in the mouse brain can be demonstrated either by culture or by histologic examination.

Antigenic and Molecular Characteristics

Pathogenic *N. fowleri* is morphologically indistinguishable from nonpathogenic *Naegleria* at the trophic stage. Differences between these amebae, however, have been demonstrated antigenically by the gel diffusion, immunoelectrophoretic, and indirect immunofluorescence techniques (17, 24, 28, 42, 54). Antigenic differences have also been shown among various species of *Acanthamoeba* (17, 24, 28, 54). Some recent studies indicate that *N. fowleri* can be distinguished from other species of *Naegleria* on the basis of isoenzyme patterns as well as the sequencing of the 5.8S rRNA gene and ITS1 and ITS2 (17, 24, 28, 42, 54, 58). Analyses of isoenzyme patterns, mitochondrial DNA, and small-subunit RNA have also been carried out for various *Acanthamoeba* species and isolates in an attempt to understand inter- and intraspecies diversity and phylogenetic relationships (3, 24, 42, 49). Similarly, a PCR assay for the detection of *B. mandrillaris* has been described previously (2). Recently, a PCR assay to detect *B. mandrillaris* in Formalin-fixed archival tissue specimens has also been described (13).

Serology

The serologic techniques discussed here have been developed as research tools and are not routinely available to clinical laboratories. Complement fixation antibody to *Acanthamoeba* spp. has been shown to be present in the sera of patients with upper respiratory tract distress and those with optic neuritis and macular disease (17, 24, 28, 42, 54). Kenney (42, 54) demonstrated increasing titers of complement fixation antibody to *Acanthamoeba* in three successive samples of serum collected over a 2-month period from each of two patients. Precipitin antibody has also been shown to be present in the serum of a patient suffering from *A. polyphaga* keratitis (18, 54). Recently, an increase in ameba immobilization antibody titers over a 16-month period was demonstrated in the serum of a Nigerian patient, who made a partial recovery from an *A. rhysodes*-induced CNS disease (28, 54).

An antibody response to *N. fowleri,* however, has not yet been defined. Most of the patients with *Naegleria* PAM died very shortly after infection (5 to 10 days), before they had time to produce detectable levels of antibody. In one case, however, in which the patient survived PAM caused by *N. fowleri,* an indirect immunofluorescence titer of 4,096 against *N. fowleri* was detected in the serum after 42 days of hospitalization (28, 42, 43, 54).

Since the recognition of *Balamuthia* GAE is relatively new, not much information is available on the serologic response of patients infected with *Balamuthia.* According to a recent report, immunofluorescent-antibody titers were determined for four patients with confirmed *Balamuthia* GAE infection, 61

patients with encephalitis of unknown causes, and 12 healthy controls. Titers ranging from 64 to 2,048 were recorded for the sera of patients with *Balamuthia* GAE, whereas six sera from patients with encephalitis of unknown causes (10% of the sera) had titers of 64 and above and none of the control sera had titers of 64 or above. It is therefore possible that patients with *Balamuthia* GAE may be diagnosed premortem by using this serologic test (42, 54).

TREATMENT

Pathogenic *N. fowleri* is exquisitely susceptible to amphotericin B in vitro (6, 17, 27, 28, 42, 43). At least several patients with PAM were reported to have recovered after receiving intrathecal and intravenous injections of amphotericin B alone or in combination with miconazole or treatment with amphotericin B in a hyperbaric chamber (17, 28, 42, 43). Although a few patients with *Acanthamoeba* sp. GAE have survived, most have died in spite of treatment with several drug combinations. According to a recent report, a Spanish AIDS patient with *Acanthamoeba* group II GAE completely recovered from this disease after surgery and treatment with sulfadiazine and fluconazole (30). Culbertson found sulfadiazine to be active against experimental *Acanthamoeba* infections in mice (17, 28, 42, 54). Jones et al. (18) found that paromomycin, clotrimazole, and hydroxystilbamidine isethionate were active against *A. polyphaga* in vitro. Several patients with *Acanthamoeba* keratitis have been successfully treated with different drug combinations administered over a long period. For example, in one study, treatment with 0.1% propamidine isethionate (Brolene) eye drops and 0.15% dibromopropamidine ointment together with topical neomycin sulfate was successful in the management of *Acanthamoeba* keratitis (56). In another study, 1% clotrimazole used in combination with propamidine isethionate and a compound of bacitracin, neomycin, and polymyxin B (Neosporin) for four patients gave excellent results (11). In a recent study, azithromycin and several phenothiazine compounds protected rat glioma cells from destruction by *Acanthamoeba* (41). Medical cure has also been achieved with topical administration of polyhexamethylene biguanide (21) or topical application of hexamidine isethionate, an analogue of pentamidine (4). A recent study carried out with 111 patients with *Acanthamoba* keratitis indicates that treatment with a combination of 0.02% polyhexamethylene biguanide and 0.1% propamidine isethionate hourly for 3 days and subsequently up to six times a day for 6 to 8 weeks is associated with a good prognosis (21), and this may prove to be the treatment of choice. The prognoses of patients without CNS infection but with disseminated cutaneous ulcers due to *Acanthamoeba* spp. are good. For example, a patient with Down's syndrome and an immunoglobulin A deficiency who also had undergone cadaveric renal transplantation developed a biopsy-confirmed *Acanthamoeba* skin ulcer. The patient was successfully cured of the infection after prolonged (more than 8 months) therapy with a regimen that included topical as well as systemic administration of a combination of drugs. His skin ulcers were cleansed twice daily with chlorhexidine gluconate solution followed by topical application of 2% ketoconazole cream. He also received pentamidine isethionate intravenously for 1 month and thereafter was given oral itraconazole therapy for 8 months; this regimen resulted in complete healing of the cutaneous ulcers (46).

Recent in vitro studies indicate that *B. mandrillaris* is susceptible to pentamidine isethiocyanate and that patients with *B. mandrillaris* infection may benefit from treatment with this drug (41). Although most patients with *B. mandrillaris* GAE have died of this disease, two patients from California and a patient from New York have survived after treatment initially with pentamidine isethionate and subsequently with a combination of sulfadiazine, clarithromycin, fluconazole, and 5-fluorocytosine (8, 19).

Intestinal and Urogenital Amebae, Flagellates, and Ciliates

AMY L. LEBER AND SUSAN NOVAK-WEEKLEY

140

Giardia lamblia and *Entamoeba histolytica* infections are two of the most common protozoal infections seen worldwide and are of serious concern on a global scale due to their prevalence and the pathogenicity of the causative agents. Most of the other protozoa described in this chapter are nonpathogenic organisms. Nevertheless, they need to be detected and differentiated from true pathogens in clinical specimens because they are indicators of exposure to fecal contamination and examination of additional specimens may reveal pathogenic protozoa. The pathogenic and nonpathogenic organisms are categorized as indicated in Table 1; however, reports of disease in patients infected with nonpathogenic species are found in the literature.

Microscopic examination of stool specimens continues to be the main tool used in the laboratory diagnosis of intestinal amebic, flagellate, and ciliate infections. The goal of microscopy is to identify pathogenic protozoa, differentiate between these and nonpathogenic species, and properly discriminate among various artifacts that may be present. Other methods for detection include antigen detection assays such as enzyme immunoassays (EIAs), immunochromatographic assays, and direct fluorescent-antibody (DFA) assays for the detection of pathogens such as the *E. histolytica*/*Entamoeba dispar* group, *E. histolytica,* and *G. lamblia.* Culture may be useful under certain limited situations. Nucleic acid-based techniques have been developed but are not yet widely available. All of these methods may not be available or necessary in every instance. See the sections below and refer to chapters 16, 18, and 135 for additional information.

AMEBAE

Taxonomy

The amebae that parasitize the intestinal tracts of humans belong to four genera: *Entamoeba, Endolimax, Iodamoeba,* and *Blastocystis*. They all belong to the phylum Sarcomastigophora, subphylum Sarcodina, which contains organisms that move by means of cytoplasmic protrusions called pseudopodia. It is noteworthy that *Dientamoeba fragilis,* once classified as an ameba, is now grouped with the flagellates. Even though this reclassification has occurred, *D. fragilis* is still identified on the basis of morphologic comparison to amebae.

Description of the Agents

Of the seven species of intestinal amebae, *E. dispar, Entamoeba hartmanni, Entamoeba coli, Endolimax nana,* and *Iodamoeba bütschlii* are nonpathogenic for humans. *E. histolytica* is pathogenic for humans, causing invasive intestinal and extraintestinal amebiasis. The pathogenicity of *Blastocystis hominis* is still controversial.

Epidemiology, Transmission, and Prevention

All amebae have a common and relatively simple life cycle. The cyst is the infectious form and is acquired by ingestion of contaminated material such as water and food or by direct fecal-oral transmission. Once the cyst arrives in the intestinal tract, excystation occurs, releasing trophozoites. Encystment occurs in the colon, presumably when conditions become unfavorable for the trophozoites. Cysts are passed in the feces and remain viable in the environment for days to weeks in water and soil if protected from desiccation. Improvements in sanitary conditions are necessary to prevent infections in areas where the organisms are endemic. Research to develop a vaccine against *E. histolytica* is ongoing, but none is currently available.

Collection, Transport, and Storage of Specimens

For detection of the amebae, laboratories receive predominantly stool specimens for examination. Both fresh and preserved specimens are useful for the diagnosis of infection, depending on the methodology employed and the circumstances of the laboratory. If fresh specimens are received for the detection of organism motility, they must be examined quickly; wet mounts for the detection of motility cannot be performed on preserved specimens. Other sample types such as aspirates and tissue samples may be received and are appropriate for testing depending on the organism suspected. For a more detailed description of collection, refer to chapter 133 of this Manual.

Direct Examination

Microscopy

All diagnostic stages of the amebae (trophozoite and cyst) can be detected in fecal specimens, the most common specimen submitted to the laboratory. The key morphologic features of

TABLE 1 Intestinal and urogenital amebae, flagellates, and ciliates of humans

Parasite	Pathogenic	Nonpathogenic
Amebae	*Entamoeba histolytica*[a] *Blastocystis hominis*	*Entamoeba dispar*[b] *Entamoeba hartmanni* *Entamoeba coli* *Entamoeba polecki* *Entamoeba gingivalis*[c] *Endolimax nana* *Iodamoeba bütschlii*
Flagellates	*Giardia lamblia* *Trichomonas vaginalis* *Dientamoeba fragilis*	*Chilomastix mesnili* *Pentatrichomonas (Trichomonas) hominis* *Trichomonas tenax*[c] *Enteromonas hominis* *Retortamonas intestinalis*
Ciliates	*Balantidium coli*	

[a] A distinction between *E. histolytica* and *E. dispar* cannot be made on the basis of morphology unless ingested RBCs are seen in the cytoplasm of the trophozoite.

[b] In rare instances, *Entamoeba moshkovskii* may be found in human stool specimens. A free-living ameba, it is nonpathogenic and morphologically identical to *E. histolytica*/*E. dispar* (119).

[c] *E. gingivalis* and *T. tenax* are found in the oral cavity and related specimens.

amebae must be used to differentiate among the various species and to distinguish between somatic cells and other material. Trophozoites must be distinguished from epithelial cells and macrophages. Cysts must be distinguished from polymorphonuclear cells. Also, yeast, pollen, molds, food particles, and other debris present in feces may cause confusion (Table 2; Fig. 1 and 2).

Morphologic examination of fecal specimens can be accomplished with fresh wet mount preparations, wet mounts of concentrated material, and permanent-stained smears. Each of these three types of preparations may be useful for visualizing certain key characteristics. Stained and unstained wet mounts of concentrated material can also be useful for identification, particularly for certain cysts such as those of *Entamoeba coli* and *I. bütschlii.* Iodine will provide color and contrast, both of which may aid in the identification of organisms in wet preparations. However, morphologic examination with permanent-stained smears by oil immersion microscopy (magnification, ×1,000) is the most useful procedure (20).

Trophozoite motility is visible only in saline wet mounts of fresh feces and is often difficult to detect. The arrangement, size, and pattern of nuclear chromatin help differentiate species within the genus *Entamoeba* from other intestinal amebae. The size and position of the nuclear karyosome are also important morphologic features. A ring of nuclear chromatin surrounding the karyosome, resembling a bull's eye, is characteristic of *Entamoeba. Endolimax, Iodamoeba,* and the flagellate *Dientamoeba* lack peripheral chromatin. The cytoplasm of the trophozoites may contain granules and ingested material such as erythrocytes (RBCs), bacteria, yeasts, and molds.

The characteristics of cysts are less variable than those of trophozoites. To aid in differentiation among the genera, the cytoplasm should be examined for the presence of chromatoidal bodies and vacuoles, particularly the large glycogen vacuole seen in *I. bütschlii.*

Evaluation, Interpretation, and Reporting of Results

It is important to remember that identification may not be possible on the basis of one morphologic feature or the characteristics of a single organism in the preparation. Nuclear and cytoplasmic features can vary within species and may overlap between species, making identification challenging. Mixed infections are not uncommon and can be missed in a cursory examination. A complete, overall assessment of the slide is necessary for correct identification. It is important to use an accurate micrometer to measure life cycle stages. Size is reliable only for the differentiation of *E. histolytica/E. dispar* from *E. hartmanni.* Also, on permanent-stained smears, shrinkage may occur, affecting the apparent size of the organism. Results of microscopy should clearly indicate the full taxonomic name of the organisms detected along with the forms of the organisms seen (cysts versus trophozoites). Except for *Blastocystis,* quantitation of the amebae on the final report is not appropriate.

E. histolytica

Epidemiology, Transmission, and Prevention

E. histolytica can be found worldwide but is more prevalent in tropical and subtropical regions. In areas where the organism is endemic, up to 50% of people may be infected. In temperate climates with poor sanitation, infection rates can approach those seen in tropical regions. Humans are the primary reservoir; infection occurs by ingestion of cysts from fecally contaminated material such as water and food. Sexual transmission also occurs.

Asymptomatic *E. histolytica* infection is equally distributed between the genders, while invasive amebiasis affects men predominantly. In the United States, groups with a higher incidence of amebiasis include immigrants from South and Central America and Southeast Asia. Also, residents of the southern United States and institutionalized individuals are more likely than others to be infected. In one study, short-term travelers to areas where *E. histolytica* and *E. dispar* are endemic were found to be at higher risk of infection with the pathogenic species, *E. histolytica,* than were residents, who were more likely to harbor the nonpathogenic species, *E. dispar* (126). In homosexual males, the infection is often transmitted by sexual behavior, with up to 30% found to be infected in certain studies. These infections are most often asymptomatic. Among human immunodeficiency virus (HIV)-infected patients in the United States, the incidence of diagnosed *E. histolytica* disease is low (13.5 cases per 10,000 person-years) (74). HIV-infected individuals in non-Western countries, such as Taiwan and Korea, do have a higher risk of invasive amebiasis, in contrast to findings from the United States (50, 87). These differing rates of invasive disease may be attributed to the higher endemicity of *E. histolytica* in the Asia-Pacific regions (51).

Clinical Significance

Among the estimated 500 million people infected each year with *E. histolytica,* there are approximately 50 million cases of colitis and liver abscess and 100,000 deaths (131). The discrepancy between the number of people infected with *E. histolytica* and the morbidity and mortality rates is explained by the existence of two morphologically similar yet distinct species: one capable of producing disease and the other not.

TABLE 2 Key features of trophozoites and cysts of common intestinal amebae[a]

Organism	Trophozoites	Cysts
E. histolytica/*E. dispar*	Size[b]: 12–60 μm; invasive forms, >20 μm Motility: Progressive, directional, rapid Nucleus[c]: 1; peripheral chromatin evenly distributed; karyosome small, compact, centrally located; may resemble *E. coli* Cytoplasm: Finely granular, like "ground glass"; may contain bacteria Note: RBCs in cytoplasm diagnostic for *E. histolytica* infection	Size: 10–20 μm; spherical Nucleus: Mature cyst, 4; immature cyst, 1 or 2; peripheral chromatin fine, uniform granules, evenly distributed; karyosome small, compact, centrally located Cytoplasm: Chromatoidal bodies may be present; elongate with blunt rounded edges; may be round or oval
E. hartmanni	Size: 5–12 μm Motility: Nonprogressive Nucleus: 1; peripheral chromatin like *E. histolytica*/*E. dispar,* may appear as solid ring; karyosome small, compact, centrally located or eccentric Cytoplasm: Finely granular, bacteria, no RBCs Note: Accurate measurement essential for differentiation from *E. histolytica*/*E. dispar*	Size: 5–10 μm; spherical Nucleus: Mature cyst, 4; immature cyst, 1 or 2 (very common); peripheral chromatin fine, evenly distributed, may be difficult to see; karyosome small, compact, centrally located Cytoplasm: Chromatoidal bodies usually present, like in *E. histolytica*/*E. dispar*
E. coli	Size: 15–50 μm Motility: Sluggish, nondirectional Nucleus: 1; peripheral chromatin clumped and uneven, may be solid ring; karyosome large, not compact, diffuse, eccentric Cytoplasm: Granular, usually vacuolated; contains bacteria, yeast, no RBCs Note: Can resemble *E. histolytica*/*E. dispar;* coinfection seen; stained smear essential	Size: 10–35 μm; spherical, rarely oval or triangular Nucleus: Mature cyst, 8; occasionally ≥16; immature cyst, ≥2; peripheral chromatin coarsely granular, unevenly arranged; may resemble *E. histolytica*/*E. dispar;* karyosome small, usually eccentric but may be central Cytoplasm: Chromatoidal bodies less frequent than in *E. histolytica*/*E. dispar;* splintered, with rough, pointed ends Note: May be distorted on permanent-stained smear due to poor penetration of fixative
E. nana	Size: 6–12 μm Motility: Sluggish, nonprogressive Nucleus: 1; no peripheral chromatin; karyosome large, "blot like" Cytoplasm: Granular, vacuolated; may contain bacteria Note: May be tremendous nuclear variation; can mimic *E. hartmanni* and *D. fragilis*	Size: 5–10 μm; oval, may be round Nucleus: Mature cyst, 4; immature cyst, 2; no peripheral chromatin; karyosome smaller than those in trophozoites but larger than those in *Entamoeba* spp. Cytoplasm: Chromatoidal bodies rare; small granules occasionally seen
I. bütschlii	Size: 8–20 μm Motility: Sluggish, nonprogressive Nucleus: 1; no peripheral chromatin; karyosome large, may have "basket nucleus" Cytoplasm: Coarsely granular, may be highly vacuolated; bacteria, yeast, and debris may be seen Note: Stained smear essential; nucleus may appear to have a halo with chromatin granules fanning around karyosome	Size: 5–20 μm; oval to round Nucleus: Mature cyst, 1; no peripheral chromatin; karyosome large, usually eccentric Cytoplasm: No chromatoidal bodies; small granules occasionally present Note: Glycogen present, large, compact, well-defined mass; cysts may collapse owing to large glycogen vacuole space
B. hominis[d]	Very difficult to identify; rarely seen	Size: 6–40 μm; generally round Description: Usually characterized by a large, central body (looks like a large vacuole) surrounded by small, multiple nuclei; central body area can stain various colors (trichrome) or remain clear

[a] Adapted from reference 30.
[b] Size ranges are based on wet preparations (with permanent stains, organisms usually measure 1 to 2 μm less).
[c] Nuclear and cytoplasmic descriptions are based on permanent-stained smears.
[d] Description of central body form.

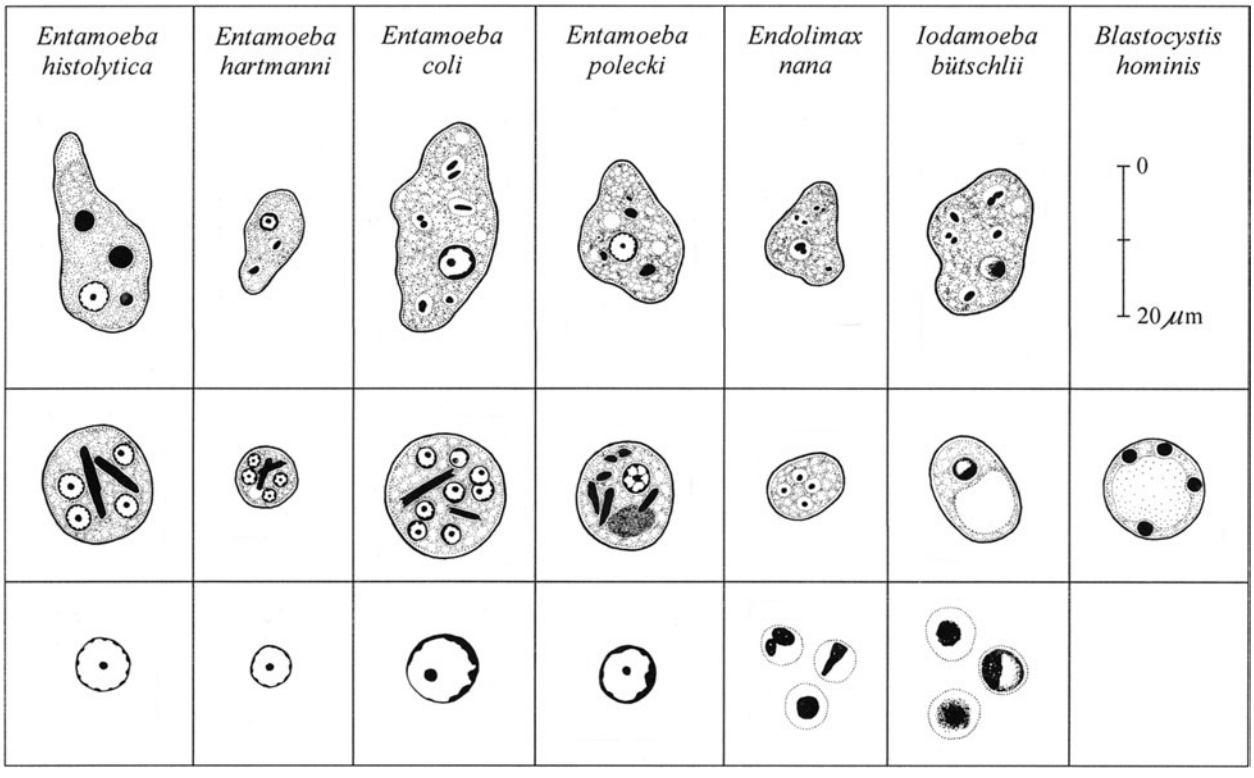

FIGURE 1 Intestinal amebae of humans. (Top row) Trophozoites. *E. histolytica* is shown with ingested RBCs. This is the only microscopic finding that allows differentiation of the pathogenic species *E. histolytica* from the nonpathogenic species *E. dispar.* An ameboid form of *B. hominis* is rarely seen and is difficult to identify. (Middle row) Cysts. For *B. hominis* the central body form is depicted. (Bottom row) Trophozoite nuclei, shown in relative proportion.

The development of axenic culture methods was a key step in confirming the existence of two species. Using organisms obtained by such cultures, Sargeaunt and Williams (104) performed isoenzyme analysis of several glycolytic enzymes and identified electrophoretic banding patterns, or zymodemes. Two groups were identified on the basis of these patterns: pathogenic zymodemes (invasive isolates) and nonpathogenic zymodemes (noninvasive isolates). The zymodeme patterns represent stable genetic differences and do not interconvert (90). Additional genetic, biochemical, and immunologic evidence has supported the existence of two distinct species. Diamond and Clark (25) redescribed the two species as *E. histolytica* Schaudinn 1903, which is the invasive human pathogen, and *E. dispar* Brumpt 1925, which is noninvasive and which does not cause disease.

Infection with *E. histolytica/E. dispar* can result in different clinical presentations: asymptomatic infection, symptomatic infection without tissue invasion, and symptomatic infection with tissue invasion. The majority of infections with *E. histolytica/E. dispar* are asymptomatic. Individuals with such infections will have a negative or weak serologic response and will primarily pass cysts in their stools. Zymodeme analysis shows that most asymptomatic individuals are infected with the noninvasive species *E. dispar* (130, 131). However, it appears that infection with both *E. histolytica* and *E. dispar* can be asymptomatic, with cyst stages being passed in the stool (11). Asymptomatic *E. histolytica* infection may be due to the existence of genetically distinct invasive and noninvasive strains of *E. histolytica* (135).

Intestinal disease results from the penetration of the amebic trophozoites into the intestinal tissues. Approximately 10% of infected individuals will have clinical symptoms, presenting as dysentery, colitis, or, rarely, ameboma. The incubation period varies from a few days to several months. Various molecules such as adhesins, amebapores, and proteases have been associated with lysis of the colonic mucosa in intestinal amebiasis (27). The 260-kDa galactose- or *N*-acetylgalactosamine-specific lectin of *E. histolytica* is an important virulence factor, mediating the attachment of the ameba to the intestinal epithelium and contact-dependent cytolysis (96). Symptoms of amebic dysentery include diarrhea with cramping, lower abdominal pain, low-grade fever, and the presence of blood and mucus in stool. The ulcers produced by intestinal invasion by trophozoites start as superficial localized lesions that deepen into the classic flask-shaped ulcers of amebic colitis. The ulcers are separated by segments of normal tissue but can coalesce. Amebae can be found at the advancing edges of the ulcer but usually not in the necrotic areas. Abdominal perforation and peritonitis are rare but serious complications. A more chronic presentation occurs with amebic colitis. It is characterized by intermittent diarrhea over a long period and can be misdiagnosed as ulcerative colitis or irritable bowel syndrome. Ameboma, a localized tumor-like lesion, results from chronic ulceration and may be mistaken for malignancy. Histologically, it consists of granulomatous tissue.

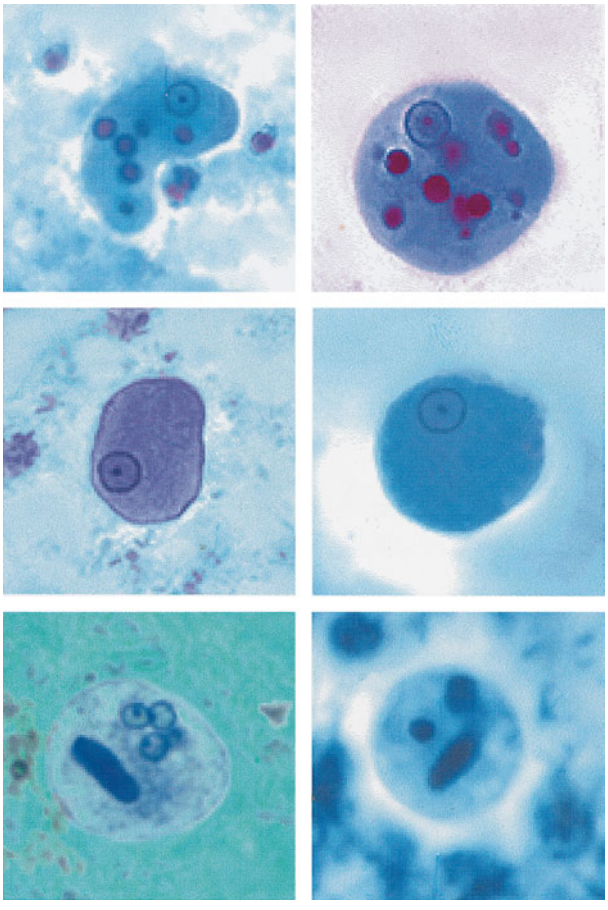

FIGURE 2 (Top row) *Entamoeba histolytica* trophozoites. Note the ingested RBCs in the cytoplasm. (Middle row) *E. histolytica/E. dispar* trophozoites. Note the absence of RBCs in the cytoplasm. (Bottom row) *E. histolytica/E. dispar* cysts. These cysts cannot be identified to the species level on the basis of morphology. Organisms are stained with Wheatley's trichrome stain. (Courtesy of L. Garcia.)

Extraintestinal disease occurs with the hematogenous spread of the organism. It can occur with or without previous symptomatic intestinal infection. The liver is the most common site of extraintestinal disease, followed by the lungs, pericardium, brain, and other organs. Symptoms can be acute or gradual and may include low-grade fever, right-upper-quadrant pain, and weight loss. Up to 5% of individuals with intestinal symptoms develop liver abscess. However, up to 50% of individuals with liver abscess have no history of gastrointestinal disease.

Direct Examination

The laboratory diagnosis of amebiasis can be made by the examination of feces, material obtained from sigmoidoscopy, tissue biopsy specimens, and abscess aspirates. Serologic testing is also useful for the diagnosis of extraintestinal amebiasis. A summary of the laboratory techniques and their performance characteristics is presented in Table 3.

Microscopy

As discussed above, the most important part of the standard microscopic examination of stool and other specimens is the permanent-stained smear. Direct wet preparations and concentration procedures may also be useful (Fig. 1; Table 2; see also chapter 135). Detection of trophozoites and cysts does not, however, allow differentiation of the pathogenic species, *E. histolytica,* from the nonpathogenic species, *E. dispar* (Fig. 1 and 2). The presence of ingested RBCs in the cytoplasm of the trophozoites is commonly regarded as diagnostic of *E. histolytica* infection. However, Haque et al. (43) found that 16% of *E. dispar* isolates had ingested RBCs; thus, this distinction between the two species is not absolute (119, 120). In tissue specimens, only the trophozoite is found, and its presence is considered diagnostic of invasive *E. histolytica* disease.

Antigen Detection

For a more definitive differentiation of *E. histolytica* and *E. dispar,* methods other than microscopy are necessary. Zymodeme analysis can accomplish this differentiation but requires culture of the organisms from the specimen and is too expensive and complex for routine laboratory use. More recently, antigen detection methods for the detection and differentiation of *E. histolytica* and *E. dispar* have become commercially available in the United States (TechLab, Blacksburg, Va.; Alexon-Trend, Ramsey, Minn.; and Biosite Inc., San Diego, Calif.). The assays are designed for use with fresh, fresh-frozen, or unfixed human fecal specimens. Depending on the kit used, the group *E. histolytica/E. dispar* or the individual species can be detected in the feces. Only Tech Labs offers an *E. histolytica*-specific kit, *E. Histolytica II*, which detects the Gal- or GalNAc-binding lectin specific to the pathogenic species (43, 95). All the antigen detection methods are relatively simple and are more sensitive and specific than microscopy (Table 3) (33, 43, 89). They cannot be used with preserved stool, as the fixative appears to denature the antigens. Although some reports of the use of preserved stool have appeared (133), more work is needed to identify additional antigens that withstand fixation before it would be practical to offer antigen tests in laboratories that receive only preserved stool specimens. Antigen assays have been used to test a number of other sample types such as serum, pus, and saliva (1, 42); the detection of antigen in serum may prove to be a sensitive means of diagnosing amebic liver abscess and intestinal disease (42, 119). Because fewer than 10% of patients with amebic liver abscesses have concurrent intestinal disease with amebae detectable in the stool, methods such as routine ova and parasite examination are not useful. Microscopic examination or culture of pus from liver abscesses likewise lacks sensitivity. In a study by Haque et al. (42), serum antigen detection by using the Tech Labs *E. Histolytica II* kit was a sensitive method for diagnosis with samples collected prior to treatment with metronidazole. Serum antigenemia appears to clear after treatment, suggesting possible utility to monitor therapy; however, this use is still experimental (42, 119).

Nucleic Acid Detection Techniques

Nucleic acid amplification techniques, such as PCR, have been developed for the detection and differentiation of *E. histolytica* and *E. dispar.* Traditional PCR has been applied to specimens such as feces and liver or brain aspirates and can detect both trophozoite and cyst DNA (28, 101, 136). More recently, real-time PCR has been used for the detection of *E. histolytica* and *E. dispar* (7, 103) and for the simultaneous detection of *E. histolytica*, *G. lamblia,* and *Cryptosporidium parvum* (124) in stool. Different extraction techniques, some of which are relatively simple, and the use of fresh and preserved material have been reported (101, 121, 125). Stool can present challenges

TABLE 3 Sensitivity and specificity of diagnostic tests for amebiasis[a]

Test and specimen type	Colitis		Liver abscess
	Sensitivity (%)	Specificity (%)	Sensitivity (%)
Microscopy			
Stool	<60	10–50	<10
Abscess fluid	NA[b]	NA	<25
Culture with isoenzyme analysis	Lower than antigen or PCR tests	Gold standard	<25
Stool antigen detection (ELISA)[c]	>95	>95	Usually negative
Serum	65 (early)	>90	~75 (late); ~100 (first 3 days)
Abscess fluid	NA	NA	~100 (before treatment)
Saliva	Not done	Not done	70
PCR			
Stool	>70	>90	Not done
Serum antibody detection (ELISA)	>90	>85	70–80 (acute stage); >90 (convalescent stage)

[a] Reprinted from reference 119 with permission.
[b] NA, not available.
[c] ELISA, enzyme-linked immunosorbent assay.

due to the presence of PCR inhibitors (84), so the inclusion of an amplification control is useful (124).

PCR has proven to be more sensitive and specific than microscopy and at least as sensitive as antigen detection, depending on the study (Table 3) (40, 119). For routine use in clinical laboratories, a PCR method would ideally involve a relatively simple sample preparation procedure and allow the use of preserved material. Because PCR and antigen detection may be approximately equal in sensitivities, an antigen detection test may be preferable due to technical ease of use and shorter time required.

Serologic Tests

Serologic testing is a useful aid, in conjunction with antigen detection or PCR, for the diagnosis of symptomatic, invasive disease. Multiple methods have been used, including indirect hemagglutination, complement fixation, latex agglutination, and EIA (119). Of patients with biopsy-proven intestinal amebiasis, 85% have serum antibodies. For patients with extraintestinal disease, serologic tests have a sensitivity approaching 99%. For asymptomatic intestinal diseases, serology is generally not useful unless the patient has invasive infection. Persons infected with *E. dispar* do not produce detectable antibodies. After cure of invasive amebiasis, serum antibodies may persist for up to 10 years; this can complicate diagnosis in areas where infection is endemic (57).

EIAs for the detection of immunoglobulin M (IgM) and IgG are widely used, and most are based on the detection of antilectin antibodies, which appear over 1 week after symptoms of *E. histolytica* infection (119). Indirect hemagglutination is useful and highly specific but may lack sensitivity compared to EIAs (119). Several investigators have reported the utility of IgA antibody testing and a link to partial immunity in individuals with detectable antilectin IgA (41, 42, 116).

Evaluation, Interpretation, and Reporting of Results

Until all laboratories have the capability to discriminate between *E. histolytica* and *E. dispar,* the method of laboratory reporting must change. In January 1997, a World Health Organization panel of experts made recommendations concerning the reporting and treatment of amebiasis (131). If microscopic diagnosis is made on the basis of the detection of trophozoites and/or cysts and no method is used to differentiate the two species, the report should indicate "*E. histolytica*/*E. dispar* detected." Laboratory reports must indicate whether trophozoites and/or cysts are present, due to differences in therapy.

Treatment

On the basis of the 1997 World Health Organization conference, treatment is not recommended for *E. dispar* infections; if *E. histolytica*/*E. dispar* is detected (no differentiation of species) in symptomatic patients, the physician must evaluate the total clinical presentation to decide whether treatment is indicated. The detection of *E. histolytica* requires treatment of the patient regardless of the symptoms.

The drugs used for the treatment of amebiasis are of two classes: luminal amebicides for cysts (paromomycin, iodoquinol, and diloxanide furoate) and tissue amebicides for trophozoites (metronidazole, tinidazole, and dehydroemetine). Invasive disease should be treated with a tissue amebicide followed by a luminal amebicide. Tissue amebicides are not appropriate for treatment of asymptomatic infections (cysts). No high-level resistance to amebicides has been detected to date. Follow-up stool examination is always necessary because of potential treatment failures. Chemoprophylaxis is never appropriate because it may lead to drug resistance and limit the utility of drugs such as metronidazole (123, 131).

B. hominis

Epidemiology, Transmission, and Prevention

B. hominis is a common intestinal parasite of humans, with a worldwide distribution. Depending on the geographic location, it may be detected in 1 to 40% of fecal specimens.

Since its first description in 1912, the taxonomic classification has changed and is still somewhat unclear. Once classified as a yeast, it is now considered a protozoan grouped with the amebae. Silberman et al. (112) reported that the analysis of rRNA indicates that *B. hominis* should be classified with the stramenopiles (examples are brown algae such as kelp, diatoms, slime nets, and water molds). Genetic, biochemical, and immunologic analyses have revealed that great diversity exists within the species (19, 75, 86). Further studies are needed to determine whether these differences constitute separate species or strains and whether there is any epidemiologic significance associated with this diversity.

The life cycle includes amebic forms, cyst stages, and the central body form, which is the classic form seen in human stool specimens. *B. hominis* produces pseudopods and reproduces by binary fission or sporulation. It is strictly anaerobic and is capable of ingesting bacteria and other debris. The membrane-bound central body occupies up to 90% of the cell and may function in reproduction. Both thin- and thick-walled cysts have been observed. The thick-walled cysts are thought to be responsible for external transmission via the fecal-oral route; the thin-walled cysts are thought to cause autoinfection (82). Human-to-human, animal-to-human, and waterborne modes of transmission have also been proposed (71, 86, 134).

Clinical Significance

The role of *B. hominis* in human disease is still controversial, and studies supporting and refuting its pathogenicity have been published (77, 110, 137). Regardless of the number of publications on each side of this debate, clinicians may decide to treat patients with *B. hominis* infection. When *B. hominis* is present in large numbers in the absence of other pathogens, it may be the cause of gastrointestinal disease. The most common symptoms cited include recurrent diarrhea without fever, vomiting, and abdominal pain. The symptoms may be more pronounced and prolonged in patients with underlying conditions such as HIV infection, neoplasia, and abnormal intestinal tract function (49, 122). Other studies suggest that symptomatic patients receiving treatment for *B. hominis* infection may improve due to the elimination of another, undetected pathogen (77). In a study of HIV-infected individuals, Albrecht et al. (5) concluded that even in patients with severe underlying immunodeficiencies, *B. hominis* is not pathogenic and its detection does not justify treatment.

Direct Examination

Microscopy

Diagnosis of infection is made by detection of the organism, typically the central body form, by routine microscopic stool examination (Table 2; Fig. 1 and 3). The size of the central body form can vary tremendously, from 6 to 40 μm. Examination of permanent-stained smears is the procedure of choice. Exposure to water before fixation (for the concentration method) will lyse the trophozoites and central body forms, yielding false-negative results. Some type of quantitation (few, moderate, or many) should be included in the laboratory report.

Other Diagnostic Methods

Culture of the organism from stool is possible and has been reported to be more sensitive than microscopy but is not routinely available (72). A serologic response to *B. hominis* has been detected using techniques such as EIA and fluorescent-antibody testing (29, 138). It is suggested that this antibody response supports the role of *B. hominis* as a human pathogen but is not useful for diagnosis. In asymptomatic individuals, a serologic response may require exposure of up to 2 years before it is detectable (58).

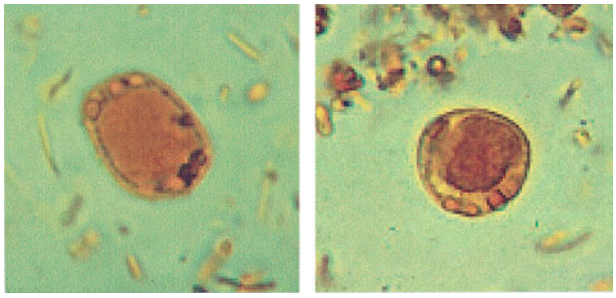

FIGURE 3 *Blastocystis hominis* on an iodine wet mount preparation. Note the peripheral nuclei and the central body form. (Courtesy of L. Garcia.)

Treatment

Until the role of *B. hominis* as an intestinal pathogen is clearly established, treatment decisions must be based on the overall clinical presentation. Current recommendations for treatment include the use of metronidazole, iodoquinol, or trimethoprim-sulfamethoxazole (2). Metronidazole appears to be the most appropriate choice at present. In vitro data on the susceptibility of *B. hominis* to various drugs are limited (137), but resistance to metronidazole has been reported (45). A failure to clear organisms from the stool has been demonstrated in patients treated with metronidazole and trimethoprim-sulfamethoxazole.

NONPATHOGENIC AMEBAE

The other species of intestinal amebae are considered nonpathogenic; except for *Entamoeba polecki,* they have a worldwide distribution and are more prevalent in warmer climates. They must, however, be differentiated from the pathogenic species, *E. histolytica.* A permanently stained smear is often essential to accomplish this goal (Table 2; Fig. 1).

E. hartmanni is a separate species that is morphologically similar to *E. histolytica/E. dispar* (Fig. 4). Size is the key differentiating characteristic. *Entamoeba coli* trophozoites may be difficult to differentiate from *E. histolytica/E. dispar* trophozoites on wet preparations. The mature cyst of *Entamoeba coli* may be refractory to fixation, making it less visible in permanent-stained smears but still detectable by the wet mount method (Fig. 5). It has been reported as the most common ameba

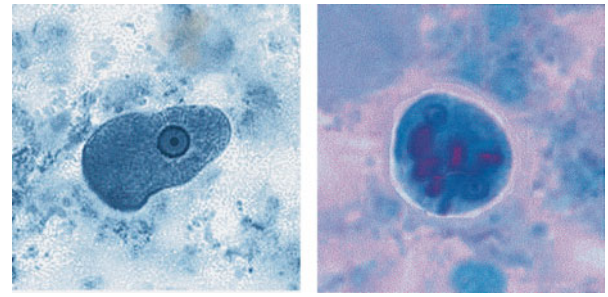

FIGURE 4 *Entamoeba hartmanni* trophozoite (left) and cyst (right). Note the "bull's eye" nucleus in the trophozoite and the numerous chromatoidal bars within the cyst. Organisms are stained with Wheatley's trichrome stain. (Courtesy of L. Garcia.)

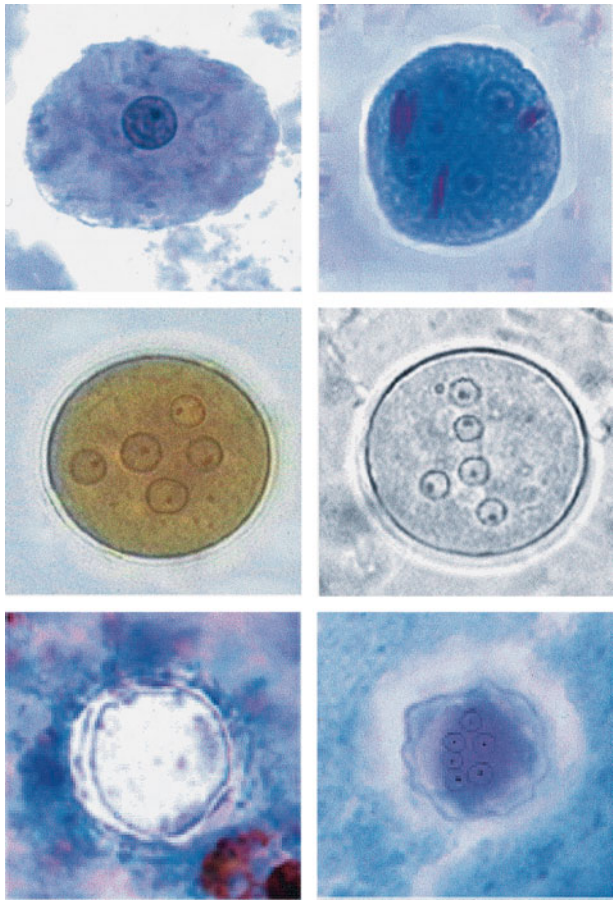

FIGURE 5 (Top row) *Entamoeba coli* trophozoite (left) and cyst (right). Note the large eccentric karyosome in the trophozoite and the chromatoidal bars with sharp pointed ends in the cyst. (Middle row) *Entamoeba coli* cyst in iodine (left) and in saline (right). The nuclei are visible; the presence of five or more nuclei is confirmatory for *Entamoeba coli.* (Bottom row) *Entamoeba coli* cyst (left; trichrome) and cyst (right; trichrome). Both cysts are very distorted and shrunken, although the nuclei can be seen in the cyst on the right. This type of shrinkage is typical of *Entamoeba coli* cysts on permanent-stained smears. (Courtesy of L. Garcia.)

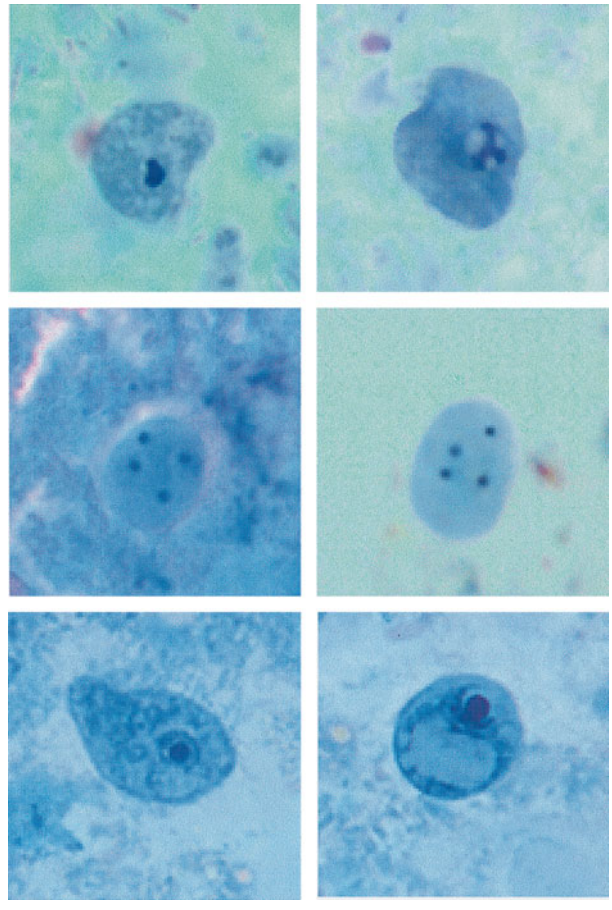

FIGURE 6 (Top row) *Endolimax nana* trophozoites. Note the typical nucleus on the left and the nuclear variation on the right. (Middle row) *E. nana* cysts. Note the typical four nuclei, none of which have peripheral chromatin. (Bottom row) *I. bütschlii* trophozoite (left) and cyst (right). Note the "basket nucleus" in the cyst, along with the large glycogen vacuole. Organisms are stained with Wheatley's trichrome stain. (Courtesy of L. Garcia.)

isolated from human stool specimens. *E. polecki* is associated with pigs, and in certain areas of the world, such as Papua New Guinea, it is the most common human intestinal parasite. The trophozoite shares characteristics with both *E. histolytica*/*E. dispar* and *Entamoeba coli;* the cyst normally has one nucleus. *Entamoeba gingivalis* was the first parasitic ameba of humans to be described. It is found in the soft tartar between teeth and can be recovered from sputum. In the trophozoite, the cytoplasm often contains ingested leukocytes. A cyst form has not been observed.

E. nana, like *E. hartmanni,* is one of the smaller intestinal amebae. It is seen in most populations as frequently as *Entamoeba coli.* There is a great deal of nuclear variation, and it can mimic *D. fragilis* and *E. hartmanni* (Fig. 6). The cysts of *E. nana* are usually oval, and both the trophozoites and the cysts are commonly present in fecal material. *I. bütschlii* has the same distribution as other nonpathogenic amebae but is less common than *Entamoeba coli* and *E. nana.* The trophozoite of *I. bütschlii* may be similar to that of *E. nana,* and differentiation between them is difficult. The cyst is very characteristic; it is round to oval and may contain a large glycogen vacuole (Fig. 6).

Treatment is not recommended for infections with any of the nonpathogenic amebae. Methods of prevention of infection with all these amebae include improved personal hygiene and improved sanitary conditions.

FLAGELLATES

Taxonomy

The flagellates that parasitize the intestinal tracts of humans belong to six genera in the phylum Sarcomastigophora, subphylum Mastigophora: *Giardia, Dientamoeba, Trichomonas, Chilomastix, Enteromonas,* and *Retortamonas* (Fig. 7).

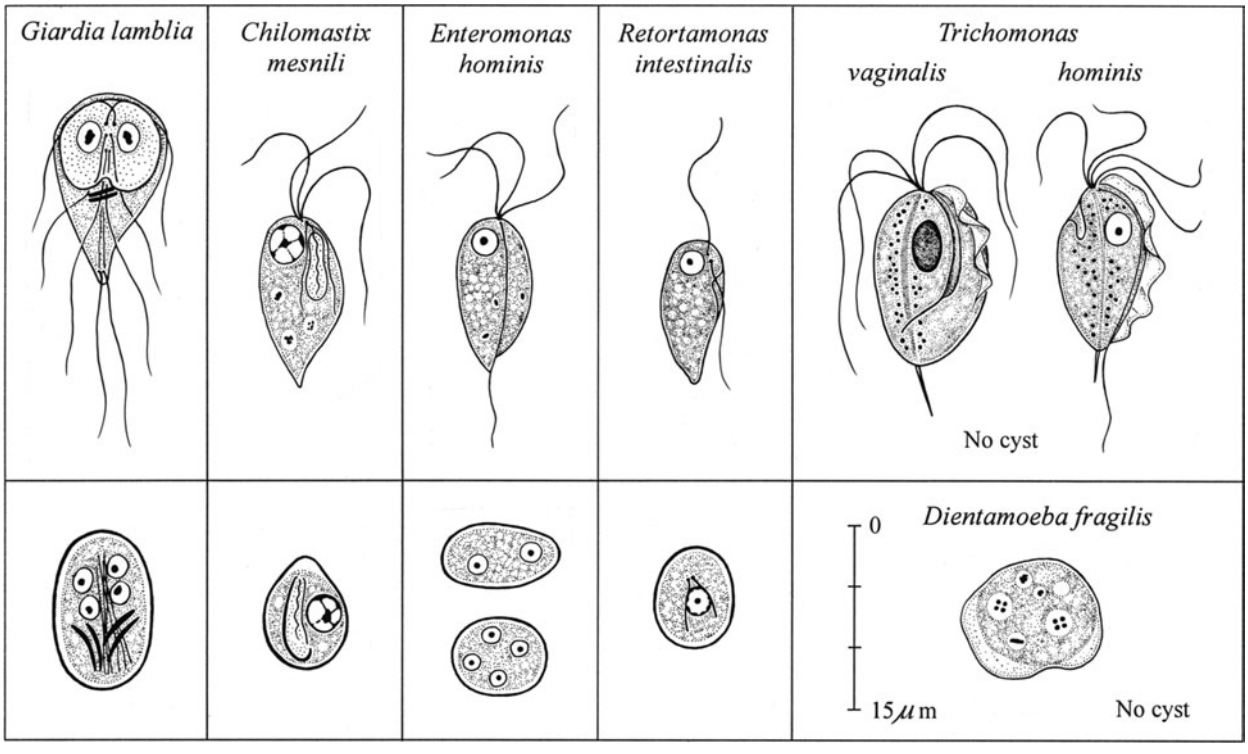

FIGURE 7 Intestinal and urogenital flagellates of humans. (Top row) Trophozoites. *T. vaginalis* is found in urogenital sites; all other flagellates are intestinal. (Bottom row) Cysts. *D. fragilis* trophozoite is shown; no cyst stage.

Description of the Agents

Some flagellates are commensals that reside in the intestinal tract and are harmless to the individual. The flagellates that are pathogenic to humans include *G. lamblia, D. fragilis,* and *Trichomonas vaginalis.* The nonpathogenic organisms are *Chilomastix mesnili, Enteromonas hominis, Retortamonas intestinalis,* and *Pentatrichomonas (Trichomonas) hominis.* As mentioned above, *D. fragilis* has been reclassified as a flagellate and appears to be closely related to the trichomonads.

Epidemiology, Transmission, and Prevention

Transmission of flagellates, with the exception of *T. vaginalis,* is initiated via the ingestion of contaminated food or water. Of the members of the six genera, all except *D. fragilis* and *Trichomonas* spp. are transmitted in a cyst form. To date, only a trophozoite form has been observed for *D. fragilis* and *Trichomonas* spp. Once in the intestine, the organism excysts, releasing trophozoites that attach to the intestinal epithelium. Completion of the life cycle in humans culminates in the release of viable cysts into the environment via the feces. Infection with any of the flagellates indicates exposure to feces regardless of the pathogenicity of the organism; preventing this exposure is the key. Measures to improve sanitary conditions are necessary to prevent the spread of infection. As yet there are no human flagellate vaccines available.

Collection, Transport, and Storage of Specimens

For the detection of flagellates and ciliates, laboratories receive predominantly stool specimens for microscopic examination. String test samples can be submitted for *Giardia* as well. Fresh or preserved specimens can be submitted, but preserved stool is the specimen of choice for most routine clinical laboratories. If fresh specimens are submitted and observed for motility, they must be examined within a specific time period depending on the consistency of the stool. Stool specimens for immunoassay or DFA assay can be fixed in formalin, which can also be used for an ova and parasite exam if immunoassays are negative for *G. lamblia*. Additional information on specimen collection and transport can be found in chapter 133 of this Manual.

Direct Examination

Microscopy

In the clinical laboratory, wet preparations and permanent-stained smears of fecal material are still the predominant specimens used to diagnose infections with flagellates. The flagellates have greater morphologic diversity relative to one another than do the amebae (described above), making determination of the genus easier (Table 4; Fig. 7). To aid in the identification of the trophozoite, key features to be noted are the shape, size, number, and position of flagella; the number of nuclei; and the presence of a spiral groove, cytostome, and characteristic features such as a sucking disk or undulating membrane. Typically, the size, shape, and number of nuclei are diagnostic characteristics used to identify cysts. Examination of permanent-stained smears is always recommended for diagnosis of infection because the wet mount may not be reflective of all organisms and stages present in the specimen.

Other Diagnostic Methods

Antigen-based tests for organisms such as *G. lamblia* are increasing in popularity due to the ease of use and increased

TABLE 4 Key features of trophozoites and cysts of common intestinal and urogenital flagellates[a]

Organism	Trophozoites	Cysts
D. fragilis	Size[b]: 5–15 μm; shaped like amebae Motility: Nonprogressive; pseudopodia are angular Flagella: None Nucleus[c]: 1 (40%) or 2 (60%); no peripheral chromatin; karyosome clusters of 4–8 granules Note: Trophozoites not visible in unstained preparation; variation in size between trophozoites can exist on the same smear; cytoplasm is finely granular, and vacuoles may be present	No cyst stage
G. lamblia	Size: 10–20 μm long, 5–15 μm wide; pear shaped Motility: Falling leaf Flagella: 4 lateral, 2 ventral, 2 caudal Nucleus: 2; not visible in unstained preparation; small central karyosomes present Note: Sucking disk is prominent on ventral side of trophozoite; organism is spoon shaped from side view	Size: 8–19 μm long, 7–10 μm wide; oval, ellipsoidal, or round Nucleus: 4 nuclei usually located on one end; not distinct in unstained preparation; no peripheral chromatin; karyosomes smaller than those in trophozoite Cytoplasm: Staining can cause shrinkage where cytoplasm pulls away from the cyst wall; 4 median bodies present Note: Poorly defined longitudinal fibers may be present
C. mesnili	Size: 6–24 μm long, 4–8 μm wide; pear shaped Motility: Stiff, rotary Flagella: 3 anterior, 1 in cytostome Nucleus: 1; not visible in unstained preparation Cytoplasm: Prominent cytostome extends over one-third to one-half of body; spiral groove across ventral surface can be hard to see; vacuoles present	Size: 6–10 μm long, 4–6 μm wide; lemon shaped with anterior hyaline knob Nucleus: Same as trophozoite; difficult to see in unstained preparation; indistinct central karyosome present Cytoplasm: Curved fibril alongside of cytostome known as "shepherd's crook"
P. hominis	Size: 5–15 μm long, 7–10 μm wide; pear shaped Motility: Jerky, rapid Flagella: 3–5 anterior, 1 posterior (extends beyond end of body) Nucleus: 1; not visible in unstained preparation Cytoplasm: Central longitudinal axostyle; undulating membrane runs the entire length of body Note: May have tremendous nuclear variation; can mimic *E. hartmanni* and *D. fragilis*	No cyst stage
T. vaginalis	Size: 7–23 μm long, 5–15 μm wide Motility: Jerky, rapid Flagella: 3–5 anterior, 1 posterior Nucleus: 1; not visible in unstained preparation Note: Undulating membrane extends one-half the length of body; no free posterior flagella	No cyst stage
E. hominis	Size: 4–10 μm long, 5–6 μm wide; oval Motility: Jerky Flagella: 3 anterior, 1 posterior Nucleus: 1; not visible in unstained preparation Note: One side of the body is flat; posterior flagellum extends free posteriorly or laterally	Size: 4–10 μm long, 4–6 μm wide; elongate or oval in shape Nucleus: 1–4; not visible in stained preparation Note: Resemble *E. nana* cysts; fibrils or flagella usually not seen
R. intestinalis	Size: 4–9 μm long, 3–4 μm wide; pear shaped or oval Motility: Jerky Flagella: 1 anterior, 1 posterior Nucleus: 1; not visible in unstained preparation Note: Very difficult to identify; rarely seen; prominent cytostome which extends half the length of body	Size: 4–9 μm long, 5 μm wide; pear or lemon shaped Nucleus: 1; not visible in unstained preparation Note: Resemble *Chilomastix* cysts; bird beak fibril arrangement; shadow outline of cytostome with supporting fibrils extends above nucleus

[a] Adapted from reference 30.
[b] Size ranges are based on wet preparations (with permanent stains, organisms usually measure 1 to 2 μm less).
[c] Nuclear and cytoplasmic descriptions are based on permanent-stained smears.

throughput compared to microscopy. In addition, nucleic acid amplification methods have been developed to detect *T. vaginalis* in clinical samples and *G. lamblia* in water and clinical samples but are not yet routinely available in the clinical laboratory. Both antigen and amplification tests for the flagellates will be discussed in more detail below. Serologic assays are available for the diagnosis of *G. lamblia* infection but are not routinely used in the clinical setting.

Evaluation, Interpretation, and Reporting of Results

It is important that a representative portion of the slide, either a wet mount or a permanent smear, be scanned before a final opinion on a specimen is given. It is also important to use an accurate micrometer to measure life cycle stages. Reports of microscopy results should clearly indicate the full taxonomic names of the organisms detected along with the forms of the organisms seen (cysts versus trophozoites). Quantitation of the number of organisms seen is not appropriate for the flagellates.

G. lamblia

Epidemiology, Transmission, and Prevention

G. lamblia is an intestinal flagellate that infects both humans and animals and is the most common cause of intestinal parasitosis in humans worldwide. Because the literature refers to this organism as *G. lamblia, Giardia intestinalis,* and *Giardia duodenalis,* it is evident that there is still debate about the classification and nomenclature of this flagellate. Previous work, based primarily on structural variations of the parasite, resulted in the proposal of three species, *Giardia muris* (mice), *Giardia agilis* (amphibians), and the intestinalis group *(Giardia duodenalis)* (3, 30). Further studies support the existence of additional species, *Giardia ardeae* (herons), *Giardia psittaci* (parakeets), and *Giardia microti* (voles and muskrats). Also, it appears that *G. lamblia (intestinalis)* is a species complex that should contain the species *G. microti* as well (83). Further studies are needed to elucidate species designations and groupings. Although these species have been proposed, *G. lamblia* is the name predominantly used in the United States and will continue to be used throughout this chapter.

It is now accepted that there is considerable genetic diversity within *G. lamblia.* Based on molecular biology, the genus *Giardia* is subdivided into major genotypes containing subgenotypes. The major genotypes of *G. lamblia* that are associated with human infections are assemblages A and B. Assemblage A is associated with a mixture of both human and animal isolates, whereas assemblage B is typically associated with human isolates only. Most zoonotic infections from animal to human occur with assemblage A (38).

Infection with *G. lamblia* occurs through fecal-oral transmission or the ingestion of cysts in contaminated food or water, and an inoculum of only 10 to 100 cysts is sufficient for human infection (99). Individuals more commonly infected in developed countries are children in day care centers, hikers, and immunocompromised individuals. Among immunocompromised individuals, infections have been documented in people with AIDS and hypogammaglobulinemia and those affected by malnutrition. Prevalence rates for this pathogen range from 1 to 7% in industrialized countries and from 5 to 50% in developing countries. Of the intestinal flagellates, *G. lamblia* is the flagellate most frequently isolated in the United States. In high-risk domestic settings, such as day care centers, prevalence rates can reach 90% (93). A *Giardia* vaccine is available for dogs and cats; this may affect the prevalence of infections in humans (88).

Infection occurs when viable cysts are ingested, excyst, and transform into trophozoites. After excystation, the trophozoite, which appears to have a propensity for the duodenum, attaches to the mucosal epithelium. Trophozoites attach to the epithelium via a sucking disk located on the ventral side of the parasite. During the course of infection, the parasites remain attached to the epithelium and do not invade the mucosa. In the intestine, trophozoites divide by binary fission to produce two identical daughter trophozoites. As they move down toward the large intestine, the trophozoites encyst, and infective cysts are excreted into the environment (30).

Clinical Significance

The majority of individuals infected with *G. lamblia* are asymptomatic. Asymptomatic versus symptomatic infection may be due to the existence of two different strains of *Giardia* with different levels of virulence. Preliminary studies have grouped *G. lamblia* into two groups, group A and group B. Group A appears to be more pathogenic and is associated with symptomatic infection. Isoenzyme and molecular studies show that group A and group B differ from one another and appear to be no more related than *E. histolytica* and *E. dispar.* The genes homologous between group A and group B *Giardia* isolates show an identity of approximately 81 to 89% (83, 91, 92). In symptomatic individuals, acute *G. lamblia* infections can mimic infections with other protozoal, viral, and bacterial pathogens. After an incubation period of approximately 12 to 20 days, patients can experience nausea, chills, low-grade fever, epigastric pain, and a sudden onset of watery diarrhea. Diarrhea is often explosive and presents as foul smelling without the presence of blood, cellular exudate, or mucus. Individuals can develop subacute or chronic infections with symptoms such as recurrent diarrhea, abdominal discomfort and distention, belching, and heartburn. In patients with chronic cases of giardiasis, diarrhea can lead to dehydration, malabsorption, and impairment of pancreatic function (14).

Direct Examination

Microscopy

Diagnosis of *G. lamblia* infection is typically established by the microscopic examination of stool for the presence of cysts and/or trophozoites. Stained smears are more helpful in identifying the trophozoite stage of the infection, although this stage can be identified in wet mount preparations (Table 4; Fig. 7 and 8). Examination of stool specimens may not be diagnostic because cyst forms can be trapped in mucus, making them difficult to detect on smears. Also, the excretion pattern of cysts can be cyclical. In these instances, other methods, such as the string test (Entero-Test; HDC Corp., San Jose, Calif.), should be used to obtain clinical samples. The string test procedure consists of a patient swallowing a weighted capsule containing gelatin and a tightly wound string. After approximately 5 h, the string is removed from the patient and the adherent material is examined as a wet mount or permanent smear (30). Endoscopy can also be used to collect clinical specimens. Because this procedure is invasive, it is used only for diagnosis of disease in patients with perplexing clinical presentations (93).

Antigen Detection

Other assays that have gained wide acceptance for the detection of *G. lamblia* in stool specimens are EIAs, DFA assays, and immunochromatographic assays. These methods

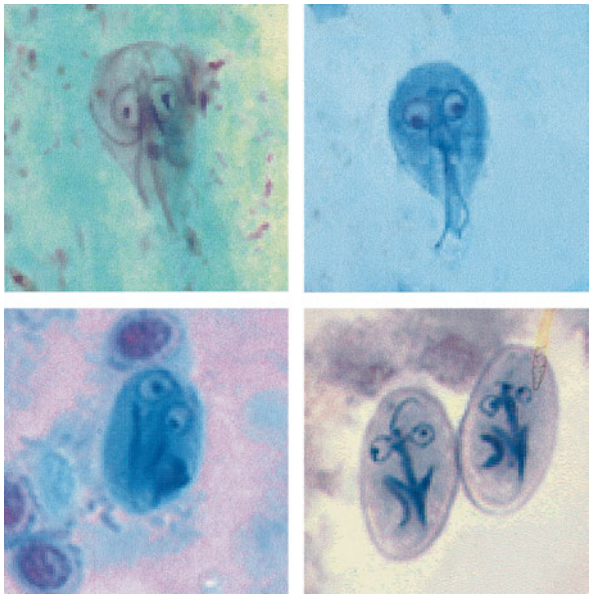

FIGURE 8 (Top row) *Giardia lamblia* trophozoites. Note the typical nuclei, axonemes, and curved median bodies. (Bottom row) *G. lamblia* cysts. The cysts on the right are stained with iron-hematoxylin. Wheatley's trichrome stain. (Courtesy of L. Garcia.)

have very high specificities (90 to 100%) and sensitivities that range from 65 to 100% (32, 56, 59, 76). Although these methods have proven to be fairly sensitive and specific compared to the routine staining of fecal smears (trichrome staining), other important pathogens may be missed if a wet mount and permanent-stained smear are not examined. The DFA assay widely used is the Merifluor reagent assay (Meridian Bioscience, Inc., Cincinnati, Ohio), but it does require the availability of a fluorescent microscope. DFA assays have a sensitivity and specificity of >95%, and there are reagents to detect *C. parvum* as well. Immunoassays are available and are useful for testing large numbers of patient specimens, and some studies have shown the performance of the EIA to be excellent compared to that of the ova and parasite exam (31, 56, 76). Two available immunoassays are the ProSpecT *Giardia* EZ (Alexon-Trend) and the ColorPAC *Giardia* assay (Becton Dickinson and Company, Sparks, Md.) (59). If the patient is immunocompromised, has traveled, or is suspected of coming into contact with another pathogen, the ova and parasite examination should be performed. Some studies suggest that the use of an immunoassay does not eliminate the need for more than one stool specimen. Positive specimens from asymptomatic patients may be missed if only one stool specimen is tested using an immunoassay (39). Some immunoassays are affected by specimens contaminated with blood. It was documented in one study that blood can interfere with the performance of the ProSpecT assay and potentially cause false-positive results (59). Immunochromatographic detection methods have also been developed for the clinical laboratory (31, 33, 34, 97). The ImmunoCard STAT (Meridian Bioscience, Inc.) has been developed to detect *G. lamblia* and *C. parvum* antigens in stool specimens by using rapid solid-phase qualitative immunochromatography. Patients negative by the ImmunoCard STAT that remain symptomatic should be tested using a routine ova and parasite exam (34). The Triage Micro parasite panel (Biosite Inc.) is an immunoassay that can detect not only *G. lamblia* antigens but also those of *E. histolytica/E. dispar* and *C. parvum* in stool specimens. Antigens in stool specimens are immobilized on a membrane containing specific antibodies to the respective intestinal parasites. The formation of color bars occurs on a specific area of the membrane depending on the parasite present in the stool. All of these assays described can be run using formalin-fixed stool. This is important in the event that the laboratory would need to run an ova and parasite exam on the same specimen. Although there are several methods now available for the detection of *G. lamblia,* parameters such as workload, skill levels of technologists, and the availability of necessary equipment should be considered in choosing a specific method.

Nucleic Acid Detection Techniques

Some investigators are now using molecular tools to diagnose *G. lamblia* infection with clinical samples (6, 38, 124). One group has developed an oligonucleotide microarray with excellent sensitivity and specificity for the detection of *G. lamblia* and other intestinal parasites in stool specimens. The assay was also able to discriminate between *Giardia* assemblages A and B (127). A multiplex PCR assay to detect specific genotypes of *G. lamblia* has also been developed which may potentially aid in epidemiologic investigations of outbreaks (85). It is important to note that molecular detection of *G. lamblia* has not been widely implemented and there are no commercial assays approved by the Food and Drug Administration for clinical use to date.

Because of the potential for contamination of municipal water supplies, routine monitoring of water for parasitic protozoa is recommended as a public health control measure. *G. lamblia* cysts can remain viable for 2 to 3 months in cold water and are fairly resistant to killing by routine chlorine treatments. DFA assays are commonly used to detect *G. lamblia* cysts in water samples, but PCR is also being used for this purpose (102). The advantage of PCR is the increased sensitivity compared to those of fluorescence assays or assays that use special stains. Research continues to enhance the ability of investigators to detect viable organisms, which is a better indication of poor water quality (129).

Treatment

For individuals diagnosed with giardiasis, the treatment of choice is metronidazole or nitazoxanide (2). Alternatives include tinidazole, paromomycin, furazolidone, and quinacrine (2) or other nitroimidazoles such as ornidazole and secnidazole (35). In most immunocompetent hosts, infection is self-limiting; however, treatment will lessen the duration of symptoms and prevent transmission. Other drugs that have been used to treat giardiasis are albendazole, mebendazole, and bacitracin (78), and there are other therapeutics on the horizon. Albendazole, mebendazole, and paromomycin have lower activity against *Giardia* than do the nitroimidazoles (35). Resistance to metronidazole and other agents has been observed clinically and in vitro (123). In vitro resistance-testing assays are available but lack the standardization required for the clinical laboratory (115).

D. fragilis

Epidemiology, Transmission, and Prevention

D. fragilis is found worldwide and is known to cause a noninvasive diarrheal illness in humans. Despite the lack of external

flagella, this parasite is currently classified as a flagellate but has historically been grouped with the amebae. Electron microscopy and antigenic analysis have aided in the classification of this organism and have demonstrated that it is closely related to *Trichomonas* and *Histomonas* species. Phylogenetic analysis of small-subunit rRNA sequences has also confirmed the relationship between *D. fragilis* and *Histomonas* (36, 111). Currently *D. fragilis* is grouped in the phylum Parabasala, class *Trichomonadea,* family *Trichomonadidae,* and possibly the subfamily *Tritrichomonadinae* (36). Colonization in humans is similar to that seen with other intestinal parasites; typically, the cecum and the proximal part of the colon are affected. Because *D. fragilis* does not have a cyst stage as part of its life cycle, the mode of transmission is less well understood. One hypothesis concerning the spread of *D. fragilis* is that transmission occurs within the eggs of *Enterobius vermicularis* or *Ascaris lumbricoides* (12). Several studies provide circumstantial evidence to support *E. vermicularis* as a vector, documenting a greater-than-expected coinfection rate with the two organisms (54).

Though *D. fragilis* has a worldwide distribution, prevalence rates for this organism vary quite substantially from 0% in Prague to 42% in Germany (54). There appears to be a higher prevalence in certain groups of individuals such as missionaries, Native Americans living in Arizona, and institutionalized individuals (132). In the United States, the prevalence is reported to be quite low. This may be due to underreporting attributable to difficulties associated with identifying the organism in clinical samples. In addition, Johnson and Clark (55) identified the existence of two genetically distinct types of *D. fragilis* with a resulting sequence divergence of approximately 2% (55, 94). The degree of divergence appears to be similar to that seen with *E. histolytica* and *E. dispar.* Since asymptomatic infections occur, this finding may lend support to the possibility that two distinct species exist, though there is no consensus on this matter (54, 55).

Clinical Significance

The frequency of symptomatic disease ranges from 15 to 25% in adults, and symptomatic disease is more common in children, in whom up to 90% of those infected have clinical signs (13, 93). Symptoms include fatigue, insufficient weight gain, diarrhea (often intermittent), abdominal pain, anorexia, and nausea. Studies have linked *D. fragilis* infection to biliary infection (118), irritable bowel syndrome (10), allergic colitis (23), and diarrhea in HIV-infected patients (69). One case report describes a patient who presented in the emergency room with acute appendicitis which was attributed to *D. fragilis* infection (105). Some individuals, mainly children, also experience unexplained peripheral blood eosinophilia (30). Diarrhea is seen predominantly during the first 1 to 2 weeks after the onset of disease. The number of *D. fragilis* organisms can vary greatly from day to day, which is similar to those of other intestinal protozoa. Abdominal pain can persist for 1 to 2 months (13). Although *D. fragilis* has been implicated in the above-mentioned clinical situations, the organism is isolated from patients with no apparent clinical symptoms. In addition, the lack of an animal model affects researchers' ability to detect specific pathological manifestations (54).

Direct Detection

Microscopy

Diagnosis of *D. fragilis* infection is similar to that of infections with other intestinal protozoa, and detection of the trophozoite in fresh or preserved stool is warranted to establish infection. Laboratories using direct microscopy may be at a disadvantage since the trophozoite can degenerate if not placed in fixative. Nonfixed trophozoites can appear rounded and refractile and are more difficult to identify microscopically. Trophozoites have been recovered from soft and formed stools, indicating the need to evaluate all types of samples (13). The recovery of *D. fragilis* is greatly enhanced by the collection of at least three stool specimens (20, 93). Morphologically, the trophozoite of *D. fragilis* contains one or two nuclei (binucleate), with two nuclei being more common. Well-trained laboratory personnel can identify *D. fragilis* trophozoites in stool specimens, but because no cyst stage exists, diagnosis from the wet mount can be difficult. Use of a permanent-stained smear is the recommended procedure for detection (Table 4; Fig. 7 and 9).

Other Diagnostic Methods

Culture has been shown to be more sensitive than microscopy; however, it is not recommended for the routine clinical laboratory (54). Antigen and antibody techniques have been used as diagnostic tools for the detection of *D. fragilis* but are not commercially available (17, 18). *D. fragilis* DNA has been detected using PCR with fresh, unpreserved stool. This technique has the promise of being more sensitive than the microscopy (117).

Treatment

The treatment of choice for symptomatic individuals is iodoquinol (diiodohydroxyquin) (2). Metronidazole, iodoquinol, and tetracycline have been used to treat children (30). Additional therapeutic options include diphetarsone, carbarsone, erythromycin, hydroxychinoline, paromomycin, and secnidazole (37, 54). If *E. vermicularis* is detected concomitantly, the treatment regimen should also include mebendazole (13).

T. vaginalis

Epidemiology, Transmission, and Prevention

T. vaginalis is a pathogenic flagellate that infects the urogenital tracts of males and females. The infection is primarily a sexually transmitted disease (STD) and is thought to be the most common curable STD among sexually active young women. There are an estimated 7.4 million new cases each year in the United States; worldwide, there are 180 million cases of trichomoniasis each year (128). The incidence of trichomoniasis differs depending on the population examined, varying from 5 to 60% in various studies. Factors such as lower socioeconomic

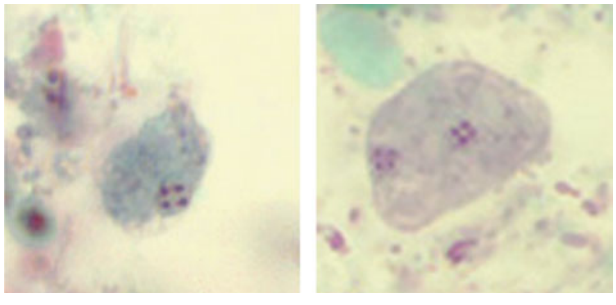

FIGURE 9 *Dientamoeba fragilis* trophozoites. The trophozoites can have one nucleus (left) or two nuclei (right). No cyst stage is known for this organism. Trophozoites are stained with Wheatley's trichrome stain. (Courtesy of L. Garcia.)

status, multiple sex partners, and poor personal hygiene are linked to a higher incidence of infection.

The estimated infection rates cited in the literature may indeed be too low because (i) trichomoniasis is not a reportable disease in the United States and other countries; (ii) the infection, particularly in men, can be asymptomatic; and (iii) laboratory tests used for diagnosis vary in their sensitivities. Despite these rates of infection and their serious medical consequences, trichomoniasis has not received adequate attention from public health and STD prevention programs (106).

The life cycle of *T. vaginalis* includes only the trophozoite stage; there is no cyst stage. The organism is similar in morphology to the other trichomonads and is characterized by a pear shape with a prominent axostyle and an undulating membrane that stops halfway down the side of the trophozoite (Table 4; Fig. 7 and 10). It is a facultative anaerobe that divides by binary fission, and it cannot survive long outside the host.

Clinical Significance

Infection in females can result in vaginitis, cervicitis, and urethritis (106). The classic vaginal discharge is described as copious, liquid, greenish, frothy, and foul smelling. The onset of symptoms, such as intense vaginal and vulvar pruritus and discharge, is often sudden and occurs during or after menstruation. The vaginal pH is usually elevated above the normal pH of 4.5, and dysuria occurs in 20% of women with *T. vaginalis* infection. Infection has also been associated with premature rupture of membranes, premature birth, and posthysterectomy cuff infections (21, 81, 114). In men, the most common symptomatic presentation is urethritis. Up to 50% of infected women are asymptomatic carriers. In men, the majority of infections are asymptomatic. Asymptomatic carriers serve as a reservoir for transmission and also remain at risk for developing disease. Trichomoniasis has been implicated as a cofactor in the transmission of HIV (53, 68). In one study, men with symptomatic *Trichomonas* urethritis were found to have increased HIV concentrations in seminal plasma compared to HIV-infected men without urethritis (47).

Neonates can acquire the organism during passage through the infected birth canal. It is estimated that 2 to 17% of female babies acquire trichomoniasis by direct vulvovaginal contamination (68). Reports have also documented *T. vaginalis* as a cause of neonatal pneumonia (79).

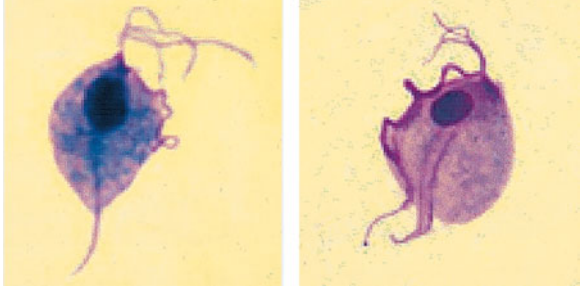

FIGURE 10 *Trichomonas vaginalis* trophozoites. Note the undulating membrane, which comes about halfway down the body. Although the membrane appears to come down farther on one of the trophozoites (right), this appearance occurs because of the photographic angle. Also, note the axostyle that penetrates the bottom of the organism. No cyst stage is known for this organism. Trophozoites are stained with Giemsa stain. (Courtesy of L. Garcia.)

Direct Detection

Microscopy

The diagnosis of *T. vaginalis* infection is commonly based on the examination of wet preparations of vaginal and urethral discharges, prostatic secretions, and urine sediments. Permanent stains such as Papanicolaou and Giemsa stains can be used, but the organisms may be difficult to recognize (65). For wet preparations, vaginal specimens are routinely collected during a speculum examination, but studies suggest that self-collected or tampon-collected specimens may be used successfully (46, 108). Specimens should be mixed with a drop of physiologic saline and examined microscopically within 1 h under low power (magnification, ×100) with reduced illumination. Specimens should never be refrigerated. The presence of actively motile organisms with jerky motility is diagnostic. The movement of the undulating membrane may be seen as the motility of the trophozoite diminishes. Polymorphonuclear cells are often present. The sensitivity of the wet preparation test is between 50 and 70%, depending on the skill of the microscopist and other factors. Perhaps the most important factor affecting sensitivity is the time between collection and examination of the specimen. Viability of the organism is essential for the detection of motility on the wet mount and drops off precipitously with time. Amies gel agar transport medium can maintain the viability for culture of *T. vaginalis* on swabs held at room temperature for 24 ± 6 h prior to inoculation of the specimen into a culture pouch (48). Because the morphology of *P. hominis*, a nonpathogenic intestinal flagellate, is very similar to that of *T. vaginalis*, care must be taken to ensure that specimens are not contaminated with fecal material.

Culture

Culture has greater sensitivity (>80%) than the wet mount method and is considered the "gold standard" method for the detection of *T. vaginalis*. Specimens must be collected properly and inoculated immediately into the appropriate medium, such as modified Diamond's, Trichosel, or Hollanders medium. Due to cost and convenience, this approach is not routinely used. Culture systems (InPouchTV [BioMed Diagnostics, San Jose, Calif.] and the system of Empyrean Diagnostics, Inc., Mountain View, Calif.) that allow direct inoculation, transport, culture, and microscopic examination are commercially available (9, 26). In situations where immediate transport of specimens is not feasible, the use of these transport/culture devices should be encouraged. Studies have also shown that a delayed inoculation protocol is as sensitive as immediate inoculation, allowing the results of microscopy to be used to determine whether further culture is necessary (109). Serologic testing is not useful for the diagnosis of trichomoniasis.

Antigen Detection

Several antigen detection methods have been developed for *T. vaginalis* and offer the advantage of being rapid and easy to perform. A latex agglutination test (TV Latex; Kalon Biological, Surrey, United Kingdom) has been shown to have excellent sensitivity (4) but is not available in the United States. An immunofluorescence assay (Light Diagnostics *T. vaginalis* DFA; Chemicon International, Temecula, Calif.) is available in the United States for testing directly from patient samples. Two immunochromatographic capillary flow assays are available commercially for the qualitative detection of *T. vaginalis* antigens from vaginal swabs. The OSOM Trichomonas Rapid Test (Genzyme Diagnostics, Cambridge, Mass.) is a dipstick assay providing results in 10 min and has

been shown to have good sensitivity and specificity (83.3 and 98.8%, respectively) compared to a combined standard of wet mount and culture (52). The Xenostrip Tv Trichomonas vaginalis test (Xenotope Diagnostics, Inc., San Antonio, Tex.) is a rapid point-of-care test that has demonstrated sensitivities of 67 to 80% and specificities of >99% in published studies (66, 98).

Nucleic Acid Detection Techniques

The Affirm VPIII (Becton Dickinson and Company) is a direct DNA probe test for the detection of organisms from vaginal swabs associated with vaginosis/vaginitis. It tests for the three most common syndromes associated with increased vaginal discharge: bacterial vaginosis *(Gardenerella vaginalis)*, candidiasis *(Candida albicans)*, and trichomoniasis. The assay has good sensitivity and specificity compared with wet mount and culture for *T. vaginalis* (90 and 98%, respectively [package insert, Affirm VPIII, version no. 670160JAAG, Becton Dickinson and Company, Sparks, Md.]). Nucleic acid-based amplification methods, such as PCR, for the detection of *T. vaginalis* have been reported in the literature, but none are yet commercially available. These amplification tests have demonstrated varying sensitivities depending on the genomic target, specimen type, and sex of the patient (44, 73, 100). PCR has a sensitivity of 85 to 100% with vaginal swabs; its sensitivity with urine is lower, ranging from 60 to 80% (61, 70, 106). For men, PCR with urine and urethral swabs has been reported and appears to be more sensitive than conventional methods (62, 107).

While the wet mount provides a rapid result at a low cost, tests with the increased sensitivities of nucleic acid probes or PCR may be indicated because of the impact of *T. vaginalis* infections on pregnancy and the link with HIV transmission (48, 106). An algorithm to reflex specimens with negative wet mounts to culture or a more sensitive methodology may be a useful diagnostic approach.

Treatment

The treatment of choice for *T. vaginalis* infections is metronidazole, with oral therapy recommended over topical treatment (16). More recently, tinidazole has received U.S. Food and Drug Administration approval for the treatment of trichomoniasis in adults (2) and may be used as a first-line agent or for refractory cases previously treated with metronidazole (22). Metronidazole is the recommended therapy for treatment for symptomatic infection during pregnancy. There are no data to support treatment for asymptomatic infections as studies have failed to demonstrate that metronidazole therapy prevents preterm birth (16, 63). All sexual partners of infected individuals should also receive treatment. Treatment failure with metronidazole is most often due to noncompliance or reinfection. True resistance to metronidazole has been documented and appears to be increasing (22, 113). While not routinely available, methods have been published for the in vitro determination of susceptibility. These methods have not been standardized, and the results can vary based on assay conditions (8, 80).

NONPATHOGENIC FLAGELLATES

C. mesnili is found worldwide and is generally considered nonpathogenic. Unlike *D. fragilis, C. mesnili* has both a trophozoite and a cyst stage. The organism is acquired through the ingestion of contaminated food or water and resides in the cecum and/or colon of the infected human or animal. The trophozoite is 6 to 24 μm long and contains a characteristic spiral groove that runs longitudinally along the body (Table 4; Fig. 7 and 11). Motility of the organism can sometimes be seen in fresh preparations, and the spiral groove may be exposed as the organism turns. Flagella are difficult to see in stained preparations. The trophozoite contains one nucleus, with a cytostome or oral groove in close proximity. The pear-shaped cyst retains the cytoplasmic organelles of the trophozoite, with a single nucleus and curved cytostomal fibril. Observing the organism in permanent-stained preparations makes identification more definitive.

P. hominis, formerly referred to as *Trichomonas hominis,* is a nonpathogenic flagellate that is similar to *D. fragilis* in that only the trophozoite stage has been observed. Although the organism is cosmopolitan in nature and is recovered from individuals with diarrhea, it is still considered nonpathogenic. The trophozoites typically inhabit the cecum. They are pyriform and contain an undulating membrane that runs the length of the parasite. The use of permanent smears is recommended for observation of these organisms in clinical specimens. The trophozoites may stain weakly, making them difficult to detect on stained smears (30).

Two additional nonpathogenic intestinal flagellates are *E. hominis* and *R. intestinalis.* Both *E. hominis* and *R. intestinalis* are found in warm or temperate climates, and infection is acquired through the ingestion of cysts. When clinical specimens are examined, it is important to note that cysts of *E. hominis* can resemble those of *E. nana,* although *E. nana* cysts containing two nuclei are rare. Because of the small sizes of *E. hominis* and *R. intestinalis,* it is difficult to detect these organisms even when permanent-stained smears are examined. This may lead to the underreporting of both organisms. *R. intestinalis* has been recovered from the pancreatic juice of a patient with small lesions of the pancreatic duct (60).

In general, treatment is not recommended for infections with the nonpathogenic flagellates. Improved personal hygiene and sanitary conditions are key methods for the prevention of infection.

CILIATES

Balantidium coli

Taxonomy

B. coli belongs to the phylum Ciliophora, the members of which are protozoa possessing cilia in at least one stage of their life cycles. The ciliophora also have two different types of nuclei, one macronucleus and one or more micronuclei.

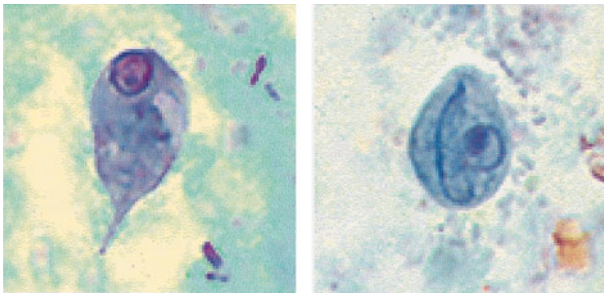

FIGURE 11 *Chilomastix mesnili* trophozoite (left) and cyst (right). Note the oral groove (feeding groove) at the right side of the trophozoite (clear area) and the curved fibril (shepherd's crook) in the cyst. Also note the typical pear or lemon shape of the cyst. Organisms are stained with Wheatley's trichrome stain. (Courtesy of L. Garcia.)

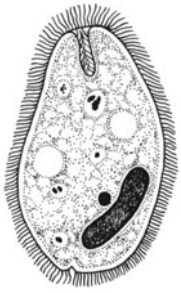
Description of the Agent

This organism has both the trophozoite and cyst forms as part of its life cycle (Table 5; Fig. 12). The cyst form is the infective stage. After ingestion of the cysts and excystation, trophozoites secrete hyaluronidase, which aids in the invasion of the tissue. The trophozoite, which is oval and covered with cilia, is easily seen in wet mount preparations under low-power magnification. The cytoplasm contains both a macronucleus and a micronucleus, in addition to two contractile vacuoles. Motile trophozoites can be observed in fresh wet preparations, but the specimen must be observed soon after collection. The trophozoite is somewhat pear shaped and also contains vacuoles that may harbor debris such as cell fragments and ingested bacteria. Cyst formation takes place as the trophozoite moves down the large intestine.



Epidemiology, Transmission, and Prevention

B. coli exists in animal reservoirs such as pigs and chimpanzees. The organism is the only pathogenic ciliate and the largest pathogenic protozoan known to infect humans. Transmission occurs by the fecal-oral route following ingestion of the cysts in contaminated food or water. Infection is more common in warmer climates and in areas where humans are in close contact with pigs. As with other intestinal protozoa, poor sanitary conditions lead to a higher incidence of infection.

Clinical Significance

Infection with *B. coli* is most often asymptomatic; however, symptomatic infection can occur, resulting in bouts of dysentery similar to amebiasis (15, 30). In addition, colitis caused by *B. coli* is often indistinguishable from that caused by *E. histolytica*. Symptoms typically include diarrhea, nausea, vomiting, headache, and anorexia. Fluid loss can be dramatic, as seen in some patients with cryptosporidiosis. The organism can invade the submucosa of the large bowel, and ulcerative abscesses and hemorrhagic lesions can occur. The shallow ulcers and submucosal lesions that result from invasion are prone to secondary infection by bacteria and can be problematic for the patient (24, 64). Death due to invasive *B. coli* infection has been reported (24). Even though the organism can invade the underlying mucosa, it does not typically spread to other organs. Infections associated with extraintestinal sites have been described on rare occasions (24, 64, 67).

TABLE 5 Key features of the ciliate *B. coli*

Stage	Characteristics
Trophozoite 	Shape and size: Ovoid with tapering anterior end; 50–100 μm long, 40–70 μm wide Motility: Rotary, boring; may be rapid Nuclei: 1 large kidney-bean-shaped macronucleus may be visible in unstained preparation; 1 small round micronucleus adjacent to macronucleus, difficult to see Cytoplasm: May be vacuolated; may contain ingested bacteria and debris; anterior cytostome Cilia: Body surface covered with longitudinal rows of cilia; longer near cytostome Note: May be confused with helminth eggs or debris on a permanent-stained smear; concentration or sedimentation examination recommended
Cyst 	Shape and size: Spherical or oval; 50–70 μm in diam Nuclei: 1 large macronucleus, 1 micronucleus, difficult to see Cytoplasm: Vacuoles are visible in young cysts; in older cysts, internal structure appears granular Cilia: Difficult to see within the thick cyst wall

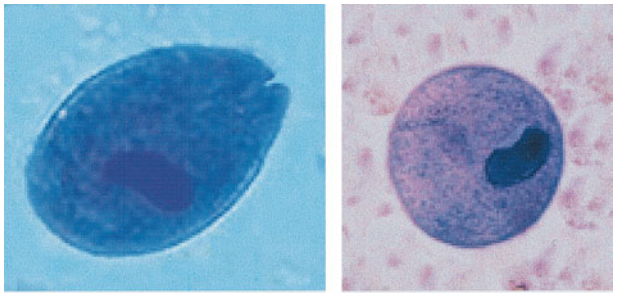


FIGURE 12 *Balantidium coli* trophozoite (left) and cyst (right). Note the single macronucleus visible in both the trophozoite and the cyst. The much smaller micronucleus is not visible. Organisms are stained with Wheatley's trichrome stain. (Courtesy of L. Garcia.)

Direct Examination

Microscopy

Either ova and parasite examination of feces or histologic examination of intestinal biopsy specimens establishes the diagnosis of *B. coli* infections. The diagnosis can be established only by demonstrating the presence of trophozoites in stool or tissue samples (67). It is very easy to identify these organisms in wet preparations and concentrated stool samples. Conversely, it can be challenging to identify *B. coli* from trichrome-stained permanent smears because the organisms are so large and have a tendency to overstain. This makes the organism less discernible and increases the chance of misidentification.

Treatment

The treatment of choice for *B. coli* infection is tetracycline, although it is considered an investigational drug when used in this context (2). Metronidazole and iodoquinol are therapeutic alternatives used in some cases (30).

SUMMARY

Clinical laboratories are now given more choices for testing in diagnostic parasitology, with assays ranging from microscopy, culture, antigen detection, and nucleic acid amplification techniques. Molecular biology has the promise to deliver more sensitive and specific methods, but to date these methods have not been fully adapted to the clinical diagnostic laboratory. Some researchers have implemented their own laboratory-developed amplification assays for better detection of intestinal protozoa such as *Giardia,*

Cryptosporidium, and *Trichomonas*. In addition to these amplification tests, rapid point-of-care tests are available for organisms such as *T. vaginalis*. Results can now be available in real time for the clinician to manage patients directly in the exam setting. Even though the field of diagnostic parasitology is changing, clinical laboratories are still faced with using microscopy for routine work-up for stool specimens due to the slow implementation of some of the new methods by commercial diagnostic companies. Not all laboratories are equipped to develop home brew molecular tests and rely on the diagnostic industry to bring products to the market. Some laboratories have switched to antigen-based methods, but many still rely on microscopy because antigen-based methods cannot detect all potential pathogens in a given stool specimen. Microscopy, as we know, cannot differentiate between pathogenic and nonpathogenic amebae and the different genotypes of *Giardia*. On the horizon are newer methodologies, such as the microarray, which would allow for the detection of multiple pathogens from a clinical specimen. Some manufacturers are developing assays for the detection of stool parasites using chemiluminescent and bead-based technologies. These exciting new areas will help increase the options that the clinical parasitology laboratory has for the diagnosis of intestinal parasitic infections.

Isospora, Cyclospora, and *Sarcocystis**

DAVID S. LINDSAY, STEVE J. UPTON, AND LOUIS M. WEISS

141

Isospora (Cystoisospora), Cyclospora, and *Sarcocystis* are intestinal coccidia infecting humans (Fig. 1 and 2). They have varied life cycles, epidemiology, treatment requirements, and diagnostic methods. Oocysts of these coccidia are found in the feces of humans (Table 1), and diagnosis is based ultimately on demonstrating oocysts in human stool samples.

TAXONOMY

Isospora, *Cyclospora,* and *Sarcocystis* are in the Phylum Apicomplexa, Subclass Class Sporozoasida, Subclass Coccidiasina, Order Eucoccidiorida, Suborder Eimeriorina. *Cyclospora cayetanensis* is in the Family Eimeriidae, while *Sarcocystis hominis* and *S. suihominis* are in the Family Sarcocystidae. The placement of *Isospora belli* is currently under debate as to whether it should be in the Family Eimeriidae or moved to the Family Sarcocystidae.

DESCRIPTION OF ORGANISM, EPIDEMIOLOGY, TRANSMISSION, AND PREVENTION

Life Cycles

Isospora belli

The life cycle is direct (monoxenous), but evidence exists that it can be facultatively heteroxenous (use two hosts). *Isospora belli* oocysts are passed in the feces unsporulated or partially sporulated (Fig. 1C and D and 2A and B). Oocysts generally complete sporulation within 72 h, although 1 to >5 days have been reported depending on temperature (59). The prepatent period, i.e., the time it takes for unsporulated oocysts to appear in the feces after sporulated oocysts are ingested, is 9 to 17 days (28, 54). The patent period, i.e., the time from when oocysts first are excreted in the feces until they can no longer be observed in the feces, is quite variable and depends on the immune status of the infected individual. Oocysts can usually be found for 30 to 50 days in immunocompetent patients, while immunosuppressed patients may continue to shed oocysts for 6 months or more (60). This prolonged oocyst shedding in immunosuppressed patients is presumably due to recycling of one or more merogonous stages or activation of dormant extraintestinal unizoites (Fig. 3).

Developmental stages of *I. belli* have been reported from intestinal biopsy specimens of the duodenum, jejunum, and occasionally ileum, and oocysts can be aspirated directly from the duodenal contents. Intestinal development occurs predominantly in epithelial cells, although meronts (schizonts) are occasionally reported from the lamina propria or submucosa (6). At least two generations of meronts, as well as macrogametocytes (female sexual stage), microgametocytes (male sexual stage), and unsporulated oocysts, have been documented in these reports.

I. belli sporozoites/merozoites are capable of traveling extraintestinally and becoming dormant as unizoite tissue cysts (Fig. 3) in a variety of tissues, including intestine, mesenteric lymph nodes, liver, and spleen (52, 57). These cysts are commonly termed "unizoites" or "hypnozoites." Unizoic cysts in histological sections are thick walled and measure 12 to 22 by 8 to 10 μm, each containing a single dormant sporozoite/merozoite measuring about 8 to 10 by 5 μm (52, 57). Presumably, the cysts are capable of reactivating patent infections once immunity wanes.

The existence of these unizoic cysts has led to speculation that a paratenic (transport) host may be involved in the life cycle of *I. belli* (52). Paratenic hosts are known to occur in the *Isospora* species that infect cats and dogs.

Isospora natalensis

The life cycle of *I. natalensis* is presumably monoxenous (direct). The oocysts are smaller and more spherical that those of *I. belli* (Table 1). Oocysts are passed in the feces unsporulated. At ambient temperature, some oocysts completed sporulation within 24 h (26). The prepatent and patent periods are unknown. One individual passed unsporulated oocysts for at least 4 days (18). Oocysts of *I. natalensis* have been reported only from patients from South Africa. The validity of this species is questionable.

Cyclospora cayetanensis

The life cycle of *C. cayetanensis* is monoxenous and involves only humans as hosts. Oocysts are passed in the feces unsporulated (Fig. 1A and 2C). At room temperature (23 to 25°C), low numbers of oocysts may sporulate within 10 to 12 days (37, 74) (Fig. 1B). However, many oocysts require 3 to 4 weeks for sporozoites to fully develop (S. J. Upton,

*This chapter contains information presented in chapter 134 by Ynes R. Ortega and Michael Arrowood in the eighth edition of this Manual.

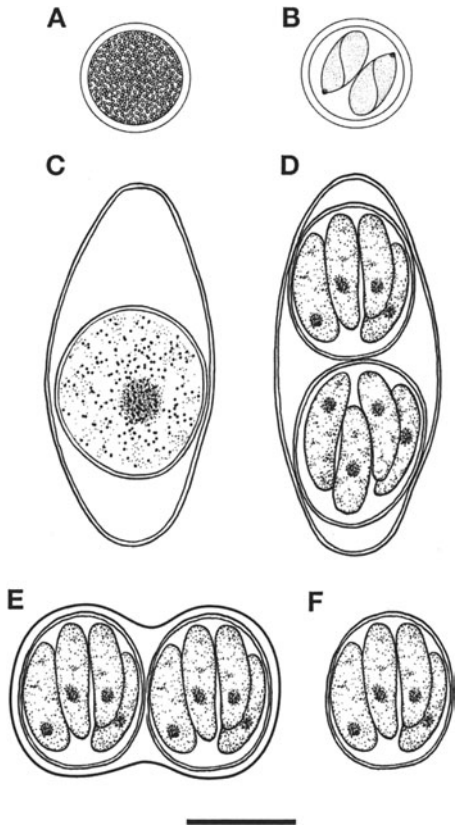

FIGURE 1 Line drawings of unsporulated and sporulated oocysts of C. *cayetanensis* (A and B) and *I. belli* (C and D) and sporulated oocyst (E) and sporocyst (F) of *Sarcocystis* species from humans.

unpublished data). The precise prepatent period is not yet known. However, the onset of clinical signs following infection generally averages 7 to 8 days postinfection and lasts 2 to 3 weeks but may range from 1 to >100 days. The length of time oocysts are shed in the feces is highly variable. Oocysts may be shed in the feces anywhere from 7 days to several months. Indigenous infections are primarily confined to tropical, subtropical, or warm temperate regions of the world. Outbreaks occur in other areas of the world due to contaminated foodstuffs.

Developmental stages of *C. cayetanensis* generally occur within epithelial cells of the lower duodenum and jejunum (4, 64, 75). There are two asexual generations followed by sexual stages and oocysts. Stages develop in supranuclear locations within enterocytes (75).

Sarcocystis hominis

The life cycle of *S. hominis* is heteroxenous. Humans are definitive hosts for *S. hominis*, and bovids are the intermediate hosts. Infection occurs when infected meat which is not cooked or is not thoroughly cooked is ingested. Known intermediate hosts include cattle *(Bos taurus)*, American bison *(Bison bison)*, water buffalo *(Bubalus bubalis)*, and European bison or Wisent *(Bison bonasus)*. These intermediate hosts harbor sarcocysts (muscle cysts) that are infective when ingested by humans. Infective bradyzoites (dormant merozoite-like stages) are present in the sarcocysts. The bradyzoites penetrate the human intestinal epithelium and develop as sexual stages (macrogametocytes and microgametocytes) in cells in the lamina propria of the intestine. Fertilization occurs and the oocysts sporulate in the lamina propria. The oocysts are "*Isospora*"-like and contain two sporocysts each with four sporozoites. The oocyst wall often ruptures as the oocyst makes its way to the intestinal lumen. This results in the shedding of individual sporocysts in the feces. Both oocysts with two sporocysts and individual sporocysts can be seen in the feces of humans with intestinal *Sarcocystis* infection (Fig. 1E and F).

Oocysts and sporocysts are fully sporulated when passed in the feces. In human volunteers, the prepatent period has been reported as 8 to 39 days and patent infections can last as long as 18 months. *Sarcocystis hominis* occurs on all continents, anywhere cattle or buffaloes have access to human feces and humans ingest raw or undercooked beef.

Sarcocystis suihominis

The life cycle of *S. suihominis* is similar to that described above for *S. hominis* except that pigs are the intermediate hosts. The prepatent period is 9 to 10 days, and patency is in

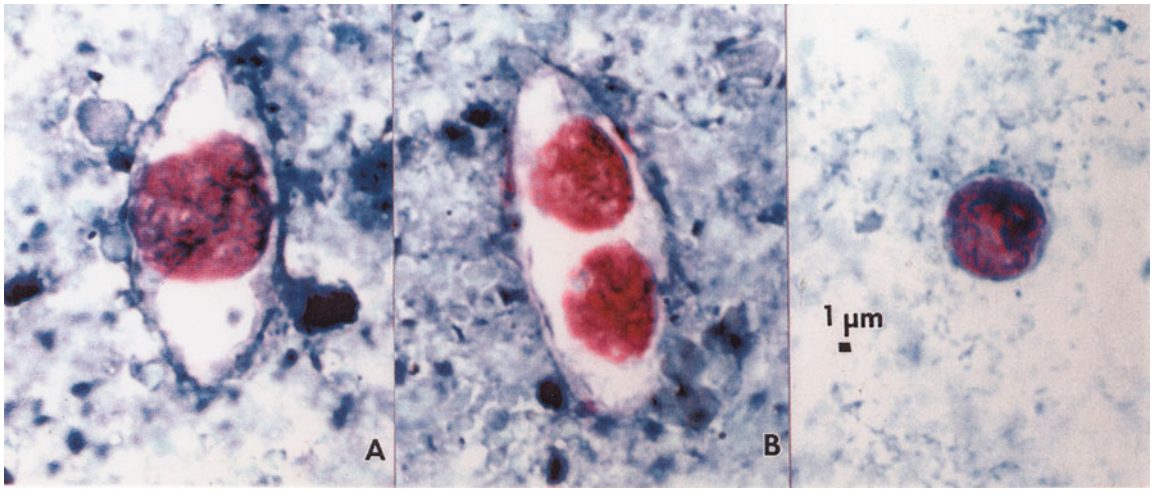

FIGURE 2 Modified Kinyoun's acid-fast-stained smears demonstrating an *I. belli* oocyst with a sporont (A), an *I. belli* oocyst with two sporoblasts (B), and a *C. cayetanensis* oocyst with a sporont.

TABLE 1 Structural data for *Isospora (Cystoisospora)*, *Cyclospora,* and *Sarcocystis* coccidial oocysts and sporocysts found in the feces of humans

Organism	Mean size (range)[a]	
	Oocysts	Sporocysts
I. belli	32 by 14 (20–36 by 10–19)	14 by 10 (12–17 by 7–11)
I. natalensis	Not given (25–30 by 21–24)	17 by 12 (not given)
C. cayetanensis	9 by 9 (8–8 by 10–10)	6 by 4 (6–7 by 3–4)
S. hominis	Not given (19 by 15)	15 by 9 (13–17 by 8–11)
S. suihominis	19 by 13 (19–20 by 12–15)	14 by 11 (12–14 by 10–11)
Sarcocystis lindemanni	Not applicable	Not applicable

[a] Data have been rounded to the nearest micrometer.

excess of 36 days (39). *S. suihominis* presumably occurs on all continents, anywhere swine have access to human feces and humans ingest raw or undercooked pork.

Human Muscular *Sarcocystis* Infection

Sarcocysts have been reported as incidental findings from both skeletal and cardiac muscle of nearly 60 humans worldwide. There are at least seven distinct types of sarcocysts present in human muscles (2). Many of these sarcocysts appeared to be similar to sarcocysts found in nonhuman primates. Humans seem to be an occasional incidental intermediate host for some *Sarcocystis* spp. in wildlife.

Epidemiology, Transmission, and Prevention

I. belli

I. belli is primarily found in tropical, subtropical, and warm temperate regions, but reports of indigenous infections from temperate areas have also been published. Most cases of infection in temperate areas involve foreign travel or homosexual contact. Unlike *Cyclospora,* large outbreaks of isosporiasis have not been reported. Transmission is via ingestion of sporulated oocysts and possibly the ingestion of raw or undercooked tissues from unknown paratenic hosts. Improving sanitation in areas of endemicity will decrease transmission of *I. belli.*

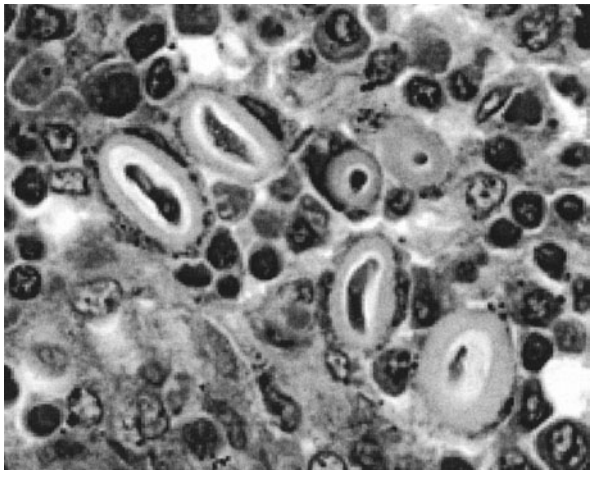

FIGURE 3 Toluidine blue-stained 1-μm section demonstrating several unizoic cysts of *I. belli*. Note the thick wall that surrounds each single zoite.

C. cayetanensis

Cyclospora is endemic in Central and South America, the Caribbean, Mexico, Indonesia, Asia, Nepal, Africa, India, southern Europe, and the Middle East. Infections in most temperate areas are correlated with the consumption of imported, contaminated fruits and vegetables such as basil (42), raspberries (38, 39, 41, 45), lettuce (10, 19), mesclun (37), or snow peas (13). One outbreak of diarrheal disease in Chicago was originally correlated with stagnant tap water (43), but no oocysts were ever recovered from a water storage tank reputed to harbor the parasite and infected individuals had attended a catered party 8 days previously (37). *C. cayetanensis* DNA has been found in water used for drinking by humans in Guatemala (21).

Better washing of produce may help remove *Cyclospora* oocysts, but many of the fruits are delicate and cannot withstand much manipulation. Most of the produce items implicated as transmitting *Cyclospora* are consumed raw, and this does not lend itself to prevention by thermal means. Nonthermal treatments such as high hydrostatic pressure (51) have been shown to inactivate *Toxoplasma gondii* oocysts, and these methods may be effective in inactivating *Cyclospora* on produce.

Sarcocystis Species

Human intestinal *Sarcocystis* species is potentially present in any region in the world where cattle, buffaloes, and swine have access to human feces and the life cycle can be maintained. The cycle has not been detected in the United States. Cultural habits that include ingestion of raw meat or undercooked meat products help maintain this life cycle in areas of endemicity. Cooking meat until an internal temperature of >67°C is achieved kills *T. gondii* tissue cysts (22), and this temperature should also kill tissue cysts of human infective *Sarcocystis* species in meat products. Preventing cattle, buffaloes, and swine from consuming human feces will also break the cycle in areas of endemicity.

Most cases of human muscular *Sarcocystis* infection have been reported from the Far East (1). It is presumed that humans become infected by ingesting sporocysts in contaminated water (1) or food.

CLINICAL DISEASE

I. belli

I. belli can cause serious and sometimes fatal disease in immunocompetent humans. Symptoms of *I. belli* infection include diarrhea, steatorrhea, headache, fever, malaise,

abdominal pain, vomiting, dehydration, and weight loss (6, 9, 79). Blood is not usually present in the feces. Eosinophilia is observed in many patients (11). The disease is often chronic, with parasites present in the feces or biopsy specimens for several months to years. Recurrences are common. Disease is more severe in infants and young children (58).

Clinical disease in *I. belli* infections is usually more severe in immunocompromised patients than in immunocompetent patients. Diarrhea produced by *I. belli* infection in AIDS patients is often very fluid and secretory-like and leads to dehydration requiring hospitalization (11). Fever and weight loss are also common findings. Other opportunistic pathogens are also common copathogens in these patients. *I. belli*-induced intestinal lesions and responses to chemotherapy are usually similar to those observed in immunocompetent patients. *I. belli* has been observed in patients with concurrent Hodgkin's disease (6), non-Hodgkin's lymphoproliferative disease (36, 70), human T-cell leukemia virus type I-associated adult T-cell leukemia (35), and acute lymphoblastic leukemia (88). These patients respond to specific anti-*I. belli* treatment. It was suggested in one report that treatment with prednisolone led to transient immunosuppression and severe *I. belli* infection in one patient (59). The patient recovered without specific treatment.

Extraintestinal cyst-like stages have been documented in AIDS patients and may play a role in relapse of infection (32, 52). These usually contain a single merozoite-like stage (Fig. 3), and many thousands of these stages can be present (52).

Infections with *I. belli* in the gallbladder epithelium (3, 31, 33) and endometrial epithelium (15) have been reported. Clinical signs in patients with parasites in these locations are not specific for coccidiosis, and parasites are located after tissue biopsy as part of a diagnostic workup. The parasites probably reach these sites as merozoites from the gut or as zoites from extraintestinal locations, and the epithelial cells of these tissues are permissive to parasite entrance and multiplication.

C. cayetanensis

Nonbloody diarrhea is the main clinical symptom of *C. cayetanensis* infection. Some individuals can be infected and show no clinical signs. In most immunocompetent patients, typical symptoms of cyclosporiasis include cycles of diarrhea with anorexia, malaise, nausea, and cramping and periods of apparent remission (37).

C. cayetanensis infection can be associated with biliary disease in both immunosuppressed patients and immunologically normal patients (72). Developmental stages of *C. cayetanensis* have been seen in the gallbladder epithelium of AIDS patients with acalculous cholecystitis by light (89) and transmission electron microscopy (14). Oocysts can be observed in the bile of patients with active biliary disease.

Intestinal *Sarcocystis* Infections

Clinical *Sarcocystis* infections in humans can manifest primarily as intestinal disease if infected meat is ingested or as muscular disease if sporocysts are ingested (27). Intestinal disease occurs soon after consumption of infected meat (3 to 6 h) and is characterized by nausea, abdominal pain, and diarrhea. Intestinal disease can be more severe in individuals who have additional enteropathogens present in the gut. Intestinal *Sarcocystis* infection combined with invasion by gram-positive bacteria has been associated with over 20 cases of segmental enterocolitis in Thailand (7, 8). Experimental studies with human volunteers have produced more severe disease in those who have ingested pork containing *S. suihominis* than in those who have ingested beef containing *S. hominis* (27). Some individuals can be infected and show no clinical signs.

Muscular *Sarcocystis* Infections

Muscular *Sarcocystis* infections in humans are usually considered subclinical or only associated with mild clinical signs (56). Many of the over 50 reported cases have been incidental findings (2) or associated with eosinophilic myostitis (80). Clinical signs associated with an outbreak of human muscular *Sarcocystis* infection occurred in 7 of 15 members of a U.S. combat unit in Malaysia (1). The signs developed about 3 weeks after the troops returned from the jungle and were fever, myalgias, bronchospasm, fleeting puritic rashes, transient lymphadenopathy, and subcutaneous nodules. Eosinophilia, elevated erythrocyte sedimentation rate, and elevated levels of muscle creatinine kinase were present in these troops (1).

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

The results obtained in the diagnostic laboratory are only as good as the material they are presented with for testing. Choosing the appropriate sample and sample fixative is extremely important (33). Universal precautions should be followed when handling fresh stool samples. If samples are to be sent to another laboratory for diagnosis, then they should be fixed in an appropriate fixative. A 5 to 10% formalin solution is an appropriate fixative for stools suspected of containing intestinal coccidia. Formalin fixation does not interfere with some of the immunodetection methods currently employed to detect *Cryptosporidium* and *Giardia,* which is a drawback of polyvinyl alcohol fixative. Oocyst structure can last several months when stools are stored at 4°C in formalin fixatives.

A single negative stool specimen is not conclusive in the examination of stools for coccidial parasites; a total of three or more stool specimens collected on subsequent days need to be examined before coccidial infection can be ruled out. Liquid stool samples can be concentrated by centrifugation, and the pellet can be used for examination using wet mounts and concentration techniques or in stained smears. Large numbers of oocysts may make diagnosis less challenging but do not always translate directly to severity of clinical signs. Some individuals may excrete oocysts and be asymptomatic.

Microscopy

Oocysts of *Isospora* and *Cyclospora* and sporocysts of *Sarcocystis* species are readily identified in fresh unstained wet mounts based on their characteristic sizes and morphologies (Table 1 and Fig. 1). This is especially true if oocysts and sporocysts are present in high numbers. Autofluorescence of oocysts of *Isospora* and *Cyclospora* and sporocysts of *Sarcocystis* is an especially useful tool (5, 23, 49, 81) and has replaced many of the staining techniques previously used for these parasites in laboratories equipped with appropriate fluorescent microscopes.

Concentration techniques like formalin-ethyl acetate (rarely formalin-ether) sedimentation or sucrose centrifugal flotation are helpful when few oocysts are present. Sucrose centrifugal flotation has been found to be superior to formalin-ether sedimentation for demonstrating oocysts of *Cyclospora* (47). The same should be true for *Isospora* and *Sarcocystis*. Direct wet smears can be very useful, and their utility approaches that of sucrose centrifugal flotation when coupled with autofluorescence examination (47). Staining

procedures may adversely affect the autofluorescence of oocysts and sporocysts.

Stained fecal smears have been widely used to demonstrate *Cyclospora* oocysts and to a lesser extent *Isospora* oocysts (23, 25, 67). *Isospora* and *Cyclospora* oocysts stain red with the modified Kinyoun's acid-fast stain, and this method is widely used (Fig. 2). The main drawback is that staining can be variable and some oocysts do not stain (85). Oocysts usually do not stain with trichrome, chromotrope, or Gram-chromotrope (85). Some *Cyclospora* oocysts stain light blue with Giemsa (85). Variations on the safranin staining technique stain *Cyclospora* oocysts orange or pinkish orange, and heating and other treatments have been used to increase the staining frequency of oocysts.

Culture

In vitro culture of coccidial parasites is most often used as a tool to study developmental biology or identify active chemotherapeutic agents. It presently has limited use in diagnosis of active human infection.

There are no reports on development of *Cyclospora,* and only one report of development of *I. belli* in culture has been published (73). Bradyzoites of *Sarcocystis suihominis* undergo sexual development and produce oocysts in cell culture (55). Schizont stages of human *Sarcocystis* species have not been reported.

Antigen Detection

The inability to produce stages in cell cultures and provide a source of diagnostic antigens has limited the usefulness of antigen detection for these coccidial parasites of humans.

Nucleic Acid Detection Techniques

No nucleic acid detection techniques have been developed for use in diagnosis of human *Sarcocystis* infections. More efforts have been placed on nucleic acid-based tests for *Isospora* and *Cyclospora.*

Detection of *I. belli* by PCR using primers based on small-subunit ribosomal RNA sequences and Southern blot hybridization has been reported (61). This method was effective for detecting *I. belli* DNA in duodenal biopsies and in stool samples. A slight cross-reactivity to *T. gondii* was observed in a nested-PCR version of this test (61).

Much attention has been placed on molecular methods to detect *Cyclospora* oocysts in stools (82, 84), in water samples (21, 77), and on produce (42, 63, 76) because of the numerous outbreaks of *Cyclospora* infections. Because *Cyclospora* organisms are closely related to *Eimeria* species (68, 69) from vertebrates, it is important that tests designed to detect *Cyclospora* in the water or on produce be examined for cross-reactivity to *Eimeria* (44). *Cyclospora* species infecting mammals other than humans may also be present in water samples or on produce, and proofs of specificity are needed for these tests designed to look at environmental sources of *Cyclospora* and to detect *Cyclospora* on produce.

Quantitative PCR assays have been developed for *Cyclospora* oocysts in stool samples (82). This method detected the DNA from as few as one oocyst of *C. cayetanensis* per 5 ml of reaction volume.

Serologic Tests

The inability to obtain usable quantities of antigens from *Isospora, Cyclospora,* and *Sarcocystis* has greatly limited the use of serological diagnostic tests for these parasites. It is very difficult to obtain enough oocysts from feces to conduct serological tests. Wang et al. (86) reported the development of an immunoglobulin G (IgG) and IgM enzyme-linked immunosorbent assay based on using *C. cayetanensis* oocysts as antigen. This study is questionable because the investigators obtained the oocysts from experimentally infected guinea pigs. Well-controlled studies indicate that humans are the only suitable host for *C. cayetanensis* (24). Attempts were made to develop an immunofluorescent-antibody test to detect IgG, IgA, and IgM specific for *Cyclospora* using sectioned oocysts (12). None of four stool-positive patients reacted in the immunofluorescent-antibody test.

TREATMENT

I. belli

The drug of choice for the treatment of *Isospora* is trimethoprim-sulfamethoxazole. Trimethoprim-sulfamethoxazole administered two to four times a day for 10 to 14 days results in a clearance of parasites, decrease in diarrhea, and decrease in abdominal pain within a mean of 2.5 days after treatment (66). Patients with human immunodeficiency virus type 1 (HIV-1) infection and $CD4^+$ cell counts less than 200 should receive secondary prophylaxis with trimethoprim-sulfamethoxazole once daily or three times a week as relapse is common. It is likely that secondary prophylaxis is not needed once the $CD4^+$ count exceeds 200, as has been demonstrated for many opportunistic pathogens in patients with HIV-1 infection.

For patients unable to tolerate sulfonamides due to allergy or intolerance, there is no standard treatment. Pyrimethamine is an effective alternative for treatment or prophylaxis in patients with sulfonamide allergies (87). Pyrimethamine should be given with folinic acid to minimize bone marrow suppression. Another alternative agent is ciprofloxacin, a fluoroquinolone that inhibits topoisomerase. In a randomized study of 22 patients with isosporiasis and HIV infection, all of the 10 patients who received trimethoprim-sulfamethoxazole had a cessation of diarrhea within 2 days and 10/12 of those who received ciprofloxacin had a cessation of diarrhea within 4.5 days (83). All three patients (two with diarrhea and one without) who had persistent *Isospora* in their stools responded to trimethoprim-sulfamethoxazole (83). In patients who responded to ciprofloxacin, continued prophylaxis with ciprofloxacin prevented recurrence of disease (83). Nitazoxanide has also been used effectively to treat *I. belli* infections in three patients (20, 71).

Other therapies have had variable efficacy in treating *I. belli* enteritis. Roxithromycin given orally decreased the diarrhea in an AIDS patient suffering from chronic *I. belli*-induced diarrhea that was not responsive to trimethoprim-sulfamethoxazole or pyrimethamine treatments. *I. belli* was not detected in stool samples while the patient was on roxithromycin (62). Spiramycin initially provided clinical improvement in an AIDS patient, but after a month on therapy the disease recurred (34).

In a study of eight AIDS patients with *I. belli* enteritis, treatment with diclazuril resulted in a resolution of diarrhea in four of eight patients (46). Diclazuril was reported to successfully treat *I. belli* in an AIDS patient who was hypersensitive to trimethoprim-sulfamethoxazole and pyrimethamine; however, the diarrhea eventually recurred (48). For two patients with *I. belli* infection, the combination of albendazole and ornidazole was effective in clearing this infection (17). Treatment with other antiprotozoal agents such as metronidazole, tinidazole, quinacrine, and furazolidone appears to be of little value in this infection (9, 78, 79, 87).

C. cayetanensis

The drug of choice for the treatment of *Cyclospora* infection is trimethoprim-sulfamethoxazole (53, 65). Clearance of parasites, decrease in diarrhea, and decrease in abdominal pain occurred within a mean of 2.5 days after treatment. Patients with HIV-1 infection and $CD4^+$ cell counts less than 200 should receive secondary prophylaxis with trimethoprim-sulfamethoxazole, as relapse occurs in up to 50% of patients with AIDS without prophylaxis. It is likely that secondary prophylaxis is not needed once the $CD4^+$ count exceeds 200, as has been demonstrated for many opportunistic pathogens in patients with HIV-1 infection.

For patients unable to tolerate sulfonamides due to allergy or intolerance there is no standard treatment. Nitazoxanide has been evaluated for activity against a broad range of pathogenic protozoa and helminths (16, 29), and in these studies its efficacy for the treatment of cyclosporiasis has been about 70%. It should be appreciated, however, that only a few patients with cyclosporiasis were treated in any of these studies (16, 29). Another alternative agent is ciprofloxacin, a fluoroquinolone that inhibits topoisomerase. In a randomized study of 20 patients with cyclosporiasis, all of the 9 patients who received trimethoprim-sulfamethoxazole had a cessation of diarrhea within 3 days and 10/11 of those who received ciprofloxacin had a cessation of diarrhea within 4 days. Only 7/11 patients treated with ciprofloxacin cleared the organism from their stool (83). Anecdotal data suggest that the following drugs are ineffective: albendazole, azithromycin, pyrimethamine, nalidixic acid, norfloxacin, tinidazole, metronidazole, quinacrine, tetracycline, doxycycline, and diloxanime furoate (L. M. Weiss, unpublished data).

S. hominis and *S. suihominis*

There is no known treatment or prophylaxis for intestinal infection, myositis, vasculitis, or related lesions in humans due to sarcocystosis. For six patients in Thailand with segmental necrotizing enteritis, treatment consisted of surgical resection of the affected areas of the intestine with antibiotics for the associated bacterial infection (7, 8). Given the efficacy of trimethoprim-sulfamethoxazole against other coccidian infections and its activity in vitro against *Sarcocystis neurona* (50), it is reasonable to assume that this drug may have some efficacy in *Sarcocystis* infection. There is a case report of albendazole having efficacy in an outbreak of eosinophilic myositis due to *Sarcocystis* spp. (1). It is likely that steroids have a role in decreasing the inflammatory response in cases of myositis and vasculitis due to *Sarcocystis* infection, but this has never been evaluated in a controlled trial. Ponazuril has had efficacy against asexual stages of *S. neurona* in a mouse model of encephalitis but has not been used in human infections (30; D. S. Lindsay and S. M. Mitchell, unpublished data).

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

Both *I. belli* and *C. cayetanensis* are usually identified by stool examination and are rarely misidentified when isolated from human feces. Quantitation of the number of organisms found per high-power field is not required. Stool examinations that are reported as negative should indicate that at least three stool examinations are needed to detect 95% of infected individuals and that using a single specimen may miss as many as 30% of infected patients. If acid-fast or similar stains are positive, then this should be indicated in the report. Computer report notes can indicate that trimethoprim-sulfamethoxazole is the drug of choice for treatment of these parasites. PCR can be used for the identification of these organisms, but it is not commercially available and should be indicated as an experimental test. Serology is not currently used for diagnosis of these diseases in humans. Of these coccidia, only *C. cayetanensis* is a reportable disease to the State Health Department and Centers for Disease Control and Prevention as it has been associated with outbreaks and the contamination of human food sources.

S. hominis and *S. suihominis* can be identified by their characteristic morphology in stool specimens or in tissue biopsy specimens. Due to the rarity of these infections, confirmation of the observed organisms should be obtained from experts in parasitology. Computer reports should indicate if confirmation of the identification of these organisms has been obtained. There is no requirement for reporting *Sarcocystis* spp. to the State Department of Health or Centers for Disease Control and Prevention.

*Cryptosporidium**

LIHUA XIAO AND VITALIANO CAMA

142

Cryptosporidium spp. inhabit the brush borders of the gastrointestinal and respiratory epithelium of various vertebrates (27), causing enterocolitis, diarrhea, and cholangiopathy in humans (19). Immunocompetent children and adults with cryptosporidiosis usually have a short-term illness accompanied by watery diarrhea, malabsorption, and weight loss. In immunosuppressed persons, however, the infection can be protracted and life-threatening (48). *Cryptosporidium* spp. are well-recognized water- and food-borne pathogens, having caused many outbreaks of human diarrheal disease in the United States and other countries (25).

TAXONOMY

Cryptosporidium spp. belong to the family Cryptosporidiidae, which is a member of the phylum Apicomplexa. The exact placement of Cryptosporidiidae in Apicomplexa is uncertain. It was long considered a member of the class Coccidea, in the order of Eimeriida or Eucoccidiorida. Recent phylogenetic studies, however, indicate that *Cryptosporidium* spp. are more related to gregarines than to coccidia (16). Extracellular gregarine-like reproductive stages in *C. andersoni* and *C. parvum* have been described (90). Thus, *Cryptosporidium* spp. are no longer considered coccidian parasites.

Recently, the taxonomy of *Cryptosporidium* has gone through revisions as the result of extensive molecular genetic studies and biologic characterizations of parasites from various animals (109). The validity of several early-described species has been established, such as *C. parvum* in ruminants and humans; *C. muris* in rodents; *C. wrairi* in guinea pigs; *C. felis* in cats; *C. meleagridis*, *C. baileyi*, and *C. galli* in birds; and *C. saurophilum* and *C. serpentis* in reptiles. Several new *Cryptosporidium* species have been named from parasites of mammals, such as *C. hominis* (previously known as *C. parvum* genotype 1 or the human genotype) almost exclusively in humans, *C. andersoni* (previously known as *C. muris*-like or *C. muris* bovine genotype) and *C. bovis* (previously known as *Cryptosporidium* bovine genotype B) in weanling calves and adult cattle, *C. canis* (previously known as *C. parvum* dog genotype) in dogs, and *C. suis* (previously known as *Cryptosporidium* pig genotype I or *C. parvum* pig genotype) in pigs. Two new species have also been found in fish: *C. molnari* and *C. scophthalmi*. Thus, there are at least 16 established *Cryptosporidium* species in fish, reptiles, birds, and mammals. There are also many host-adapted *Cryptosporidium* genotypes that do not yet have designated species names, such as *Cryptosporidium* horse, rabbit, mouse, ferret, deer mouse, skunk, squirrel, bear, deer, deer-like, cervine, fox, mongoose, wildebeest, duck, woodcock, snake, tortoise, goose I and II, muskrat I and II, opossum I and II, marsupial I and II, and pig II genotypes (109).

DESCRIPTION OF AGENT

Cryptosporidium spp. are intracellular parasites that primarily infect epithelial cells of the stomach, intestine, and biliary ducts. In birds and in severely immunosuppressed persons, the respiratory tract is sometimes also involved. The infection site varies according to species, but almost the entire development of *Cryptosporidium* spp. occurs between the two lipoprotein layers of the apical membrane of the epithelial cells (27), with the exception of *C. molnari* and *C. scophthalmi*, for which oogonial and sporogonial stages are located deeply within the epithelial cells (1).

Cryptosporidium infections in humans or other susceptible hosts start with the ingestion of viable oocysts. Upon contact with gastric and duodenal fluid, four sporozoites are liberated from each excysted oocyst, invade the epithelial cells, and develop to trophozoites surrounded by a parasitophorous vacuole. Within the epithelial cells, trophozoites undergo several generations of asexual amplification called merogony, leading to the formation of different types of meronts containing 4 to 8 merozoites. The latter differentiate into sexually distinct stages called macrogamonts and microgamonts (containing microgametes) in a process called gametogony. New oocysts are formed in the epithelial cells from the fusion of macrogamonts and microgametes, sporulate in situ in a process called sporogony, and contain four sporozoites. It is believed by some that about 20% are "thin walled" and may excyst within the digestive tract of the host, leading to the infection of new cells (autoinfection). The remaining 80% of oocysts are excreted into the environment; are resistant to low temperature, high salinity, and most disinfectants; and can initiate infection in a new host without further development upon ingestion. The time from ingestion of infective oocysts to the completion of endogenous development and excretion of new oocysts varies with species, hosts, and infection doses; it is usually between 4 and 14 days (27).

*This chapter contains information presented in chapter 134 by Ynes R. Ortega and Michael Arrowood in the eighth edition of this Manual.

The only extracellular stages in *Cryptosporidium* life cycle are oocysts, which are the environmental stage of the parasite, and released sporozoites, merozoites, and microgametes, which are briefly in the lumen of the digestive tract (27). However, recently, a gregarine-like extracellular stage has been described for *C. andersoni* and *C. parvum,* which undergoes multiplication through syzygy, a sexual reproduction process involving the end-to-end fusion of two or more parasites (90).

To date, eight *Cryptosporidium* spp. have been reported to exist in humans: *C. hominis, C. parvum, C. meleagridis, C. felis, C. canis, C. muris, C. suis,* and *Cryptosporidium* cervine genotype. Humans are most frequently infected with *C. hominis* and *C. parvum*. The former almost exclusively infects humans and thus is considered an anthroponotic parasite, whereas the latter infects mostly humans and domestic and wild ruminants and thus is considered a zoonotic pathogen. Other species, such as *C. meleagridis, C. felis,* and *C. canis,* are less common. In contrast, *C. muris, C. suis,* and *Cryptosporidium* cervine genotypes have been found only in a few human cases (107, 109, 110). Despite an earlier suggestion that unusual zoonotic species usually infect immunocompromised persons, results of a recent study in Peru suggest that there is no significant difference in the distribution of *Cryptosporidium* species between AIDS patients and children living in the same geographic area (13).

EPIDEMIOLOGY, TRANSMISSION, AND PREVENTION

Cryptosporidium spp. have a worldwide distribution, and their oocysts are ubiquitously present in the environment. There were 2,769 to 3,787 annual cases of reported human cryptosporidiosis in the United States during 1999–2002 (42). Humans can acquire cryptosporidiosis through several transmission routes, such as direct contact with infected persons or animals and consumption of contaminated water (drinking or recreational) or food. However, the relative role of each in the transmission of *Cryptosporidium* infection in humans is unclear.

Anthroponotic versus Zoonotic Transmission

Studies in the United States and Europe have shown that cryptosporidiosis is more common in homosexual men than in persons in other human immunodeficiency virus (HIV) transmission categories (40), indicating that direct person-to-person or anthroponotic transmission of cryptosporidiosis is common. Contact with persons with diarrhea has been identified as a major risk factor for sporadic cryptosporidiosis in the United States, the United Kingdom, and Australia (47, 88, 92). This is exemplified by the high prevalence of cryptosporidiosis in day care facilities and nursing homes in developed countries.

Only a few case control studies assessed the role of zoonotic transmission in the acquisition of cryptosporidiosis in humans. In the United States, the United Kingdom, and Australia, contact with farm animals is a major risk factor in sporadic cases of human cryptosporidiosis (37, 47, 88, 92). Contact with pigs, dogs, or cats is also a risk factor for cryptosporidiosis in children in Guinea-Bissau and Indonesia (55, 72), although it is a protective factor in Australia (88). A weak association was observed between the occurrence of cryptosporidiosis in HIV-positive persons and contact with dogs, but not other animals (36). In other studies, no increased risk in the acquisition of cryptosporidiosis was associated with contact with animals (75, 82).

The distribution of *C. parvum* and *C. hominis* in humans is probably a good indicator of the transmission routes. Thus far, studies conducted in tropical countries such as Peru, Thailand, Malawi, Uganda, Kenya, and South Africa showed a predominance of *C. hominis* in children or HIV-positive adults. This is also true for the United States, Canada, Australia, and Japan. In Europe, however, several studies have shown slightly higher prevalence of *C. parvum* than *C. hominis* in both immunocompetent and immunocompromised persons (110). In contrast, Kuwaiti children are almost exclusively infected with *C. parvum* (99). The differences in the distribution of *Cryptosporidium* genotypes in humans are considered an indication of differences in infection sources (58); the occurrence of *C. hominis* in humans is most likely due to anthroponotic transmission, whereas the predominance of *C. parvum* in a population has been considered the result of zoonotic transmission. Thus, in most tropical countries, it is possible that anthroponotic transmission of *Cryptosporidium* plays a major role in human cryptosporidiosis, whereas in Europe, both anthroponotic and zoonotic transmissions are important. Indeed, in areas with a high percentage of infections due to *C. parvum*, massive slaughtering of farm animals and restriction of visits to farms during foot-and-mouth disease outbreaks can result in a reduction in the proportion of human infections due to *C. parvum* (45).

Nevertheless, recent subtyping studies based on sequence analyses of the 60-kDa glycoprotein (GP60) gene have shown that not all *C. parvum* infections in humans are results of zoonotic transmission (2, 63, 107). Among several *C. parvum* subtype families identified, IIa and IIc (previously known as Ic) are the two most common families. The former has been identified in both humans and ruminants, thus acting as a zoonotic pathogen, whereas the latter has been seen only in humans (2, 107) and thus is an anthroponotic pathogen. In Lima, Peru, all *C. parvum* infections in children and HIV-positive persons are due to the subtype family IIc, indicating that anthroponotic transmission of *C. parvum* is common in certain areas (109). Even in the United Kingdom, where zoonotic transmission is known to play a significant role in the transmission of human cryptosporidiosis, anthroponotic transmission of *C. parvum* is also common (63).

Waterborne Transmission

Epidemiologic studies have frequently identified water as a major route of *Cryptosporidium* transmission in areas where the disease is endemic (29, 79, 106). In most tropical countries, *Cryptosporidium* infections in children usually peak during the rainy season, and waterborne transmission is considered a major route of cryptosporidiosis in these areas (9, 10, 77, 80, 100).

Seasonal variations in the incidence of human *Cryptosporidium* infection in industrialized nations have also been attributed to waterborne transmission (12, 22, 68, 92). In the United States, there are two annual peaks in the number of cryptosporidiosis cases among HIV-positive persons: one in spring and one in late summer (50, 94). In the general population, there is also an annual late summer peak in sporadic cases of cryptosporidiosis (92). It is generally accepted that the late summer peak of cryptosporidiosis cases is due to recreational activities such as swimming and water sports, suggesting that waterborne transmission may be important in cryptosporidiosis epidemiology.

The role of drinking water in sporadic *Cryptosporidium* infection is not clear. For Mexican children living near the United States border, cryptosporidiosis is associated with consumption of municipal water instead of bottled water (57). In England, there is an association between the number of glasses of tap water drunk at home each day and the occurrence of sporadic cryptosporidiosis (47). In the United States,

drinking untreated surface water was identified as a risk factor for the acquisition of *Cryptosporidium* in a small case control study (29), and residents living in cities with surface-derived drinking water generally have higher levels of antibodies against *Cryptosporidium* antigens in their blood than those living in cities with ground water as drinking water, indicating that drinking water plays a role in the transmission of human cryptosporidiosis (28). Nevertheless, case control studies conducted in both immunocompetent persons and AIDS patients in the United States have failed to show a direct linkage of *Cryptosporidium* infection to drinking water (56, 95).

Numerous waterborne outbreaks of cryptosporidiosis have occurred in the United States, Canada, the United Kingdom, France, Australia, Japan, and other industrialized nations (25, 61, 91). These include outbreaks associated with both drinking water and recreational water (swimming pools and water parks). After the massive cryptosporidiosis outbreak in Milwaukee in 1993, the water industry has adopted more stringent treatments of source water. Currently, the number of drinking water-associated outbreaks is in decline in the United States and the United Kingdom. Even though five *Cryptosporidium* species are commonly found in humans, thus far only *C. parvum* and *C. hominis* are associated with cryptosporidiosis outbreaks, with *C. hominis* responsible for more outbreaks than *C. parvum* (68, 81, 107). This is even the case for the United Kingdom, where *C. parvum* is more common than *C. hominis* in the general population.

Foodborne Transmission

The role of food in the transmission of cryptosporidiosis is much less clear. *Cryptosporidium* oocysts have been isolated from several foodstuffs, and these have been associated mainly with fruits, vegetables, and shellfish (26, 89). Direct contamination of food by fecal materials from animals or food handlers has been implicated in several foodborne outbreaks of cryptosporidiosis in industrialized nations. In most instances, human infections were usually due to consumption of contaminated fresh produce and nonpasteurized apple cider or milk (71, 85).

Very few case control studies have examined the role of potentially contaminated food as a risk factor in the acquisition of *Cryptosporidium* infection in areas where the disease is endemic. A pediatric study in Brazil failed to show any association between *Cryptosporidium* infection and diet or type of food hygiene (82). Case control studies conducted in the United States, the United Kingdom, and Australia have actually shown a lower prevalence of *Cryptosporidium* infection in immunocompetent persons with frequent consumption of raw vegetables (47, 88, 92). Nevertheless, it is estimated that about 10% of *Cryptosporidium* infections in the United States are foodborne (70).

Prevention

As for any pathogens that are transmitted by the fecal-oral route, good hygiene is the key in preventing the acquisition of *Cryptosporidium* infection (53). Immunosuppressed persons especially should take necessary precautions in preventing the occurrence of cryptosporidiosis (65). These include washing hands after going to bathrooms, changing diapers, and contacting pets or soil (including gardening); avoiding drinking water from lakes and rivers, swallowing water in recreational activities, and drinking nonpasteurized milk, milk products, and juices; and following safe-sex practices (avoiding oral-anal contact). During cryptosporidiosis outbreaks or when a community advisory to boil water is issued, individuals should boil water for 1 min to kill the parasite or use a tap water filter capable of removing particles less than 1 μm in diameter. Immunosuppressed persons also should avoid eating raw shellfish and should not eat uncooked vegetable salads and unpeeled fruits when traveling to areas where cryptosporidiosis is endemic (such as tropical countries) (65).

CLINICAL SIGNIFICANCE

In developing countries, human *Cryptosporidium* infection occurs mostly in children younger than 5 years old, with peak occurrence of infections and diarrhea in children less than 2 years of age (9, 10, 77). Frequent symptoms include diarrhea, abdominal cramps, vomiting, headache, fatigue, and low-grade fever (79). The diarrhea can be voluminous and watery but usually resolves within 1 to 2 weeks without treatment. Not all infected children have diarrhea or other gastrointestinal symptoms, and the occurrence of diarrhea in children with cryptosporidiosis can be as low as 30% in community-based studies (10). Even subclinical cryptosporidiosis exerts a significant adverse effect on child growth, as infected children with no clinical symptoms experience growth faltering, both in weight and in height. Children can have multiple episodes of cryptosporidiosis, implying that the anti-*Cryptosporidium* immunity in children is short-lived or incomplete (9, 10, 77). Cryptosporidiosis has been associated with increased mortality in developing countries in hospitalized children (100).

In developed countries, pediatric cryptosporidiosis occurs in older children than in developing countries, probably due to later exposures to a contaminated environment as a result of better hygiene (99). Cryptosporidiosis is also common in elderly people attending nursing homes where person-to-person transmission probably also plays a major role in the spread of *Cryptosporidium* infections (76). In the general population, a substantial number of adults are probably susceptible to *Cryptosporidium* infection, as sporadic infections occur in all age groups in the United States and the United Kingdom and traveling to developing countries and consumption of contaminated food or water can frequently lead to infection (22, 37, 92). Hemodialysis patients with chronic renal failure more commonly develop cryptosporidiosis (101).

Unlike in developing countries, immunocompetent persons with sporadic cryptosporidiosis in industrialized nations usually have diarrhea (37, 88). The median number of stools per day during the worst period of the infection is 7 to 9.5 (88). Other common symptoms include abdominal pain, vomiting, and low-grade fever (37, 88). Patients infected with *C. hominis* are more likely to have joint pain, eye pains, recurrent headache, dizziness, and fatigue than those infected with *C. parvum* (46). The duration of illness has a mean or median of 9 to 21 days, with a median loss of 5 work or study days and hospitalization of 7 to 22% of patients (22, 37, 88).

Cryptosporidiosis is common in immunocompromised persons, including AIDS patients, persons with primary immunodeficiency, and cancer and transplant patients undergoing immunosuppressive therapy (48, 69). It is frequently associated with chronic, life-threatening diarrhea (48). In HIV-positive persons, the occurrence of cryptosporidiosis increases as the $CD4^+$ lymphocyte cell counts fall, especially below 200 cells/μl (48, 67). Manabe et al. described four clinical syndromes of cryptosporidiosis in the United States: chronic diarrhea (36% of patients), cholera-like disease (33%), transient diarrhea (15%), and relapsing illness (15%) (64). Sclerosing cholangitis and other biliary involvements, however, are also very common in AIDS patients with cryptosporidiosis (19). Symptoms of cryptosporidiosis in AIDS patients vary in severity, duration, and responses to drug treatment (64, 67). Much of this variation can be explained by the degree of

immunosuppression (67). In addition, variation in the infection site (gastric infection, proximal small intestine infection, or ileo-colonic infection, versus pan-enteric infection) has been seen in AIDS patients with cryptosporidiosis, and this anatomic localization may also contribute to differences in disease severity and survival (60). Cryptosporidiosis in AIDS patients is associated with increased mortality and shortened survival (64).

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

At the moment, almost all active *Cryptosporidium* infections are diagnosed by analysis of stool specimens. Stool specimens are usually collected fresh or in fixative solutions such as 10% buffered formalin (31). Stool specimens fixed in formalin are preferred for routine diagnosis of cryptosporidiosis. For outbreak investigations, *Cryptosporidium* spp. present are sometimes genotyped by PCR methods, which require the use of fresh stool specimens or stools preserved in 2.5% potassium dichromate. It is recommended that whenever possible multiple specimens (three specimens passed at intervals of 2 to 3 days) from each patient should be examined if *Cryptosporidium* infection is suspected and the examination of the initial stool specimen is negative. This is because carriers with low oocyst shedding are common (87), and examination of single specimens can lead to the detection of only 53% of infections (39).

Examination of intestinal or biliary biopsy specimens is sometimes used in the diagnosis of cryptosporidiosis in AIDS patients (39). However, the sensitivity of the diagnosis depends on the location of tissues examined; the duodenum is usually infected with *Cryptosporidium* only in severe infection, and the terminal ileum has significantly higher detection rates than the duodenum (39). Thus, upper endoscopic biopsies are much less sensitive than lower endoscopic biopsies in diagnosing cryptosporidiosis. However, lower endoscopy is generally considered too invasive and risky for many AIDS patients.

DIRECT EXAMINATION

A variety of methods are used in the detection of *Cryptosporidium* in stool specimens, including microscopy, culture, antigen detection, and nucleic acid detection techniques (6).

Microscopy

Stool specimens can be examined directly for *Cryptosporidium* oocysts by microscopy of direct wet-mount or stained fecal materials if the number of oocysts in specimens is high. *Cryptosporidium* oocysts in humans generally measure 4 to 6 μm. Occasionally, *C. muris* oocysts are also found, which are more elongated and measure 6 to 9 μm. More often, oocysts present are concentrated using either traditional ethyl acetate or Weber-modified ethyl-acetate concentration methods (104). Concentrated stool specimens can be examined by microscopy in several ways. *Cryptosporidium* oocysts can be detected by bright-field microscopy in direct wet mounts. This allows the observation of oocyst morphology and more accurate measurement of oocysts, which is frequently needed in biologic studies. Differential interference contrast can be used in microscopy, which produces better images and visualization of internal structures of oocysts. Morphology and morphometrics measurements, however, are generally not enough for *Cryptosporidium* species differentiation (109), as many *Cryptosporidium* species look similar by microscopy and have similar morphometrics measurements.

More often, *Cryptosporidium* oocysts in concentrated stool specimens are detected by microscopy after staining of the fecal smears. Many special stains have been used in the detection of *Cryptosporidium* oocysts, but modified acid-fast stains are the most commonly used (6). Modified acid-fast staining is commonly used in developing countries because of its low cost, ease of use, lack of need for special microscopes, and ability to simultaneously detect several other pathogens such as *Isospora* and *Cyclospora* (Fig. 1). Two stains widely used in detecting *Cryptosporidium* oocysts are the modified Ziehl-Neelsen acid-fast staining and modified Kinyoun's acid-fast stains (6). Oocysts are stained bright red to purple against a blue or green background in modified acid-fast staining (Fig. 1).

Recently, immunofluorescence assays (IFA) have been used increasingly in *Cryptosporidium* oocyst detection by microscopy, especially in industrialized nations. Compared to acid-fast staining, IFA has higher sensitivity and specificity (52). Many commercial IFA kits are marketed for the detection of *Cryptosporidium;* some of these kits include reagents allowing simultaneous detection of *Giardia* cysts (Table 1). Oocysts appear apple green against a dark background in immunofluorescence microscopy (Fig. 2). Because of its high sensitivity and specificity, IFA has been used by some as the "gold standard" or reference test (33, 52). It has been shown that most antibodies used in immunofluorescent detection of *Cryptosporidium* recognize carbohydrate epitopes on the oocyst wall (111). As the monoclonal antibodies used in commercial IFA kits react with oocysts of almost all *Cryptosporidium* species, IFA cannot identify organisms at the species level (38, 111).

The sensitivity of most microscopic methods is probably low. The detection limit for the combination of ethyl acetate concentration and IFA was shown to be 10,000 oocysts per gram of liquid stool and 50,000 oocysts per gram of formed stool (103, 105). The sensitivity of modified acid-fast staining was 10-fold lower (103), probably because acid-fast stains do not consistently stain all oocysts (30).

Culture

The in vitro cultivation of *Cryptosporidium* spp. remains inefficient despite recent advances (7). Thus, the low parasite yields and oocyst production have limited the usefulness of parasite culture in the diagnosis of *Cryptosporidium* infection. Nevertheless, in vitro cultivation of early *Cryptosporidium* developmental stages in several epithelial cell lines (HCT-8, MDBK, Caco-2, etc.) has been used widely in research studies to assess potential drugs and oocyst disinfection methods and to characterize parasite development, differentiation, and biochemistry (7). The recent development of procedures for long-term maintenance of *C. parvum* and *C. hominis* in cell and cell-free culture could promote the use of in vitro cultivation methods in routine diagnosis of *Cryptosporidium* infection (41).

Antigen Detection

Cryptosporidium infection can also be diagnosed by the detection of *Cryptosporidium* antigens in stool specimens by immunoassays. Antigen capture-based enzyme immunoassays (EIA) have been used in the diagnosis of cryptosporidiosis since 1990 (18, 33). In recent years, EIAs have gained popularity because they do not require experienced microscopists and can be used to screen a large number of samples. In clinical laboratories, several commercial EIA kits are commonly used (Table 1). High specificity (99 to 100%) has been generally reported for these EIA kits (21, 33, 52). Sensitivities, however, have been reported to range from 70% (52)

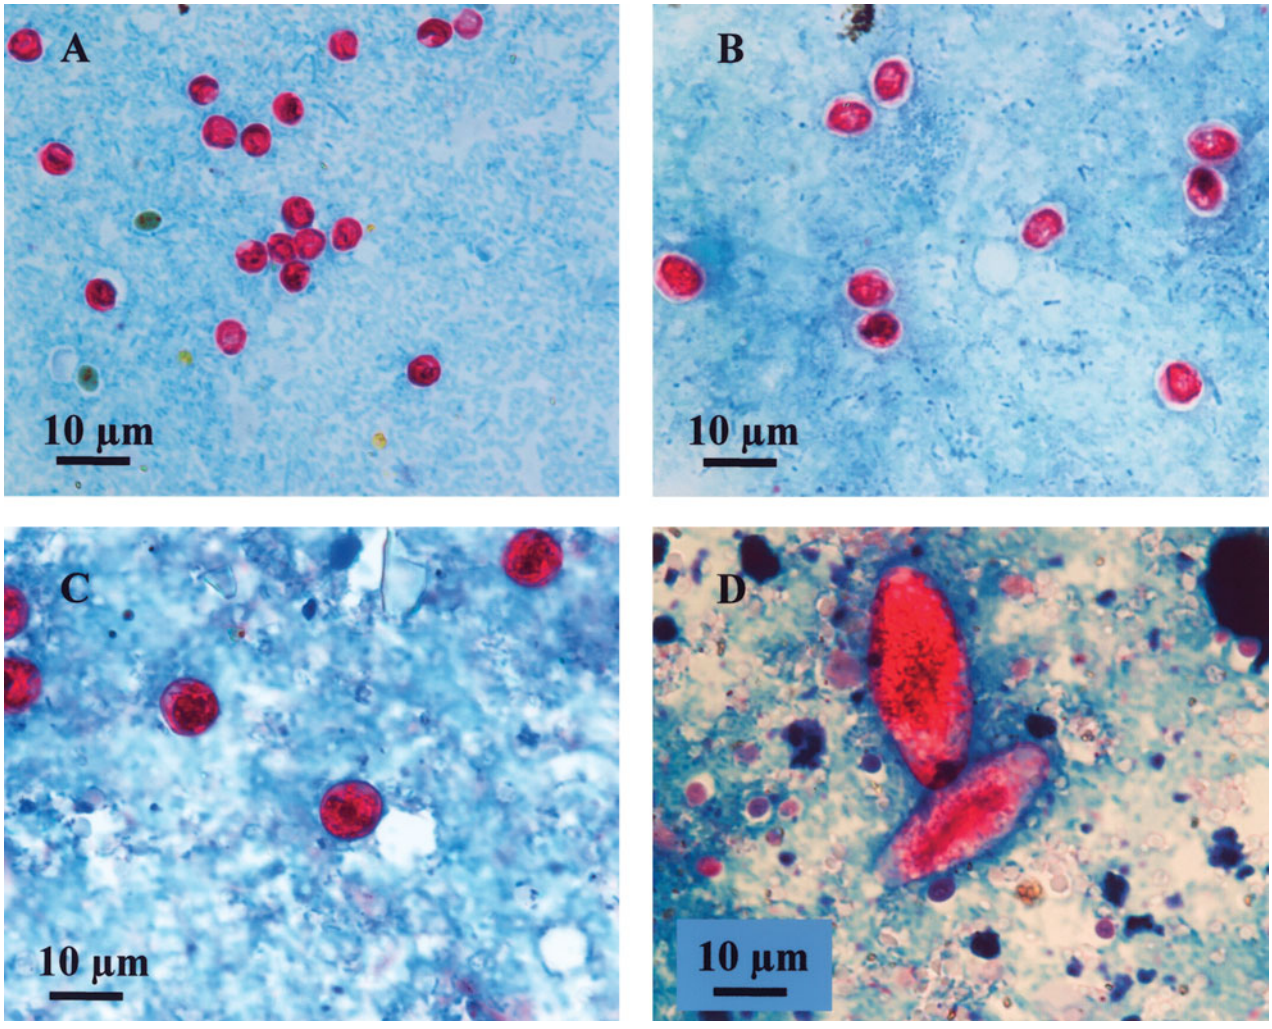

FIGURE 1 Oocysts of *Cryptosporidium hominis* (4 to 6 μm) (A), *Cryptosporidium muris* (6 to 8 μm) (B), *Cyclospora cayetanensis* (8 to 10 μm) (C), and *Isospora belli* (20 to 30 by 10 to 20 μm) (D) stained by the modified Ziehl-Neelsen acid-fast stain.

to 94 to 100% (11, 33). Nevertheless, occasional false positivity of EIA kits is known to occur in the detection of *Cryptosporidium* (18), and manufacturers' recalls of EIA kits have occurred because of high nonspecificity (3, 23). If a patient is in the carrier state or during self-cure, the number of oocysts may drop below the sensitivity levels of these kits (49, 52). Most of the EIA kits have been evaluated only with human stool specimens. Their usefulness in the detection of *Cryptosporidium* spp. in animals may be compromised by the high specificity of antibodies. For example, the ProSpecT *Cryptosporidium* EIA does not detect many *Cryptosporidium* species that are genetically distant from *C. parvum,* such as *C. muris, C. andersoni, C. serpentis,* and *C. baileyi* (38).

In the last few years, several lateral flow immunochromatographic assays have been marketed for rapid detection of *Cryptosporidium* in stool specimens (Table 1). In the few evaluation studies conducted with two of the assays, these assays have been shown to have high specificities (>98%) and sensitivity (98 to 100%) (32, 34, 52, 54). However, a recent study has shown a sensitivity of 68% for one of the assays (52). These rapid assays have also been affected by quality control problems and have been subjected to several manufacturers' recalls because of false-positive results (4, 5).

Nucleic Acid Detection Techniques

Molecular techniques, especially PCR and PCR-related methods, have been developed and used in the detection and differentiation of *Cryptosporidium* spp. for many years. Earlier PCR methods do not have the ability for species differentiation or genotyping and thus can be used only in the determination of the presence or absence of *Cryptosporidium* spp. The primer sequences of these techniques are mostly based on undefined genomic sequences from *C. parvum* bovine isolates, which tend to be more polymorphic than structural or housekeeping genes. Therefore, PCR methods targeting undefined *C. parvum* genomic sequences are unlikely to amplify efficiently DNA from *Cryptosporidium* spp. that are more distant from *C. parvum,* such as *C. muris, C. canis, C. felis,* and *C. suis* (51).

Several PCR-restriction fragment length polymorphism-based genotyping tools have been developed for the detection and differentiation of *Cryptosporidium* at the species level (20, 78, 98, 108). Most of these techniques are based

TABLE 1 Some commercial diagnostic assays for the detection of *Cryptosporidium* oocysts or antigens

Product	Manufacturer, country	CLIA certified	Intended use
Immunofluorescent assays			
Merifluor Cryptosporidium/Giardia	Meridian Biosciences, United States	Yes	Clinical and water
Crypto Cel	Cellabs, Australia	No	Clinical
Crypto/Giardia Cel	Cellabs, Australia	No	Clinical
Cryptosporidium/Giardia Direct Fluorescent Antigen Assay	IVD Research, Inc., United States	No	Clinical

Cryptosporidium Dipstick	Cypress Diagnostics, Belgium	No	Veterinary

on the small subunit rRNA gene. Other genotyping techniques are designed mostly for the differentiation of *C. parvum* and *C. hominis* (73, 81, 96); as a result, they cannot detect and differentiate other *Cryptosporidium* spp. or genotypes. Their usefulness in the analysis of human stool specimens is compromised by their inability to detect *C. canis, C. felis, C. suis,* and *C. muris* (51).

Several subtyping tools have also been developed to characterize the diversity within *C. parvum* or *C. hominis* (110). One of the most commonly used techniques is microsatellite analysis (63). Although it is not a strict microsatellite locus by definition, results of a series of recent studies have shown high sequence polymorphism in the GP60 gene (also known as gp15/45/60, gp40/15) (2, 17, 99). Most of the genetic heterogeneity in this gene is present in the number of a trinucleotide repeat (TCA, TCG, or TCT), although extensive sequence differences are also present between groups (families) of subtypes. Other subtyping tools include sequence analysis of the 70-kDa heat shock protein gene, heteroduplex analysis and nucleotide sequencing of the double-stranded viral RNA, and single-strand conformation polymorphism-based analysis of the second internal transcribed spacer (110). A multilocus mini- and microsatellite subtyping tool for *C. parvum* and *C. hominis* has also been developed (63). The usefulness of subtyping tools has been demonstrated by the analysis of samples from foodborne and waterborne outbreaks of cryptosporidiosis (17, 35, 59, 107, 110).

SEROLOGIC TESTS

Serologic tests are sometimes used in studies of the prevalence of cryptosporidiosis in communities and epidemiologic investigations of cryptosporidiosis outbreaks. Electrophoretic and Western blot analysis showed that specific antibody response appeared between days 4 and 15 postinoculation. The two main target antigens had apparent molecular masses of 15 to 17 and 23 kDa (86). These two antigens, Cp17 (also called gp15) and Cp23 (also called the 27-kDa antigen), have been used by many researchers in the detection of *Cryptosporidium* antibodies by enzyme-linked immunosorbent assays (ELISA) or Western blotting (14, 28, 83, 84). Native Cp17 extracted by Triton from oocysts of *C. parvum* and recombinant *C. parvum* Cp23 expressed in *Escherichia coli* are usually used in these assays (83, 102). ELISA methods using these two antigens generally have higher sensitivity and specificity than earlier methods that use crude oocyst

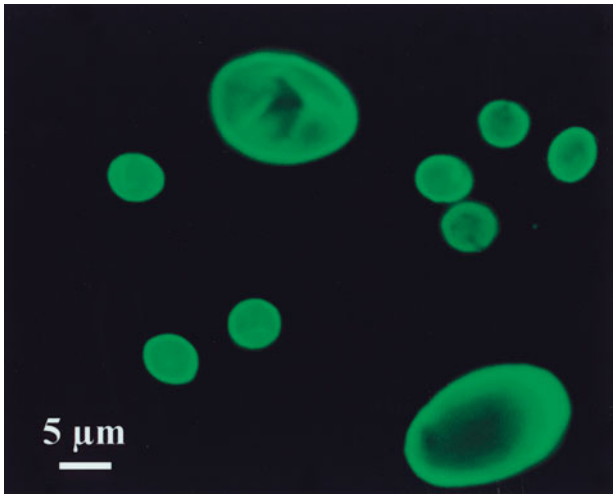

FIGURE 2 *Cryptosporidium hominis* oocysts (4 to 6 μm) and *Giardia duodenalis* cyst (11 to 14 μm by 7 to 10 μm) under immunofluorescence microscopy.

antigens (83). Most researchers use both antigens in serologic studies.

Western blotting or ELISA methods based on Cp17 and Cp23 have been used in research studies of *Cryptosporidium* transmission in immunocompromised persons (24), children (97), and the general community (28) and in investigations of cryptosporidiosis outbreaks (66). Recently, a multiplex bead assay based on these two antigens has been developed for the detection of *Cryptosporidium* antibodies in sera and oral fluids (74). These serologic assays are not intended for the diagnosis of active *Cryptosporidium* infection, as antibodies to both the 27- and 17-kDa antigens have a half-life of about 12 weeks (84). All these tests are not yet commercially available.

TREATMENT

Numerous pharmaceutical compounds have been screened for anti-*Cryptosporidium* activities in vitro or in laboratory animals (93). Some of those showing promising results have been used in the experimental treatment of cryptosporidiosis in humans, but few have been shown to be effective in controlled clinical trials (48). Oral or intravenous rehydration is used whenever severe diarrhea is associated with *Cryptosporidium* infection (43). Nitazoxanide (NTZ) is the only FDA-approved drug for the treatment of pediatric cryptosporidiosis. It has also been recently approved for the treatment of giardiasis in adult patients. Clinical trials have demonstrated that NTZ can shorten clinical disease and reduce parasite loads (8, 93). This drug, however, is not yet approved for the treatment of *Cryptosporidium* infections in immunodeficient people, even though it is likely to be partially effective in patients not severely immunosuppressed (8). For this population, paramomycin and spiramycin have been used in the treatment of some patients, but their efficacy remains unproven (48).

In industrialized nations, the most effective treatment and prophylaxis for cryptosporidiosis in AIDS patients is the use of highly active antiretroviral therapy (HAART) (15). It is believed that the eradication and prevention of the infection are directly related to the replenishment of $CD4^+$ cells in treated persons, rather than antiparasitic activities of these drugs (15), even though some of the protease inhibitors used in HAART, such as indinavir, nelfinavir, and ritonavir, have been shown to have anticryptosporidial activities in vitro and in laboratory animals (44). Relapse of cryptosporidiosis is common in AIDS patients who have stopped HAART (15, 62).

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

Cryptosporidiosis is a notifiable disease in most states in the United States. Thus, the detection of the parasite or its antigens in stools or tissues should be reported to the local health department in addition to the physicians. Because most routine diagnostic tests cannot differentiate *Cryptosporidium* species, the detection of *Cryptosporidium* oocysts or antigens in stools or other specimens should be reported as *Cryptosporidium* positive without referring to the nature of the species involved. From a public health point of view, the reporting of a significant number of cases above background levels in industrialized nations indicates the likely occurrence of outbreaks of cryptosporidiosis or false positivity of diagnostic kits (3–5, 23). In situations like this, it is crucial to have the test results verified with a confirmatory test such as IFA or PCR and to report them to the state or local public health department. The inclusion of both positive and negative controls in each test run will reduce the occurrence of test errors.

Microsporidia*

RAINER WEBER, ALEXANDER MATHIS, AND PETER DEPLAZES

143

THE ORGANISMS

The nontaxonomic term "microsporidia" refers to a group of obligate intracellular, spore-forming protists belonging to the phylum Microspora. More than 140 microsporidial genera and 1,200 species that are parasitic in every major animal group have been identified (35). To date, seven genera *(Enterocytozoon, Encephalitozoon, Nosema, Pleistophora, Vittaforma, Trachipleistophora,* and *Brachiola)* and unclassified microsporidia, assigned to the collective group *Microsporidium,* have been implicated in human infections (Table 1).

Microsporidia develop intracellularly exclusively and have no metabolically active stages outside the host cell. A life cycle (Fig. 1) involving a proliferative merogonic sequence followed by a sporogonic sequence results in environmentally resistant spores of unique structure. Mature spores contain a tubular extrusion apparatus (polar tube) for injecting infective spore contents (sporoplasm) into the host cell.

Microsporidia are true eukaryotes because they have a membrane-bound nucleus, an intracytoplasmic membrane system, and chromosome separation on mitotic spindles, but they are unusual eukaryotes in that they have bacterium-like ribosomes, no recognizable mitochondria, no peroxisomes, and simple vesicular Golgi membranes. Compared with those of other eukaryotes, the genomes of microsporidia are reduced in size and complexity (29). The genome sizes of different microsporidia vary between 2.3 and 19.5 Mb, and the numbers of chromosomes range from 7 to 16 (57). The compactness of the microsporidial genomes results from the loss of genes and from the reduction of coding and noncoding elements. The small-subunit (SSU) rRNA genes of microsporidia, e.g., are significantly shorter than those of other eukaryotes and even those of some prokaryotes.

It has been postulated that, phylogenetically, microsporidia are ancient protists that diverged before the mitochondrial endosymbiosis (Fig. 2). However, genes related to some mitochondrial functions in *Encephalitozoon cuniculi* were sequenced, implying that microsporidia have retained a mitochondrion-derived organelle (29). Indeed, tiny organelles with double membranes were visualized by using antibodies against the mitochondrial heat shock protein 70 in the microsporidian *Trachipleistophora hominis* (58). Furthermore, phylogenetic analyses involving several genes found microsporidia to branch within the zygomycete group, indicating that their ancestors may have been a mitochondriate eukaryote and that microsporidia are a sister group of fungi (26, 30). Also, structural features of the organisms such as the presence of chitin in the spore wall, diplokaryotic nuclei, and electron-dense spindle plaques associated with the nuclear envelope suggest a possible relationship between fungi and microsporidia.

DESCRIPTION OF THE GENERA AND SPECIES

The species are illustrated in Fig. 1.

Nosema spp. develop in direct contact with host cell cytoplasm, nuclei are paired (diplokaryotic), divisions are by binary fission, and sporonts are disporoblastic. Only one species of human origin, *Nosema ocularum,* has been retained in this genus. It will probably require reclassification, but insufficient information is currently available for a new generic assignment. Spores measure 3 by 5 μm and have polar tubes with 9 to 12 coils.

Brachiola spp. have diplokaryotic nuclei and develop in direct contact with host cell cytoplasm. Additionally, the organisms produce electron-dense extracellular secretions and vesiculotubular appendages. Disporoblastic sporogony of *Brachiola vesicularum* produces 2.9- by 2-μm diplokaryotic spores containing 8 to 10 anisofilar coils of the polar filament arranged in one to three rows, usually two (5). On the basis of diplokaryotic nuclei, disporoblastic sporogony, and the formation of vesiculotubular secretions, *Nosema connori* and *Nosema algerae,* also discovered in human infections, have been reclassified as species of *Brachiola*. Spores of *Brachiola connori* measure 2.0 to 2.5 by 4.0 to 4.5 μm and contain polar tubes with approximately 11 coils (6). Spores of *Brachiola algerae* measure 3.7 by 2.0 μm and have 7 to 11 coils of the polar tube (33).

Vittaforma corneae, originally classified as *Nosema corneum,* was transferred to a new genus on the basis of ultrastructural features (42). Nuclei are diplokaryotic, sporogony is polysporoblastic, sporonts are ribbon shaped, and all stages including spores are individually enveloped by a cisterna of host endoplasmic reticulum studded with ribosomes. The spores contain polar tubes with five to seven coils and measure 1.2 by 3.8 μm.

* This chapter contains information presented in chapter 135 by Rainer Weber and Elizabeth U. Canning in the eighth edition of this Manual.

TABLE 1 Microsporidial species pathogenic in humans, and clinical manifestations

Microsporidial species	Clinical manifestations	
	Immunocompromised patients	Immunocompetent persons
Enterocytozoon bieneusi	Chronic diarrhea, wasting syndrome, "AIDS-cholangiopathy," cholangitis, acalculous cholecystitis, chronic sinusitis, chronic cough, pneumonitis	Self-limiting diarrhea in adults and children, traveler's diarrhea, asymptomatic carriers
Encephalitozoon hellem	Disseminated infection, keratoconjunctivitis, sinusitis, bronchitis, pneumonia, nephritis, ureteritis, cystitis, prostatitis, urethritis	Possibly diarrhea[a]
Encephalitozoon intestinalis (formerly *Septata intestinalis*)	Chronic diarrhea, cholangiopathy, sinusitis, bronchitis, pneumonitis, nephritis, bone infection, nodular cutaneous lesions	Self-limiting diarrhea, asymptomatic carriers
Encephalitozoon cuniculi	Disseminated infection, keratoconjunctivitis, sinusitis, bronchitis, pneumonia, nephritis, hepatitis, peritonitis, symptomatic and asymptomatic intestinal infection, encephalitis	Not described; two HIV-seronegative children with seizure disorder and presumed *E. cuniculi* infection presumably were immunocompromised
Pleistophora sp.	Myositis	Not described
Pleistophora ronneafiei	Myositis	Not described
Trachipleistophora hominis	Myositis, keratoconjunctivitis, sinusitis	Keratitis
Trachipleistophora anthropophthera	Disseminated infection	Not described
Brachiola connori (formerly *Nosema connori*)	Disseminated infection	Not described
Brachiola vesicularum	Myositis	Not described
Brachiola algerae (formerly *Nosema algerae*)	Myositis, nodular cutaneous lesions	Keratitis
Nosema ocularum	Not described	Keratitis
Vittaforma corneae (formerly *Nosema corneum*)	Disseminated infection	Keratitis
Microsporidium ceylonensis[b]	Not described	Corneal ulcer, keratitis
Microsporidium africanum[b]	Not described	Corneal ulcer, keratitis
Microsporidia (not classified)	Not described	Keratoconjunctivitis in a contact lens wearer

[a] *E. hellem* has been detected using PCR among persons with traveler's diarrhea and coinfection with *Enterocytozoon* sp. (41); thus, the pathogenic role of *E. hellem* remains unknown. Microscopic detection of *E. hellem* spores in stool has not been reported so far.

[b] *Microsporidium* is a collective generic name for microsporidia that cannot be classified because available information is not sufficient.

Pleistophora spp., including *Pleistophora ronneafiei,* which is pathogenic in humans, have unpaired nuclei, and all stages are multinucleate plasmodia, which divide into smaller multinucleate segments. Meronts have a thick, amorphous coat, which separates from the surface in sporogony to form a sporophorous vesicle. Sporogonic divisions give rise to a large and variable number of spores, packaged in the persistent sporophorous vesicle. The spores contain polar tubes with 9 to 12 coils and measure 2 to 2.8 by 3.3 to 4.0 μm (4).

T. hominis also forms spores in sporophorous vesicles, but these arise from repeated binary fissions and not from multinucleate plasmodia. The vesicles, which contain 2 to more than 32 spores, enlarge as the number of spores increases. The nuclei are unpaired in all stages of development. The pear-shaped spores measure 2.4 by 4.0 μm and have about 11 anisofilar coils (24, 27). *Trachipleistophora anthropophthera* is similar to *T. hominis* but appears to be dimorphic as two different forms of sporophorous vesicles and spores have been observed (47).

Enterocytozoon bieneusi develops in direct contact with host cell cytoplasm (Fig. 3). The proliferative and sporogonial forms are rounded multinucleate plasmodia with unpaired nuclei measuring up to 6 μm in diameter. The oval spores measure 0.7 to 1.0 by 1.1 to 1.6 μm. The polar tube, derived from electron-dense disks in sporonts, has five to seven isofilar coils that appear in two rows when seen in transverse section by transmission electron microscopy (16).

Encephalitozoon spp. develop intracellularly in parasitophorous vacuoles bounded by a membrane of presumed host cell origin. Nuclei of all stages are unpaired. Meronts divide repeatedly by binary fission and lie close to the vacuolar membrane. Sporonts appear free in the center of the vacuole and divide into two or four sporoblasts, which mature into spores. The spores measure 1.0 to 1.5 by 2.0 to 3.0 μm, and the polar tube has four to eight isofilar coils.

E. cuniculi was isolated from a range of animals before human infections were identified. Human isolates of three *Encephalitozoon* spp. and animal isolates of *E. cuniculi* are morphologically almost identical. In 1991, *Encephalitozoon hellem* was distinguished from *E. cuniculi* on the basis of different protein patterns found by sodium dodecyl sulfate-polyacrylamide gel electrophoresis separation and immunoblotting (18). In 1993, *Septata intestinalis* was described and named, based upon the morphological finding that the intracellular vacuoles containing the parasites showed a unique parasite-secreted fibrillar network surrounding the developing organisms, so that the

vacuoles appeared septate (3). Subsequently, on the basis of phylogenetic analyses, *S. intestinalis* was reclassified as *Encephalitozoon intestinalis,* and it was confirmed that the three *Encephalitozoon* spp. are indeed distinct organisms. Finally, with the use of immunological and molecular methods, three different strains of *E. cuniculi* have been identified which differ in animal host preferences and geographic distributions (20).

Microsporidium is a collective generic name for microsporidia that cannot be classified because available information is not sufficient. *Microsporidium ceylonensis* and *Microsporidium africanum* have been assigned to the group name (6).

NATURAL HABITATS

Human microsporidial infections have been documented globally. The sources of microsporidia infecting humans and their modes of transmission are uncertain. Ingestion of the environmentally highly resistant spores is probably the normal mode of transmission. Possible transmission by the aerosol route has also been considered because microsporidia have been found in respiratory specimens. Studies with mammals suggest that *Encephalitozoon* spp. can be transmitted transplacentally from mother to offspring, but no congenitally acquired human infections have been reported (6, 52).

Direct zoonotic transmission of microsporidia infecting humans has not been verified but appears likely because many microsporidial species can infect both humans and animals (15, 35) (Fig. 2A). *E. cuniculi* is considered to be a zoonotic parasite (34). Two of the three different strains of *E. cuniculi* which were detected in natural infections in rabbits and dogs have been isolated from human immunodeficiency virus (HIV)-infected patients (13, 20). In addition to documentation in humans, *E. hellem* has been detected in psittacines kept in aviaries and in a variety of wild birds, and *E. intestinalis* has been reported in single studies with domestic animals in Mexico (2) and gorillas in Uganda (35). *E. bieneusi* has been found mainly in humans, but the parasite has also been detected in domestic animals (pigs, cattle, cats, dogs, and chickens), in wildlife, and in rhesus monkeys experimentally infected with simian immunodeficiency virus (35). Analyses of the rRNA genes' internal transcribed spacers show considerable genetic variation among isolates of the species *E. bieneusi* of human and animal origin. Of 16 human-infecting *E. bieneusi* genotypes identified so far, four seem to have zoonotic potential as they have also been discovered in vertebrate hosts (Fig. 2B) (35). Also, an insect-pathogenic microsporidian, *B. algerae,* was isolated from three patients (11, 49, 50).

Epidemiologic studies suggest water contact as a risk factor for microsporidiosis, and *E. bieneusi, E. intestinalis,* and *V. corneae* homologous DNA has been detected in sewage effluent, groundwater, and surface water. Nevertheless, the importance of possible waterborne transmission requires further investigation.

CLINICAL SIGNIFICANCE

Although microsporidiosis appears to occur most frequently in persons infected with HIV, it is emerging as an infection in other immunocompromised hosts (such as organ transplant recipients and patients with idiopathic or other CD4 T lymphocytopenia) as well as in immunocompetent individuals (Table 1) (52). Microsporidiosis has been associated with abnormalities in structures and functions of infected organs, but the mechanisms of pathogenicity of the different microsporidial species are not sufficiently understood. Patients with severe cellular immunodeficiency appear to be at the highest risk for developing microsporidial disease. Unfortunately, little is known about immunity to this infection, although the importance of T cells has been demonstrated in experiments with athymic mice. It is not understood whether microsporidiosis in immunocompromised patients is primarily a reactivation of latent infection acquired prior to the state of suppressed immunity or whether microsporidial disease is caused by recently acquired infection.

E. bieneusi

E. bieneusi infects the enterocytes of the small intestine and epithelial cells of the biliary tree and respiratory tract. Clinical disease is probably caused by the continuous excess loss of epithelial cells. *Enterocytozoon* infection may be accompanied by alterations in small bowel physiology such as decreased brush border sucrase, lactase, and maltase activities, as well as malabsorption.

E. bieneusi is estimated to be one of the most important HIV-associated intestinal pathogens, present in 5 to 30% of patients with chronic diarrhea, weight loss, or cholangiopathy, particularly when CD4 lymphocyte counts are below 0.1×10^9/liter (55). Upper or lower respiratory tract infections have been detected in a few patients (54), but systemic infection due to *E. bieneusi* has not been documented. Case reports have documented that the parasite is also a cause of diarrhea in organ transplant recipients.

In immunocompetent adults and in children, *E. bieneusi* is associated with self-limited watery diarrhea (lasting up to 2 to 3 weeks), particularly among persons who reside or have traveled in tropical countries (41). Furthermore, the parasite has been identified among elderly persons with acute or chronic diarrhea.

Encephalitozoon spp.

Encephalitozoon spp. infect epithelial and endothelial cells, fibroblasts, macrophages, and possibly other cell types, as reported for humans and mammals. *Encephalitozoon* (identified as *E. cuniculi* because this was the only species known at that time) was initially identified in two children with a seizure disorder (53).

The spectrum of recognized *E. cuniculi*- and *E. hellem*-associated disease in patients with AIDS, organ transplant recipients, and otherwise immunocompromised patients includes keratoconjunctivitis, intraocular infection, sinusitis, bronchiolitis, pneumonitis, nephritis, ureteritis, cystitis, prostatitis, urethritis, hepatitis, sclerosing cholangitis, peritonitis, diarrhea, and encephalitis (13, 18, 52, 53). Clinical manifestations may vary substantially, ranging from an asymptomatic carrier state to organ failure.

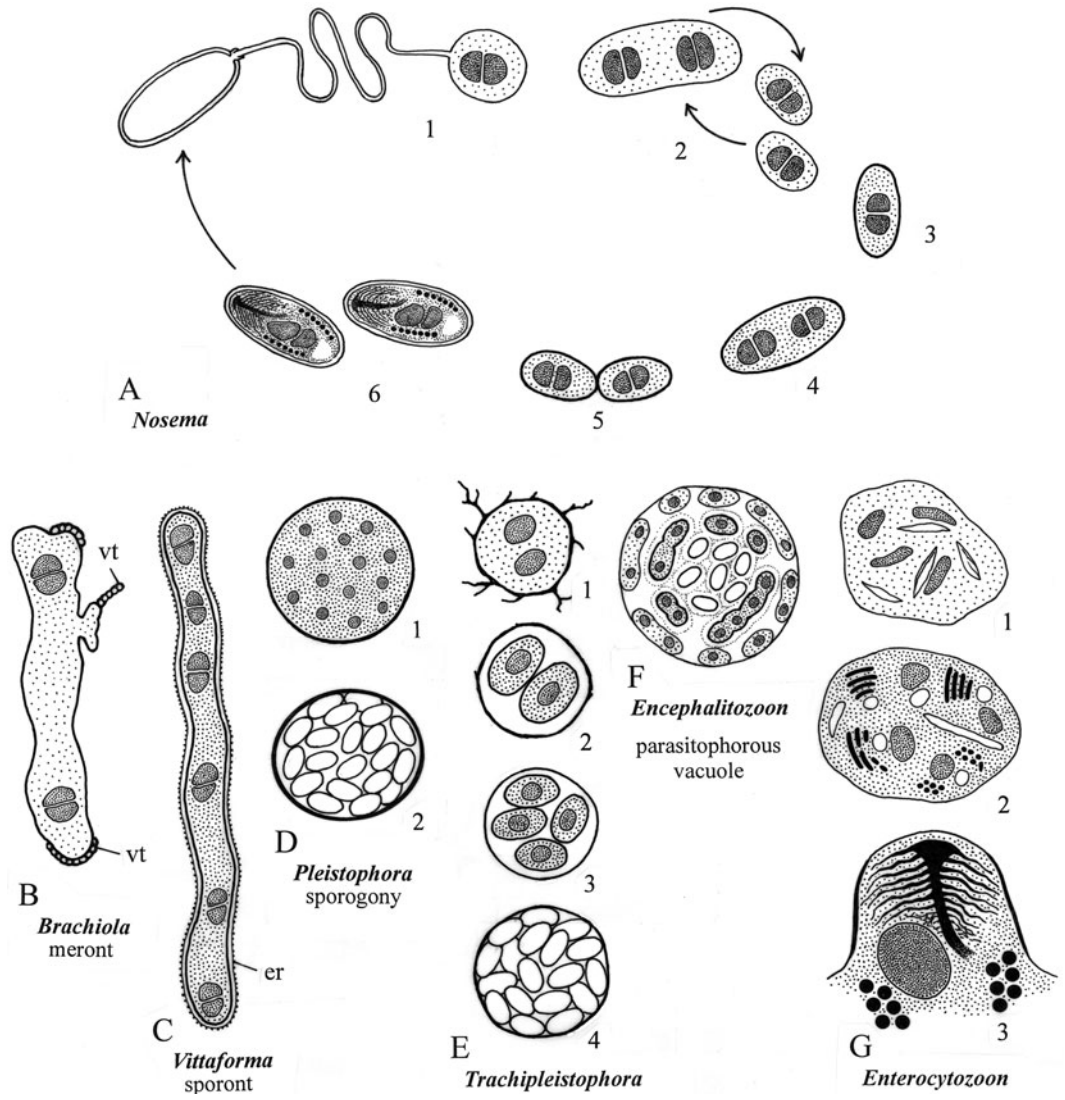
E. intestinalis infects primarily enterocytes, but the parasite is also found in intestinal lamina propria, and dissemination to the kidneys, airways, and biliary tract appears to occur via infected macrophages (3). Chronic diarrhea and disseminated disease due to *E. intestinalis* have been diagnosed mainly in immunodeficient patients. A case of nodular cutaneous *E. intestinalis* infection was observed in a patient with AIDS (31). Furthermore, *E. intestinalis* has been detected in stool specimens from otherwise healthy children and adults, with or without diarrhea, living in Mexico (22) and among travelers with diarrhea returning from tropical countries.

Other Microsporidia

Different microsporidial species have been isolated from otherwise healthy persons who presented with keratoconjunctivitis,

severe keratitis, or corneal ulcers (Table 1) (9, 52). Also, keratoconjunctivitis due to microsporidia has been diagnosed in an immunocompetent contact lens wearer.

In immunocompromised patients, myositis has been linked to infections with different microsporidia, including *Pleistophora* sp. (32), *P. ronneafiei* sp. nov. (4), *T. hominis* (24), *B. vesicularum* (5), and *B. algerae* (11). *B. algerae* has also been isolated from erythematous skin nodules from a boy with acute lymphocytic leukemia (50).



T. anthropophthera has been identified at autopsy in cerebral, cardiac, renal, pancreatic, thyroid, hepatic, splenic, lymphoid, and bone marrow tissue of patients with AIDS who initially presented with seizures (61). Disseminated infection due to *B. connori* was found at autopsy in a 4-month-old athymic male infant (Table 1).

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

Spores of enteropathogenic microsporidia can be detected in stool specimens or duodenal aspirates that have been fixed in 10% formalin or in sodium acetate-acetic acid-formalin, fresh stool samples, or biopsy specimens. The spores of microsporidia causing disseminated infection can usually be detected in fresh or fixed urine sediments, other body fluids (including sputum, bronchoalveolar lavage fluid, nasal secretions, cerebrospinal fluid, and conjunctival smears), corneal scrapings, or tissue. For histological examination, tissue specimens are fixed in formalin. For electron microscopy, fixation of tissue with glutaraldehyde is preferred. Collection of fresh material (without fixative) may be useful for cell culture and for molecular identification. Microsporidial spores are environmentally resistant and, if prevented from drying, can remain infectious for periods of up to several years.

DETECTION PROCEDURES

The most robust technique for the diagnosis of microsporidial infection is light microscopic detection of the parasites themselves. Spores, the stages at which microsporidia pathogenic in humans are usually identified, are small, ranging in size from 1 to 4 μm. Evaluation of patients with suspected intestinal microsporidiosis should begin with light microscopic examination of stool specimens, and microsporidia which cause systemic infection are best detected in urine sediments or other body fluids. Definitive species identification of

microsporidia is made by electron microscopy, antigenic analysis, or, preferably, molecular analysis (25, 56).

Examination of Stool Specimens

Preparation of Smears, Staining, and Microscopic Examination

Smears are prepared using 10 to 20 μl of unconcentrated stool that is very thinly spread onto slides. Most of the procedures that have been adapted for the concentration of ova and parasites fail to concentrate microsporidial spores present in stool specimens. The formalin-ethyl acetate concentration and different flotation methods remove significant amounts of fecal debris, and smears prepared from these concentrates appear easier to read by light microscopic examination than smears prepared from unconcentrated specimens. Such concentration techniques, however, lead to a substantial loss of microsporidial spores and may give false-negative results (51).

The most commonly used stains are chromotrope-based stains (51) and chemofluorescent optical brightening agents (45, 46), including calcofluor white M2R (American Cyanamid Corp., Princeton, N.J.), the Fungi-Fluor kit (Polysciences Inc., Warrington, Pa.), Fungiqual A (Medical Diagnostics, Kandern, Germany), Cellufluor (Polysciences Inc.), Uvitex 2B (Ciba Geigy, Basel, Switzerland; not commercially available), and other chemofluorescent stains. Regardless of which staining technique is used, the use of positive control material is essential. The detection of microsporidial spores requires adequate illumination and magnification, i.e., magnification of ×630 or ×1,000 (oil immersion). The differences in the sizes of *Enterocytozoon* spores (1 to 1.5 μm) and *Encephalitozoon* spores (2 to 3 μm) often permit a tentative identification of the genus from light microscopic examination of stool specimens.

Chromotrope-Based Staining Procedures

Microsporidial spores are ovoid and have a specific appearance when stained with chromotrope stains (Fig. 4 and 5, right panel) (51). The spore wall stains bright pinkish red, some spores appear transparent, and other spores show a distinct pinkish red-stained belt-like stripe that girds the spores diagonally or equatorially. Most background debris in stool specimens counterstains a faint green (or blue, depending on the staining technique). Some other fecal elements, such as yeasts and some bacteria, may also stain reddish, but they are distinguished from microsporidial spores by their sizes, shapes, and staining patterns.

Several modifications of the original chromotrope staining solution (51) have been proposed, including modifications of the counterstain and changes in the temperature of the standard chromotrope staining solution and in the

FIGURE 1 Generalized life cycle of microsporidia and identifying characteristics of the genera known to infect humans. Light stippling indicates merogonic stages; heavy stippling indicates sporogonic stages; no stippling indicates spores and sporoplasm. (A) Basic life cycle, illustrated by *Nosema.* Development may occur in direct contact with host cell cytoplasm *(Nosema*, *Brachiola*, and *Enterocytozoon)* or in isolation by host cell membranes *(Vittaforma* and *Encephalitozoon)* or a cyst-like sporophorous vesicle of parasite origin *(Pleistophora* and *Trachipleistophora)*.1, Sporoplasm: the infective stage emergent from the spore. It may have unpaired nuclei (monokaryotic) or two nuclei in close apposition (diplokaryotic), depending on the genus. 2, Merogony: proliferative stage. It may have a simple plasma membrane, but a surface coat is present in *Brachiola*, *Pleistophora,* and *Trachipleistophora*. Division can be by binary or multiple fission into two or more individuals. 3, Sporont: the first stage of sporogony. If not already present, a surface coat is added (this step is delayed in *Enterocytozoon*). 4, Sporogony: divisions culminating in spore production. Binary or multiple fissions give rise to sporoblasts. 5, Sporoblasts: end products of sporogony, which mature into spores. 6, Spores: resistant stages for transmission. Spores are characterized by an extrusion apparatus (polar tube), which serves to conduct the sporoplasm into a host cell. The polar tube may be of uniform diameter (isofilar) or show a sharp decrease in diameter in the most posterior coils (anisofilar). (B to G) Identifying characteristics of genera. (B) *Brachiola*. Members of this genus are diplokaryotic and disporoblastic; the life cycle is like that of *Nosema,* but meronts are of bizarre shapes and possess a surface coat with vesiculotubular structures (vt) embedded in it and extended from it. (C) *Vittaforma*. Members of this genus are diplokaryotic and polysporoblastic; all stages, including spores, are isolated in a close-fitting, ribosome-studded cisterna of host endoplasmic reticulum (er). (D) *Pleistophora*. Members of this genus are monokaryotic and polysporoblastic; meronts and sporonts are multinucleate stages called plasmodia; a thick surface coat is already present on meronts and sporonts (1); this coat separates from the sporogonial plasmodium to form a cyst-like vesicle, the sporophorous vesicle; the plasmodium divides within it to produce numerous spores (2). (E) *Trachipleistophora*. Members of this genus are monokaryotic and polysporoblastic. The meront surface coat has branched extensions (1); these are withdrawn when the coat separates to form the sporophorous vesicle around a uninucleate sporont; the sporont undergoes a series of binary fissions (2 and 3) and finally encloses numerous spores (4). (F) *Encephalitozoon*. Members of this genus are monokaryotic and di- or tetrasporoblastic; all stages of the life cycle, developing from the sporoplasm, occur concurrently within a host cell vacuole (parasitophorous vacuole); merogonic stages are appressed against the vacuole wall; sporogonic stages are free; the vacuole is finally packed with spores, so that it superficially resembles a sporophorous vesicle. (G) *Enterocytozoon*. Members of this genus are monokaryotic and polysporoblastic; meronts (1) have irregular nuclei and lucent clefts; sporonts (2) are multinucleate with rounded nuclei and have highly characteristic electron-dense disks, which are polar tube precursors; all spore organelles are formed prematurely, so that constriction around the sets of organelles and a nucleus (3) gives rise directly to almost mature spores. The surface coat is deposited only during constriction.

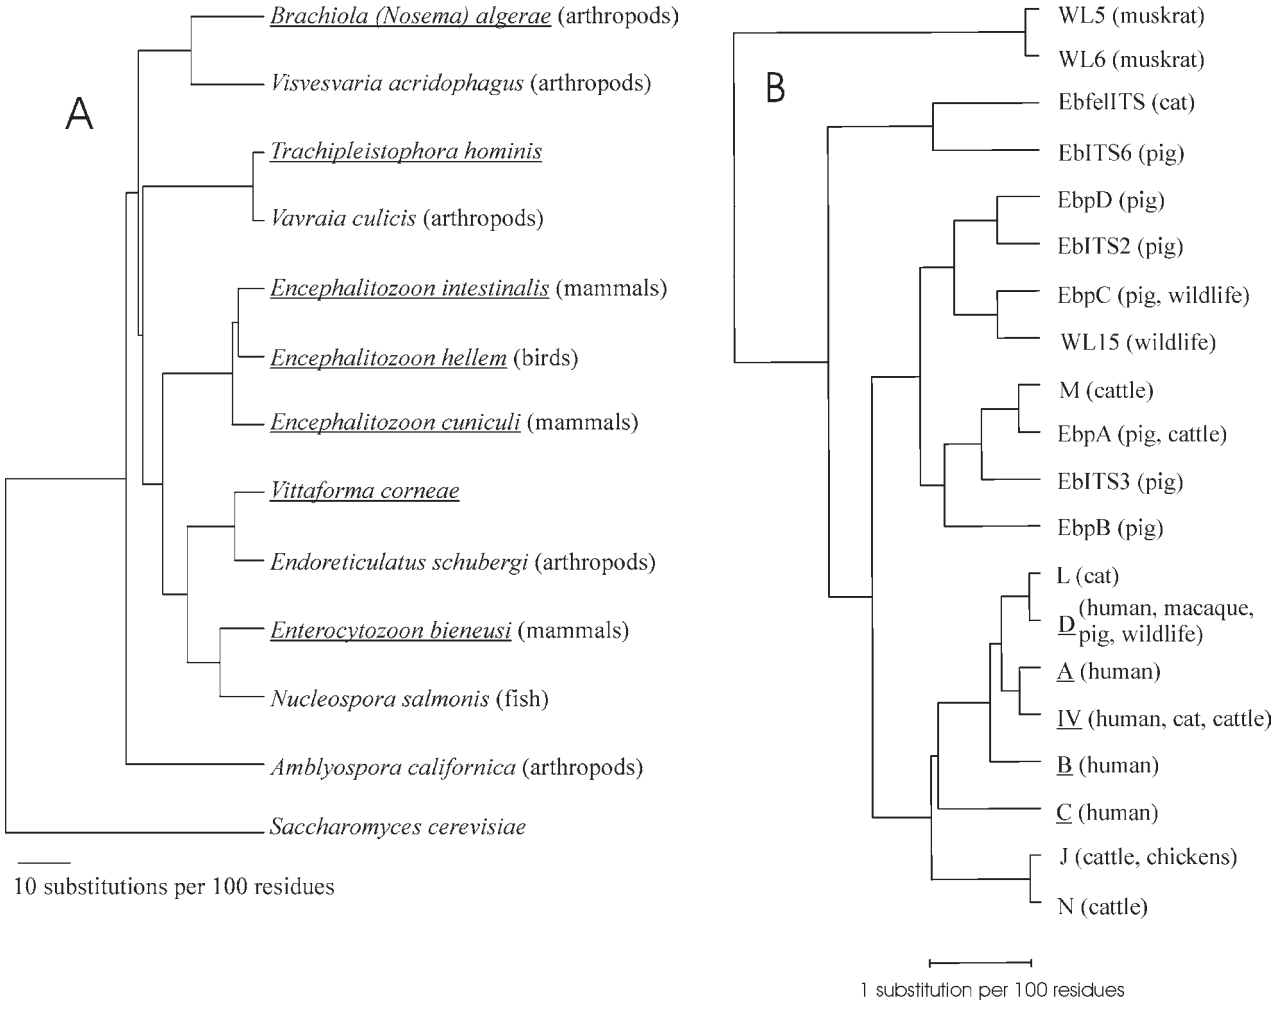


FIGURE 2 (A) Phylogeny of microsporidia generated from the SSU RNA gene sequences of microsporidian species identified in humans (underlined) and selected other species (Kimura's distance, unweighted pair group method of analysis). Known animal hosts are indicated in parentheses; the brewer's yeast *Saccharomyces cerevisiae* serves as an outgroup. No corresponding gene sequences are known for the human-infecting microsporidian species *P. ronneafiei*, *T. anthropophthera*, *B. connori* (formerly *N. connori*), *B. vesicularum*, *N. ocularum*, *M. ceylonensis*, and *M. africanum*. (B) Dendrogram of rRNA internal transcribed spacer sequences of human-infecting *E. bieneusi* genotypes (those confirmed in independent studies are underlined) and selected genotypes with animal hosts (host species are indicated in parentheses). Human-infecting genotypes cluster together, indicating a certain degree of host preference. The eight novel *E. bieneusi* genotypes recently identified in a single study of HIV-infected patients (43) cluster within the branch containing all other human-infecting genotypes (for a detailed dendrogram, see reference 43). All sequences are deposited in GenBank (Kimura's distance, unweighted pair group method of analysis). Adapted from reference 35.

staining time (19). An acid-fast trichrome stain (28) which permits visualization of acid-fast cryptosporidial oocysts as well as microsporidial spores on the same slide and a "quick-hot" Gram-chromotrope staining technique (40) have also been developed.

Chemofluorescent Agents

Chemofluorescent optical brightening agents are chitin stains, which require examination with a fluorescent microscope. With the correct wavelength illumination, the chitinous wall of the microsporidial spores fluoresces brightly, facilitating the detection of spores (45). However, staining is not specific, and fungi, of which small species may be present in fecal material, and other fecal elements may also be brightened. Some experience is necessary to distinguish the microsporidia.

Epidemiological comparisons of the chromotrope staining technique with methods that use chemofluorescent optical brighteners indicate that these tests are robust for routine use and that the sensitivities of both methods are similarly high (19). Some laboratories use both staining techniques because the chromotrope stains result in a highly specific visualization of spores whereas the chemofluorescent agents may be more sensitive but may produce false-positive results.

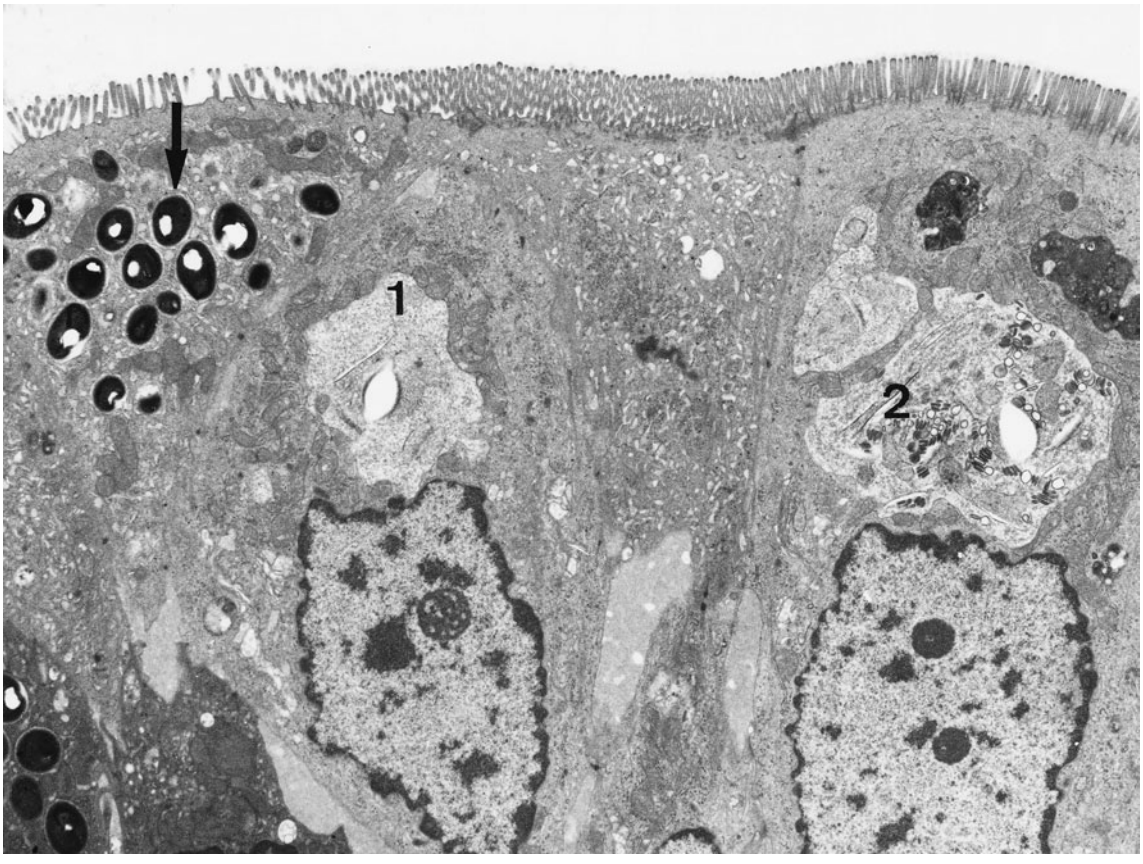

FIGURE 3 Transmission electron micrograph showing the duodenal epithelium of an HIV-infected patient infected with *E. bieneusi*. The different developmental stages between the enterocyte nuclei and the microvillus border include a proliferative plasmodium (1), late sporogonial plasmodia (2), and mature spores (arrow). Magnification, ×5,370. (Courtesy of M. A. Spycher, University Hospital, Zurich, Switzerland.)

Immunofluorescent-Antibody Tests

Immunofluorescence procedures for the detection of *Encephalitozoon* and *Enterocytozoon* microsporidial spores are promising but not commercially available. Diagnostic application of polyclonal antibodies in fecal samples has been hampered by high levels of background staining, cross-reactions with yeast and bacteria, and sensitivity lower than those of chromotrope or chemofluorescent staining procedures (19). Monoclonal antibodies against *Encephalitozoon* spp. (21) and *E. bieneusi* (1) have been generated, of which some have been evaluated for diagnostic purposes with stool specimens (commercially not available).

Cytological Diagnosis

Microsporidial spores have been detected in sediments obtained by centrifugation of body fluids for 10 min at 500 × *g*, including duodenal aspirates, bile, biliary aspirates, urine (Fig. 5, right panel), bronchoalveolar lavage fluid (Fig. 5, middle panel), and cerebrospinal fluid, and in smears of conjunctival swabs, sputum, and nasal discharge. Microscopic examination of stained smears of centrifuged duodenal aspirate obtained during endoscopy is a highly sensitive technique for the diagnosis of intestinal microsporidiosis. Because microsporidial infection often involves multiple organs, the detection of microsporidia in virtually any tissue or body fluid should prompt a thorough search of other sites. Particularly for patients with suspected disseminated microsporidiosis, urine specimens should be examined (52, 56).

Examination of Biopsy Specimens and Corneal Scrapings

Examination of duodenal and terminal ileal tissue has resulted in the detection of intestinal microsporidia, but the parasites are rarely found in colonic tissue sections. Microsporidial species causing disseminated infection have been found in almost every organ system (52, 61).

Only highly experienced pathologists have reliably and consistently identified microsporidia in tissue sections by using routine techniques such as hematoxylin and eosin staining. Ultrathin plastic sections stained with methylene blue-azure II-basic fuchsin or with toluidine blue may facilitate detection. In our experience, tissue Gram stains (Brown-Brenn or Brown-Hopps) have proved to be the most useful for the rapid and reliable identification of HIV-associated microsporidia in routine paraffin-embedded tissue sections (Fig. 5, left panel) and corneal scrapings (51, 56). The microsporidial spores are gram variable, and they are readily identified because of the contrasting dark blue or reddish staining against a faint brown-yellow background. Others prefer a silver stain (Warthin-Starry stain) (23), the chromotrope-based staining technique, or chemofluorescent agents.

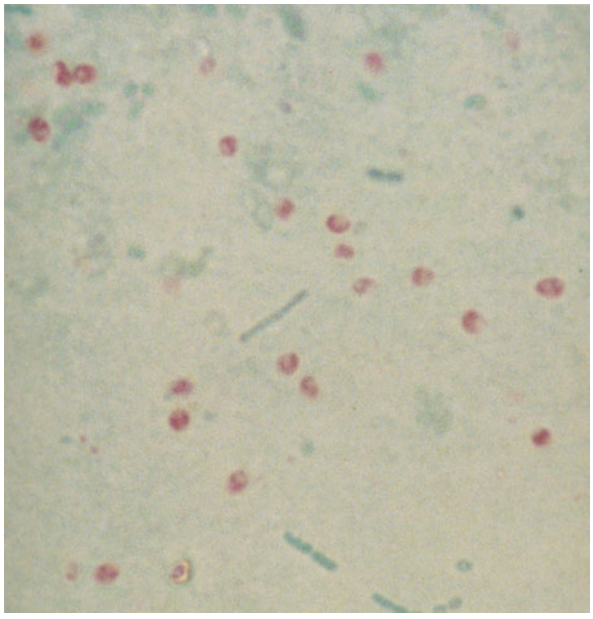

FIGURE 4 Smear of a stool specimen from a patient with AIDS and chronic diarrhea, showing pinkish red-stained spores of *E. bieneusi* that measure 0.7 to 1.0 by 1.1 to 1.6 μm. Chromotrope staining was used. Magnification, ×1,000 (oil immersion).

Molecular Techniques

Universal panmicrosporidian and genus- or species-specific primer pairs that target the rRNA genes and their application in the diagnosis of intestinal microsporidial infection have been described previously (57). The detection and identification of *E. bieneusi* and the different *Encephalitozoon* spp. have been successfully performed with fresh stool specimens, formalin-fixed stool specimens, intestinal tissue obtained by endoscopic biopsy, urine specimens, and other body fluids (12, 13). A real-time PCR method was developed for quantitation of *E. bieneusi* DNA (36) and *E. intestinalis* DNA (37) in stool specimens. Furthermore, in situ hybridization to visualize *E. bieneusi* in tissue sections has been developed (8).

ISOLATION OF MICROSPORIDIA

Microsporidia cannot be grown axenically. *Encephalitozoon* spp., *T. hominis, V. corneae,* and *B. algerae* have been isolated with different cell culture systems, including RK-13 (rabbit kidney), MDCK (Madin-Darby canine kidney), and MRC-5 (human embryonic lung fibroblast) cells and other cells (6, 14, 48). Only short-term in vitro propagation has been accomplished with *E. bieneusi* (48). The isolation of microsporidia has no relevance for diagnostic purposes but is an important research tool and is necessary for the development of immunoassay reagents.

IDENTIFICATION

The identification of microsporidia and their taxonomy have been based primarily upon ultrastructural characteristics. Microsporidial ultrastructure is unique and pathognomonic for the phylum, and ultrastructural features can distinguish all microsporidial genera (Fig. 1) (6). Nevertheless, morphologic features alone do not sufficiently characterize all microsporidial species pathogenic for humans. The characterization of the three *Encephalitozoon* spp., which share most of

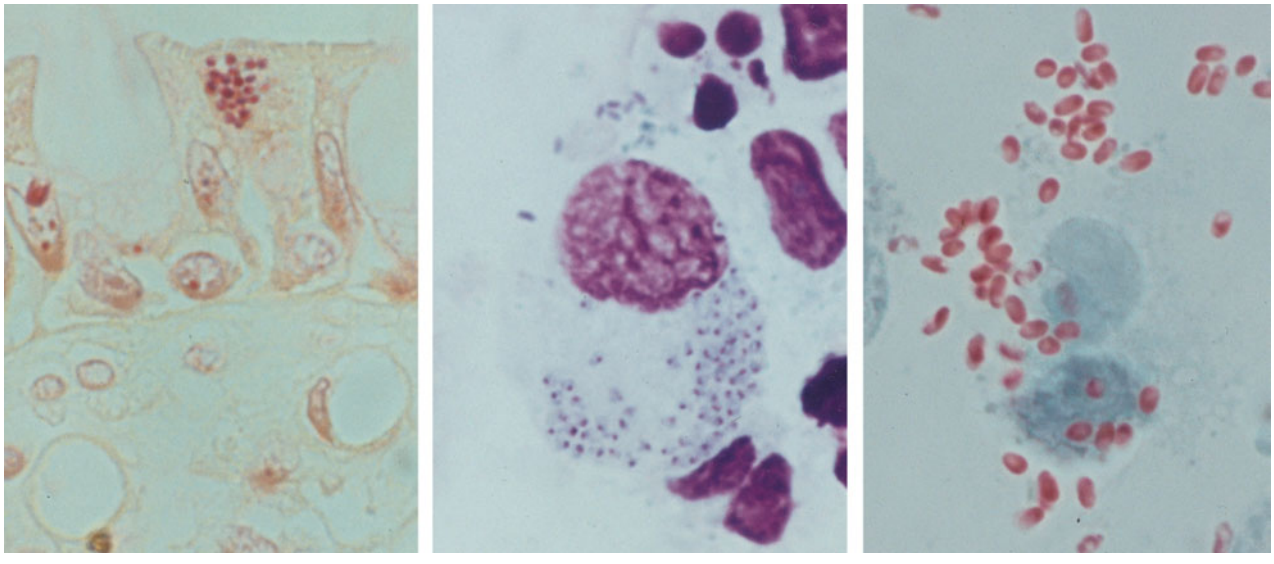

FIGURE 5 (Left) Terminal ileal tissue obtained by ileocolonoscopy from a patient with AIDS and chronic diarrhea due to *E. bieneusi* infection. Gram-labile microsporidial spores, measuring 0.7 to 1.0 by 1.1 to 1.6 μm, are found at a supranuclear location within small intestinal enterocytes. Brown-Brenn stain was used. Magnification, ×1,000. (Middle) Cytospin preparation of bronchoalveolar lavage fluid from a patient with AIDS and intestinal *E. bieneusi* infection, showing intracellular microsporidia. Giemsa stain was used. Magnification, ×1,000 (oil immersion). (Right) Urine sediment from a patient with AIDS and disseminated *E. cuniculi* infection, showing pinkish red-stained microsporidial spores measuring 1.0 to 1.5 by 2.0 to 3.0 μm. Chromotrope stain was used. Magnification, ×1,000 (oil immersion).

their morphologic features, requires antigenic or molecular analyses, which may also reveal subtype-specific variation (18, 20). Phylogenetic relationships of different microsporidia pathogenic in humans, including *E. bieneusi* (35), *Pleistophora*-like organisms (10), *E. cuniculi, E. hellem,* and *E. intestinalis* (59, 60), have been investigated by analyses of SSU rRNA sequences, protein-encoding genes, and gene sequences encoding the largest subunit of the RNA polymerase.

SEROLOGIC TESTS

Serologic assays (including the carbon immunoassay, indirect immunofluorescence test, and enzyme-linked immunoadsorbent assay and Western blot immunodetection) have been useful in detecting specific antibodies to *E. cuniculi* in several species of animals. However, the value of such tests for humans has controversially been discussed because of possible cross-reactivity of the spore wall antigens of the *Encephalitozoon* spp. Furthermore, the results of serologic studies with humans were not substantiated by the detection of parasites in individuals with antibody responses. Recently, by employing recombinant antigens of the polar tube of *E. cuniculi,* improved specificity was demonstrated, and the development of serodiagnostic tools seems feasible (44). *Enterocytozoon,* the most frequent microsporidian pathogen in humans, has not been continuously propagated to produce antigens.

ANTIMICROBIAL SUSCEPTIBILITY

Albendazole has been found to cause growth deformities of *Encephalitozoon* and *Vittaforma* and to reduce or eradicate the parasites propagated in cell cultures but does not destroy mature microsporidial spores, so these may sustain infection (17). Fumagillin, its analog TNP-470, and nikkomycin Z have been shown to inhibit completely or partially the replication or spore germination of *Encephalitozoon* and *Vittaforma* in vitro (17). Numerous antiprotozoal drugs and antibiotics have been tested in vitro, with negative findings. In vitro systems to investigate *E. bieneusi* are not available.

Treatment studies with humans are limited, and only two randomized controlled trials have been conducted. Albendazole can result in clinical cure of HIV-associated encephalitozoonosis in parallel with the cessation of spore excretion (38). In contrast, albendazole is not effective for *Enterocytozoon* infection and does not reduce the parasite load, although previous observations had suggested that clinical improvement may occur in some patients. Oral purified fumagillin appeared to eradicate *E. bieneusi* in many patients, but serious adverse events and parasitic relapse were observed (39).

E. bieneusi-associated diarrhea as well as systemic infection due to *Encephalitozoon* spp. is observed mainly in severely immunodeficient patients with CD4 lymphocyte counts below 0.05 to 0.1×10^9/liter. Observational studies showed that an improvement of immune functions by potent antiretroviral combination therapy results in complete clinical response and normalization of intestinal architecture which parallels the clearance of intestinal microsporidia (7).

INTERPRETATION AND REPORTING OF RESULTS

Microsporidia are predominantly opportunistic pathogens capable of causing disease in severely immunodeficient HIV-infected persons (with CD4 cell counts below 200/μl) and otherwise immunocompromised patients including organ transplant recipients. Therefore, stool examination or examination of other specimens is particularly indicated for these patient groups, and it is prudent to consider microsporidia as the etiologic agents when they are detected in clinical specimens from such patients. Furthermore, various microsporidial species may cause self-limited diarrhea or keratoconjunctivitis in immunocompetent and otherwise healthy persons.

Routine diagnosis of microsporidiosis is based upon microscopic detection of microsporidial spores. Although sensitive and specific, light microscopic examination does not allow the identification of the organisms to the genus and species level. This can be achieved in most cases by electron microscopy, which is relatively insensitive for the detection of microsporidia because only small samples are examined and sampling errors may occur, or by specific immunofluorescence staining of organisms and by PCR-based procedures (both are commercially not available).

Immunocompetent patients may excrete lower numbers of microsporidial spores in feces or urine, and therefore, the threshold of the current light microscopic detection procedures may not be sufficient for the reliable detection of microsporidia in this group.

Nematodes

HARSHA SHEOREY, BEVERLEY-ANN BIGGS, AND PETER TRAYNOR

144

A quarter of the world's population is infected with intestinal nematodes, and these parasites are a major cause of poor health. Most infections occur in resource-poor settings where sanitation is inadequate. Women and children have the greatest morbidity. Immigrants and refugees, travelers, and war veterans often unknowingly harbor helminths for years after leaving an area where the parasites are endemic. Clinical features of infection are usually directly proportional to the intensity of the worm infection. Effective school-based drug therapy programs are under way in many developing countries (14). Laboratory diagnosis is based primarily on microscopic examination of feces and differention of species based on the morphologies of eggs or larvae detected (Fig. 1–3). The sensitivity of this procedure depends on the stage of the infection and is affected by factors such as the variability of the number of eggs or larvae excreted.

TAXONOMY OF NEMATODES

There are various morphological features by which nematodes are identified. At a high taxonomic level, the nature of the anterior regions of the alimentary canal (e.g., the esophagus), the form of the head (presence, number of lips, teeth, etc.), and the form of the tail, especially in the male, are important features. At the species level, details of the male tail, such as the arrangement of caudal papillae and the length and shape of the spicules (sclerotized copulatory aids), are important. In the majority of cases, males carry more taxonomically useful information than females; the latter may often be unidentifiable to the species level in the absence of males. Some studies suggest that nematodes are actually related to the arthropods and priapulids in a newly recognized group, the Ecdysozoa (1). All these nematodes belong to the superkingdom *Eukaryota,* subkingdom *Metazoa,* and phylum Nematoda (for details, see the Taxonomy Browser at http://www.ncbi.nlm.nih.gov/Taxonomy/taxonomyhome.html/index.cgi).

ASCARIS LUMBRICOIDES (ROUNDWORM)

Taxonomy

A. lumbricoides belongs to the class *Chromadorea,* order *Ascaridida,* superfamily *Ascaridoidea,* and family *Ascarididae*.

Of the three genera of ascaridid nematodes regularly occurring as parasites of humans, only *Ascaris* is a true human parasite. The others *(Toxacara* and *Toxascaris)* are common parasites of cats and dogs and occasionally infect humans. Ascaridids are related to anisakids, with three distinct lips, but differ in that their life cycle is linked to terrestrial rather than aquatic conditions.

Description

Eggs

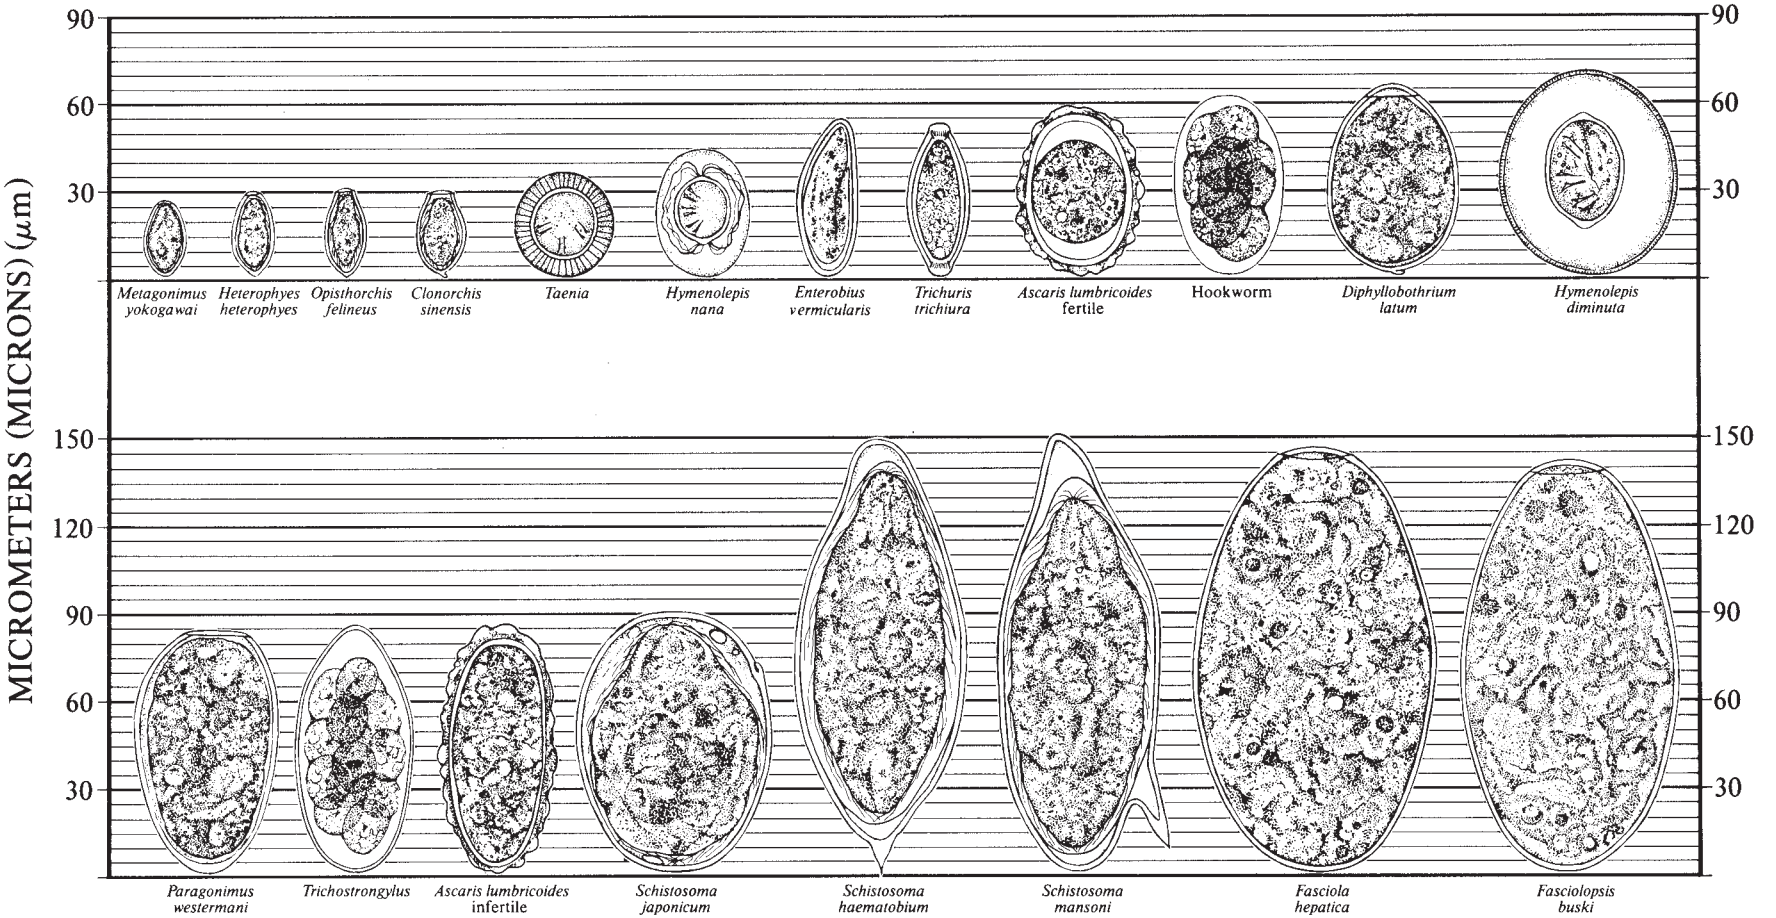
Eggs of *A. lumbricoides* (Fig. 2A to C) are usually seen in two forms: unfertilized and fertilized. The egg shell of a fertilized egg (45 to 75 by 35 to 50 μm) consists of an inner lipid layer responsible for selective permeability, a chitin-protein layer responsible for structural strength, and an outer vitelline layer. The inner layer contains a lipoprotein, ascaroside, which helps the egg survive exposure to formaldehyde, disinfectants, and other chemicals. The fertilized egg frequently has an uneven deposit of mucopolysaccharide with adhesive properties present on its outer surface. Eggs appear brown due to staining by bile. The unfertilized eggs have thinner walls and distorted mammillations. These eggs are usually more elongated in shape, measure 85 to 95 by 43 to 47 μm, and may have a pronounced mammillated coat or an extremely minimal mammillated layer. The presence of only unfertilized eggs strongly suggests that only female worms are present in the intestine. During the development of the eggs, the parent worm must supply the zygotes with sufficient nutrients to ensure progression to the infective second-stage larvae and subsequent survival.

Larvae

First-stage larvae develop inside the eggs and molt to form the second-stage larvae. Soon after hatching in the jejunum, second-stage larvae have a typical filariform appearance (measuring approximately 250 by 14 μm), growing to approximately 560 by 28 μm just before a further molt occurs in the lungs. In the lungs, the larvae develop over 8 or 9 days to reach a length of approximately 1 mm. The larvae must either have sufficient reserves or feed directly to ensure successful migration back to the gut and more developmental molts. Growth is rapid after the fourth and final molt in the intestine.

Worms

Adult male and female *A. lumbricoides* worms (Fig. 2D) are pinkish cream, with males approximately 15 to 31 cm and



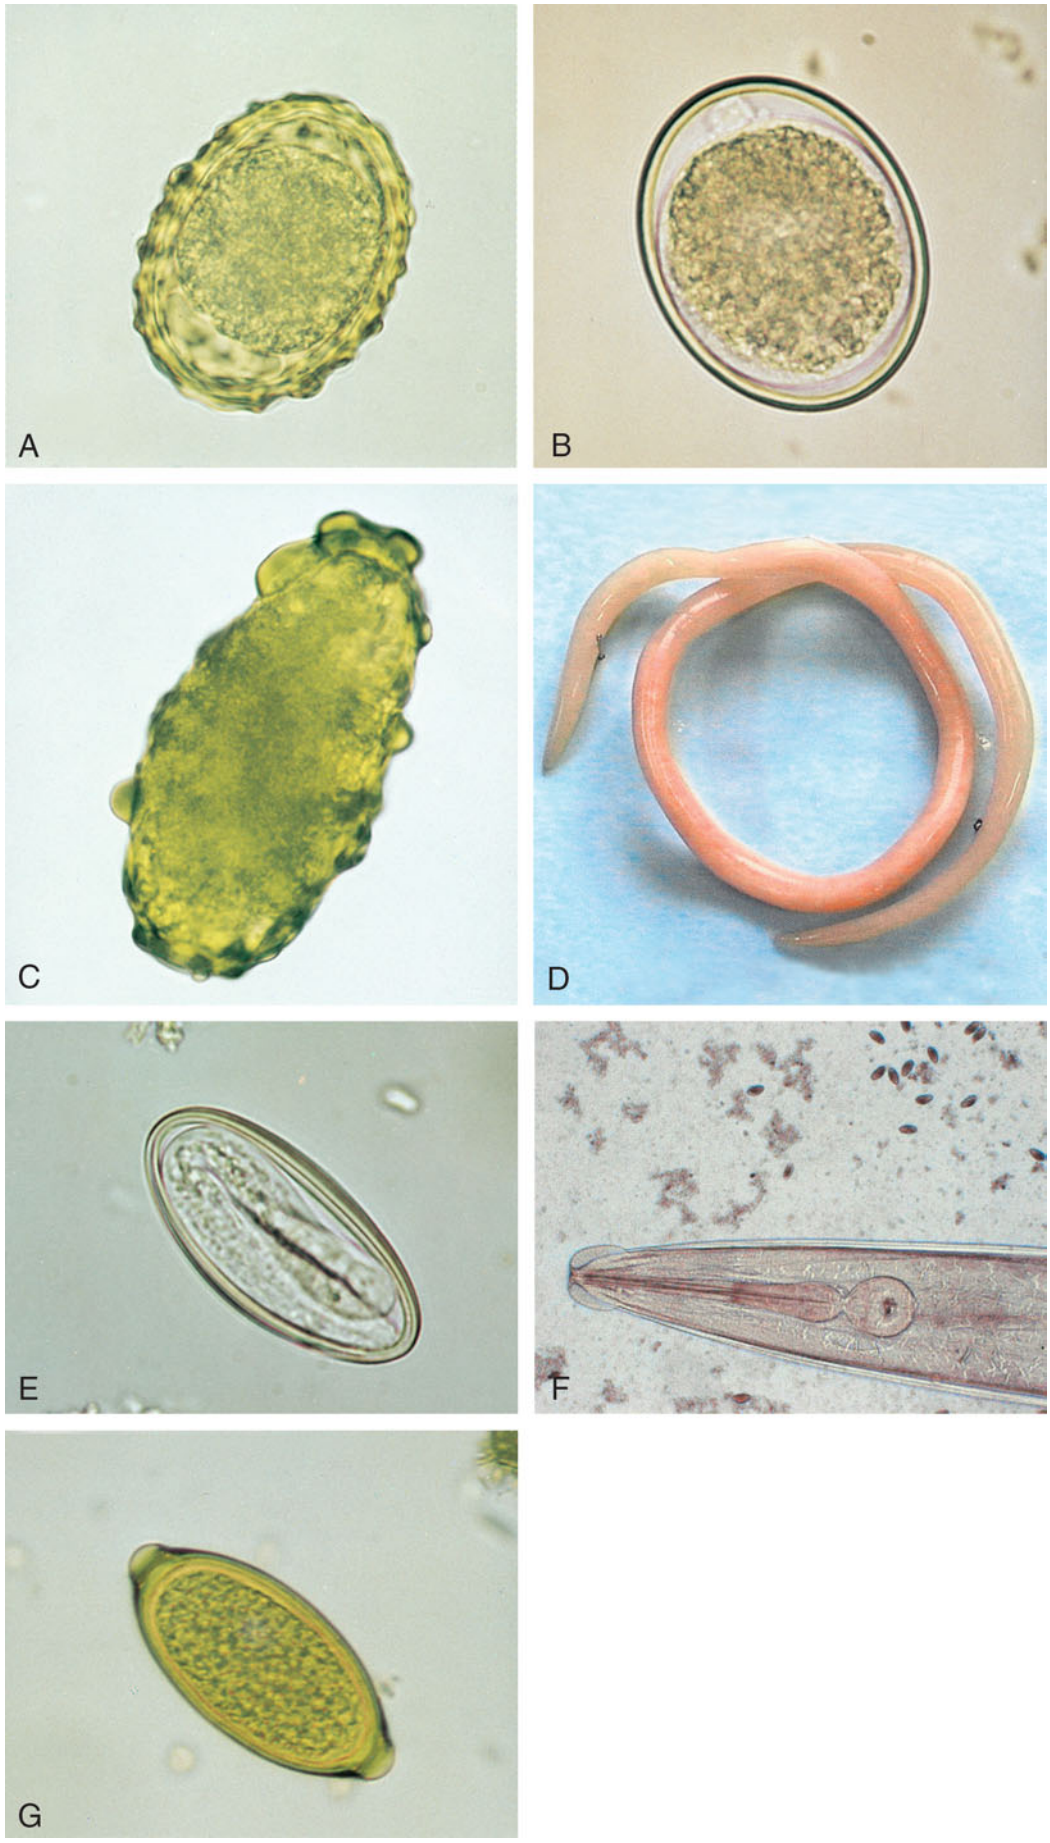


FIGURE 1 Relative sizes of helminth eggs.

A
B
C
D
E
F
G

females 20 to 35 cm in length. The males, often smaller than the females of the same age, have a curved posterior tail, which accommodates the copulatory aids. Adult worms live in the lumen of the host's small intestine and feed on digestion products.

Epidemiology and Prevention

A. lumbricoides infection is one of the most common human infections, with an estimated 1.2 billion people infected worldwide. It has a worldwide distribution and is most common in tropical and subtropical areas of the developed and underdeveloped world. It is particularly associated with crowding and poor sanitation.

Preventive measures consist of health education about personal hygiene and sanitation, and drug therapy.

Transmission and Life Cycle

Eggs passed in feces (diagnostic stage) develop in the soil over 10 to 15 days (Table 1) and may survive in this form for years. Infection follows the ingestion of embryonated eggs (infective stage) that hatch in the small intestine. Larvae penetrate the intestinal mucosa, and the venous circulation carries them to the lungs. From here they migrate to the trachea and are swallowed. They then complete their development into mature adult worms in the small intestine, with eggs produced after 60 to 70 days. A minority of individuals develop heavy infections and act as an important source of transmission.

The prepatent period (from egg ingestion to egg production) is approximately 2 months.

Clinical Significance

Initial infection is usually asymptomatic. The migration of larvae through the lungs may result in eosinophilic pneumonitis with fever, dyspnea, and bronchospasm. This may occur up to 2 weeks after infection and lasts approximately 3 weeks. Bronchospasm may be prominent and is occasionally fatal.

The clinical features in established infections relate to the worm burden. Most infections are light and asymptomatic, but nonspecific abdominal symptoms may occur. There is increasing risk of intestinal obstruction with increasing worm burden. Intestinal obstruction has a high mortality rate in some settings (2). Heavy infections are also associated with malnutrition and impaired growth in children.

Ectopic ascariasis occasionally occurs when adult worms enter hepatobiliary and pancreatic ducts or the appendix and cause obstruction. This may result in biliary colic, cholecystitis, acute cholangitis, acute pancreatitis, appendicitis, or a hepatic abscess. It occurs more commonly in countries with high rates of infection where the parasite is endemic. (For more on the clinical significance of *A. lumbricoides,* see reference 12.)

Diagnosis

The primary diagnosis of infection is by demonstration of the presence of eggs in feces (see references 4 and 5). The fertilized eggs are round to oval, bile stained, mammillated, and thick walled. Often both fertilized and unfertilized eggs are found in the same stool. Multiple specimens taken on separate days may be required. Both direct and concentration methods such as formalin-ethyl acetate sedimentation should be used for optimal yield. The flotation technique may not concentrate dense unfertilized eggs. Decorticated fertile eggs and infertile eggs may be difficult to recognize (Fig. 2A to C). Motile larvae may sometimes be seen in expectorated sputum but rarely in feces. Occasionally, an adult worm (usually female) may be passed in feces or may spontaneously migrate out of the anus, mouth, or nares, particularly in children. Rarely, multiple worms may be passed in children who have lived in areas where the worms are endemic. The female worm is easily identified by its cylindrical body and tapering ends (Fig. 2D) (males are slightly smaller but are rarely seen). Distinguishing features include a lateral white line along the entire length of the body, three lips at the anterior end, and a tough cuticle. No other human parasite is as large as *A. lumbricoides*; hence, it is usually easy to identify. However, with faulty or old plumbing, earthworms may be found in toilet bowls and these may be presented for identification.

Treatment

Albendazole or mebendazole is effective (see chapter 150; see also reference 13).

For a summary of *A. lumbricoides*, see Table 2.

ENTEROBIUS VERMICULARIS (PINWORM OR THREADWORM)

Taxonomy

E. vermicularis belongs to the class *Chromadorea,* order *Oxyurida,* superfamily *Oxyuroidae,* and family *Oxyuridae.*

Only the genus *Enterobius* of the *Oxyuridae* regularly occurs in humans and other primates.

Description

Eggs

Pinworm eggs (Fig. 2E) are ovoid, 50 to 60 by 20 to 35 μm, and asymmetrically flattened on one side and appear colorless when recovered from the perianal skin. The outer layer of the egg shell is albuminous and sticky, enabling the egg to adhere readily. When laid, the egg contains an immature first-stage larva, but this develops rapidly to become infective.

Larvae

Hatched-out larvae complete molting and development in the large bowel.

Worms

Adult female worms (Fig. 2F) measure approximately 8 to 13 by 0.3 to 0.5 mm, with typical lips at the anterior end and a long, pointed tail (hence the name pinworm). Male worms are 2.5 by 0.2 mm but are rarely seen.

FIGURE 2 Various eggs and adult worms of intestinal nematodes (magnification, ×850). (A) Fertile egg of *A. lumbricoides.* (B) Decorticated fertile egg of *A. lumbricoides.* (C) Infertile egg of *A. lumbricoides.* (D) *A. lumbricoides* adult worm with typical cylindrical body with tapering ends and thick cuticle. The *A. lumbricoides* adult worm is the largest of the human pathogenic nematodes, 15 to 35 cm in length. (E) Embryonated infective egg of *E. vermicularis.* (F) *E. vermicularis* adult female. Adult females are usually 8 to 13 by 0.3 to 0.5 mm in size. Shown is the anterior end of a female worm with the characteristic lips. Typical eggs can also usually be seen in the field. (G) Egg of *T. trichiura.*

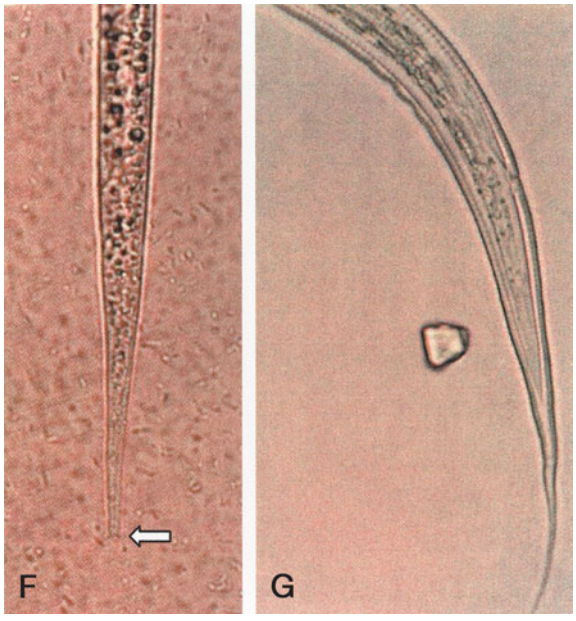

FIGURE 3 *(Continued)*

Epidemiology and Prevention

E. vermicularis infection has a worldwide distribution and is more common in children than adults.

Preventive measures consist of health education about personal hygiene and sanitation, and drug therapy.

Transmission and Life Cycle

Adult worms inhabit the cecum, appendix, and ascending colon. The female migrates down the colon when mature and deposits her eggs on perianal and perineal skin (diagnostic stage). More than 10,000 eggs may be deposited, become infective within 6 h (Table 1), and remain viable for up to 5 days.

Transmission is either direct from the anal and perianal regions to the mouth, usually by fingernail contamination (autoinfection), or from exposure to a contaminated environment. When swallowed, the embryonated eggs (infective stage) hatch in the small bowel. Larvae pass from the small bowel to the large bowel, where they mature into adult worms. Retroinfection is thought to be possible where larvae migrate from the anal skin back to the rectum.

The prepatent period (from egg ingestion to egg production) is 3 to 4 weeks.

Clinical Significance

Many patients are asymptomatic or present with pruritus ani and perineal pruritus. The pruritus may be severe and is worse at night. Excoriation from scratching and secondary bacterial infection are often evident. Children are most commonly infected. With heavy worm burdens, poor concentration, enuresis, and emotional distress are features. Occasionally, the presence of worms in the appendix contributes to inflammation and true appendicitis (3). Reinfection (autoinfection or retroinfection) is also possible.

General symptoms, including abdominal pain, weight loss, and loss of appetite, may occur.

The presence of ectopic worms and eggs in several sites, including the female genitourinary tract, the epididymis, and the peritoneum, has been reported (12). They rarely cause serious complications. (For more on the clinical significance of *E. vermicularis*, see reference 12.)

TABLE 1 Usual times for completion of life cycles under favorable conditions[a]

Nematode	Time for life cycle completion:	
	Within host	In external environment
Ascaris lumbricoides	8 wk	10–15 days
Enterobius vermicularis	4–7 wk	6 h
Hookworms	4–7 wk	5–6 days
Strongyloides stercoralis	4 wk	3–4 days (direct)
Trichuris trichiura	10–12 wk	21 days

[a] Modified from reference 15.

Diagnosis

The primary diagnosis of infection is by demonstration of the presence of eggs on the skin in the perineal area by using the "sticky tape" method (eggs adhere to cellulose tape and can then be detected microscopically) (see references 4 and 5). Repeated preparations may be required. Commercial collection kits (Evergreen Scientific or Swube [Becton Dickinson]) are available in some countries. Eggs are rarely present in feces. Eggs are non-bile stained, ovoid, asymmetrical with a characteristic "football" shape (concave on one side and flat on the other), smooth, and thick walled and may contain a partially or fully developed larva (Fig. 2E). Specimens should ideally be taken early in the morning before a bath or use of the toilet. If an opaque tape is submitted by mistake, a drop of immersion oil on the top of the tape will clear it enough for microscopy.

Occasionally, adult female worms may be seen in feces, around the anal opening, or upon colonoscopy as white or cream-colored threadlike worms (hence the name threadworm). Characteristic eggs may be seen within the distended female or extruded from the genital pore by putting a little pressure on the worm (Fig. 2F).

Treatment

Albendazole or mebendazole is the drug of choice. Pyrantel and piperazine are effective, but reinfection is common (see chapter 150; see also reference 13).

It is important to treat other family members and close contacts and to decontaminate the environment by washing bed linen and clothes. Advice should be given on adequate hygiene and hand washing.

For a summary of *E. vermicularis*, see Table 2.

HOOKWORMS

Taxonomy

Ancylostoma duodenale (Old World Hookworm)

A. duodenale belongs to the class *Chromadorea,* order *Rhabditida,* suborder *Strongylida,* superfamily *Ancylostomatoidea,* family *Ancylostomatidae,* and subfamily *Ancylostomatinae.*

Necator americanus (New World Hookworms)

N. americanus belongs to the class *Chromadorea,* order *Rhabditida,* suborder *Strongylida,* superfamily *Ancylostomatoidea,* family *Ancylostomatidae,* and subfamily *Bunostominae.*

TABLE 2 Summary of common nematodes

Parasite	Major clinical presentations of infection	Prepatent period	Laboratory findings	Treatment of choice
Ascaris lumbricoides	Symptoms relate to worm burden; most infections are light and asymptomatic; migratory phase, eosinophilic pneumonitis Symptoms of established infection include: • History of passing/vomiting worm • Mild gastrointestinal symptoms • Small-bowel obstruction in children with heavy worm burdens • Ectopic ascariasis involving appendix or hepatobiliary or pancreatic ducts • Malnutrition and growth retardation in children	2 mo	Demonstration of eggs in feces; identification of worm passed; eosinophilia, low or absent	Albendazole or mebendazole
Enterobius vermicularis	Many infections are asymptomatic; pruritis ani occurs mainly at night; excoriation from scratching and secondary infection are common; general symptoms include weight loss and loss of appetite; occasionally ectopic, involving appendix or female genital tract	3–4 wk	Demonstration of eggs in "sticky tape" preparation; eosinophilia, low or absent	Albendazole or mebendazole Prevent reinfection and treat contacts
Hookworms	Pruritic rash or "ground itch" on extremities at site of entry of larvae; migratory phase, cough and wheezing due to eosinophilic pneumonitis Symptoms of established infection include: • Iron-deficiency anemia • Hypoproteinemia leading to chronic malnutrition and growth disorders in children • Enteropathy with gastrointestinal symptoms • Light infections may be asymptomatic	4–8 wk	Demonstration of eggs or larvae in feces; culture (agar plate method or Harada-Mori technique); eosinophilia, usually moderate	Albendazole or mebendazole; iron therapy if anemia is present
Strongyloides stercoralis	Chronic infection occurs due to autoinfection; recurrent, migratory, linear rash when larvae enter perianal skin, or "larva currens"; urticarial rashes also occur; enteropathy causing intermittent or chronic diarrhea, sometimes with malabsorption; pulmonary symptoms and hypereosinophilia may occur during autoinfection; Loeffler-like syndrome; gram-negative-bacterial septicemia or meningitis due to transfer of bowel flora by migrating larvae; hyperinfection syndrome (disseminated) in immunocompromised or debilitated individuals, leading to severe enteropathy and respiratory symptoms	2–4 wk	Demonstration of larvae in feces; culture (agar plate method or Harada-Mori technique); demonstration of antibodies in serum; eosinophilia, usually moderate	Ivermectin
Trichuris trichiura	Usually asymptomatic or mild gastrointestinal symptoms; epigastric pain, vomiting, distension, anorexia, and weight loss; trichuris dysentery, sometimes with rectal prolapse, may occur in heavy infections; growth retardation in children due to chronic malnutrition and anemia	3 mo	Demonstration of eggs in feces; eosinophilia, low or absent	Albendazole or mebendazole

Ancyclostoma and *Necator* are the two genera of *Ancylostomatidae* that infect humans. Other genera may occur as rare "accidental" parasites.

Description

Eggs

Eggs (Fig. 3A) of *A. duodenale* and *Necator americanus* are indistinguishable, being characteristically oval shaped with a thin shell and measuring approximately 56 to 75 by 36 to 40 μm. Characteristically, they have a clear space between the developing embryo and the thin egg shell. Survival of eggs is maximized in moist, shady, warm soil, where larvae hatch within 1 to 2 days.

Larvae

First-stage rhabditoid larvae (Fig. 3E and G) from the hatched eggs measure about 200 μm in length. They feed on organic debris and molt, with the resulting second-stage larvae measuring up to 500 μm. After another molt, the

infective, nonfeeding third-stage larvae measure from 500 to 700 μm, those of *Ancylostoma* being generally longer than those of *Necator*. Development from first-stage to infective filariform larvae occurs within 5 to 8 days; the latter remain viable in the soil for several weeks.

Worms

For both species, male worms (5 to 11 mm) are shorter than females (7 to 13 by 0.4 to 0.5 mm), and *A. duodenale* is generally longer and more sturdily built than *N. americanus*. Adult worms are rarely seen since they remain firmly attached to the intestinal mucosa, feeding on blood obtained by puncturing the capillary network in the intestinal mucosa. It has been estimated that a single *A. duodenale* worm can withdraw as much as 0.2 ml of blood per day, whereas *N. americanus* withdraws approximately 0.05 ml.

Epidemiology and Prevention

An estimated 740 million people are infected in poor regions of the tropics and subtropics, especially in Asia and sub-Saharan Africa (8, 9).

Preventative measures consist of health education about personal hygiene and the need to wear shoes, avoidance of soil contamination, and drug therapy.

Transmission and Life Cycle

Entry of third-stage or filariform larvae (infective stage) by direct penetration of the skin initiates human infection, followed by migration to the lungs within 10 days. *A. duodenale* can also infect if swallowed, but *N. americanus* cannot. *N. americanus* requires an obligatory lung migration, whereas the ingestion of *A. duodenale* larvae can result in direct maturation to the adult stage in the intestine. Larvae leave the lungs after 3 to 5 weeks, pass through the trachea and pharynx, enter the gastrointestinal tract, and attach to the intestinal mucosa, where they mature into adults (Table 1). Attachment and the release of anticlotting factors result in blood loss, which is greater with *A. duodenale*. Hookworms may survive in the host for several years. Eggs are passed in the feces (diagnostic stage) into the environment, where they hatch into rhabditiform larvae which mature into filariform larvae and infect new hosts.

The prepatent period (from larva penetration to egg production) is 4 to 8 weeks.

Clinical Significance

The major clinical manifestation of hookworm infection is iron-deficiency anemia due to intestinal blood loss and depletion of iron stores. The degree of iron deficiency induced by hookworms depends on the intensity and duration of infection, the species of hookworm, and the iron status of the host. Young children, adolescent girls, women of reproductive age, and pregnant women are most at risk for iron-deficiency anemia because of relatively low iron stores. Anemia during pregnancy is linked to maternal mortality, impaired lactation, prematurity, and low-birth-weight infants.

Patients with light worm burdens are usually asymptomatic. Moderate and heavy worm burdens cause epigastric pain and tenderness, nausea, weight loss, and diarrhea. This may lead to protein-losing enteropathy and hypoalbuminemia. In those who develop iron-deficiency anemia, common symptoms are lethargy and fatigue, exertional dyspnea, and palpitations. In children, chronic malnutrition, impaired physical growth, and impaired cognitive development may occur.

A pruritic rash is often present at the site of penetration of larvae ("ground itch"). This must be differentiated from cercarial dermatitis and creeping eruptions from other causes. In some patients, mild cough and wheezing occur in response to larval migration through the lungs. (For more on the clinical significance of hookworms, see reference 12.)

Diagnosis

The primary diagnosis of infection is by demonstration of the presence of eggs in feces (see references 4 and 5). Multiple specimens taken on separate days may be required. For optimal yield, both direct and concentration methods such as formalin-ethyl acetate sedimentation should be used. Eggs are non-bile stained and usually have a 4- to 8-cell-stage embryo (Fig. 3A). Occasionally, a 16- to 32-cell-stage embryo or a developing larva may be seen, especially if there is delay in processing a fresh (unfixed) fecal specimen. These should be differentiated from *Strongyloides stercoralis* larvae by their morphological features (Fig. 3C to G). Hookworm eggs may be confused with *Trichostrongylus* eggs, which are generally larger and in an advanced stage of cleavage (Fig. 3B).

Although larvae are rarely seen in adequately fixed feces specimens, motile larvae may be seen occasionally in expectorated sputum. Culture for the larval stage by the Harada-Mori technique or agar plate method is useful to detect light infections (see "*Strongyloides stercoralis*" below for details) (Fig. 3C to G).

Adult worms are very rarely passed in feces. However, a colonoscopic or gastroscopic specimen may be submitted for identification. Usually, the worm is firmly attached to the mucosa. The adult worm can be identified by the structure of the buccal capsule.

When blood examination shows iron-deficiency anemia, the diagnosis of hookworm infection should be considered for people from areas where the infection is endemic.

Treatment

The two most practical and effective drugs for treating hookworm infections are albendazole and mebendazole. These benzimidazole drugs should be avoided in the first trimester of pregnancy. Pyrantel is also effective and can be used in pregnancy (see chapter 150; see also reference 13). Iron supplementation should be given to those who are iron deficient.

For a summary of hookworms, see Table 2.

STRONGYLOIDES STERCORALIS

Taxonomy

S. stercoralis belongs to the class *Chromadorea,* order *Rhabditida,* superfamily *Panagrolaimoidea,* and family *Strongyloididae.*

Members of the family *Strongyloididae* exhibit an irregular alternation of generations, with a parasitic parthenogenetic female alternating with a free-living sexual generation. Only one genus, *Strongyloides,* occurs in humans. Note that reclassification at the superfamily level has occurred; the family *Strongyloididae* previously belonged to the *Rhabditoidea* superfamily.

Description, Transmission, and Life Cycle

Eggs

Eggs of the parasitic female are deposited within the mucosa of the small intestine and usually hatch before reaching the lumen. As a result, they are rarely excreted in the feces (*Strongyloides fullerborni,* seen in Papua New Guinea, is an exception). Eggs of the free-living adult female are partially

embryonated and oval in shape and measure approximately 50 to 70 μm in length.

Larvae

First-stage, rhabditiform larvae (Fig. 3C, D, and F) measure approximately 180 to 380 by 14 to 20 μm and are characterized by a muscular esophagus comprising the anterior third of the body. A short buccal cavity and a prominent genital primordium located midbody (Fig. 3D) help to distinguish them from other nematodes such as hookworms (Fig. 3E). In the soil, first-stage larvae follow a direct or indirect course of development. In the direct cycle, larvae develop rapidly into infective third-stage, filariform larvae; in the indirect cycle, first-stage larvae develop into a free-living generation of adult male and female worms. Third-stage, or filariform, infective larvae are long and thin compared to those in the rhabditiform stages. Third-stage larvae are 500 to 600 by 16 μm, and their tails are notched (pointed in hookworm larvae) (Fig. 3F and G).

Worms

Parasitic male forms do not occur. Parasitic females are small and thin, measuring approximately 2 to 3 mm in length and 30 to 50 μm in width. The anterior portion is thicker than the posterior and contains the esophagus.

The free-living adult female is approximately half the size of its parasitic counterpart, although nearly twice as thick (approximately 80 μm). While the reproductive systems are morphologically similar, the uterus in the free-living adult female contain significantly more eggs. The free-living adult male is slightly smaller than the female, approximately 50 μm in width.

Transmission is via penetration of the skin or mucous membranes by filariform larvae (infective stage) that are carried to the lungs in the venous circulation. Larvae penetrate alveolar walls, migrate through the tracheobronchial tree, are swallowed, and finally reside in the mucosa of the upper small intestine. Here, they reach maturity and commence egg production; the eggs hatch immediately to release rhabditiform larvae, most of which are excreted in feces (diagnostic stage). In the soil, development into filariform larvae occurs, with the potential to infect new hosts (Table 1).

Some rhabditiform larvae develop into infective filariform larvae in the bowel lumen, penetrate the intestinal mucosa or perianal skin, and repeat the cycle of maturation within the same host. This process of autoinfection, albeit uncommon among intestinal nematodes, results in chronic infections that may persist for 40 years or more.

The prepatent period (from larva penetration to egg production) is 2 to 4 weeks.

Epidemiology and Prevention

Strongyloides lives in warm moist soil and is widely distributed in the tropics and subtropics, similar to hookworms. There are an estimated 30 to 100 million patients infected with *S. stercoralis* worldwide. Risk groups include those living in areas where the parasite is endemic, immigrants and refugees, indigenous peoples, and war veterans previously exposed in areas where the parasite is endemic.

Preventative measures include good personal hygiene and wearing shoes in areas where transmission may occur.

Clinical Significance

S. stercoralis infections are often chronic, lasting for several decades. Most patients have low worm burdens and are asymptomatic or have intermittent cutaneous and/or gastrointestinal symptoms.

A recurrent, pruritic, serpiginous, erythematous rash may occur due to larval migration in the skin ("larva currens"). This is most commonly seen on the buttocks, groin, and trunk and may move about under the skin over 1 to 2 days. Other, less distinctive urticarial and papular rashes also occur.

Intermittent or chronic diarrhea, abdominal pain and bloating, nausea, and anorexia are the main gastrointestinal symptoms.

Although pulmonary symptoms are uncommon in uncomplicated strongyloidiasis, passage of larvae through the lung may be associated with a cough, wheezing and dyspnea, and patchy infiltrates upon radiography (Loeffler-like syndrome).

Severe complicated strongyloidiasis may occur in immunocompromised or debilitated individuals and is due to accelerated autoinfection in the face of waning immunity. Hyperinfection syndrome is associated with the presence of many adult worms in the intestinal mucosa and penetration of the bowel wall by large numbers of filariform larvae. Severe gastrointestinal and/or respiratory symptoms and large numbers of larvae in stool and sputum are the main features. It may be complicated by malabsorption or paralytic ileus. Gram-negative bacterial septicemia and meningitis may develop if enteric bacteria are spread into blood or cerebrospinal fluid during mucosal penetration by larvae. Larvae can occasionally disseminate to the central nervous system, peritoneum, liver, and kidneys. Disseminated strongyloidiasis may mimic many other diseases, including severe bacterial sepsis and tropical pulmonary eosinophilia. It should be considered a possibility in immunosuppressed patients who have been at risk of infection in the past.

Patients on long-term steroid therapy are most at risk for severe disease. Those with impaired cellular immunity due to other causes (e.g., organ transplants, AIDS, and lymphatic malignancies) are also at risk.

Strongyloides species from animals can occasionally infect humans and produce persistent skin lesions similar to those produced by *S. stercoralis*. However, the life cycle is not completed and infection is not established (7). (For more on the clinical significance of *S. stercoralis*, see reference 12.)

Diagnosis

The laboratory diagnosis of strongyloidiasis can be difficult (see references 4 and 5). It is based on either demonstrating the presence of the larvae in feces or demonstrating antibodies to *S. stercoralis* in blood. Eggs or adult worms are very rarely detected. Microscopy of feces may detect the first-stage (rhabditiform) larvae. The sensitivity of this method is generally low, as larvae are shed sporadically and numbers depend on the stage and severity of the infection. Hence, multiple specimens collected over several days should be examined. Coproculture is a method of concentration of larvae on a freshly passed stool specimen (not refrigerated or preserved) transported without delay to the laboratory. This should be attempted for all suspected cases, especially with patients from areas where the infection is endemic who are candidates for immunosuppressive therapy (because of organ transplant or treatment for malignancies, etc.). Various methods available for culture are as follows (for details, see reference 6):

1. Agar plate culture. A small amount of feces is placed on an agar plate, and the plate is sealed. If larvae are present, they travel on the surface of the plate, carrying bacteria from the feces. Colonies of these bacteria appear on the surface as tracks with a characteristic sinusoidal pattern. The plates are examined by microscopy for confirmation of the

presence of larvae. This is the easiest culture method to perform and is now the recommended procedure (16).

2. Harada-Mori technique. Feces are placed on a filter paper dipping into a small amount of water placed in a tube. The larvae in the feces move towards the water, which can subsequently be tested by microscopy for the presence of larvae.

3. Petri dish filter paper slant method. This procedure is similar to the one previously described but is done in a petri dish.

4. Baermann technique. This requires a special apparatus and relies on the principle that larvae will actively migrate out of the feces placed on a wire mesh covered with several layers of gauze.

Occasionally, hookworm larvae may hatch out in feces which have been left at warm temperatures for long periods before processing. Hookworm larvae can be differentiated from *S. stercoralis* larvae as the hookworm larvae have a long buccal cavity and inconspicuous genital primordium (Fig. 3C to E). The presence of larvae of *Strongyloides* in expectorated sputum or duodenal aspirate may also be demonstrated via enteroscope or string test (Entero-Test capsule) (6). Occasionally, last-stage (filariform) *Strongyloides* larvae may be seen in feces or sputum in cases of hyperinfection or in cases in which the culture methods described above are used.

Although eosinophilia is common during acute infection, it does not reliably correlate with infection and may be intermittent in chronic infection.

Demonstration of anti-*Strongyloides* antibodies in blood should be used as a screening test or as an adjunct for diagnosis. Used in conjunction with eosinophil counts, it is very useful to monitor treatment. Antibody levels decline after 6 months of effective treatment (11) and may be negative by 12 to 24 months. The sensitivity of the commercially available enzyme immunoassay (immunoglobulin G enzyme-linked immunosorbent assay; IVD Research, Inc.) using the *S. stercoralis* filariform antigen test is ~90% and much higher than those of indirect hemagglutination and indirect fluorescent-antibody assays. Higher sensitivity (~95%) has been reported for the Centers for Disease Control and Prevention *Strongyloides* enzyme immunoassay (EIA) for patients with proven infection (11). Sensitivity may be lower for severely immunocompromised patients. The specificity of EIA is ~85% as cross-reactions in patients with filarial and other nematode infections may occur. If the test is positive for antibodies, efforts should be made to establish a parasitological (based on microscopy and culture) diagnosis and to exclude the possibility of infection with other parasites that could result in cross-reacting antibodies.

Treatment

S. stercoralis infection should always be treated because of the potential for development of severe complicated disease. Ivermectin is the drug of choice. Repeated cycles may be required for immunocompromised patients. Albendazole and mebendazole are less effective than ivermectin (thiabendazole, although effective, is no longer used due to frequent severe side effects) (16; see chapter 150 and reference 13).

Monitoring with stool microscopy, eosinophil counts, and serology is recommended until infection is eradicated.

For a summary of *S. stercoralis*, see Table 2.

TRICHURIS TRICHIURA (WHIPWORM)

Taxonomy

T. trichiura belongs to the class *Enoplea,* order *Trichocephalida,* superfamily *Trichonelloidea,* and family *Trichuridae.*

Description

Eggs

Eggs of *T. trichiura* (Fig. 2G) are lemon shaped with a characteristic plug at each end ("tea tray with handles"). In feces, eggs are brown and measure 50 to 55 by 20 to 24 μm.

Larvae

After hatching in the intestine, the second-stage larval form measures about 260 by 15 μm in length. The second-stage larvae burrow into the intestinal mucosa and undergo four larval molts. The adult worm is then intimately associated with the wall of the large intestine.

Worms

Adult worms are found in the large intestine, with a highly characteristic shape from which the name whipworm is derived. The long, thin anterior end lies in a burrow in the mucosa, and the thicker end, which contains the reproductive tract, extends into the intestinal lumen. Worms are whitish, and the males (30 to 45 mm) are shorter than the females (35 to 50 mm) and have a coiled posterior end. Adult females produce up to 20,000 eggs/day and live for approximately 3 years.

Epidemiology and Prevention

Trichuris has a worldwide distribution and is often associated with *Ascaris* and hookworm infections in children in tropical and subtropical areas.

Preventative measures include health education about personal hygiene, avoidance of soil contamination, and drug therapy programs in areas where infection is endemic.

Transmission and Life Cycle

Transmission is direct via oral ingestion of embryonated eggs (infective stage) from contaminated soil. Following ingestion, larvae are released and pass into the large bowel, where they reside and mature into adults in mucosal crypts. The eggs passed in feces contain an unsegmented ovum (diagnostic stage), and once the eggs are in warm, moist conditions in soil, they become infective 2 to 4 weeks after passage (Table 1).

The prepatent period (from egg ingestion to egg production) is 3 months.

Clinical Significance

The clinical features are related to the intensity of infection, as is the case with the other intestinal nematodes. Light infections are asymptomatic or present with mild gastrointestinal symptoms.

Epigastric pain, vomiting, distension, anorexia, and weight loss may occur with heavier infections, and trichuris dysentery syndrome, sometimes complicated by rectal prolapse, may be seen. Children with severe infections may develop growth retardation due to chronic malnutrition and anemia. (For more on the clinical significance of *T. trichiura*, see reference 12.)

Diagnosis

The primary diagnosis of infection is by demonstration of the presence of eggs in feces (see references 4 and 5). Multiple specimens collected on separate days may be required. Both direct and concentration methods such as formalin-ethyl acetate sedimentation should be used for optimal yield. The eggs are bile stained and thick walled with mucoid plugs at

both ends, giving them a characteristic tea tray appearance (Fig. 2G).

Adult worms are rarely passed in feces and are occasionally found upon colonoscopy (10). When they are seen, they have a cylindrical coiled body and a coiled thicker tail, giving them the appearance of a whip (hence the name whipworm).

Treatment

Albendazole or mebendazole is the drug of choice (see chapter 150; see also reference 13).

For a summary of *T. trichiura*, see Table 2.

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

Specimens should be collected before antibiotics or antiparasitic drugs are given (for details, refer to chapters 5 and 133). It is important to transport and process feces specimens for parasitic examination as soon as possible. Clinicians and collection staff should be encouraged to either send fresh specimens to the laboratory without delay or use commercially available preservative kits. If delay is inevitable, specimens should be refrigerated or transported in commercially available vials or kits with a preservative such as polyvinyl alcohol or sodium acetate-acetic acid-formalin. If these are not available at the point of collection, preservatives should be added as soon as the specimen is received in the laboratory. Excellent directions for proper collection are available with these kits. Discussion on which preservative to use depends on various considerations such as whether permanent-stained smears or immunoassays are required, etc. (For details, see reference 6.) Refrigeration and the use of preservatives should be avoided if *Strongyloides* larval culture is required.

Specimens that are obviously dry or drying out should be rejected, and a fresh specimen should be collected.

There is no maximum limit on the amount of specimen, but it should be reasonable for the laboratory staff to handle. Very small amounts are not acceptable as the chances of drying are high and those of finding parasites are low. Two or three specimens collected over a period of 7 to 10 days are optimal.

Worms passed or taken at colonoscopy should be transported to the laboratory without delay in a closed, clean container of appropriate size. Worms can be preserved in 50% alcohol or 5% formalin (avoid higher concentrations as dehydration can occur).

For sputum specimens, proper instructions should be given to patients emphasizing quality, avoidance of saliva, and inclusion of mouthwash before deep coughing (expectorating). Sputum and aspirates should be transported to the laboratory and processed immediately.

All specimens should be collected in clean, wide-mouthed containers with tight-fitting lids and handled using standard precautions, e.g., latex gloves should be worn by anyone handling the specimens.

LABORATORY METHODS: DIRECT EXAMINATION

The specimen should be handled in a work cabinet, and gloves and gown should be worn. Examine the specimen and note its consistency. Look for any motile worms or segments of worms. Select and sample areas that look watery, purulent, or bloody. If feces are formed, take specimens from the sides and middle for the concentration technique.

Wet preparations in saline and iodine are prepared from direct specimens or concentrates and covered with a coverslip. Scan the whole coverslip at low-power magnification (×100) with a microscope. Most helminth eggs and larvae can be identified at this magnification and can be confirmed at high power (×400) on the basis of their shapes, sizes, and characteristic features (Fig. 1 to 3). Thin smears should be prepared from the concentrate for permanent staining, which may be useful to diagnose mixed infections with protozoa.

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

Make note of the adequacy and quality of the specimen submitted. If it is inadequate, mention it on the report.

In developed countries, any helminth eggs or larvae found in feces are significant and treatment is recommended, even if the patient is asymptomatic. However, treatment of asymptomatic cases is not necessary in developing countries as many of these parasites are endemic and reinfection is common.

Examples of reports are as follows:

1. Larvae of *S. stercoralis* detected by fecal culture.
2. Eggs of *E. vermicularis* not detected on the sticky tape preparation. Please send properly collected repeat specimen. Contact the laboratory for instructions if required.
3. No parasites detected in current specimen. Low numbers of parasites may be missed. Please send well-collected repeat specimen. Contact the laboratory for instructions if required.

In a clinically significant case, if the first specimen is negative, ask for further specimens. The time of collection is also important, especially when *Enterobius* is suspected. If the specimen is inadequate, e.g., delayed, dry, or insufficient, a repeat specimen should be requested. A freshly collected specimen and/or use of preservative kits should be encouraged where possible.

There is no need to quantitate helminth parasites as this does not necessarily correlate with clinical illness. However, in rare instances, this may be required for epidemiological studies or for clinical assessment of children.

We thank Norbert Ryan, senior scientist, Victorian Infectious Diseases Reference Laboratory, Melbourne, Australia, for reviewing the section.

Filarial Nematodes

TESS McPHERSON AND THOMAS B. NUTMAN

145

Filarial worms are arthropod-transmitted nematodes or roundworms that dwell in the subcutaneous tissues and the lymphatics. Although eight filarial species commonly infect humans, four are responsible for most of the pathology associated with these infections. These are (i) *Wuchereria bancrofti,* (ii) *Brugia malayi,* (iii) *Onchocerca volvulus,* and (iv) *Loa loa.* In general, each of the parasites is transmitted by biting arthropods. The distributions and vectors of all the filarial parasites of humans are given in Table 1. Each goes through a complex life cycle that includes an infective larval stage in the insects and an adult worm stage in which the parasite resides in humans, either in the lymph nodes or adjacent lymphatics or in the subcutaneous tissue. All filariae have adult female worms that produce microfilariae. These offspring either circulate in the blood or migrate through the skin. The microfilariae can then be ingested by the appropriate biting arthropod and develop into infective larvae that are capable of initiating the life cycle once more. Certain species *(W. bancrofti, Brugia* spp., and *L. loa)* circulate in the blood with a defined circadian rhythm, or "periodicity," which can be nocturnal (typical of the lymphatic filariae) or diurnal *(L. loa)*. Other species lack periodicity and are found in the peripheral blood at all hours of the day and night. When absent from the peripheral blood in lymphatic filarial infections, microfilariae are found in the deeper visceral capillaries, particularly in the pulmonary capillaries.

Microfilariae are relatively simple in their organization and structure (Fig. 1). They are vermiform and, in stained preparations, appear to be composed of a column of nuclei interrupted along its length by spaces and special cells that are the precursors of body organs or organelles. Some species of microfilariae are enveloped in a sheath, whereas others have no sheath (Table 1 and Fig. 2).

All of the filariae are transmitted by species of blood-sucking arthropods such as mosquitoes, midges, blackflies, and tabanid flies, in which the microfilariae develop into the infective stage (Table 1). Subsequent development of the infective larvae into the gravid, adult stage in the vertebrate host requires several months and in some cases a year or more.

Because the adult worms are typically sequestered in the tissues, diagnosis of infection depends on finding microfilariae in either blood or skin, depending on the species. Adult worms are long lived, whereas the life spans of microfilariae range from 3 months to 3 years. Infection is generally not established unless exposure to infective larvae is intense and prolonged. Furthermore, the clinical manifestations of these diseases develop rather slowly.

Although these parasites are not endemic in humans in nontropical or subtropical areas, they are often seen in immigrants or in individuals who have resided in or traveled to areas where filariae are endemic. There are significant differences in the clinical manifestations of filariasis, or at least in the time periods over which the infection is acquired, between patients native to the areas where the disease is endemic and those who are travelers or recent arrivals in these same areas. Characteristically, the disease in previously unexposed individuals is more acute and intense than that found in natives of the region where the disease is endemic (30); however, early removal of newly infected individuals tends to speed the end of clinical symptomatology or at least halt the progression of the disease (39).

LYMPHATIC FILARIAL PARASITES

Taxonomy

W. bancrofti, B. malayi, and *Brugia timori* each belong to the phylum Nematoda, class *Secernentea,* subclass *Spiruria,* order *Spirurida,* superfamiliy *Filarioidea,* and family *Filariidae*.

Description of the Agents

There are three lymphatic-dwelling filarial parasites of humans: *W. bancrofti, B. malayi,* and *B. timori*. The adult worms usually reside in either the afferent lymphatic channels or the lymph nodes. These adult parasites may remain viable in the human host for decades. The morphologic appearances and other characteristics of the parasites can be found in Table 1 and Fig. 1 and 2.

Epidemiology and Transmission

Wuchereria bancrofti

W. bancrofti is the most common and widespread species of filaria infecting humans. It has an extensive distribution throughout tropical and subtropical areas of the world, including Asia and the Pacific Islands, Africa, areas of South America, and the Caribbean Basin. Humans are the only definitive host for this parasite and are therefore the natural reservoir for infection. There are both periodic and subperiodic forms of the parasite. Generally, the subperiodic form is

TABLE 1 Filarial parasites of humans

Species	Distribution	Vector	Primary pathology	Location	Periodicity	Size (μm)	Tail	Sheath	
								Presence	Staining properties
Wuchereria bancrofti	Tropics	Mosquito	Lymphatic, pulmonary	Blood, hydrocele fluid	Nocturnal, subperiodic	298 by 7.5–10	Pointed tail devoid of nuclei	+	Does not stain
Brugia timori	Indonesia	Mosquito	Lymphatic	Blood	Nocturnal	300+	Nuclei in tail	+	Tends not to stain
Brugia malayi	Southeast Asia	Mosquito	Lymphatic, pulmonary	Blood	Nocturnal, subperiodic	270 by 5–6	Nuclei in tail	+	Bright pink with Giemsa
Onchocerca volvulus	Africa, Central and South America	Blackfly	Dermal, ocular, lymphatic	Skin	None	309 by 5–9	No nuclei in tail	–	
Mansonella streptocerca	Africa	Midge	Dermal	Skin	None	210 by 5–6	Crooked tail into which column of nuclei extends	–	
Loa loa	Africa	Deerfly	Allergic	Blood	Diurnal	Up to 300	Irregularly arranged nuclei extend to end of tail	+	Does not stain
Mansonella perstans	Africa, South America	Midge	Probably allergic	Blood	None	203 by 4–5	Blunt tail contains nuclei	–	
Mansonella ozzardi	Central and South America	Midge	Unknown	Blood	None	224 by 4–5	Long tail with no nuclei in it	–	

found only in the Pacific Islands (including Cook and Ellis Islands, Fiji, New Caledonia, the Marquesas, Samoa, and the Society Islands). Elsewhere, *W. bancrofti* is nocturnally periodic. The natural vectors are *Culex fatigans* mosquitoes in urban settings and usually anopheline or aedean mosquitoes in rural areas.

Brugia malayi and *Brugia timori*

The distribution of brugian filariasis is limited primarily to China, India, Indonesia, Korea, Japan, Malaysia, and the Philippines. Two forms of the parasites *B. malayi* and *B. timori* can be distinguished by the periodicities of the microfilariae. With nocturnally periodic forms, microfilariae are present in the peripheral blood primarily at night, whereas with the subperiodic forms, microfilariae are present in the blood at all times but are at maximal levels in the afternoon.

The nocturnal-parasite form of brugian filariasis is more common and is transmitted in areas of coastal rice fields (by mansonian and anopheline mosquitoes), and the subperiodic parasite form is found in the swamp forests (mansonian vector). Although humans are the common host, *B. malayi* infection can be a natural infection of cats. *B. timori* infection has been described only on two islands in Timor.

Clinical Significance (Description of Clinical Presentation)

Lymphatic filariasis (LF) causes a variety of clinical manifestations. The four most common presentations are asymptomatic (or subclinical) microfilaremia, lymphedema, hydrocele formation, and acute attacks. Less frequently, LF can present with chyluria or tropical eosinophilia (6, 19, 35). The range of clinical disease varies somewhat according to the geographic location and the species of nematode causing the infection (43). Additionally, the disease in previously unexposed individuals is more acute and intense than that found in natives of the region where the disease is endemic (30, 39). Patients with asymptomatic (or subclinical) microfilaremia rarely come to the attention of medical personnel except through the incidental finding of microfilariae in the peripheral blood. Although they may be clinically asymptomatic, virtually all persons with *W. bancrofti* or *B. malayi* microfilaremia have some degree of subclinical disease that includes dilated (and tortuous) lymphatics (visualized by imaging) and, in men with *W. bancrofti*, scrotal lymphangiectasia (detectable by ultrasound) (14). Despite these findings, the majority of individuals appear to remain clinically asymptomatic for years. Relatively few progress to either the acute or chronic stage of infection (11). Development of lymphedema may not present until long after the initial infection. Lymphatic dysfunction develops as a primary event in response to adult filarial parasites and host immune responses in virtually all infected persons. This has been shown to be progressive during infection and permanent once established (9). Lymphedema most commonly affects the lower extremities but can also affect arms, breasts in females, and the scrotum in males. Secondary effects such as thickening of the subcutaneous tissues, hyperkeratosis fissuring of the skin, and hyperplastic skin changes can occur. Recurrent infections (acute dermatolymphangioadenitis [ADLA]) in the context of chronic skin changes and lymphatic dysfunction play a major role in lymphedema disease development and progression to elephantiasis (33, 36). Acute attacks of LF include a variety of clinical entities that present with inflammation. True filarial adenolymphangitis (AFL), felt to reflect the death of an adult worm, presents with inflammation, swelling, and retrograde lymphangitis extending peripherally

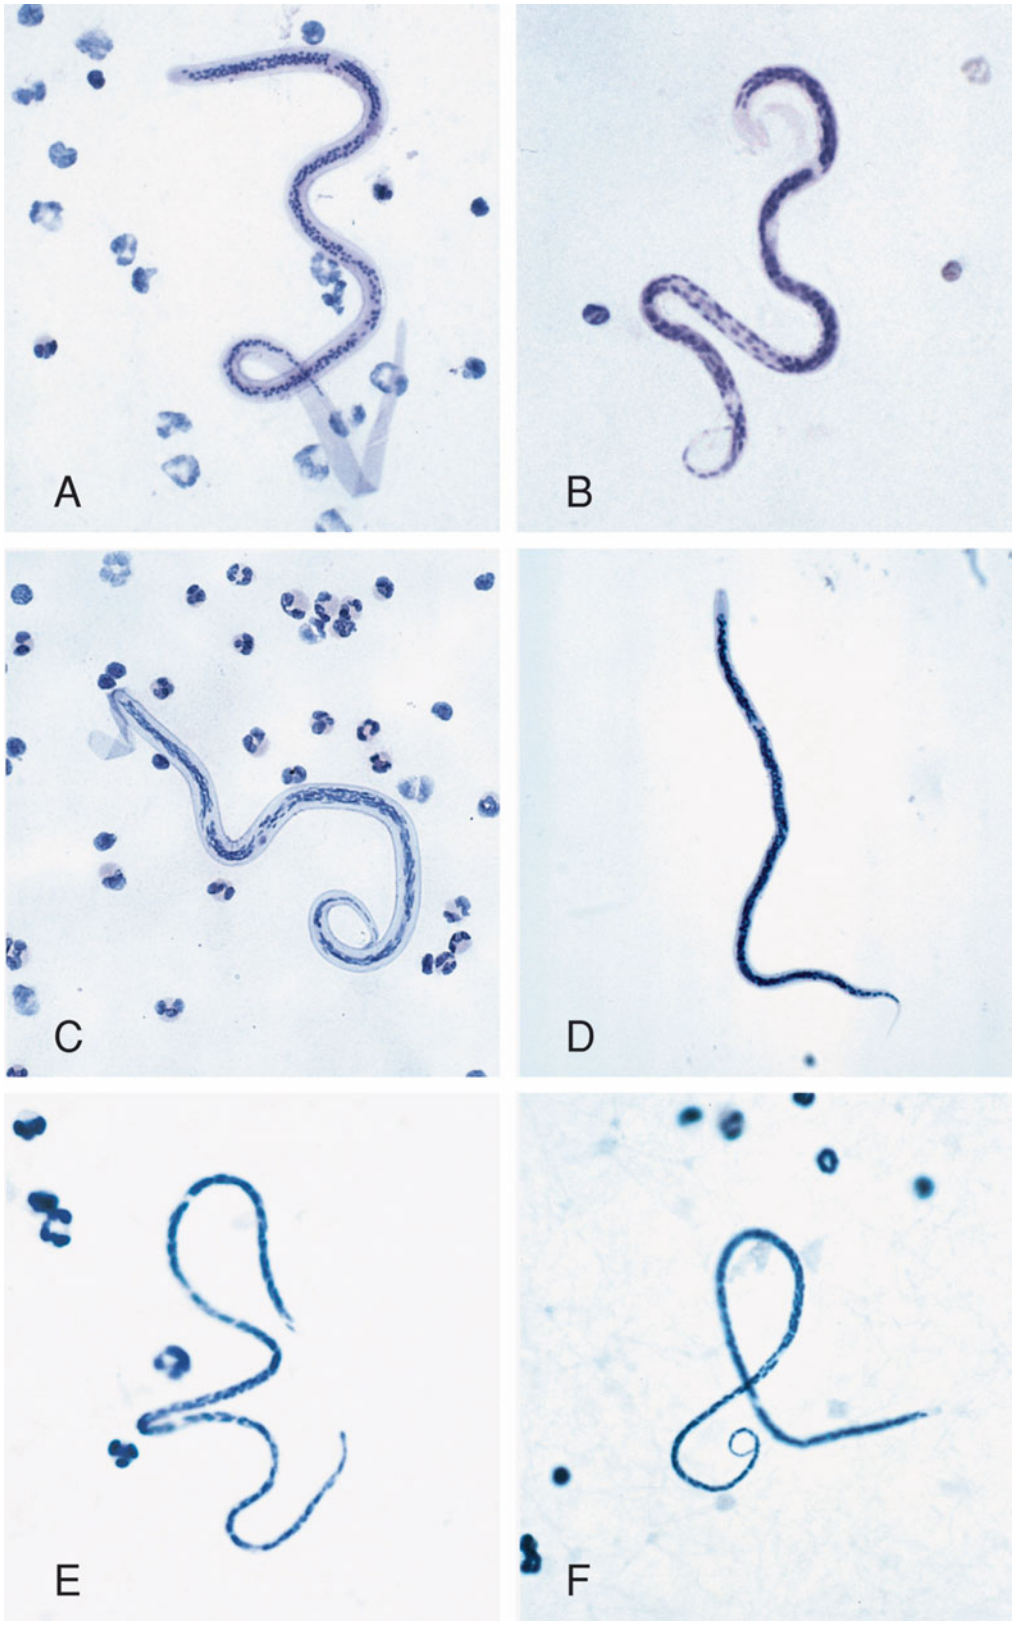

FIGURE 1 Common microfilariae found in humans. Organisms are stained with hematoxylin. Magnification, ×325. (A) *W. bancrofti;* (B) *B. malayi;* (C) *L. loa*; (D) *O. volvulus;* (E) *M. perstans;* (F) *M. ozzardi.*

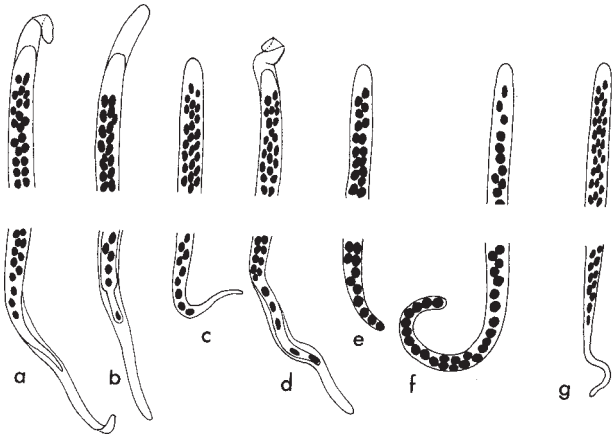

FIGURE 2 Diagrammatic representation of the anterior and posterior extremities of the common microfilariae found in humans. (a) *W. bancrofti;* (b) *B. malayi;* (c) *O. volvulus;* (d) *L. loa;* (e) *M. perstans;* (f) *M. streptocerca;* (g) *M. ozzardi*.

from the draining node where the parasites presumably reside. Regional lymph nodes are often enlarged, and the entire lymphatic channel can become indurated and inflamed. The second type of acute attack is now labeled bacterial adenolymphangitis or ADLA. Changes in the skin predispose to entry lesions, in particular in the toe webs (3, 46). For these reasons, limbs become susceptible to recurrent bacterial infections (10, 27). The clinical pattern of ADLA is distinctly different from that of AFL (10). The lymphangitis develops in a reticular rather than in a linear pattern, and the local and systemic symptoms, including edema, pain, fever, and chills, are frequently more severe (45). These cause considerable acute-disease morbidity and progression of lymphedema to elephantiasis (37). AFL and ADLA occur in both the upper and the lower extremities with both bancroftian and brugian filariasis, but involvement of the genital lymphatics occurs almost exclusively with *W. bancrofti* infection.

Hydrocele formation occurs in bancroftian filariasis when adult worms block retroperitoneal and subdiaphragmatic lymphatics. In males, this causes accumulation of straw-colored lymph either unilaterally or bilaterally between the visceral and parietal layers of the tunica vaginalis. The condition presents as a translucent mass obscuring palpation of the testis and differs from a congenital hydrocele or herniation in that the tunica is sealed at the top and peritoneal fluid is not communicated (38, 56). If there is obstruction of the retroperitoneal lymphatics, renal lymphatic pressure can increase to the point at which they rupture into the renal pelvis or tubules so that chyluria is seen. The chyluria is characteristically intermittent and is often prominent in the morning just after the patient arises.

Tropical pulmonary eosinophilia (TPE) is a distinct syndrome that develops in some individuals infected with lymphatic filarial species. This syndrome affects males more often than females, often during the third decade of life. The majority of cases have been reported from India, Pakistan, Sri Lanka, Brazil, Guyana, and Southeast Asia. The main features include a history of residence in regions where filariae are endemic, paroxysmal cough and wheezing that are usually nocturnal, weight loss, low-grade fever, and adenopathy. Patients are rarely found to have microfilariae in the blood. Chest X rays may be normal but generally show increased bronchovascular markings; diffuse miliary lesions or mottled opacities may be present in the middle and lower lung fields. Tests of pulmonary function show restrictive abnormalities in most cases and obstructive defects in half. Total serum immunoglobulin E (IgE) levels (10,000 to 100,000 ng/ml) and antifilarial antibody titers are characteristically elevated. TPE is now considered to be a form of occult filariasis in which rapid clearance of the microfilariae occurs, presumably on the basis of host immunologic hyperresponsiveness to the parasite (34). Although there is no single clinical or laboratory criterion that aids in distinguishing TPE from other pulmonary diseases associated with the tropics, the presence of high levels of antifilarial antibodies and a rapid clinical response to diethylcarbamazine (DEC) favor the diagnosis of TPE (51).

Diagnosis

Diagnosis of bancroftian and brugian filarial infection can be made noninvasively in some cases by ultrasound. This allows adult worms to be visualized in lymphatics or can identify dilated lymphatics. Definitive identification of parasites can be achieved with appropriate samples of blood or tissue. The timing of blood collection is critical and should be based on the periodicity of the microfilariae endemic in the region involved. (Table 1). Recent developments in immunodiagnostic and molecular biology techniques give further options for diagnosis.

Ultrasound

In cases of suspected LF due to *W. bancrofti,* high-frequency ultrasound of the scrotum or female breast coupled with Doppler may result in the identification of motile adult worms within dilated lymphatics. Adult worms may be visualized in the lymphatics of the spermatic cord in up to 80% of infected men with microfilaremia (11).

Direct Examination

Parasites can be identified by direct examination of blood or other fluids (such as chyle, urine, and hydrocele fluid). This examination should take advantage of the periodicity of each organism as well as the characteristic morphologic appearance (Table 1 and Fig. 2).

Microscopy

A small volume of fluid is spread onto a clean slide. The slide is then air dried, stained with Giemsa, and examined microscopically. The microfilariae of *W. bancrofti* are sheathed, lie in smooth curves in stained smears, and are 298 μm long by 7.5 to 10.0 μm in diameter. The column nuclei are dispersed; there is a short headspace, and the pointed tail is devoid of nuclei (Fig. 1A). The sheath stains faintly or not at all with Giemsa. The microfilariae of *W. bancrofti* must be distinguished from other sheathed microfilariae. The morphology of the *B. malayi* microfilariae is similar to that of the *W. bancrofti* microfilariae, with the *B. malayi* microfilariae being sheathed but somewhat smaller (279 by 5 to 6 μm). They can be differentiated from the *W. bancrofti* microfilariae by the presence of subterminal and terminal nuclei in the tails (Fig. 1A and B). *B. timori* microfilariae are similar to those of *B. malayi,* with conspicuous terminal and subterminal nuclei; however, *B. timori* microfilariae are larger (more than 300 μm long) than *B. malayi* microfilariae. Additionally, the *B. malayi* sheath stains bright pink with Giemsa, whereas the *B. timori* sheath tends not to stain and that of *W. bancrofti* does not stain (4).

Because microfilariae may be present in the blood in only small numbers, sensitive procedures such as Nuclepore

filtration and Knott's concentration technique are also used routinely to detect infections.

Nuclepore Filtration

A known volume of anticoagulated blood is passed through a polycarbonate (Nuclepore) filter with a 3-μm pore. A large volume (50 ml) of distilled water is passed through (the water will lyse or break open the red blood cells, leaving the worms intact and more easily visible). The filter is then air dried, stained with Wright's or Giemsa stain, and examined by microscopy. For studies in the field, 1 ml of anticoagulated blood can be added to 9 ml of a solution of 2% formalin–10% Teepol and stored for up to 9 months before performance of filtration.

Knott's Concentration Technique

Anticoagulated blood (1 ml) is placed in 9 ml of 2% formalin. The tube is centrifuged at 1,200 × *g* for 1 min. The sediment is spread onto a slide and dried thoroughly. The slide is then stained with Wright's or Giemsa stain and examined microscopically.

Antigen Detection

Assays for circulating antigens of *W. bancrofti* permit the diagnosis of microfilaremic and cryptic (amicrofilaremic) infection. Two tests are commercially available. One is an enzyme-linked immunosorbent assay available from Trop-Bio, and the other is a rapid-format immunochromatographic card available from Binax. Both assays have sensitivities that range from 96 to 100% and specificities that approach 100% (7, 53). Both tests can be used with blood drawn at any time of day or night, thus avoiding the need for specific bleeding times depending on the periodicity of the microfilariae. Neither of the tests is approved by the U.S. Food and Drug Administration. There are currently no tests for circulating antigens in brugian filariasis.

Nucleic Acid Detection Techniques

In appropriate laboratories, PCR can demonstrate the presence of parasite DNA and is now the most sensitive technique for definitive diagnosis of infection (55, 59). For each of the lymphatic-dwelling parasites, primers and probes have been identified that are 100% specific and provide sensitivities that are often 10-fold greater than that of detection of the parasites themselves.

Serologic Tests

Immunologically based diagnosis with measurement of IgG or IgG4 responses against crude extracts of *Brugia* or *Dirofilaria* worms suffers from poor specificity. There is extensive cross-reactivity among filarial antigens and antigens of other helminths, including the common intestinal roundworms; however, serologic tests have a role in diagnosis, as a negative test effectively excludes past or present infection. These tests are available commercially as well as from the National Institutes of Health.

Treatment and Prevention

The available chemotherapy for LF is DEC, ivermectin, and albendazole. DEC remains the treatment of choice for the individual with active LF (microfilaremia, antigen positivity, or the presence of adult worms detected upon ultrasound), although albendazole has also been shown to have some macrofilaricidal efficacy (8). If the adult parasites survive, microfilaremia along with clinical symptoms can recur within months after conclusion of the therapy. Chronic low-dose DEC (e.g., in DEC salt) may also result in cure (33). Evidence shows that the use of these drugs in combination can increase effectiveness (42, 50). The current global elimination campaign uses these three drugs in various combinations for mass treatment of communities where LF is endemic (22).

Most pathogenic filarial nematodes apart from *L. loa* harbor bacterial endosymbionts. These *Wolbachia* species are vital for parasite larval development and adult-worm fertility and viability. New approaches for treatment use antibiotics (e.g., the tetracyclines) that target the *Wolbachia*. Microfilarial levels have been seen to be reduced with these treatments (49). Once lymphedema is established, antifilarial medication is not useful if the patient does not have active infection. Management of lymphedema should concentrate on local skin care with appropriate treatment of entry lesions and on exercise and elevation (52). Antifilarial medication is also not indicated in the management of bacterial ADLA (46). This should be managed with skin care and antibiotics if indicated (45). Hydroceles can be drained repeatedly or managed surgically (56).

Avoidance of mosquito bites is usually not feasible for residents of areas where LF is endemic, but visitors should make use of insect repellent and mosquito nets. Repellent-impregnated bed nets have been shown to have a salutary effect. DEC can kill developing forms of filarial parasites and has been shown to be useful as a prophylactic agent in humans. Community-based intervention is the current approach to the elimination of LF as a public health problem (5). The underlying tenet of this approach is that mass annual distribution of antimicrofilarial chemotherapy (albendazole with either DEC [in all areas but those where onchocerciasis is coendemic] or ivermectin) will profoundly suppress microfilaremia. If the suppression is sustained, then transmission can be interrupted (29). Community education and clinical care for persons already suffering from the chronic sequelae of LF are important components of filariasis control and elimination programs (44). Vaccines may have a role in the future (41).

ONCHOCERCA VOLVULUS

Taxonomy

O. volvulus belongs to the phylum Nematoda, class *Secernentea,* subclass *Spiruria,* order *Spirurida,* superfamily *Filarioidea,* and family *Onchocercidae.*

Description of the Agent

The adult worms of *O. volvulus* typically reside in nodules comprised primarily of host tissue. These adult parasites may remain viable in the human host for decades. The morphologic appearance and other characteristics of microfilariae and adult worms can be found in Table 1 and Fig. 1 and 2.

Epidemiology and Transmission

Onchocerciasis, sometimes called river blindness, is caused by infection with *O. volvulus,* a subcutaneous tissue-dwelling filarial worm. Approximately 18 million people are infected, mostly in equatorial Africa, the Sahara, Yemen, and parts of Central and South America (Guatemala, Venezuela, Mexico, Ecuador, Colombia, and Brazil). The infection is transmitted to humans through the bites of blackflies of the genus *Simulium,* which breed along fast-flowing rivers in the above-mentioned tropical areas.

Clinical Significance (Description of Clinical Presentation)

The major disease manifestations of onchocerciasis are localized to the skin, lymph nodes, and eyes. Onchocerciasis is a cumulative infection. Intense infection leads to the disease's most severe complications and is felt to reflect repeated inoculation with infective larvae (26).

Skin

Pruritus is the most frequent manifestation of onchocercal dermatitis. This pruritus may be accompanied by the appearance of localized areas of edema and erythema. Typically, skin disease appears as papular, pruritic dermatitis. If the infection is prolonged, lichenification and pigment changes (either hypo- or hyperpigmentation) can occur; these often lead to atrophy, development of "lizard skin," and mottling of the skin.

Onchocercomata

Onchocercomata, subcutaneous nodules that can be palpable and/or visible, contain the adult worm. In African patients, they are common over bony prominences; in Latin American patients, nodules tend to develop preferentially in the upper part of the body, particularly on the head. Nodules vary in size and characteristically are firm and not tender. It has been estimated that, for every palpable nodule, there are four deeper nonpalpable ones (2).

Lymph Nodes

Lymphadenopathy is frequently found, particularly in the inguinal and femoral areas. The underlying pathology consists of scarring of the lymphoid areas (*O. volvulus* infection in Africa) or follicular hyperplasia (*O. volvulus* infection in Yemen). As the lymph nodes enlarge, they can come to lie within areas of loose skin (so-called "hanging groin") that predisposes to inguinal and femoral hernias.

Eyes

Onchocercal eye disease can take many forms and may lead to severe visual loss or blindness. Usually seen in persons with moderate or heavy infections, the ocular disease spares no part of the eye. Conjunctivitis, anterior uveitis, iridocyclitis leading to secondary glaucoma, sclerosing keratitis, optic atrophy, and chorioretinal lesions can be seen (48).

Systemic Manifestations

Some heavily infected individuals develop cachexia with loss of adipose tissue and muscle mass. Among adults who become blind, there is a three- to fourfold increase in the mortality rate.

Diagnosis

Definitive diagnosis depends on finding an adult worm in an excised nodule or, more commonly, microfilariae in a skin snip sample. Microfilariae can occasionally be found in the blood and in urine, typically after treatment. Microfilariae may also be seen in the cornea and in the anterior chamber of the eye when viewed with a slit lamp. For skin snipping, a small piece of skin is elevated by the tip of a needle or skin hook held parallel to the surface, and a scalpel blade is used to shave off the skin area stretched across the top surface of the needle. Alternatively, a sclerocorneal punch can be used to obtain a blood-free circular skin specimen.

Skin snip samples are generally obtained from an area of affected skin or from the scapular, gluteal, and calf areas (in the African form) or the scapular, deltoid, and gluteal areas (in the Central American form). Once obtained, the skin snip specimens are incubated in a physiologic solution (such as normal saline); the emergent microfilariae can be seen under a microscope typically within hours in heavy infections or after up to 24 h in light infections.

Direct Examination

Microscopy

Microfilariae lack a sheath and are approximately 309 μm long by 5 to 9 μm in diameter. The tails are tapered, usually bent or flexed, and without nuclei (Fig. 1D and 2c).

Nucleic Acid Detection Techniques

Because detection of parasites in the skin or eye is invasive and insensitive, immunodiagnostic assays may be preferable. Assays using PCR to detect onchocercal DNA in skin snip specimens are now in use in laboratories and are highly sensitive and specific (58).

Serologic Tests

IgG antifilarial antibody assays, while positive for individuals with onchocerciasis, suffer from the same lack of specificity and positive predictive value seen in the assays for bloodborne filarial infections; however, the combined use of three groups of recombinant antigens provides sensitivities and specificities that approach 100% for the diagnosis of onchocerciasis (40). Although no recombinant antigen test is available commercially, an experimental rapid card test that detects IgG4 antibodies in serum or whole blood to a recombinant protein (OV-16) has been shown to have >90% sensitivity and specificity (54).

Treatment

The major goals of therapy are to prevent irreversible lesions and to alleviate symptoms. Surgical excision of nodules is recommended when the nodules are located on the head because of the proximity of the microfilaria-producing adult worms to the eye, but chemotherapy is the mainstay of treatment. Ivermectin, a semisynthetic macrocyclic lactone, is now considered first-line therapy for onchocerciasis. It is characteristically given yearly or semiannually. With treatment, most patients have a mild reaction or no reaction. Pruritus, cutaneous edema, and/or a maculopapular rash occur in approximately 1 to 10% of treated individuals. Significant ocular complications are extremely rare, as is hypotension (1 in 10,000) (15, 16). In areas of Africa where *O. volvulus* and *L. loa* are coendemic, however, ivermectin is contraindicated (as it is for pregnant or breast-feeding women) because of severe posttreatment encephalopathy seen in patients, especially children, who are heavily microfilaremic with *L. loa*. Although ivermectin treatment results in a marked drop in microfilarial density, its effect can be short lived (<3 months in some cases). Thus, it is occasionally necessary to give ivermectin more frequently for persistent symptoms (18). A 6-week course of doxycycline that targets the *Wolbachia* endosymbiont has been demonstrated to be macrofilaristatic (rendering the female adult worms sterile for long periods of time) (21).

Prevention

Prevention of infection is being achieved by mass treatment programs using ivermectin (20). Vector control has been beneficial in those areas where infection is highly endemic in which breeding sites are vulnerable to insecticide spraying, but most areas where onchocerciasis is endemic are not

suited to this type of control. Community-based administration of ivermectin every 6 to 12 months is now being used to interrupt transmission in areas where the disease is endemic. This measure, in conjunction with vector control, has already helped reduce the prevalence of disease in foci of endemicity in Africa and Latin America. No drug has proven useful for prophylaxis for *O. volvulus* infection (57).

LOA LOA

Taxonomy

L. loa belongs to the phylum *Nematoda,* class *Secernentea,* subclass *Spiruria,* order *Spirurida,* superfamily *Filarioidea,* and family *Onchocercidae.*

Description of the Agent

The adult parasite lives in the subcutaneous tissues in humans; microfilariae circulate in the bloodstream with a diurnal periodicity that peaks between 12:00 noon and 2:00 p.m. The morphologic appearances and other characteristics of adult worms and microfilariae can be found in Table 1 and Fig. 1 and 2.

Epidemiology and Transmission

The distribution of *L. loa* is limited to the rain forests of West and Central Africa. Tabanid flies (deerflies) of the genus *Chrysops* are the intermediate hosts.

Clinical Significance (Description of Clinical Presentation)

L. loa infection may be present as asymptomatic microfilaremia, with the infection being recognized only after subconjunctival migration of an adult worm (the so-called eye worm). The classic clinical presentation is with episodic Calabar swelling (localized areas of transient angioedema) found predominantly on the extremities. If associated inflammation extends to the nearby joints or peripheral nerves, corresponding symptoms develop. Nephropathy, presumed to be immune complex-mediated, encephalopathy, and cardiomyopathy due to marked eosinophilia can occur, but rarely.

There appears to be a difference between the presentations of loiasis in those native to the area where the disease is endemic and those who are visitors (23). The latter tend to have a greater predominance of allergic symptomatology. The episodes of Calabar swelling tend to be more frequent and debilitating, and such patients rarely have microfilaremia. In addition, those who are not native to the area where the disease is endemic have extreme elevation of eosinophils in the blood, as well as marked increases in antifilarial antibody titers.

Diagnosis

Definitive diagnosis is made parasitologically, either by finding microfilariae in the peripheral blood or by isolating the adult worm from the eye or subcutaneous biopsy material following treatment. The diagnosis must often be made on clinical grounds, however, particularly in travelers (usually amicrofilaremic) to a region where the disease is endemic.

Direct Examination

Microscopy

The microfilariae are sheathed and are up to 300 μm long (females, 50 to 70 mm long and 0.5 mm wide; males, 25 to 35 mm long and 0.25 mm wide). In contrast to those of the lymphatic filariae, the nuclei extend to the end of the tail; however, they are somewhat irregularly arranged along the length of the tail (Fig. 1C and 2d). The sheath does not stain with Giemsa.

Nucleic Acid Detection Techniques

PCR-based assays for the detection of *L. loa* DNA in blood are now available in research laboratories and are highly sensitive and specific (47).

Serologic Tests

Available methods using crude antigen extracts from *Brugia* or *Dirofilaria* species do not differentiate between *L. loa* and other filarial pathogens. The utility of such testing in populations in which the disease is endemic is limited by the presence of antifilarial antibodies in up to 95% of individuals in some regions. An *L. loa*-specific recombinant protein has been tested and has good specificity but only limited (50%) sensitivity (24). Antifilarial IgG and IgG4 may be useful in confirming the diagnosis of loiasis in visitors to areas where the disease is endemic who have suggestive clinical symptoms or unexplained eosinophilia.

Treatment and Prevention

DEC is effective against both the adult and the microfilarial forms of *L. loa,* but multiple courses are frequently necessary before the disease resolves completely. In cases of heavy microfilaremia, allergic or other inflammatory reactions can take place during treatment, including central nervous system involvement with coma and encephalitis. Heavy infections can be treated initially with apheresis to remove the microfilariae and with glucocorticoids followed by small doses of DEC. If antifilarial treatment has no adverse effects, the prednisone dose can be rapidly tapered and the dose of DEC can be gradually increased. Albendazole or ivermectin (although not approved for this use by the Food and Drug Administration) has been shown to be effective in reducing microfilarial loads. DEC is an effective prophylactic regimen for loiasis (31).

MANSONELLA SPP.

Taxonomy

Mansonella perstans, Mansonella ozzardi, and *Mansonella streptocerca* each belong to the phylum Nematoda, class *Secernentea,* subclass *Spiruria,* order *Spirurida,* superfamiliy *Filarioidea,* and family *Onchocercidae.*

Description of the Agents

The adult worms of *M. perstans* reside in the body cavities (pericardial, pleural, and peritoneal) as well as in the mesentery and the perirenal and retroperitoneal tissues, whereas the location of the adult worms of *M. ozzardi* is unknown. The microfilariae of both parasites circulate in the blood without periodicity. For *M. streptocerca,* the adult parasites reside in the skin. *M. streptocerca* microfilariae are found predominantly in the skin. The morphologic appearances and other characteristics of adult worms and microfilariae can be found in Table 1 and Fig. 1 and 2.

Epidemiology and Transmission

M. perstans (formerly *Dipetalonema perstans* and *Acanthocheilonema perstans*) is distributed across the center of Africa and in northeastern South America. The infection is transmitted to humans through the bites of midges (*Culicoides* species). *M. streptocerca* (formerly *Dipetalonema streptocerca* and *Tetrapetalonema streptocerca*) is found largely in the tropical

forest belt of Africa from Ghana to Zaire. It is transmitted to the human host by biting midges (*Culicoides* species). The distribution of *M. ozzardi* is restricted to Central and South America as well as certain Caribbean islands. The parasite is transmitted to the human host by biting midges *(Culicoides furens)* and blackflies *(Simulium amazonicum)*.

Clinical Significance (Description of Clinical Presentation)

Although most patients with *M. perstans* infection appear to be asymptomatic, the clinical manifestations of this infection include transient angioedematous swellings of the arms, face, or other body parts (not unlike the Calabar swellings of *L. loa* infection); pruritus; fever; headache; arthralgias; neurologic or psychologic symptoms; and right-upper-quadrant pain. Occasionally, pericarditis and hepatitis occur.

The major clinical manifestations of *M. streptocerca* infection are related to the skin: pruritus, papular rashes, and pigmentation changes. These are thought to be secondary to inflammatory reactions around microfilariae. Most infected individuals also show inguinal lymphadenopathy. Lymph nodes of affected individuals may show chronic lymphadenitis with scarring; however, many patients are completely asymptomatic (28).

The clinical details of *M. ozzardi* infection are poorly characterized. Furthermore, many consider *M. ozzardi* to be nonpathogenic; however, headache, articular pain, fever, pulmonary symptoms, adenopathy, hepatomegaly, and pruritus have been ascribed to infection with this organism.

Diagnosis

For *M. perstans* infections, diagnosis is made parasitologically by finding the microfilariae in the blood or in other body fluids (serosal effusions). Microfilariae are small (203 by 4 to 5 μm) and have a blunt tail filled with nuclei. Perstans filariasis is often associated with peripheral blood eosinophilia and antifilarial antibody elevations (1). The diagnosis of *M. ozzardi* infection is made by demonstrating the presence of the characteristic microfilariae in the peripheral blood. These microfilariae are small (224 by 4 to 5 μm) and have long, attenuated tails devoid of nuclei (Fig. 1F and 2g). The diagnosis of streptocerciasis can be made by finding the characteristic microfilariae upon examination of skin snip specimens (see the previous section on onchocerciasis diagnosis). In areas where both *O. volvulus* and *M. streptocerca* are endemic, care must be taken to correctly identify the microfilariae. *M. streptocerca* microfilariae have no sheath, are long and slender, and measure approximately 210 by 5 to 6 μm. The most characteristic feature of *M. streptocerca* is its crooked tail (Fig. 2f), which contains nuclei.

Treatment and Prevention

Mansonella perstans

While DEC remains the treatment of choice, there is little evidence that it is efficacious. If cure is attained, usually with multiple (8 to 10) courses of therapy, patients lose their symptoms along with their eosinophilia.

Mansonella streptocerca

DEC is particularly effective in treating infection with both the microfilarial and the adult form of *M. streptocerca.* Following treatment, as in onchocerciasis, one can often see debilitating urticaria, arthralgias, myalgias, headaches, and abdominal discomfort. Ivermectin is currently the drug of choice for treatment of this infection (12, 13).

Mansonella ozzardi

DEC has little or no effect on *M. ozzardi* infection; ivermectin is again the drug of choice for treatment of this infection (17, 25, 32).

There currently are no good preventative measures for any of these infections.

Cestodes

HECTOR H. GARCIA, JUAN A. JIMENEZ, AND HERMES ESCALANTE

146

Cestodes have as their key characteristic a flattened body composed of the head or scolex (bearing the fixation organs—suckers, hooks, and bothria), the neck (where the cellular reproduction occurs, to form the strobila), and the strobila, formed by numerous segments or proglottids. As new proglottids develop in the neck region, existing ones mature as they become more distal. The more-distal proglottids are gravid, almost completely occupied by a uterus full of eggs which are passed with the stools of the carrier, either inside complete proglottids or free after proglottid breakage. In some species, proglottids can actively migrate out of the anus.

Tapeworms live in the lumen of the small intestine with the head or scolex as the only fixation organ, attached to the mucosa. They absorb nutrients from the host's intestine both at the head and through their tegument. Accordingly, they have developed cephalic fixation organs like hooks, suckers, or shallow grooves as longitudinal suction sulci (bothria) (Fig. 1), and a specialized tegument.

Four species of cestode tapeworms inhabit the human intestine: *Diphyllobothrium latum, Taenia saginata, Taenia solium,* and *Hymenolepis nana*. They differ widely in size, intermediate host, and other characteristics, from the 12-m *D. latum* to the 3-cm *H. nana* (Table 1). More rarely *Dipylidium caninum* and *Hymenolepis diminuta* can also inhabit the human gut; these parasites are reviewed in "Less Common Helminths" (chapter 148). In addition, a number of cestode larvae can produce human disease if infective tapeworm eggs are ingested, mainly cysticercosis *(Taenia solium),* cystic hydatid disease *(Echinococcus granulosus),* and alveolar hydatid disease *(Echinococccus multilocularis)*. Rarer larval cestode infections affecting humans include coenurosis *(Taenia multiceps),* sparganosis *(Spirometra mansonoides),* and cysticercosis by *Taenia crassiceps.* Tapeworms and especially tapeworm larval infections still represent an important cause of morbidity and mortality, not only in most underdeveloped countries but also in industrialized countries, particularly in rural areas or among immigrants from areas of endemicity.

DIPHYLLOBOTHRIUM LATUM

Known as the fish tapeworm, *D. latum* is the longest intestinal parasite of humans. Also common in fish-eating mammals such as canids or felids (reservoir hosts), it differs from other adult tapeworms infecting humans in its morphology, biology, and epidemiology.

Taxonomy

D. latum is included in the phylum Platyhelminthes, subphylum Neodermata, class Cestoidea, subclass Eucestoda, order Pseudophyllidea, family Diphyllobothriidae, and genus *Diphyllobothrium.*

Description of Agent

Adult Tapeworm

The adult parasite can grow to 15 m in length and apparently can live for 20 years or longer in the small intestine. It is ivory in color and has a scolex which is provided with bothria on its dorsal and ventral aspects (9). *Diphyllobothrium* proglottids are much wider than they are long (~8 by 4 mm) and are easy to recognize because their genital pore is located in the center of the proglottid rather than in the lateral edges as in all other tapeworms of humans. The coiled uterus in the center of the gravid proglottids looks yellow-brown in freshly passed specimens. The uterine pore is located in the center of the proglottid near the genital pore.

Eggs

Unembryonated, operculate eggs are passed in the feces. *D. latum* eggs are oval and resemble those of trematodes but are smaller (58 to 75 μm long by 44 to 50 μm wide) and have a better defined wall. The abopercular end usually has a small knoblike protrusion. Eggs are usually numerous, and expulsion of proglottid chains is usual.

Larvae

After the eggs embryonate in a water environment for several weeks, ciliated six-hooked embryos (coracidia) hatch. Coracidia must be ingested by appropriate species of freshwater copepods (genus, *Cyclops*) for further development. In the copepod a solid-bodied larva, the procercoid, develops as a second larval stage and becomes infective for the second intermediate host (fish). In fish, the procercoid migrates to the flesh and develops in the third larval stage, the plerocercoid or sparganum, which is the infective stage for human or animal (canids or felids) hosts.

Epidemiology, Transmission, and Prevention

The geographic distribution of *D. latum* includes lake areas in Scandinavia, other areas of northern Europe, the former USSR, Finland, northern Japan, and North America, principally the

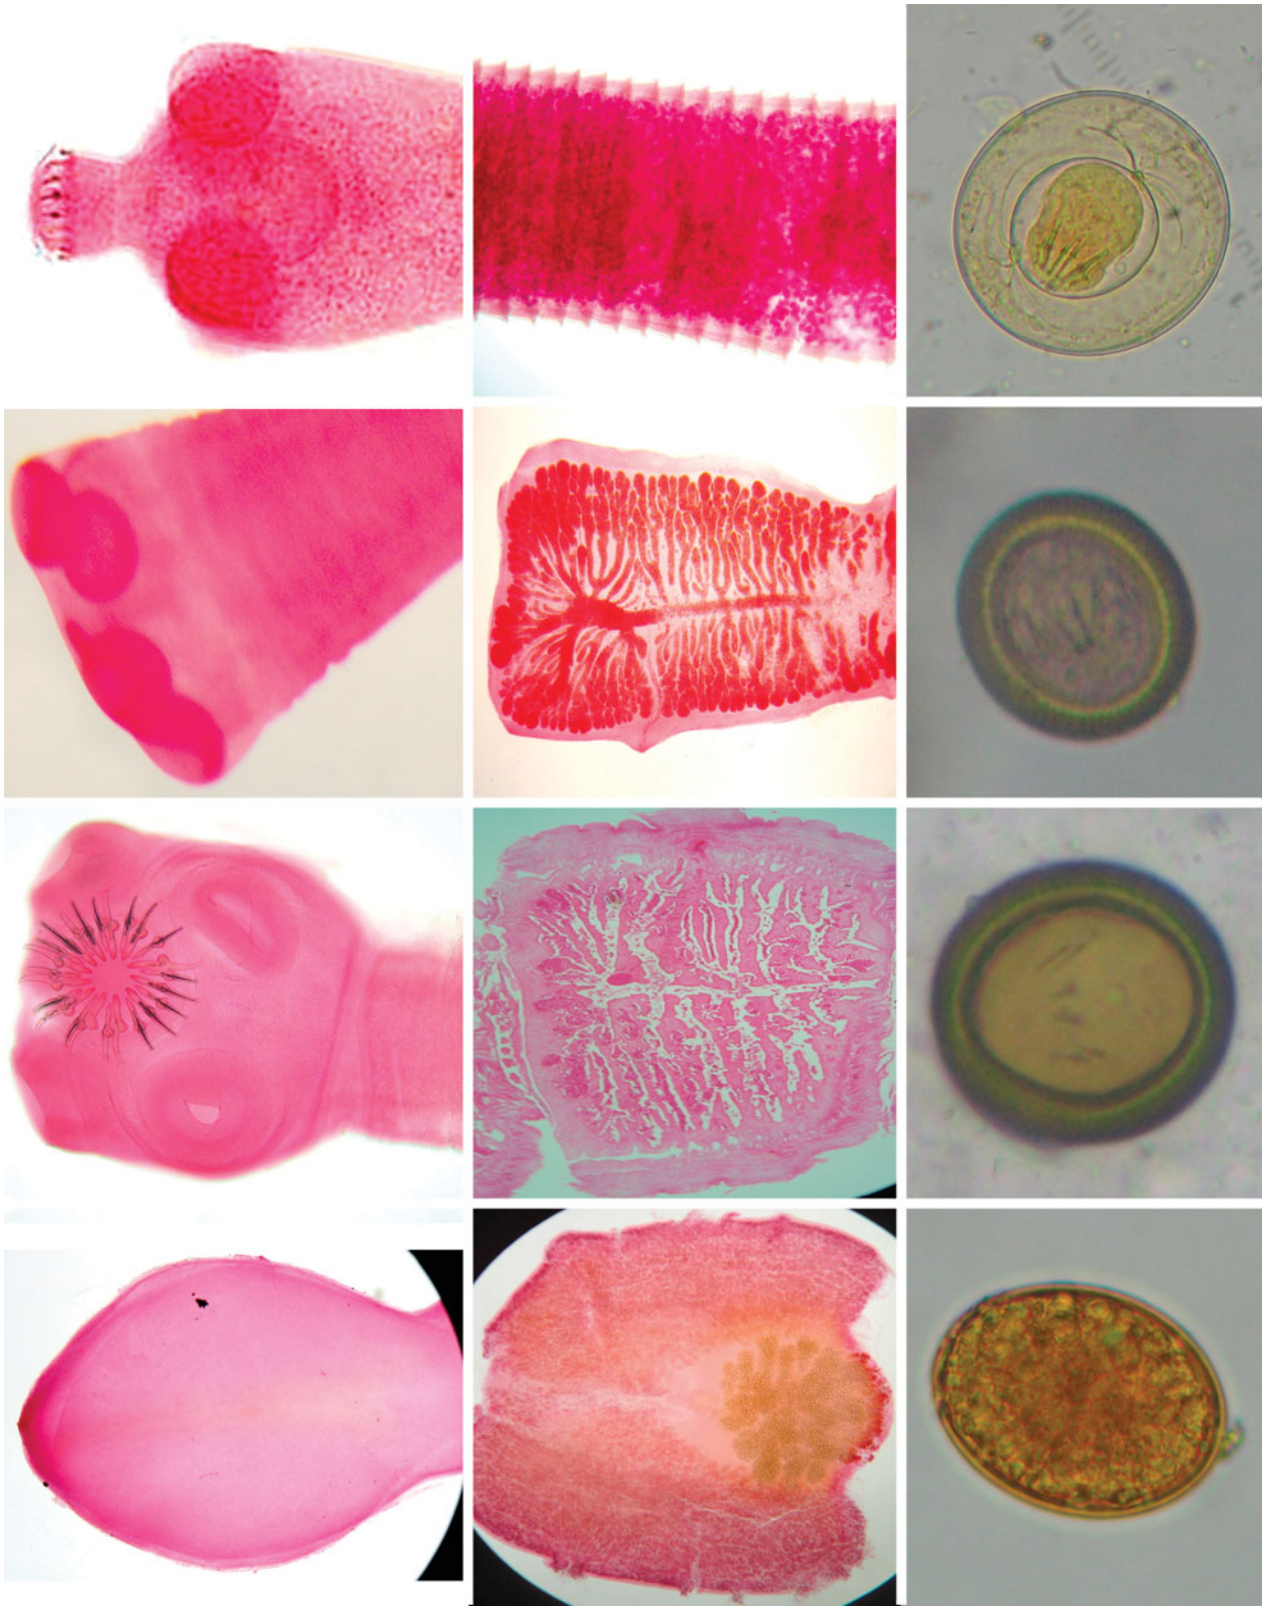

FIGURE 1 Scolex, gravid proglottids, and eggs of *H. nana*, *T. saginata*, *T. solium*, and *D. latum*. Note the coiled, central uterus in *D. latum*, the absence of hooks in the scolex of *T. saginata*, and the similar appearances of the eggs of *T. saginata* and *T. solium*.

TABLE 1 Some characteristics of main cestodes infecting humans

Organism	Length (cm)	Scolex	Gravid proglottids	Intermediate host(s)
D. latum	1,200	Spatulate, two bothria	Rosette-shaped central uterus	Copepods, fish
T. saginata	600	Squared, four suckers, no hooks	>15 main lateral uterine branches	Cattle
T. solium	300	Squared, four suckers, hooks (double crown)	<12 main lateral uterine branches	Pigs, humans
H. nana	3	Knoblike, four suckers, hooks (single crown)	Bag-shaped uterus	Insects, rodents, humans

upper Midwest, Alaska, Canada, and the southwestern coast of South America. Several other *Diphyllobothrium* species *(D. pacificum, D. cordatum, D. ursi, D. dendriticum, D. lanceolatum, D. dalliae,* and *D. yonagoensis)* have also been reported to infect humans but less frequently (3, 28). *Diphyllobothrium pacificum,* identified by Nybellin in 1931, is a parasite of seawater found along the western coast of South America, specifically in Peru and Chile. *D. pacificum* is much smaller than *D. latum* and usually measures 50 to 200 cm long, although it can occasionally reach 3 to 4 m.

The most common sources of human *Diphyllobothrium* infection are the pike burbot, perch, ruff, and turbot (28). Infected fish (undercooked, raw, or insufficiently treated flesh) transmit plerocercoids to humans or fish-eating mammals. Infection with *Diphyllobothrium* is preventable by eating well-cooked fish or fish that has been deep-frozen (at least –10°C for 24 h).

Clinical Significance (Description of Clinical Presentation)

Infected individuals notice passing segment chains with their stools. The parasite may produce no clinical symptoms in some people, but when it reaches a large size it may cause mechanical bowel obstruction, diarrhea, abdominal pain, and, particularly in northern European countries, pernicious anemia resulting from B12 vitamin deficiency because the tapeworm competes with the intestinal epithelium for the uptake of the vitamin. This condition is rare outside Scandinavian countries, and some authors postulate a genetic predisposition.

Collection, Transport, and Storage of Specimens

For identification purposes eggs are well preserved in 5 to 10% formalin solutions. For DNA recovery, 95% ethanol would be a better option. Electron microscopy may require cacodylate buffer or other glutaraldehyde media. Adult tapeworm material is better defined if it is washed in saline, relaxed for better visualization of its internal structures by warming the saline at 55°C for a short period (5 min), and then placed between two glass slides and stored in a fixative solution. Fixatives could be 10% formalin, acetic acid-formaldehyde-alcohol, or sodium acetate-acetic acid-formaldehyde. Fixed pieces can be stained by injecting Semichon's carmine or India ink. The proglottids can also be sectioned and stained using hematoxylin and eosin; however, morphological characteristics can be more easily seen in whole mounts.

Direct Examination

Microscopy

Eggs can be easily seen by microscopical examination of stools. Either flotation or sedimentation techniques may be used. However, since the eggs are operculated, they generally do not float using the flotation concentration method; both the surface film and sediment need to be examined if this concentration method is used. For that reason, most laboratories routinely use the sedimentation concentration method. Low-magnification microscopy should easily permit identification of the characteristic scolex or proglottids when available (Fig. 1). Neither culture nor antigen detection is relevant for the detection and identification of *D. latum*.

Nucleic Acid Detection Techniques

Although several groups have described genus variation in *Diphyllobothrium* by using nucleic acid detection methods, the information has no clinical relevance in terms of routine tapeworm recovery and identification (19).

Serologic Tests

Serologic tests are not available.

Treatment

Both praziquantel and niclosamide are effective drugs. At recommended doses both are associated with only mild side effects, mostly gastrointestinal.

Evaluation, Interpretation, and Reporting of Results

Both stool microscopy and parasite identification are unambiguous. Eggs or tapeworm pieces should be reported as *D. latum* eggs (except in South America, where *D. pacificum* is more frequently found).

TAENIA SAGINATA

Known as the beef tapeworm, *Taenia saginata* is still endemic to most of the world. Humans are its only definitive host. While *T. saginata* infections do not carry major risks for the host, differential diagnosis with *Taenia solium* is important because the latter can cause neurocysticercosis.

Taxonomy

T. saginata is included in the phylum Platyhelminthes, subphylum Neodermata, class Cestoidea, subclass Eucestoda, order Cyclophyllidea, family Taeniidae, and genus *Taenia*.

Description of Agent

Adult Tapeworm

The adult *T. saginata* tapeworm attains lengths of 4 to 8 m and has a scolex provided with four suckers and an unarmed

(no hooks) rostellum. Gravid proglottids are longer than they are wide (18 to 20 mm by 5 to 7 mm). Each proglottid has a genital pore at the midlateral margin. In mature proglottids, the ovary has only two lobes and presents a vaginal sphincter. Gravid proglottids, which are highly muscular and active, break off from the strobila and actively migrate out of the anus (a pathognomic characteristic of this species).

Eggs

Eggs from *T. saginata* and *T. solium* are indistinguishable by morphological characteristics. They are spherical, measure 30 to 40 μm in diameter, and have a quite characteristic thick, yellow-brown, radiate shell (embryophore) composed of collagen subunits, which gets thicker as the eggs mature. Eggs are frequently surrounded by a thin layer of vitelum (Fig. 1). Within the egg is a six-hooked embryo, the oncosphere.

Larvae

The unarmed scolex is invaginated into a fluid-filled bladder, the cysticercus. Larval cysts are 4 to 6 mm long by 7 to 10 mm wide and have a pearl-like appearance in tissues.

Epidemiology, Transmission, and Prevention

T. saginata is distributed worldwide, although it is especially prevalent in some parts of Africa, Central and South America, eastern and western Asia, and some countries in Europe. Cattle serve as the intermediate host, and ingestion of eggs from contaminated pasturelands by grazing cattle results in development in cattle tissues of the infective cysticercus stage. After ingestion of the cysticercus in raw or inadequately cooked beef, it takes approximately 2 to 3 months for the infection to become patent in the human host.

In Southeast Asia there is a human tapeworm morphologically very similar to *Taenia saginata* (*Taenia saginata asiatica, Taenia asiatica,* or Taiwan taenia). In this tapeworm, the cysticercus stage occurs in the liver of pigs and less frequently in cattle. The adult tapeworm infects the human host, and its appearance is very similar to that of *T. saginata* (6, 7).

Clinical Significance (Description of Clinical Presentation)

Although patients may exhibit no symptoms with this infection, they usually notice passing proglottids or find them in their underwear. The mature worm can also cause abdominal discomfort, diarrhea, and occasionally intestinal obstruction as a result of its large size.

Collection, Transport, and Storage of Specimens

For collection, transport, and storage of specimens, see *Diphyllobothrium* above.

Direct Examination

Microscopy

Typical *Taenia* eggs can be found in feces. Sedimentation or the less used Kato-Katz method is apparently more sensitive for the detection of *Taenia* eggs in stools than other concentration techniques. Finding of *Taenia* eggs does not allow a diagnosis of infection by this species; it is usually made by identification of gravid proglottids that have been passed in feces or have actively migrated out of the anus. Identification of the proglottids is based on shape and size and mainly on the morphology of the uterus, which can be demonstrated after injection with India ink or staining with carmine or hematoxylin stains. In *T. saginata* there are 15 to 20 primary lateral branches on each side of the central uterine stem (Fig. 1).

Antigens in stools (coproantigen) have been detected by enzyme-linked immunosorbent assay (ELISA) since 1990, but this assay is used mainly in research settings because of scarce availability.

Nucleic Acid Detection Techniques

Species-specific PCR techniques have been described to detect parasite DNA and differentiate *T. saginata* from *T. solium*. Most of these assays require actual parasite material, although some are apparently able to establish the difference with DNA from eggs in feces (13, 21).

Serologic Tests

Serum antigen detection ELISAs for *T. saginata* cysticercosis in cattle have been developed using monoclonal antibodies to *T. saginata.* Although these assays can detect parasite burdens of <50 cysts per animal, they have not yet been routinely applied except in research settings (4, 12, 26).

Treatment

Both praziquantel and niclosamide are effective drugs. At recommended doses both are associated with only mild side effects, mostly gastrointestinal. In regions where *T. solium* is endemic, there is a possibility that latent neurocysticercosis may respond to praziquantel and cause severe headaches or seizures. Niclosamide is not absorbed from the gastrointestinal tract and thus does not carry this risk (15).

Evaluation, Interpretation, and Reporting of Results

Eggs should be reported as "*Taenia* sp." because direct observation does not confirm the species. The finding of *Taenia* sp. eggs should be notified to the attending physician to ensure prompt treatment. The presence of the scolex in the parasite material expelled (spontaneously or posttreatment) should be reported both because it allows species diagnosis and because if it is not found, the chances of treatment failure increase.

TAENIA SOLIUM

Known as the pork tapeworm, *T. solium* has an extensive geographic distribution. This infection has a huge impact on human health because of its association with seizure disorders caused by infection of the human brain with its larval stage (neurocysticercosis) (11).

Taxonomy

T. solium is included in the phylum Platyhelminthes, subphylum Neodermata, class Cestoidea, subclass Eucestoda, order Cyclophyllidea, family Taeniidae, and genus *Taenia.*

Description of Agent

Adult Tapeworm

The adult *T. solium* tapeworm measures 2 to 4 m and has a scolex provided with four suckers and a rostellum armed with two crowns of hooks. Gravid proglottids have similar length and width (approximately 1 cm). Each proglottid has a genital pore at the midlateral margin. In mature proglottids, the ovary has two main lobes and one accessory lobe (lacking in *T. saginata*), and a vaginal sphincter muscle is lacking (present in *T. saginata*). Gravid proglottids have few (<12) lateral

branches on the central uterine stem (Fig. 1). Since the eggs of *T. solium* are infective to humans and can cause cysticercosis, extreme caution in the handling of these proglottids or infective stools is recommended.

Eggs

Eggs from *T. saginata* and *T. solium* are indistinguishable by morphological characteristics. They are spherical, measure 30 to 40 μm in diameter, and have a quite characteristic thick, yellow-brown, radiate shell (embryophore) composed of collagen subunits, which gets thicker as the eggs mature. Eggs are frequently surrounded by a thin layer of vitelum (Fig. 1). Within the egg is a six-hooked embryo, the oncosphere.

Larvae

The fluid-filled bladder (cysticercus) larvae are bigger than those of *T. saginata,* measuring approximately 8 to 10 mm in diameter. They lodge in the pig's tissues, mostly in muscle and brain.

Epidemiology, Transmission, and Prevention

T. solium taeniasis and cysticercosis are highly endemic to all parts of the developing world where pigs are raised as a food source, including Latin America, most of Asia, sub-Saharan Africa, and parts of Oceania. The infection is now also increasingly diagnosed in industrialized countries due to immigration of tapeworm carriers from zones of endemicity (7, 11).

As for *T. saginata,* humans are the only definitive host. Ingestion of contaminated pork containing *T. solium* cysticerci causes human taeniasis. Conversely, *T. solium* eggs cause cysticercosis in pigs (the usual intermediate host) and humans. Pigs acquire cysticercosis by eating stools contaminated with infective eggs in places where deficient sanitation exists. Humans get infected by fecal-oral contamination from a tapeworm carrier, commonly in the household or another close environment.

Clinical Significance (Description of Clinical Presentation)

Human infection is acquired by ingestion of infective cysticerci in inadequately cooked pork or pork products. Taeniasis seems mostly asymptomatic, and most patients do not even notice passing proglottids in stools. The clinical significance of *T. solium* infections relates to the risk of neurocysticercosis (see below), which is high for tapeworm carriers and their close contacts (11).

Collection, Transport, and Storage of Specimens

For collection, transport, and storage of specimens, see the corresponding section in "*Diphyllobothrium*" above. Handling of *T. solium* proglottids or contaminated stools should be done with appropriate biosafety conditions to avoid cysticercosis.

Direct Examination

Microscopy

Typical *Taenia* eggs can be found in feces. Sedimentation or the less used Kato-Katz method is apparently more sensitive for the detection of *Taenia* eggs in stools than other concentration techniques. Finding of *Taenia* eggs does not allow a diagnosis of infection by the species, which is usually made by identification of gravid proglottids that have been passed in feces. Identification of the proglottids is based on shape and size and mainly on the morphology of the uterus, which can be demonstrated after injection with India ink or staining with carmine or hematoxylin stains. In *T. solium* there are few primary branches on each side of the central uterine stem (Fig. 1).

Antigens in stools (coproantigen) have been detected by ELISA since 1990. Coproantigen detection ELISA is much more sensitive than microscopy and thus highly recommended for the diagnosis of human taeniasis (specifically in the case of *T. solium* because of the risks of cysticercosis transmission), but its availability is still limited.

Nucleic Acid Detection Techniques

Species-specific PCR techniques that differentiate *T. saginata* from *T. solium* have been described. Most of these assays require actual parasite material, although some are apparently able to establish the difference with DNA from eggs in feces (13, 21).

Serologic Tests

Recently, stage-specific serological assays directed to the adult tapeworm have been developed, with high sensitivity and specificity. Mostly, serology is directed to the detection of *T. solium* antibodies in relation to the diagnosis of neurocysticercosis. Antibody detection by enzyme-linked immunoelectrotransfer blot assay is the method of choice, with a sensitivity of 98% in cases with more than one viable larval cyst and specificity of 100%. *T. solium* antigen detection in serum or cerebrospinal fluid has been performed in cases of human cysticercosis, based on a known genus-specific cross-reaction in ELISAs for *T. saginata*. Although these assays can detect parasite burdens of <50 cysts in infected animals, they have not yet been routinely applied except in research settings.

Treatment

Both praziquantel and niclosamide are effective drugs. At recommended doses both are associated with only mild side effects, mostly gastrointestinal. In regions where *T. solium* is endemic, there is a possibility that latent neurocysticercosis may respond to praziquantel and cause severe headaches or seizures. Niclosamide is not absorbed from the gastrointestinal tract and thus does not carry this risk (15).

Evaluation, Interpretation, and Reporting of Results

Eggs should be reported as "*Taenia* sp." because direct observation does not confirm the species. The finding of *Taenia* sp. eggs should be notified to the attending physician to ensure prompt treatment and minimize the chances of cysticercosis in the patient or his/her contacts. The presence of the scolex in the parasite material expelled (spontaneously or posttreatment) should be reported both because it allows species diagnosis and because if it is not found, the chances of treatment failure increase.

HYMENOLEPIS NANA

H. nana is the smallest of the intestinal tapeworms of humans and also the most common tapeworm infection throughout the world. It can be transmitted from person to person (an intermediate host is not necessarily required) (28).

Taxonomy

H. nana is included in the phylum Platyhelminthes, subphylum Neodermata, class Cestoidea, subclass Eucestoda, order Cyclophyllidea, family Hymenolepididae, and genus *Hymenolepis.*

Description of Agent

Adult Tapeworm

The adult parasite measures 2 to 4 cm and seems to live approximately 1 year. The scolex has four suckers and one crown of hooks.

Eggs

The eggs are 30 to 50 μm in diameter and thin shelled, and they contain a six-hooked oncosphere that lies in the center of the egg and is separated from the outer shell by considerable space. The oncosphere is surrounded by a membrane that has two polar thickenings from which arise four to eight filaments extending into the space between it and the outer shell (Fig. 1). These filaments are not seen in *H. diminuta.* Eggs may hatch inside the host's intestine, and the embryos (oncospheres) invade the mucosa to develop into larval stages.

Larvae

The cysticercoid larvae have an invaginated scolex but no fluid-filled bladder. They lodge in the intestinal mucosa and emerge to the intestinal lumen as young tapeworms after a few days.

Epidemiology, Transmission, and Prevention

H. nana is normally a parasite of mice, and its life cycle characteristically involves various beetles as intermediate hosts. In humans, transmission is usually accomplished by direct ingestion of infective eggs containing oncospheres. When eggs are ingested, a solid-bodied larva, a cysticercoid, first develops in the wall of the small intestine. Subsequently, the larva migrates back into the intestinal lumen, where it reaches maturity as an adult tapeworm in 2 to 3 weeks. In beetles that ingest eggs of *H. nana,* the cysticercoids develop in the body cavity and have thick protective walls around them. Although humans may acquire the infection by accidental ingestion of infected beetles (often occurring in dry cereals), direct infection is far more common and is the primary reason why *H. nana* usually occurs in institutional and familial settings in which hygiene is substandard. A feature of human *H. nana* infection is the opportunity for internal autoinfection with the parasite, which may result in large worm burdens. Autoinfection occurs when eggs discharged by adult tapeworms in the lumen of the small intestine hatch rapidly and invade the wall of the intestine; here, cysticercoids are formed, and they subsequently reenter the intestine to mature as adult worms.

Clinical Significance (Description of Clinical Presentation)

Most infections cause no symptoms. However, hymenolepiasis can be associated with abdominal pain, diarrhea, headaches, or irritability, probably in infections with heavier worm burdens (23, 30).

Collection, Transport, and Storage of Specimens

For collection, transport, and storage of specimens, see the corresponding section in "*Diphyllobothrium*" above.

Direct Examination

Microscopy

Diagnosis of the infection rests on finding the spherical eggs in feces by microscopy. Either flotation or sedimentation techniques are of help. Proglottids (Fig. 1) are rarely seen, since they disintegrate after breaking off from the main strobila. Neither culture, antigen detection, nor nucleic acid detection techniques are relevant for the detection and identification of *H. nana.*

Serologic Tests

Antibody detection ELISAs have been used in research settings but are of no clinical use (1).

Treatment

Both praziquantel and niclosamide are effective drugs. At recommended doses both are associated only with mild side effects, mostly gastrointestinal. A second dose of praziquantel after 10 to 15 days may decrease the likelihood of relapses. Niclosamide needs to be administered for 7 days because it is not absorbed and thus does not affect the cysticercoid larvae in the intestinal mucosa. Nitazoxanide has been reported to be useful as a therapeutic alternative (29).

Evaluation, Interpretation, and Reporting of Results

Eggs are characteristic and should be reported as *H. nana* eggs. The closest differential diagnosis is with *H. diminuta,* which rarely infects humans. The eggs of *H. diminuta* are bigger and have a wider interior space and thus can be differentiated by microscopy.

LARVAL CESTODES INFECTING THE HUMAN HOST

The larval stages of *T. solium, Echinococcus granulosus, Echinococcus multilocularis,* and, less frequently, *Sparganus* sp., *Taenia multiceps,* and *Taenia crassiceps* can invade the human tissues. These are briefly described below.

Cysticercosis *(Taenia solium)*

In the normal life cycle of *T. solium,* humans are the definitive host and pigs act as the intermediate host, hosting the larval stage or cysticercus. Porcine cysticercosis is a serious economic problem for pig farmers. However, the most serious manifestations are found in human cysticercosis (11). Larval vesicles located in the central nervous system (Fig. 2) cause seizures or other neurological symptoms. Indeed, neurocysticercosis is associated with a significant proportion of seizure cases in areas of endemicity (22, 24). Clinical manifestations of neurocysticercosis are related to individual differences in the number, size, and topography of lesions and in the severity of the host's immune response to the parasites. Symptoms and signs are varied and nonspecific, and recognition of a typical syndrome is not possible. Parasites in the brain parenchyma usually cause seizures and headache, whereas those located in the cerebral ventricles or in the subarachnoid space ("racemose" cysticercosis) cause intracranial hypertension and hydrocephalus. Diagnosis is made using brain imaging, either computed tomography (CT) scan or magnetic resonance imaging (MRI), and confirmed by serology. CT has a lower cost (quite important for poor areas where the disease is endemic), is more available, and has better sensitivity for the detection of calcified parasites. Conversely, MRI has better sensitivity for small lesions, those located close to the skull, and intraventricular parasites. The serological assay of choice is an immunoblot using seven purified glycoprotein larval antigens, which has 98% sensitivity and 100% specificity except in cases with a single lesion, for which sensitivity drops to approximately 70% (31). Antigen detection assays have been described, but no controlled data on sensitivity and specificity are yet available. Treatment of

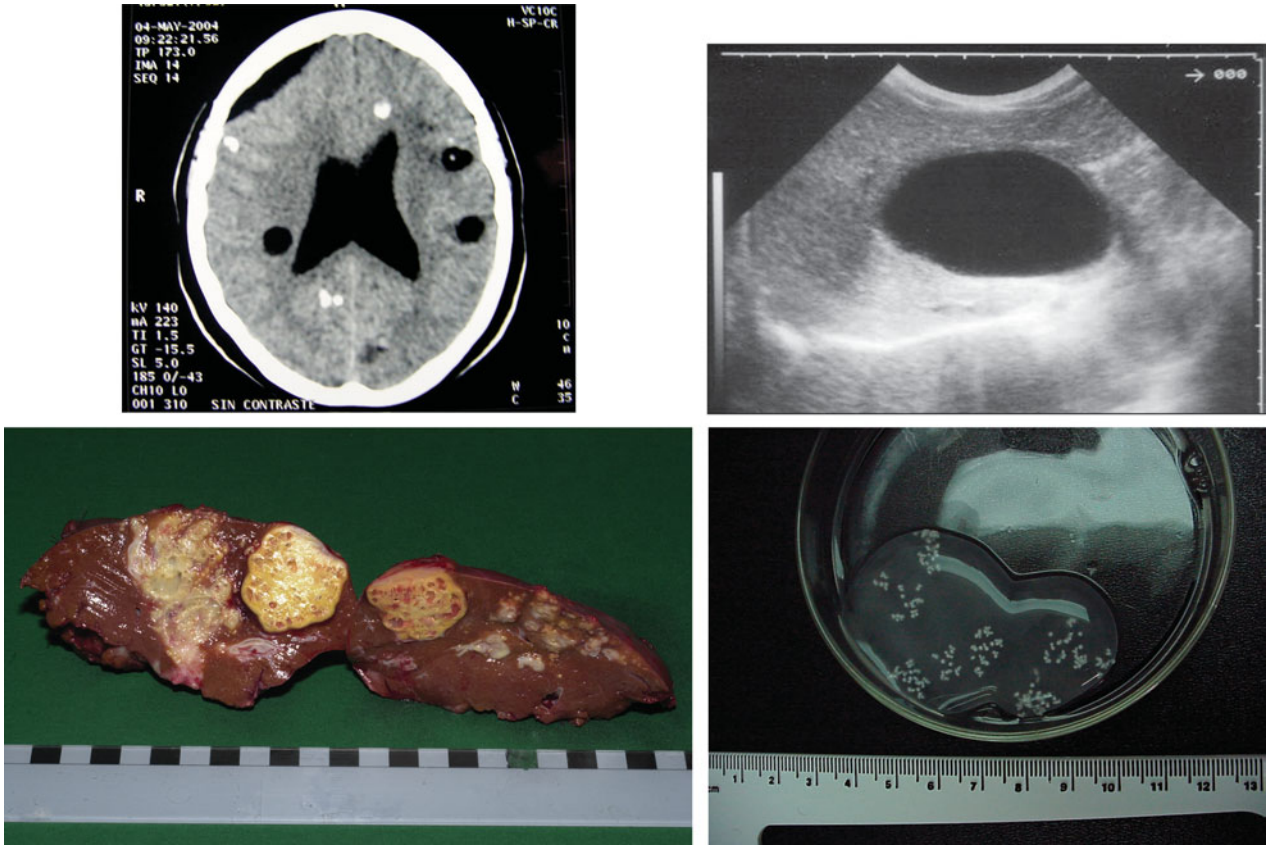

FIGURE 2 Larval cestodes infecting the human host. *Taenia solium* cysticerci in the human brain (neurocysticercosis), shown in a noncontrasted MRI of the brain. *Echinococcus granulosus* hydatid in the human liver (hydatid disease) as seen on liver ultrasound (kind contribution of Enrico Brunetti, Università di Pavia, Pavia, Italy). *Echinococcus multilocularis* alveolar hydatid disease in human liver (kind courtesy of K. Buttenschoen and P. Kern, University Hospital Ulm, Ulm, Germany). *Taenia multiceps* coenurus showing multiple scolices in the cystic wall.

neurocysticercosis uses antiparasitic agents (albendazole or praziquantel) for viable parasites, usually given with steroids to ameliorate the inflammation produced by the death of the cyst. Surgery is limited to excision of single, big lesions or implantation of ventricle-peritoneal shunts. Antigen detection assays permit patient monitoring and follow-up of antiparasitic treatment (10).

Cystic Hydatid Disease *(Echinococcus granulosus)*

In the normal life cycle of *Echinococcus granulosus,* the dog is the definitive host and herbivores (mainly sheep) act as the intermediate host. These become infected with the larval stage (cystic hydatid) by ingesting infective eggs dispersed from the feces of the infected dog. Human cystic hydatid disease is an important cause of human morbidity, requiring costly surgical and medical treatment. This cestodiasis is still endemic to most of the Old World, particularly in Greece, Cyprus, Bulgaria, Lebanon, and Turkey; some other European countries; South America; and Africa. Sporadic autochthonous transmission is currently recognized in Alaska and other states in the United States (5). The affected organs are most commonly liver and lungs and more rarely heart, brain, bone, or other locations. Diagnosis is made using ultrasound or CT scan for liver infection or chest X rays or CT for lung infections (Fig. 2). Antibody detection by serology is of much help, although sensitivity is lower than for other infections, reaching 80 to 85%. It is more sensitive for hepatic than for pulmonary cases. Treatment uses antiparasitic agents (albendazole or albendazole plus praziquantel) for small cysts or presurgery; PAIR (puncture, injection, aspiration, and reinjection), which is a technique of ultrasound- or CT-guided aspiration and sterilization of the cyst's contents; or either laparoscopic or open surgery (18, 33). Spillage of cyst contents could lead to acute anaphylactic reactions or dissemination of infection in the surroundings. Cystic lesions may resolve without therapy in a proportion of patients (25).

Alveolar Hydatid Disease *(Echinococcus multilocularis)*

The adult stage of *E. multilocularis* lives in the small intestine of the definitive host, commonly wild predators in the northern hemisphere, occurring in parts of Europe, Asia, Japan, and North America, including Alaska (2, 16). The larval stages infect microtine rodents that usually serve as the common intermediate host. Human infections (causing alveolar hydatid disease) occur by accidental ingestion of the oncosphere by contamination with the feces of the definitive host. The manifestation of alveolar hydatid disease resembles a slowly developing "malignant tumor" of the liver, with subsequent invasion

of the blood vessels and bile ducts and metastatic dissemination. The lesions vary in size and can produce minor foci up to large infiltrating structures in the host's tissue. Thus, alveolar hydatid disease differs greatly in the pathology and clinical course from cystic hydatid disease. This disease often affects persons aged over 50 years and is characterized by a chronic course lasting for months or years. Clinical manifestations relate to the extent of tumor-like lesions of the cyst. Beside physical examination, diagnosis usually is based on imaging techniques including ultrasound, CT, and MRI supported by serology. Treatment is mainly surgical. Chemotherapy with benzimidazole agents is restricted to residual, postsurgical, or inoperable lesions (17).

Sparganosis *(Spirometra mansonoides)*

Mainly found in Southeast Asian countries, the metacestode larvae of *Spirometra* species can invade the human tissues either by ingestion of contaminated crustaceans in drinking water or of infected meat (frog or snake) or by direct contact via a poultice. The most commonly affected sites are subcutaneous tissues and the eye. The diagnosis rests on the pathological demonstration of the larvae after excision by biopsy (32).

Coenurosis *(Taenia multiceps* or *Taenia serialis)*

Taenia multiceps and *Taenia serialis* have canids as definitive hosts and sheep as their normal intermediate host, harboring the larvae or coenurus. The coenurus is a vesicle containing a transparent fluid, with a fine membrane in which multiple (500 to 700) scolices can be seen. Infected sheep lose their balance and rotate around their site, become dizzy, and fall (screw disease). It infrequently causes coenuriasis in humans. Human infections have largely been confined to the African continent, but a few cases have been described from France, England, and North and South America. The space-occupying coenurus usually invades the brain, producing lethal lesions. Diagnosis is based on pathological demonstration of the typical larval membrane and multiple scolices (14, 27).

Cysticercosis *(Taenia crassiceps)*

T. crassiceps is a common tapeworm of the red fox. Larval forms are generally found in subcutaneous tissues and body cavity of rodents. Human cases are quite rare, mostly in immunocompromised patients (subcutaneous, muscular, or ocular infections) (8, 20).

Trematodes

MALCOLM K. JONES AND DONALD P. McMANUS

147

At least 70 species of digenean trematode have been recorded as adult parasites from humans. All of these species are endoparasitic, occupying a variety of tissue sites (see Tables 1 through 3). Adult trematodes have a distinctive morphology, often with a leaf-like body plan. The most prominent morphological features in most species are two rounded suckers. One of these, the oral sucker, surrounds the mouth, while the other, the ventral sucker, lies approximately one-third of the way along the body and serves as a primary attachment organ (28). Adults of trematodes infecting humans are rarely encountered because of their endoparasitic nature and are seen usually only after anthelmintic purging or at autopsy. Hence, diagnosis of the diseases caused by these helminths relies to a large extent on direct observations of excreted ova.

Detailed descriptions of the life cycles of digenean parasites of humans are shown (Fig. 1 and 2). There are many subtle variations in life cycle patterns, but there are two predominant life cycle strategies among these trematodes (Fig. 1 and 2). The first strategy, exemplified by the schistosomes, is one in which humans are infected by direct invasion of the skin by cercariae. The second strategy is seen among the so-called foodborne digeneans (21), a diverse assemblage of species which enter humans with ingested food (Fig. 2).

Two features of the digenean life cycle are noteworthy. First, digeneans often display high specificity in their choice of first intermediate host. So intimate are these host-parasite associations that the geographical distribution of a digenean is determined largely by that of its snail host. For this reason, many digeneans show a focal distribution in countries where they are endemic. Second, most human parasites are zoonotic, requiring the cooccurrence of other mammalian or avian hosts in an area of endemicity to maintain human infection (26).

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

Observation of eggs in human excreta is diagnostic for all digeneans of humans. With few exceptions (17, 33), the eggs have a distinct morphology and their presence is pathognomonic of specific infection. Despite the diverse range of body sites infected by adult trematodes, the eggs of most species are voided with feces. Exceptions to this include *Schistosoma haematobium,* and rarely other schistosomes, whose eggs are excreted with urine, and *Paragonimus* species, whose eggs may be observed in sputum.

Detailed instructions on handling of human fecal material are provided in chapter 133. Digenean eggs range in size from 20 to 150 μm and can be identified with low-power objective lenses (i.e., 10× and 40× lens objectives). There is great variation in egg sizes among different species and, in areas where fasciolids are endemic, for example, it is important to scan slides at lower magnification. Whereas the eggs of most digeneans are unembryonated when excreted, the eggs of schistosomes and some other groups contain fully differentiated larvae in feces or urine. The eggs of schistosomes hatch spontaneously upon exposure to freshwater. Although observations of viable schistosome miracidia may be advantageous for species identification, spontaneous hatching may hinder direct observations of eggs. Fresh stool samples or stained preparations can be used for direct examination. Sedimentation techniques (chapter 135) may be useful for diagnosis in light, early, or chronic infections, when egg excretion is low. Among currently available diagnostic techniques, the Kato-Katz thick smear is a standard method for qualitative and quantitative field diagnosis of intestinal schistosomiasis and geohelminth infections (2, 6, 27).

The eggs of human parasitic digeneans are ovoid, usually with a yellow to brown, translucent shell (see Fig. 4). The eggs usually are without adorning features, although diagnostic spines and polar ridges and an operculum ("lid") may be present. Diagnostic features, therefore, are the shape and size of the egg, texture and adornments of the eggshell, the presence or absence of an operculum, and the extent of postzygotic development of the embryo.

DIGENEANS OF THE CIRCULATORY SYSTEM—SCHISTOSOMES

Schistosome species responsible for human disease are shown in Table 1, along with their distribution, snail hosts, and treatment. Currently, 200 million people in 74 countries have schistosomiasis, although 85% of cases occur in sub-Saharan Africa (10). Of these, some 120 million people are symptomatic and 20 million have severe illness.

Taxonomy

Schistosomes are characterized by dioecious adults, cercariae with a forked tail and a two-host life cycle (Fig. 1). Adult schistosomes occupy an intravascular site, either in the mesenteric vessels or the vesical plexus. Five species

TABLE 1 Geographical distribution, intermediate hosts, and egg morphology of the major schistosomes infecting humans

Species	Disease and geographic area	Snail hosts	Drug	Eggs (specimen and size)
S. mansoni	Intestinal schistosomiasis, infecting humans and sometimes other mammals: Angola, Benin, Botswana, Burkina Faso, Burundi, Cameroon, Central African Republic, Chad, Republic of the Congo, Cote d'Ivoire, Democratic Republic of Congo, Equatorial Guinea, Eritrea, Ethiopia, Gabon, The Gambia, Ghana, Guinea, Guinea-Bissau, Kenya, Liberia, Madagascar, Malawi, Mali, Mauritania, Mozambique, Namibia, Nigeria, Rwanda, Senegal, Sierra Leone, South Africa, Swaziland, Togo, Uganda, Tanzania, Zambia, Zimbabwe, Egypt, Libya, Oman, Saudi Arabia, Somalia, Sudan, Yemen, Antigua, Brazil, Dominican Republic, Guadeloupe, Martinique, Montserrat, Puerto Rico, St. Lucia, Suriname, Venezuela	*Biomphalaria* species. In Africa and Asia: many species in *B. alexandrina, B. choanomphala, B. pfeifferi, B. sudanica* species groups. In Americas: *B. glabrata* and 2 other species.	P,[a] 20 mg/kg, 2–3 doses. Community programs usually give 40 mg/kg in single dose.	Feces (rarely urinary). Size: 140 by 61 μm
S. japonicum	Intestinal schistosomiasis, infecting humans and bovines: China, Indonesia, Philippines	*Oncomelania hupensis, O. nosophora, O. formasona, O. hupensis quadrasi,* and *O. lindoensis*	As above, but 60 mg/kg in single dose in community programs	Feces. Size: 85 by 60 μm
S. haematobium	Genitourinary schistosomiasis: Algeria, Angola, Benin, Botswana, Burkina Faso, Burundi, Cameroon, Central African Republic, Chad, Republic of the Congo, Cote d'Ivoire, Democratic Republic of Congo, Egypt, Ethiopia, Gabon, The Gambia, Ghana, Guinea, Guinea-Bissau, Iran, Iraq, Jordan, Kenya, Lebanon, Liberia, Libya, Madagascar, Malawi, Mali, Mauritania, Mauritius, Morocco, Mozambique, Namibia, Niger, Nigeria, Oman, Saudi Arabia, Senegal, Sierra Leone, Somalia, South Africa, Sudan, Swaziland, Syria, Togo, Tunisia, Uganda, Tanzania, Yemen, Zambia, Zimbabwe	*Bulinus* species. Many species in the *B. (Physopsis)* and *B. (Bulinus)* subgenera of *Bulinus*.	As for *S. mansoni*	Urine (rarely feces). Size: 150 by 62 μm
S. mekongi	Intestinal schistosomiasis: Cambodia, Laos, Thailand	*Neotricula aperta*	As for *S. japonicum*	Feces. Size: 57 by 66 μm
S. intercalatum	Rectal schistosomiasis: Cameroon, Central African Republic, Chad, Republic of the Congo, Democratic Republic of Congo, Equatorial Guinea, Gabon, Mali, Nigeria, Sao Tome, and Principe	*Bulinus (Physopsis) africanus, Bulinus (B.) camerunensis*		Feces. Size: 176 by 66 μm
S. bovis, S. mattheei, S. margrebowiei	African schistosomes infecting bovines and wildlife. Rare human infections.	*Bulinus* spp.		
S. sinesium, S. malayensis	Asian schistosomes infecting animals. Rare human infections.			
Species of *Austrobilharzia, Gigantobilharzia,* and *Trichobilharzia*	Swimmers' itch, cercarial dermatitis, worldwide distribution	*Bulineus, Lymnaea, Nassarius, Physa, Planorbis, Stagnicola*		Eggs not observed in humans

[a] P, praziquantel.

TABLE 2 Geographical distribution, hosts, and life histories of lung and hepatic digeneans of humans

Family	Species	Location in human host	Disease and geographic area	Snail hosts	Source of metacercariae	Human infection	Drug[a]	Eggs (specimen and size)
Fasciolidae	*F. hepatica* and *F. gigantica*	Bile ducts	Fasciolosis, worldwide as disease of livestock; humans: Australia, Bolivia, China, Cuba, Egypt, Ecuador, Iran, North Africa, Peru, Portugal, Turkey, Vietnam	*Lymnea truncatulata, L. tomentosa, L. viatrix*	Vegetation: wet grass, watercress, water mint, semiaquatic vegetables	Emerging disease, 2.4 million infections worldwide	T, 10 mg/kg	Feces. Size: *F. hepatica,* 130–150 by 60–85 μm; *F. gigantica,* 160–190 by 70–90 μm.
Opisthorchiidae	*C. sinensis, O. viverrini,* and *O. felineus*	Bile ducts	Opistorchiasis/clonorchiasis, China, former Soviet Union, Cambodia, Korea, Laos, Taiwan, Thailand, Vietnam	*C. sinensis:* various freshwater snails *(Alocinma, Bulinus, Parafossarulus) O. viverrini* and *O. filineus:* freshwater snails from genus *Bithynia* and related genera	Many species (>100) of freshwater fish	Focal but major disease in Thailand. Strong association with cholangiocarcinoma for *O. viverrini.*	P, 25 mg/kg for 2 days	Feces. Size: *C. sinensis,* 23–35 by 10–20 μm, *O. viverrini* and *O. felineus,* 30 by 12 μm.
Opisthorchiidae	*O. guayaquilensis, Metorchis albidus, M. comjunctus, Pseudamphistomum aethiopicum, P. truncatum*	Bile ducts	Opisthorchiasis: Asia	Not listed	Fish	Rare cases		
Troglotrematidae	*Paragonimus africanus, P. heterotremus, P. mexicanus, P. miyazakii, P. skrijabini, P. uterobilateralis, P. westermani*	Pulmonary cysts, also abdominal cavity, brain	Paragonimiasis: Cameroon, China, Colombia, Costa Rica, Cote d'Ivoire, Ecuador, Equatorial Guinea, Gabon, Guatemala, Honduras, India, Indonesia, Japan, Laos, Liberia, Malaysia, Mexico, Nepal, Nicaragua, Nigeria, North Korea, Panama, Papua New Guinea, Peru, Philippines, Poland, Russian Federation, Samoa, South Korea, Sri Lanka, Taiwan, Thailand, Venezuela, Vietnam	Operculate snail: *Semisulcospira, Thiara, Oncomelania*	Freshwater crabs, crayfish	Focal, but high prevalence in areas of endemicity, major cause of human disease. Pulmonary disease and more rarely extrapulmonary infection in brain and body cavity	T, 20 mg/kg; P, 35 mg/kg for 3 days	Feces, sputum. Size: varies with species.
Dicrocoeliidae	*Dicrocoelium* species	Bile ducts	Dicrocoeliasis: human cases in Czech Republic, Kenya, Nigeria, Russian Federation, Saudi Arabia, Somalia, Spain, United States	Land snails: Order Stylommatophora	Insects (ants)	Rare disease in humans. Spurious infections brought about by ingestion of infected animal livers	P?	Fecal, bile. Size: 38–45 by 22–30 μm; brown, thick-walled, embryonated, operculate

[a] T, triclabendazole; P, praziquantel.

TABLE 3 Digeneans of the human intestine[a]

Family	Genera	Disease and geographic area	Snail hosts	Source of metacercariae	Human infection	Drug[b]	Eggs (specimen and size)
Echinostomatidae	*Echinochasmus, Echinoparyphium, Echinostoma, Episthmium, Euparpyhium, Himasthla, Hypoderaeum, Paryphostomum*	Echinostomiasis: China, Egypt, Hungary, India, Indonesia, Italy, Japan, Korea, North and South America, Philippines, Romania, Singapore, Taiwan, Thailand	Families Viviparidae, Planorbidae	Fish (loach), molluscs (snails, clams), amphibians (tadpoles, frogs)	Focal, prevalence 5–44%	P	Feces. 100 by 65–70 μm.
Fasciolidae	*Fasciolopsis*	Fasciolopsiasis: Bangladesh, Cambodia, China, India, Indonesia, Korea, Laos, Pakistan, Taiwan, Thailand, Vietnam	Family Planorbidae	Water plants (water chestnut, caltrop, lotus roots, bamboo), other aquatic vegetation	Widespread but focal; prevalence rates up to 60% in children	P, 15–40 mg/kg; MB, 100 mg/kg	Feces. 130–140 by 80–85 μm.
Gastrodiscidae	*Gastrodiscoides, Gastrodiscus*	Gastrodiscoidiasis: China, India, Myanmar, Philippines, Russia, Thailand, Vietnam	*Helicorbus*	Squid, plants, crustaceans (crayfish), amphibians (frogs, tadpoles)	Rare, focal	NR	Feces. 127–169 by 62–75 μm.
Heterophyidae	*Appophalus, Centrocestus, Cryptocotyle, Diorchitrema, Haplorchis, Heterophyes, Heterophyopsis, Metagonimus, Phagicola, Procercovum, Pygidiopis, Stellantchasmus, Stichodora*	Metagonimiasis or heterophyiasis: Balkans, Brazil, China, Egypt, Greenland, Indonesia, Israel, Japan, Korea, Philippines, Russia, Spain, Sudan, Taiwan, Tunisia, Turkey, United States	Families Thiaridae, Littoriniidae	Fish (freshwater or brackish, carp, mullet, cyprinoids), crustaceans (shrimp)	Low prevalence, but common; cases with heavy infections of clinical significance	P, 10–20 mg/kg	Feces
Nanophyetidae	*Nanophyetus salmincola*	Nanophyetiasis: Russia, United States	*Oxytrema silicula*	Fish (salmon, trout)	Rare	P	64–97 by 34–55 μm

[a] Modified from Fried et al. (13).
[b] Abbreviations: P, praziquantel; MB, mebendazole, NR, not recorded.

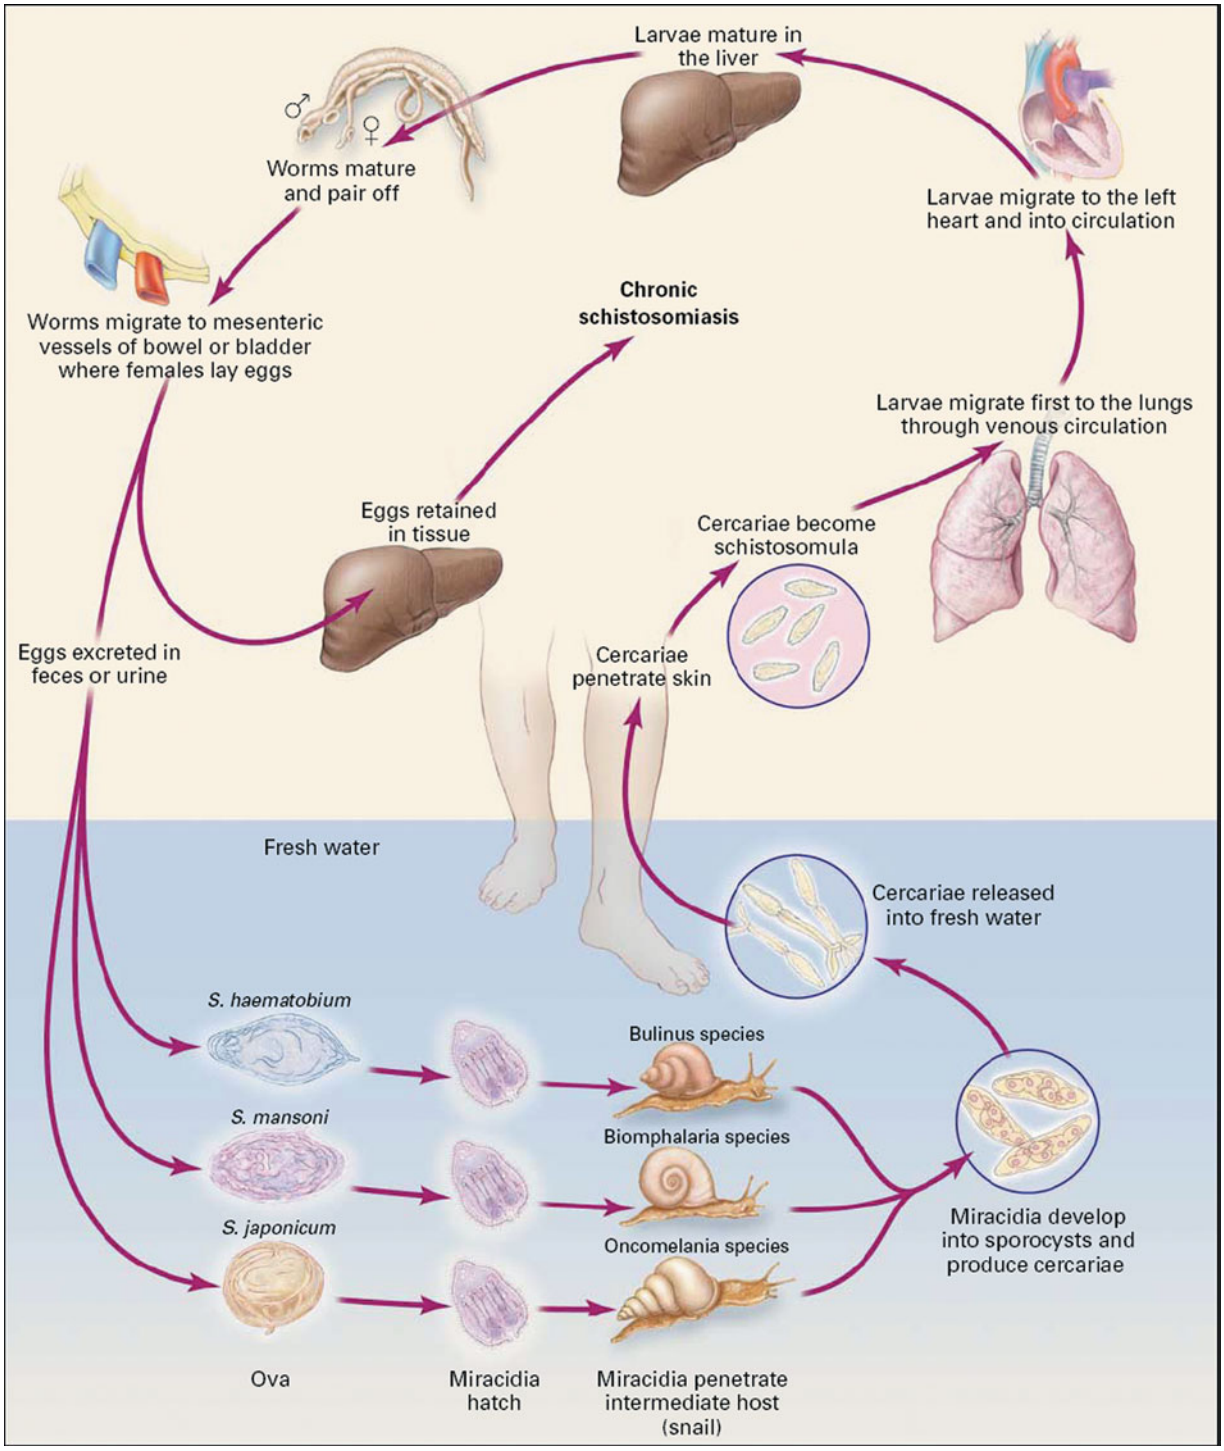

FIGURE 1 Five species of *Schistosoma* are known to infect humans. Infection with *Schistosoma mansoni, S. japonicum, S. mekongi,* or *S. intercalatum* adults occurs in mesenteric veins; *S. haematobium* adults occur in the vesical plexus. Humans are infected after cercarial penetration of the skin. After penetration, the cercariae shed their bifurcated tails, and the resulting schistosomula enter capillaries and lymphatic vessels en route to the lungs. After several days, the worms migrate to the portal venous system, where they mature and unite. Pairs of worms then migrate to the site of patent infection. Egg production commences 4 to 6 weeks after infection. Eggs pass from the lumen of blood vessels into adjacent tissues, and many then pass through the intestinal or bladder mucosa and are shed in the feces or urine (see the text). In freshwater, the eggs hatch, releasing miracidia that, in turn, infect specific freshwater snails (Table 1). Reprinted from the *New England Journal of Medicine* (32), used with permission.

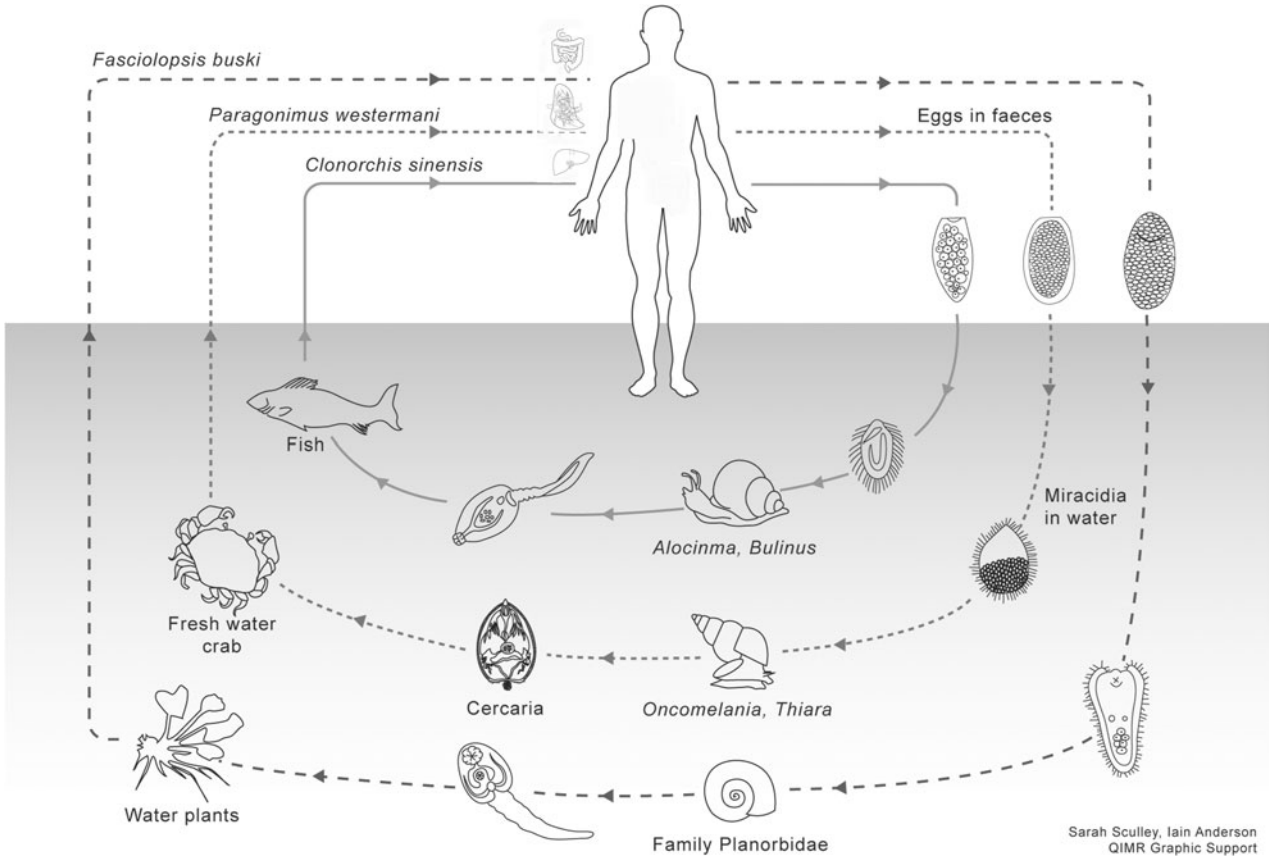

FIGURE 2 Life cycles of some foodborne trematodes, exemplified by *C. sinensis,* a parasite of human liver and bile ducts, *P. westermani,* a parasite of human lungs, and *F. buski,* an intestinal parasite. The life cycles of all species involve a snail as first intermediate host. After reproductive generations in the snail, a cercaria emerges which encysts in or on the second intermediate host or on vegetation. The second intermediate host for each species is listed in Table 2. Adapted from an illustration from the *Atlas of Medical Parasitology* (http://www.cdfound.to.it/HTML/atlas.htm), used with permission.

commonly infect humans, of which three (*S. mansoni, S. japonicum,* and *S. haematobium*) are the most important (Table 1). Morphological descriptions of adult worms, which are not encountered in diagnostic samples, are summarized elsewhere (28).

Hepatosplenic Schistosomiasis

The most extensively studied schistosome, *S. mansoni,* occurs throughout sub-Saharan Africa, Egypt, the Middle East, Madagascar, eastern countries of South America, and some islands of the Caribbean (Table 1). It is believed that the species was carried to South America with the slave trade. The distribution of this parasite overlaps that of *S. haematobium* in many parts of Africa. *Schistosoma japonicum* is responsible for significant disease in foci in Asia (10) (Table 1) and has been eradicated from Japan. Schistosomiasis in the Mekong Basin, once attributed to *S. japonicum,* is now known to be caused by *Schistosoma mekongi.* Sustained control efforts in China have reduced the number of infected people from approximately 12 million to 1 to 2 million by the late 1980s and less than 1 million in 1998 (9, 10). Unlike most other human schistosomes, *S. japonicum* is a zoonosis, and large bovines, especially water buffalo, are of primary concern in perpetuating the life cycle (26). Control strategies in China are directed at mass or targeted chemotherapy of humans and zoonotic hosts, thereby minimizing human morbidity due to schistosomiasis.

S. mekongi has a highly focal distribution in the Mekong Basin, with foci of endemicity in Laos and Cambodia (4). Although originally regarded as a subspecies of *S. japonicum,* the species was recognized as distinct based on morphological characteristics and life cycle patterns. In 1990, some 80,000 people of an at-risk population of over 150,000 people were infected, but the number of infected individuals was reduced to 7,000 by mass chemotherapy (34). After cessation of chemotherapy campaigns, prevalence has increased again in Laos (9).

Schistosoma intercalatum is responsible for rectal schistosomiasis in regions of Africa. The species occurs as two geographically isolated strains (now considered as distinct species [19]), the Cameroon and the Democratic Republic of Congo strains, which display highly focal distribution (10). This parasite belongs to the *S. haematobium* group of species, characterized by, among other features, eggs with a terminal spine (compare with Fig. 3).

Genitourinary Schistosomiasis

S. haematobium, the sole agent of urinary schistosomiasis, occurs in much of the African continent as well as Madagascar and the Middle East (10, 28) (Table 1). Adult

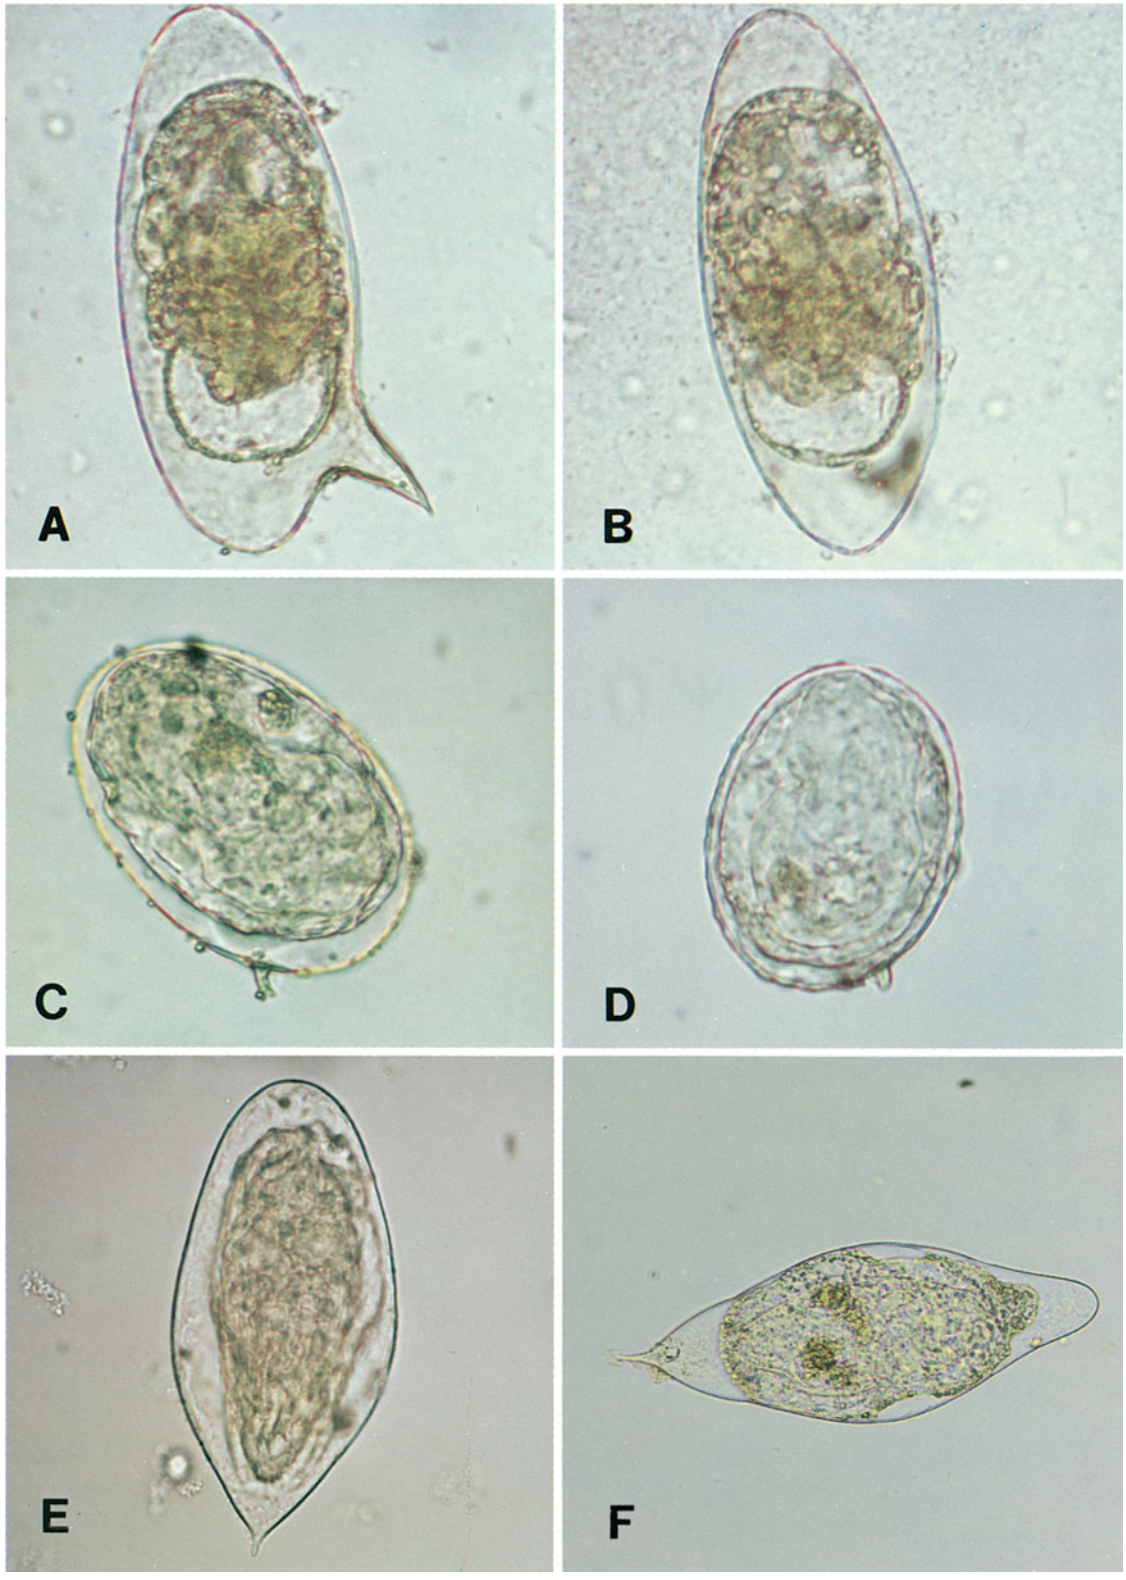

FIGURE 3 Eggs of schistosome species (magnification, ×600). (A) *S. mansoni;* (B) *S. mansoni* egg with typical lateral spine not in view; (C) *S. japonicum;* (D) *S. mekongi;* (E) *S. haematobium;* (F) *S. intercalatum.* (Panels C through E are from reference 3; used with permission.)

worms live in the vesical plexus, and eggs pass from the host across the bladder wall and are excreted with urine.

Epidemiology, Transmission, and Prevention

The life cycles of schistosomes are shown in Fig. 1. Humans are infected through direct penetration of the skin by cercariae. Endemicity is governed by the geographic distribution of snail hosts. The recent development of large-scale dams in countries of endemicity has led to changes in transmission dynamics (10). The impact of the Three Gorges Dam in China on the transmission of *S. japonicum* is uncertain but may lead to increased geographical distribution of the parasite in that country (26). Within regions of endemicity, factors contributing to schistosome transmission include the distribution biology and population dynamics of the snail hosts, extent of contamination of freshwater with feces or urine, and degree of exposure of humans to contaminated water.

Clinical Significance

Cercarial dermatitis occurs in schistosomiasis but is more commonly reported after infection with avian schistosomes (Table 1) and *Schistosoma spindale.* Acute toxemic schistosomiasis (Katayama fever) can occur with any schistosome species but is more apparent in nonimmune individuals and may be characterized by fever, headache, generalized myalgias, right-upper-quadrant pain, and bloody diarrhea (32).

Eggs (Fig. 3) are laid by female worms in the vasculature and must traverse endothelia and gut or bladder mucosa to escape the body. In those schistosomes infecting mesenteric veins, eggs pass through the wall of the intestine or rectum, while for *S. haematobium,* the eggs escape across the bladder wall. For all species, however, many ova become entrapped in tissues. The chronic effects of schistosomiasis, therefore, relate to the site of adult infections and granulomatous and fibrotic responses to entrapped parasite eggs (32). Granulomas occur in many tissues in response to entrapped eggs; however, most accumulate in tissues fed by vasculature leading from the site of infection. Eggs retained in the gut wall induce inflammation, hyperplasia, and ulceration, and occult blood occurs in the feces. A suggested relationship between colorectal cancer and schistosomiasis remains controversial (31). Eggs entrapped in the liver lead to portal hypertension and splenic and hepatic enlargement, potentially giving rise to the formation of fragile esophageal varices. Ascites also is common.

In urinary schistosomiasis, granulomatous inflammatory response to embolized eggs gives rise to dysuria, hematuria, and proteinuria, calcifications in the bladder, obstruction of the ureter, renal colic, hydronephrosis, and renal failure. Secondary bacterial infection of the bladder and other affected tissues may occur. There is consistent association between *S. haematobium* infection and squamous-cell carcinoma of the bladder (32). *S. haematobium* infection causes genital disease in approximately one-third of infected women, leading to vulval and perineal disease and tubal infertility, and may facilitate the transmission of human immunodeficiency virus.

Direct Examination

The presence of schistosome eggs (Fig. 3) (3) in feces or urine is diagnostic of schistosomiasis. Eggs of hepatosplenic schistosomes may be observed by light microscopy in stool specimens with or without suspension in saline. Formalin-based techniques for sedimentation and concentration are particularly useful, especially for patients releasing few eggs. Hatching tests, in which fecal matter is suspended in nonchlorinated water in darkened vessels with directed surface light, have been used to detect motile miracidia. It is often important to observe larval activity (flame cell beating or miracidial swimming) in eggs for diagnosis of active infection. In chronically infected patients with a typical clinical presentation but with negative urine and feces specimens, a biopsy of bladder or rectal mucosa must be used for diagnosis. However, parasitological examination remains the most sensitive diagnostic procedure available.

Examination of stools with the Kato-Katz technique is used in field studies for quantification of fecal egg burdens. The Kato-Katz method gives a theoretical sensitivity cutoff of 20 eggs per g of feces (12), but large daily variation in egg shedding and the uneven distribution of eggs in feces may lead to inconsistent counts. It has been recommended for *S. mansoni* infections that either five replicate slides or sets of triplicate slides made from stools collected on two successive days be used for assessment of infection status (6).

Sedimentation or concentration methods are most useful for diagnosis of *S. haematobium* from urine samples. In addition, the use of tests for blood, protein, and eosinophils in urine, while not specific, may be indicative of infection (1). Serological detection of schistosome infections is useful, but its use is limited because antibodies persist after parasitologic cure and because of problems of cross-reactivity (32). A positive serologic test may be diagnostic for patients for whom there are no excreted eggs. Enzyme-linked immunosorbent assays (ELISA) and immunoblot tests using soluble egg antigen and recombinant antigens are used (1), as are tests for evidence of peripheral-blood eosinophilia, anemia, hypoalbuminemia, elevated urea and creatinine levels, and hypergammaglobulinemia (1, 32). Portable ultrasound is useful for assessment of pathologic damage to tissues. The use of questionnaires for populations in which the disease is endemic is helpful in revealing infections caused by *S. japonicum* and *S. haematobium,* but for *S. mansoni* this method may lead to underestimation of prevalence (36).

PCR tests for schistosomes in stools use high-repeat nuclear genomic (30) or mitochondrial sequences (14). Both tests report high sensitivity, at times exceeding that of direct coprological examination. The mitochondrial sequence probes, which amplify sequences spanning the *cox2/nad6* genes for *S. japonicum* and *S. mansoni, nad1-2* for *S. japonicum,* and *nad5* for *S. mansoni,* show absolute specificity and an absence of false-positive reactions (14).

Treatment

The drug of choice for schistosomiasis, and effectively the only drug available for use, praziquantel, has seen widespread application in many regions of endemicity. There has been spectacular success in mass treatment campaigns with praziquantel in many countries, and its use has become more widespread because the cost of drug production has reduced dramatically in recent years. Despite this, the anthelmintic has some limitations, being effective against only adult forms in which it induces spastic muscle contractions and tegument degradation (15). Praziquantel has been suggested as a compound therapy with oxamniquine, and there have been reports of efficacy with triclabendazole (35). The development of praziquantel-resistant schistosomes cannot be discounted.

The effects of artemesinin derivatives against schistosomes have been studied in experimental model and clinical field settings. Artemether acts against schistosomules and may provide protection against reinfection (5). The use of artemether is contraindicated in areas in which malaria is coendemic, since widespread use may lead to drug resistance in *Plasmodium.*

Schistosome Dermatitis (Swimmer's Itch)

This minor ailment arises from infection with a number of avian and mammal schistosomes (Table 1). The avian schistosome cercariae cannot migrate from the dermal layers of human skin and induce local dermatitis accompanied by itching, pruritus, and papule formation.

FOODBORNE DIGENEANS

All other digeneans we will consider are a diverse assemblage of taxa, some of which infect humans through ingestion of uncooked food (Fig. 2; Tables 2 and 3). The vast majority of these species are zoonotic. The primary epidemiological features governing human infection include the distribution of suitable snail intermediate hosts, human food consumption behaviors, the presence of suitable zoonotic hosts, and the potential for water contamination with human or animal excreta.

Trematodes of the Respiratory System—*Paragonimus* (Troglotrematidae)

Taxonomy

Paragonimiasis is caused by a number of species distributed throughout Asia, Africa, and the Americas (Table 2). The most common species infecting humans is *Paragonimus westermani,* which occurs in China and other Southeast Asian nations. Adult *Paragonimus* species inhabit the lungs, where they induce formation of encapsulating cysts. The flukes are large and fleshy, measuring 8 to 16 by 4 to 8 mm. Taxonomic information on the species is presented elsewhere (7).

Epidemiology, Transmission, and Prevention

The life cycle of *Paragonimus* is shown in Fig. 2 and Table 2. Of the more than 40 species, 9 have been recorded as human parasites. Eggs are passed in the lungs and are transferred up the bronchial tree with sputum. Eggs may be spat with sputum or swallowed and passed with feces. The first intermediate hosts are freshwater snails. Human infection arises after ingestion of uncooked or marinated freshwater crabs or crayfish (1), but unwashed hands of food preparers and contaminated utensils also may be a source of human infection. After ingestion, the immature flukes penetrate the intestinal wall and migrate to the lungs through the body cavity. All species are zoonotic, infecting carnivores, pigs, and rodents.

Clinical Significance

Some 20.7 million people have paragonimiasis, and a further 195 million are at risk of infection. Signs of infection include fever with dry cough, sometimes blood-stained sputum containing eggs, chest pain, dyspnea, and bronchitis, and symptoms sometimes resemble those of pulmonary tuberculosis. Peripheral blood eosinophilia is common. The flukes induce the formation of an epithelial cyst, measuring approximately 1 cm in diameter, and which may calcify over time. Parasites may also occur in extrapulmonary locations, and serious complications occur when parasites are found in the brain. The necrosis of brain tissues and extensive granulomatous inflammatory response may induce symptoms similar to those of cerebral cysticercosis, caused by the cestode *Taenia solium* (1).

Diagnosis

Diagnosis of paragonimiasis is largely dependent on observation of the eggs (3) (Table 2 and Fig. 4) in sputum, feces, or pleural effusions. A cough with brown sputum is indicative of lung infection, and the sputum should be examined for eggs. The cysts formed around adult worms appear in X rays as characteristic rings or nodules, but direct observation of eggs is required to differentiate the disease from pulmonary tuberculosis. Serological tests include ELISAs using either 32- and 35-kDa antigens or parasite yolk ferritin as antigen (1). Pleurisy with eosinophilia and a dominant immunoglobulin M antibody titer may be indicative of paragonimiasis (29). A PCR-based method to detect a 500-bp sequence of nuclear genomic DNA has been used for molecular diagnosis in experimental models of *Paragonimus heterotremus* (16).

Treatment

The current WHO recommendation for treatment is administration of triclabendazole at 20 mg/kg of body weight in two divided doses (20). Praziquantel, administered at 25 mg/kg for 2 to 3 consecutive days, has been used (20).

Trematodes of the Liver

At least 13 species of flukes, belonging to the families Fasciolidae, Opisthorchiidae, and Dicrocoeliidae (18) (Table 2), have been recorded as adult worms from the liver and bile ducts of humans. Most human liver fluke species belong to the family Opisthorchiidae. Infections with members of the family Dicrocoeliidae are not considered further here. Brief information on the family is provided (Table 2), and the reader is referred to other reviews (28).

Family Opisthorchiidae

Taxonomy

Of the opisthorchiid parasites infecting humans (Table 2), only three species are of major significance, namely, *Opisthorchis viverrini, Opisthorchis felineus,* and *Clonorchis sinensis.* Adult opisthorchiids of humans are macroscopic, flattened flukes, approximately 5 to 10 mm in length.

Epidemiology, Transmission, and Prevention

The life cycle information is presented in Fig. 2 and Table 2. In opisthorchiids, the metacercariae are found encysted in the muscles of cyprinid fish (18). In regions of high endemicity, infection rates can be as high as 90% in humans and up to 97% in fish hosts. Individuals are infected by eating undercooked fish. In Thailand, consumption of traditional foods, including marinated fish, leads to infection with *O. viverrini* (33).

Clinical Significance

Disease severity varies among the different species (33) and with the intensity of infection. *C. sinensis* infects approximately 7 million people in China, Hong Kong, India, North Korea, Siberia, Taiwan, and Vietnam. *O. viverrini* infects about 9 million people in Thailand, Laos, and Cambodia, and *O. felineus* is widespread throughout Northern Europe and Asia, infecting about 1.5 million people. All three species live in the bile duct and are thought to feed on biliary epithelia. Light infections are usually asymptomatic, but heavy infections can induce disease. Symptoms most commonly are associated with an acute phase of infection and may include fever, abdominal pain, hepatitis-like symptoms, and eosinophilia. A number of asymptomatic hepatobiliary abnormalities are associated with infection (24). A strong correlation exists between chronic *O. viverrini* infections and cholangiocarcinoma.

Diagnosis

Eggs of opisthorchiids (Fig. 4) are embryonated when laid, are oval and yellowish brown, and are operculate, with

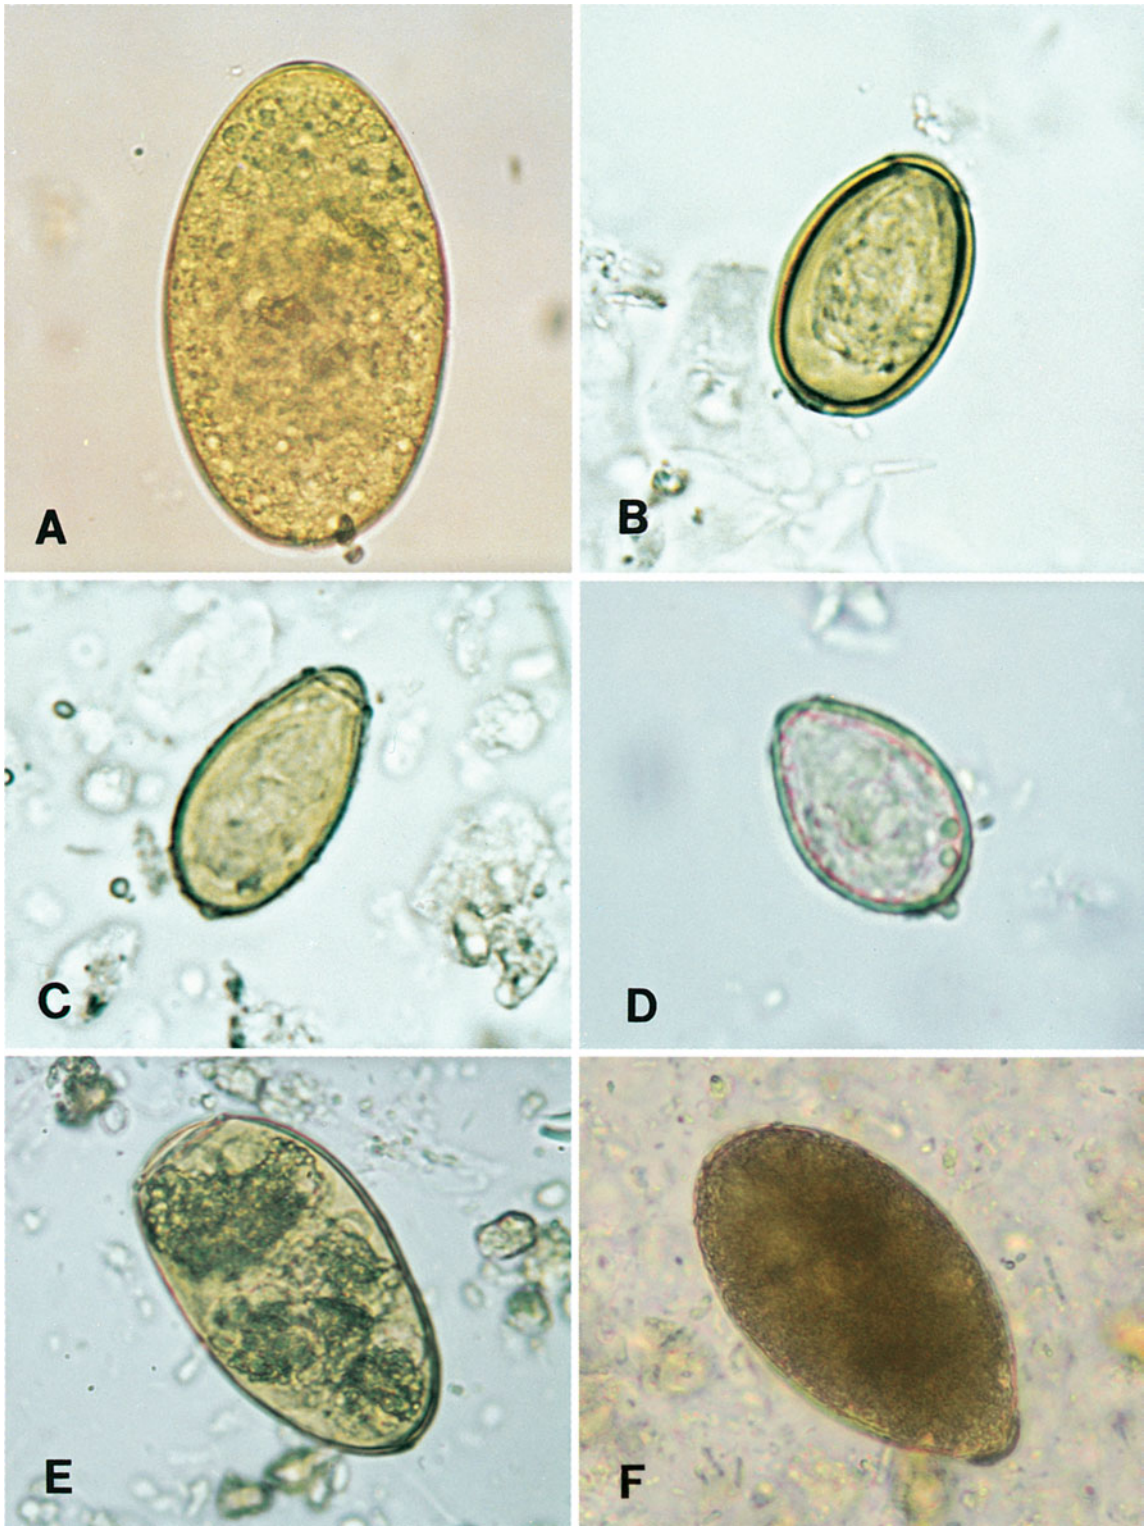

FIGURE 4 Eggs of trematode parasites. (A) *F. buski* (magnification, ×500); (B) *H. heterophyes* (magnification, ×1,500); (C) *C. sinensis* (magnification, ×1,500); (D) *O. viverrini* (magnification, ×1,500); (E) *P. westermani* (magnification, ×600); (F) *N. salmincola* (magnification, ×750). (Panels B through D are from reference 3; used with permission.)

a shoulder or thickened region of eggshell surrounding the operculum. The shell surface may appear rough and may have a small knob at the abopercular pole of the egg (18). The eggs are smaller than those of many other digeneans of humans, ranging from 20 to 35 μm in length. Opisthorchiid eggs may be confused with those of other taxa, especially the heterophyids (see below). Differential diagnosis may be arrived at by patient history and by examination of purged worms in feces after anthelmintic treatment.

Many antigen assays for *O. viverrini* have been tested, but most are plagued by cross-reactivity problems and persistence of antibodies after parasitologic cure (37). A coproantigen ELISA has been developed using monoclonal antibodies raised against adult *O. viverrini* E/S antigen and has displayed high specificity and sensitivity, whereas ELISAs for circulating antibodies show high sensitivity but low specificity (1). A PCR test, based on a 334-bp molecular probe amplifying a highly repetitive nuclear genomic sequence, also shows promise (37). Recently, a multiplex PCR assay using mitochondrial sequences has been developed for opisthorchioids of humans. For this assay, the single reaction uses two sets of primers designed for a 612-bp product corresponding to the *nad2-V-A-D-nad1* region of the mitochondrial genome of *C. sinensis* and for a 1,357-bp product spanning *nad1-N-P-I-K-nad3* for *O. viverrini* (23).

Treatment

Treatment for clonorchiasis or opisthorchiasis relies on oral administration of praziquantel. The benzimidazole drugs, albendazole and mebendazole, have been tested in animal models and clinical trials, with encouraging efficacy, as has artemether (20).

Family Fasciolidae

Taxonomy

Fascioliasis, caused by flukes of the genus *Fasciola,* is primarily a disease of herbivorous mammals. Until recently, fascioliasis was considered a sporadic infection of humans, but estimates indicate that some 2.4 million persons in 61 countries are infected and there are 180 million individuals at risk throughout the world (25). The two causative species, *Fasciola hepatica* and *Fasciola gigantica,* have a worldwide distribution in domesticated animals; human disease is focal and regions where human fascioliasis is endemic are recognized (1, 25, 28).

Epidemiology, Transmission, and Prevention

Fasciolid metacercariae encyst on semiaquatic or moistened vegetation, predominantly watercress, grass, water mint, or salad vegetables (Fig. 2 and Table 2). The frequency of the parasites in domesticated animals does not necessarily correlate with human disease. Areas of low human endemicity include regions of France and Chile; regions of high endemicity are in Peru and Bolivia (25). Most of the areas with high endemicity are regions where *F. hepatica* is present. While common zoonotic hosts are cattle and sheep, other hosts, such as pigs, equines, and rats, may serve as reservoir hosts for human infection. Children more commonly are infected than adults, suggestive of the development of an age-dependent immunity (38).

Clinical Significance

Many infections with fasciolids remain asymptomatic. Acute disease arises because of extensive tissue damage as parasites migrate through the hepatic parenchyma to gain access to the bile ducts. Parasite activity in the bile ducts leads to proliferation of ductal epithelium, inflammation, and fibrosis. Heavy infections can lead to cholestasis and result in hepatic atrophy and periportal cirrhosis (1). Common symptoms in chronic infection include biliary colic and cholangitis. Eosinophilia is common in all stages of disease.

Diagnosis

The eggs of fasciolids are large compared with those of other digeneans (Table 2). *Fasciola* eggs cannot be distinguished from those of the related intestinal parasite *Fasciolopsis buski* (Fig. 4) and also resemble those of *Gastrodiscoides* (Table 3). Liver fasciolids have a long (2-month) prepatent period, and because of this, fascioliasis is one disease where serological diagnosis is valuable. Immunological tests, particularly ELISA, based on a cysteine protease, display high sensitivity and specificity (11).

Treatment

Fasciola species appear to be insensitive to praziquantel, and triclabendazole is the drug of choice (Table 2). Recently, there have been reports of triclabendazole-insensitive isolates in livestock and humans (20). New derivatives of triclabendazole are being tested in clinical trials for use in humans (20).

Trematodes of the Intestine

Most trematodes infecting humans are parasites of the intestine and, of these, most belong to two families, the Echinostomatidae and Heterophyidae. Fried et al. (13) list the digenean families with species parasitizing humans, of which we will mention the two families above and the Fasciolidae and Nanophyetidae. Summary information on some families of intestinal trematodes is presented in Table 3. Families Brachylaimidae, Diplostomidae, Gymnophallidae, Lecithodendriidae, Microphallidae, Paramphistomatidae, Plagiorchiidae, and Strigeidae are rarely encountered in humans and are not considered further in this chapter. For further information on intestinal trematodes not provided here, the reader is referred to chapter 148 and to Fried et al.

Echinostomatidae

Echinostomatid flukes are small, typically 3 to 10 mm in length and 1 to 3 mm in width, with a large ventral sucker and distinctive collared spines. At least 24 species are known to parasitize humans, mostly in Asia (Table 3). All species are zoonotic and focal in distribution, and foci are often in the vicinity of fresh- or brackish water habitats. Humans are infected by eating a range of raw or undercooked vertebrate and invertebrate foods (Table 3), including snails. In most cases, infection is asymptomatic. Heavy infections can lead to a range of symptoms including flatulence, colic, and diarrhea. Some heavy infections in children have been fatal. Eggs of echinostomatids are similar in shape to those of fasciolids but are smaller (Table 3). Interspecific variation in egg size occurs among the echinostomes, and species identification is not possible unless adult worms are obtained by purgation with anthelmintics. A single dose of praziquantel is recommended for treatment (20).

Fasciolidae

Fasciolopsis buski is the largest fluke parasitizing humans, measuring 8 to 10 cm in length and 1 to 3 cm in width (22). Adult worms inhabit the duodenum and jejunum of humans and a small range of other hosts that include pigs, horses, cattle, goats, and sheep. The species is distributed focally in many countries (Table 3). Adults attach and feed on the

intestinal wall. Human disease relates to the severity of infection, and symptoms vary from intestinal disturbance and pain, associated with eosinophilia, to severe diarrhea, gastric pain, bowel obstructions, and nausea. Feces are often profuse, are yellow-green, and may contain undigested food particles. The intermediate hosts of *F. buski* are shown in Table 3. Humans are infected by eating aquatic plants on which metacercariae are encysted or by drinking metacercariae that have encysted on the water surface (13).

The eggs of *F. buski* are large, operculate, nonembryonated, ellipsoidal, and yellow (Table 3 and Fig. 4). The eggs are very similar to those of other fasciolids from which species may be distinguished by observation of purged adults. The current drug of choice is praziquantel, but albendazole and mebendazole have also been tested (13, 20).

Heterophyidae

Many species of heterophyid trematodes are known to infect humans (8, 13). Heterophyids are mostly small parasites, less than 0.5 mm in length. Some species are marine. The most commonly encountered heterophyids of humans are *Heterophyes heterophyes* and *Metagonimus yokogawai.* The former species has been reported in humans from Egypt, Sudan, Iran, Turkey, Tunisia, China, Taiwan, the Philippines, Indonesia, and India (13). *M. yokogawai* is common in China, Indonesia, Japan, Korea, Taiwan, and Siberia.

The adult flukes are intestinal inhabitants of a wide range of piscivorous birds and mammals. Eggs (Fig. 4) are embryonated when passed from the host but do not hatch until ingested by a snail intermediate host (28). Cercariae will encyst in a range of fish including mugilids, cyprinids, and gobiids. Humans are infected by consumption of raw, freshly salted, or undercooked fish (Table 3).

Disease symptoms in humans relate to infection intensity and arise because of parasite irritation of the intestinal mucosa. Eggs may on occasion pass into the bloodstream and lodge in tissues. These eggs have been known to cause fatal myocarditis in the Philippines (1). Diagnosis of heterophyids is facilitated by observation of eggs in feces (Table 3). Heterophyid eggs are similar in size to those of opisthorchiid liver flukes, and care must be taken to differentiate the infections. Often this can be achieved only by examination of purged adult worms. The recommended treatment for heterophyid infection is a single dose of praziquantel (Table 3).

Nanophyetidae

This family of small oval flukes parasitizes mammals, including humans. One species, *Nanophyetus salmincola,* is found along the coastal U.S. Pacific Northwest as metacercariae of salmonid fish. The species may be the most commonly encountered human trematode endemic to North America. Praziquantel is efficacious for nanophyetiasis.

Less Common Helminths

GARY W. PROCOP AND RONALD C. NEAFIE

148

This chapter covers the less common causes of helminthic parasitic infections, particularly those caused by the less common nematodes and cestodes. The trematodes are covered in entirety in chapter 147. This chapter is not inclusive, given the wide variety of helminthic parasites that have been reported to cause human disease, but includes some of the most interesting and challenging of parasitic diseases. The reader who desires further information about these and other helminths of medical importance is directed to *Pathology of Infectious Diseases,* volume 1, *Helminthiasis,* by the Armed Forces Institute of Pathology (AFIP) (2). The Centers for Disease Control and Prevention's (CDC) parasitology website (http://www.dpd.cdc.gov/dpdx) is another excellent resource for information regarding parasitic infections.

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

The collection, transport, and storage of specimens are similar regardless of the helminth present, so these guidelines are consolidated here to reduce duplication. Worms present in the lumen of the gastrointestinal tract, such as *Anisakis,* can be retrieved by endoscopy. Surgical resection specimens may contain a worm or larvae. The intact worm and surgical specimens may be preserved and transported in 10% neutral buffered formalin. Stool is an important diagnostic specimen for parasites that reproduce within the intestinal tract, e.g., *Capillaria philippinensis,* and should be collected and fixed in a standard manner for the detection of eggs and parasites (i.e., formalin and polyvinyl alcohol), if available. Blood for serology should be handled in a standard manner. Additional information about serologic tests for the diagnosis of parasites covered in this chapter is available through the CDC at http://www.dpd.cdc.gov/dpdx/HTML/DiagnosticProcedures.htm.

LESS COMMON NEMATODES

Anisakis and Related Species

Description of Agent(s)

Anisakis species (of which *Anisakis simplex* is the type species), *Pseudoterranova (Phocanema) decipiens,* and *Contracaecum* species are nematodes of the family Anisakidae.

Epidemiology, Transmission, and Prevention

The larvae of anisakids, which are present in many varieties of fish, cause human infections if raw or poorly cooked fish is consumed (11). Fish that have been salted or pickled may still contain viable anisakid larvae. Disease may be prevented by consuming only thoroughly cooked fish.

Clinical Significance

The clinical features vary depending on the stage of disease. Early, within 12 h of eating infected fish, nonspecific gastric discomfort is experienced while the larvae are associated with only the superficial aspects of the mucosa. Superficial larvae may migrate up the esophagus and cause coughing, potentially with expectoration of the worm. More severe symptoms occur if the worm penetrates through the mucosa into the submucosal and deeper tissues (Fig. 1). This evokes hypersensitivity, leukocytosis, and eosinophilia (13, 14). Sudden, intense abdominal pain may be thought to represent appendicitis, acute gastritis, a gastric ulcer, or Crohn's disease (30). Diarrhea and constipation may occur, and the stool contains occult blood.

Direct Examination/Microscopy

The intact worms are white to cream, nonsegmented larvae that measure 10 to 50 mm by 0.3 to 1.2 mm. One dorsal and two subventral reduced lips and a triangular boring tooth are useful for identification. Histopathologic analysis of infected tissues often demonstrates cross-sections of the worm and the host inflammatory response, which contains numerous eosinophils. Cross-sectional studies are useful for identifying the type of anisakid present.

Serologic Tests

Serologic tests to detect the immunologic response to *Anisakis* and related species are available at commercial reference laboratories in the United States. Although this test is not currently performed at the CDC, they may be contacted for assistance in locating a commercial vendor, if necessary. A variety of serologic assays have been developed, which vary in sensitivity and specificity. These identify most infected individuals (85 to 95%), with a demonstrable serologic response occurring from 10 to 35 days postinfection. Cross-reactivity with other ascarids may occur. This may be desirable to detect the related species, e.g., *Pseudoterranova,* but would limit the utility of this assay in certain populations, such as those likely

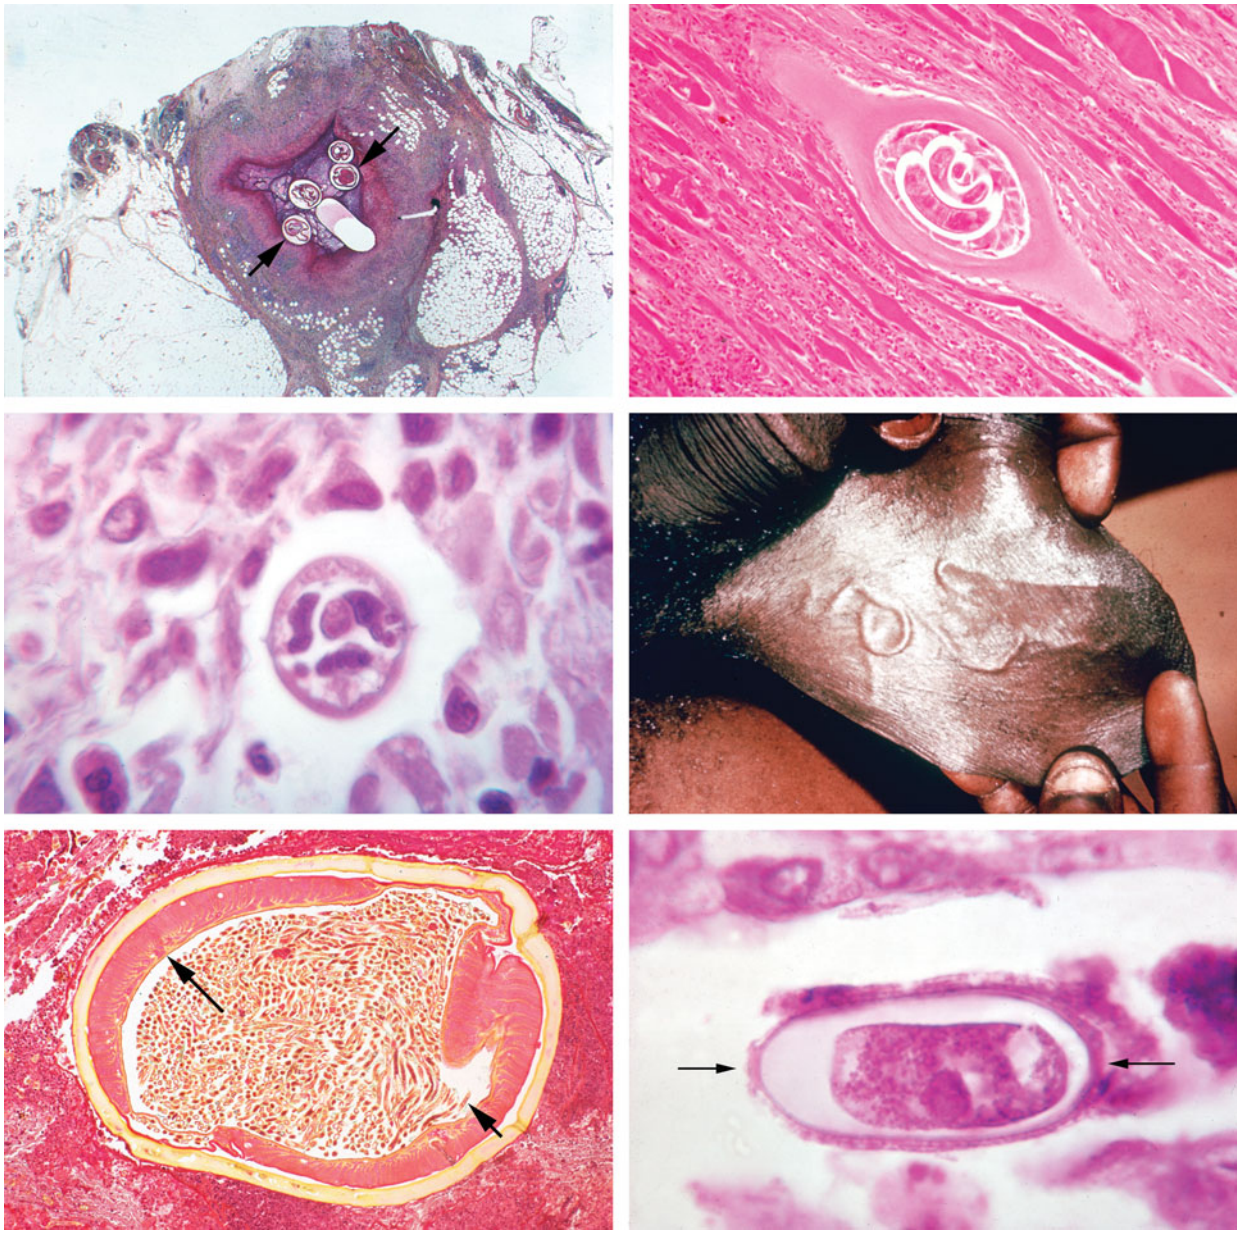

FIGURE 1 (top row, left) This *Anisakis* species (arrows) has penetrated into the deep tissues of the abdomen. Multiple cross-sections of the worm, which is 300 μm in diameter, are seen in the omentum. Movat stain; original magnification, ×2.5 (AFIP negative no. 96-5760).

FIGURE 2 (top row right) This coiled first-stage *T. spiralis* larva is in a "nurse cell." Note the hyaline, amorphous appearance of the external aspect of the nurse cell and the surrounding chronic inflammatory infiltrate. The worm diameter is 35 μm. Hematoxylin and eosin stain; original magnification, ×30 (AFIP negative no. 70-6004).

FIGURE 3 (middle row, left) The minute lateral alae are useful in the identification of *Toxocara* species. The worm diameter is 18 μm. Hematoxylin and eosin stain; original magnification, ×500 (AFIP negative no. 69-4372).

FIGURE 4 (middle row, right) The serpiginous tract of a female *D. medinensis* worm is demonstrated in the scrotum of this patient (AFIP negative no. 74-9011).

FIGURE 5 (bottom row, left) Rhabditiform larvae (short arrow) fill the body cavity of this gravid *D. medinensis* worm. Also note the presence of the two prominent bands of somatic muscle (long arrow). The worm diameter is 1.1 mm. Movat stain; original magnification, ×25 (AFIP negative no. 92-8429).

FIGURE 6 (bottom row, right) The bipolar plugs (arrows), pitted egg shell, and rectangular shape are characteristic of *Capillaria* species. This photomicrograph is from human small intestine and demonstrates an egg 40 μm long. Hematoxylin and eosin stain; original magnification, ×490 (AFIP negative no. 69-1287).

to harbor intestinal ascarids. Conversely, more specific assays have been devised to detect *Anisakis,* but these unfortunately do not detect the related species that may cause anisakiasis.

Treatment

Removal of the larva via endoscopy while it is only associated with the superficial mucosa is the most efficacious treatment, whereas surgical resection may be needed for more deeply insinuated larvae (47). Antihelminthic drugs do not appear to be useful, but corticosteroids may be used to decrease the associated inflammation.

Trichinella Species

Description of Agent(s)

Trichinella spiralis is the most important cause of human disease in this genus, but other species, such as *Trichinella pseudospiralis* and *Trichinella britovi,* may also cause trichinosis (23).

Epidemiology, Transmission, and Prevention

Trichinosis occurs worldwide. The life cycle of *T. spiralis* is simple in that the infected mammal that first serves as the definitive host also harbors infective larvae encysted in its muscle (i.e., the intermediate host) (Fig. 2) (4). The domestic pig is the most important host for the transmission of this roundworm to humans, but the meat of bear, walrus, and wild pigs may also contain infective larvae. The parasitic cycle is propagated in the barnyard between pigs and rodents. Disease may be prevented by eating only thoroughly cooked meat products of potential hosts and by attempting to control trichinosis in these hosts through good animal husbandry practices.

Clinical Significance

Infections vary from mild, subclinical disease to a severe illness, depending upon the parasite load. The clinical manifestations vary with the stage of infection. Gastrointestinal symptoms, associated with adult worms, last only about a week and include nausea, vomiting, abdominal pain, and diarrhea and/or constipation. Fever, facial edema that is particularly predominant around the eyes, myalgia, and marked peripheral eosinophilia are the four cardinal features of trichinosis. These are caused by the penetrating, migrating larvae. Light infections may only result in peripheral eosinophilia. The migration of larvae may cause organ-specific features. If the brain and meninges are primarily affected, neurologic symptoms predominate, whereas involvement of the myocardium causes myocarditis, and possibly arrhythmias causing sudden death. Larvae encyst not in these tissues, but rather in skeletal muscle.

Direct Examination/Microscopy

The direct microscopic examination of a muscle biopsy sample, performed by simply compressing the fresh muscle fibers between glass slides and observing microscopically, may disclose larvae. More commonly, larvae will be detected in the histopathologic analysis of the formalin-fixed, paraffin-embedded tissue sections (Fig. 2).

Serology

Antibody response begins 3 to 5 weeks after infection in most patients (80 to 100%) and follows the acute phase of disease. Therefore, the conversion from a negative serologic test during acute illness to a positive test is strong evidence of disease. The tests are highly sensitive, and although they are less than 100% specific, the cross-reactivity usually results in test values in the equivocal range. This test is available at the CDC and from several commercial vendors.

Treatment

Therapy varies according to the stage of disease. Thiabendazole is active against the intestinal worm, but not against the larvae. There is no proven method to kill the encysted larvae, but albendazole or another similar agent is used for therapy. Well-controlled therapeutic studies, however, are lacking. Corticosteroids, salicylates, and antihistamines may lessen symptoms associated with inflammation.

Toxocara Species

Description of Agent(s)

Toxocara canis is the intestinal ascarid of dogs and other canids, whereas *Toxocara cati* is the intestinal ascarid of cats. Although larvae of both species can cause toxocariasis in humans, most infections are caused by *T. canis* (20).

Epidemiology, Transmission, and Prevention

Toxocariasis has a worldwide distribution, but the prevalence of zoonotic disease varies widely by geographic area. The seroprevalence of human disease reflects helminthic control in dogs and cats. The highest infection rates occur among the poor, often in rural settings (19). The natural cycle of *Toxocara* begins with the passage of unembryonated eggs in the feces of the definitive host. The adult female worm may release up to 85,000 eggs per day. Therefore, one stool passage into an environment such as a sandbox can cause significant contamination. Between 10 and 20 days are required for the L2 (i.e., second-stage) larvae to develop in the eggs; the eggs at this stage are infective. If the eggs are ingested by a suitable definitive host, then the larvae penetrate the intestinal tract and migrate through the liver, bloodstream, and lungs, until they are swallowed to mature into adult worms in the intestinal tract. When the eggs are ingested by a nonpermissive host, such as a child, the resulting *Toxocara* larvae cannot complete their life cycle, but rather wander aimlessly in the aberrant host, causing visceral larva migrans. Another means of contracting disease is by ingesting raw or undercooked meat from a paratenic host (i.e., another aberrant host, such as a pig, that contains wandering larvae). Prevention is achieved foremost through zoonotic control by deworming dogs and cats, most importantly puppies, which are particularly permissive for infection and are often associated with children. Other preventive measures include avoidance of animal feces, thorough washing of fruits and vegetables, and thorough cooking of meats from potential paratenic hosts (42).

Clinical Significance

Toxocara infections are one of the most common helminthic infections of humans. Fortunately, most infections are subclinical, producing only mild disease for which a definitive diagnosis is not sought. The most severe forms of disease occur with involvement of the eyes, or significant involvement of the heart, brain, or other vital organs (3, 15, 34, 41). Pregnant women with toxocariasis may have miscarriages.

Direct Examination/Microscopy

Eggs are not produced in the human, so a stool evaluation is not helpful. However, occasionally the eggs of other geohelminths such as *Ascaris,* hookworm, or *Trichuris* may be present because of common risk factors. The detection of the migrating larvae in surgically excised tissues by histopathologic evaluation provides the definitive morphological diagnosis.

The single minute lateral alae and the cross-sectional diameter are useful criteria for identifying these parasites in histologic sections (Fig. 3) (35).

Serology Tests

Serologic studies for *Toxocara* should be interpreted with caution, since a positive result could represent previous, asymptomatic infection. The sensitivity and specificity of these assays are high, but less than 100%. These parameters cannot be determined with confidence, since there is not a better parasitological test to confirm the presence of a true infection. These tests, however, are useful in the appropriate clinical context and have been successfully used in seroepidemiologic studies. Tests are available at CDC and from commercial reference laboratories.

Treatment

There is no proven therapy. Anthelminthic therapy with albendazole or a similar therapeutic is often used. Corticosteroids may be necessary to control the inflammatory response in patients with a large parasite burden. Eye infections require a combined medical and surgical approach (21).

Dracunculus medinensis

Description of Agent

D. medinensis, also known as the guinea worm, is not a filarial worm, but rather a member of the family Dracunculidae (23). Other *Dracunculus* species exist that infect a variety of other animals.

Epidemiology, Transmission, and Prevention

Dracunculiasis is found only in the rural parts of Africa. Disease occurs more commonly in the dry season, affects men more commonly than women, and is most common in individuals from 10 to 60 years old, which taxes the productivity of affected communities. An intensive effort by the World Health Organization (WHO), local governments, and numerous other humanitarian organizations has significantly decreased the annual incidence of disease (1, 7, 45). At the beginning of this program (1986), an estimated 3.5 million people in 20 countries were affected. The annual incidence of worldwide disease diminished by an astounding 98% by December 2001, and seven countries completely eradicated the disease.

Infection follows drinking contaminated freshwater that contains copepods, which harbor the infective larvae. After ingestion, the larvae migrate to the retroperitoneum, where they mature and mate. The female worm eventually migrates to a subcutaneous location where a blister forms, which bursts upon contact with water and releases numerous larvae. The larvae are ingested by a copepod, wherein they become infective. Preventive measures are centered on education and providing clean drinking water (25, 26).

Clinical Significance

Patients are asymptomatic during larval penetration of the gastrointestinal tract and retroperitoneal maturation and mating of the worms. Symptoms are secondary to inflammation and tissue damage caused by worm migration. Although lesions are most common in the lower extremities, they may occur anywhere in the body, producing a serpiginous path of the migrating worm under the skin (Fig. 4). The large blister that is formed may become secondarily infected. Dead worms may be absorbed, calcify, or produce symptoms secondary to location (e.g., a joint).

Direct Examination/Microscopy

The presence of the end of a worm protruding from a burst blister or ulcer in the appropriate setting is diagnostic. The microscopic analysis of these worms in cross-section demonstrates a cuticle 30 to 50 μm thick, indistinct lateral cords, prominent dorsal and ventral bands of smooth muscle, and a large uterus filled with rhabditoid larvae that fills the body cavity (Fig. 5).

Serologic Tests

Serologic tests are usually not necessary for the diagnosis, given the obvious findings in people at risk for disease, but they are useful for seroprevalence studies and to identify infected individuals prior to the partial emergence of the adult worm.

Treatment

The oldest and traditional treatment, as depicted in the ancient Egyptian medical text the *Papyrus Ebers,* consists of removing the gravid worm by wrapping the exposed end around a stick and applying gentle pressure for days. Treatment with thiabendazole and metronidazole, although not lethal for the worm, facilitates removal by this process (9). Although often effective, risks include rupture of or breaking the worm prior to full removal. Currently, surgical excision is preferred. Anti-inflammatory agents and antihistamines are important for symptomatic relief. Antibiotics may be necessary to curtail secondary bacterial infections, and tetanus vaccination is important.

C. philippinensis

Description of Agent

C. philippinensis is a trichurid nematode responsible for intestinal capillariasis (12, 31).

Epidemiology, Transmission, and Prevention

The natural parasitic cycle of *C. philippinensis* likely involves marine, fish-eating birds as the definitive hosts and fish as the intermediate hosts. Humans become infected by ingesting raw or undercooked fish that harbor the infective larvae. Larvae at various stages of maturation may be found in the lumen of the intestine of the definitive host or the patient. Therefore, the population of parasites within the lumen of the bowel may increase (hyperinfection) without the consumption of additional contaminated fish. Thorough cooking of fish is protective.

Clinical Significance

Infections with *C. philippinensis* are rare, but because intraintestinal hyperinfection is possible, they may be fatal. Nonspecific gastrointestinal complaints predominate early in the course of disease. As the disease progresses and the number of worms increases, there is continued diarrhea with malabsorption leading to cachexia (18). Endoscopy may be useful for establishing the diagnosis (46). Death occurs secondarily to malnutrition, or because of secondary bacterial infections (enteritis and/or septicemia).

Direct Examination/Microscopy

The microscopic examination of the stool may demonstrate a mixture of eggs and larvae. The eggs of *C. philippinensis* (Fig. 6), which also have bipolar plugs, are superficially reminiscent of the more commonly recognized trichurid worm, *Trichuris trichiuria*. The plugs of *C. philippinensis,* however, are

nonprotruding, the egg is more rectangular, and there is a distinctive pitting of the egg shell (6). The adults superficially resemble *Strongyloides stercoralis* but may be differentiated by the presence of stichocytes and three bacillary bands, the latter being most easily recognized in cross-section.

Serologic Tests

Serologic tests are not available from the CDC or from commercial reference laboratories. Experimental serologic tests have been developed which, like the coproantigen, hold promise as future diagnostic tools (17).

Treatment

Mebendazole is the drug of choice, but albendazole and thiabendazole may also be used. Relapsing disease requires prolonged antihelminthic therapy. Aggressive electrolyte replacement and monitoring are critical, as are control of diarrhea and administration of nutrients.

Gnathostoma Species

Description of Agent(s)

Gnathostoma species are gastric spirurid nematode parasites for which the definitive hosts are a variety of mammals (29). Infective L3 (i.e., third-stage) larvae cause disease in humans, and gnathostomiasis may be considered a subtype of visceral larva migrans. *Gnathostoma spinigerum* is the most common cause of human disease, but *Gnathostoma hispidum, Gnathostoma nipponicum,* and *Gnathostoma doloresi* may also cause human disease.

Epidemiology, Transmission, and Prevention

G. spinigerum has essentially a worldwide distribution. Dogs and cats are the primary definitive host for this gnathostome, whereas *G. hispidum* and *G. doloresi* infect wild and domestic pigs and *G. nipponicum* is a parasite of weasels.

The adult male and female gnathostomes live in the stomach of the definitive host, where they mate, and eggs are passed in the stool. After development in water, the eggs hatch and release first-stage larvae that infect the *Cyclops* copepod, wherein the larvae mature. When a second intermediate host, such as fish, snakes, or frogs, eats the copepod, the larvae penetrate the gastric wall of the new host, wherein they migrate to the musculature and encyst. If an appropriate definitive host eats the secondary intermediate host, the advanced L3 larvae excyst and penetrate the gastric wall. After penetration, the L3 larvae migrate through the liver, muscles, and connective tissues, only to return to the stomach and mature into adults. Humans are accidental hosts in which the nematode larvae cannot mature to adulthood and continue to migrate aimlessly. The parasite is transmitted to humans through the ingestion of raw or undercooked meat from a secondary intermediate host. Disease can be prevented by thoroughly cooking potentially infected foods.

Clinical Significance

The clinical presentations of gnathostomiasis are protean, since the wandering larvae may be present in any tissue or organ system (22, 38, 39). Although the infection is not commonly fatal, significant morbidity may be associated with infection. Early after the ingestion of food that contains infective larvae, the patient may experience nonspecific gastrointestinal symptoms, such as nausea, vomiting, diarrhea, and epigastric pain.

Direct Examination/Microscopy

Mature (adult) gnathostomes are not present in humans, but L3 larvae are. This form is morphologically similar to the adult form but is smaller, measuring 3 to 4 mm in length by 630 μm in diameter (*G. spinigerum*). The head bulb contains four rows of cephalic hooklets, with approximately 45 hooklets per row. The body of the larva, like that of the adult, is covered with transverse rows of sharply pointed spines that diminish toward the posterior end of the worm. An entire worm may be spontaneously expelled or may require surgical excision.

Serologic Tests

Serologic assays have been developed predominantly in areas of endemicity. These are not available in the United States, but the CDC can assist in identifying a source for testing, if necessary. The possibility of cross-reactivity should be considered with this and several other serologic assays for helminthic parasites, and should be used only in the appropriate clinical context.

Treatment

Surgical removal of the parasite is the foremost effective treatment, which may be aided by advanced imaging tools (5). There have been some reports claiming successful treatment with albendazole and diethylcarbamazine, but the efficacy of these agents remains to be determined. Symptomatic relief with antihistamines and corticosteroids may be considered.

Angiostrongylus cantonensis

Description of Agent

A. cantonensis is a filariform worm and the most important cause of angiostrongyliasis (37).

Epidemiology, Transmission, and Prevention

A. cantonenesis is widely distributed throughout the world but represents an important public health threat in Southeast Asia and the Asian Pacific Islands. This parasite persists in a wide variety of rodents, which serve as the definitive host, wherein the adult worms reside in the pulmonary artery and the right side of the heart. Eggs released from the adults lodge in pulmonary capillaries, where they hatch and release larvae. The larvae subsequently migrate up the trachea and are swallowed and passed in the feces. These larvae infect mollusks, the intermediate host, wherein maturation to the infective L3 larvae occurs. A number of animals, including shrimp, crabs, fish, and frogs, may eat the infected mollusks and serve as important paratenic hosts. Rodents that ingest either the infected mollusk or tissues from the paratenic host thereby become infected. In the definitive host, the infective larvae penetrate the intestine, become blood borne, and migrate to the central nervous system, where they molt twice. Thereafter, the worms reenter the systemic circulation and finally reside in the right ventricle and pulmonary artery to mature and complete the cycle. Prevention of disease can be achieved through control of the local rat population and thorough cooking of mollusks and potential paratenic hosts.

Clinical Significance

The clinical manifestations reflect the worm burden and the site of worm residence, the central nervous system. The worms tend to remain associated with the brain and meninges in human infections (Fig. 7). Patients demonstrate signs and symptoms typical of meningitis or meningoencephalitis, with headache, fever, possibly eosinophilia (10 to

60%), and any of a number of neurologic disturbances, depending on the location of the worms. The cerebrospinal fluid (CSF) demonstrates pleocytosis, eosinophilia (26 to 75%), and elevated protein and occasionally will contain immature worms. Alternatively, patients may have infections of the eye, with retinal detachment and blindness. Less commonly, human infections may result in pulmonary disease.

Direct Examination/Microscopy

Demonstration of the worms in histologic sections, or intact in clinical specimens from the CSF or eye, definitively establishes the diagnosis. Eosinophilia in the CSF may be the first indicator of a possible parasitic infection of the central nervous system. The differential diagnosis of the causes of CSF eosinophilia, however, is broad and includes other parasitic infections, e.g., *Gnathosoma* or *Toxocara* spp., allergic reactions, and coccidioidomycosis. The gross appearance of an adult female worm is distinctive, with the spiral winding of the uteri and ovarian branches imparting a "barber pole" appearance. Cross-section of the female demonstrates a large intestine and two uteri, whereas cross-section of the male reveals a large intestine and a single reproductive tube. Eggs are not produced in human tissues.

Serologic Tests

Serologic assays are powerful tools for the diagnosis of angiostrongylosis, particularly since the parasite is usually located in a difficult-to-access location, the central nervous system. The evolution of these assays has resulted in a highly sensitive and specific assay, particularly when purified, non-cross-reacting antigens are used. Although intrathecal antibody is not always produced, the presence of intrathecal antibody synthesis provides strong evidence of infection. This assay is available from some commercial vendors in the United States.

Treatment

The optimal treatment has not been established. Fortunately, the disease is often self-limited. Removal of CSF and the administration of corticosteroids and nonsteroidal anti-inflammatory agents have been used to control pain and inflammation. A variety of antihelminthic medications have been used, with mebendazole the current drug of choice. Careful monitoring of the patient is important, since antihelminthic therapy may sometimes exacerbate the symptoms (24).

Dirofilaria immitis

Description of Agent

D. immitis, the filarial dog heartworm, causes human pulmonary dirofilariasis (10, 44).

Epidemiology, Transmission, and Prevention

Although dogs are the most important host for *D. immitis,* other mammals, such as fox and bear, are also suitable hosts. The blood of infected dogs or other suitable hosts contains microfilariae that are released from the adult worm, which resides in the right ventricle of the heart. These are taken into the mosquito during a blood meal, wherein they mature into infective L3 larvae and are capable of being transferred to another mammal during a blood meal. The larvae migrate through subcutaneous tissues and eventually enter the bloodstream and the right side of the heart, wherein they mature into adults if the host is suitable. Humans, however, are unsuitable hosts, and the worm dies before reaching maturity, is swept into the pulmonary arterial circulation, and becomes lodged in the subsegmental pulmonary arteries and arterioles, causing thrombosis, infarction, inflammation, and eventually a granulomatous reaction surrounded by a wall of fibrous tissue (Fig. 8).

The geographic distribution of disease reflects the prevalence of canine dirofilariasis. The areas of highest prevalence in the United States are in the south, particularly along the Gulf and Atlantic coasts and along the Mississippi River (40). Dog ownership is not a risk factor for disease. Prevention is centered around control of zoonotic disease. The use of mosquito repellents, particularly in areas of high endemicity, should also help interrupt transmission.

Clinical Significance

Slightly more than half of the patients with dirofilariasis are asymptomatic. The remainder have nonspecific symptoms, such as cough, chest pain, hemoptysis, low-grade fever, chills, and malaise (10). Only 5 to 10% have peripheral blood eosinophilia. In addition to the pulmonary manifestation, *D. immitis* has also rarely been identified in subcutaneous abscesses, the abdominal cavity, the eyes, and the testes. *Dirofilaria* species other than *D. immitis* are more likely to be found in a subcutaneous location (Table 1). The nodules caused by *D. immitis* are often discovered by a routine chest radiograph (40). These are usually single, but occasionally two or three nodules may be present.

Direct Examination/Microscopy

The pulmonary nodules produced by *D. immitis* are characteristically small (0.8 to 4.5 cm; mean, 1.9 cm), subpleural, spherical, and well circumscribed. *D. immitis* has a smooth, thick cuticle (5 to 25 μm) with the three distinct layers characteristic of the genus *Dirofilaria;* other *Dirofilaria* species that infect humans have a similar cuticle, but with external longitudinal ridges (Fig. 9 and 10). The thick, multilayered cuticle projects inwardly at the lateral chords, forming two prominent, opposing internal longitudinal ridges. The somatic musculature is typically prominent, but the lateral chords are usually poorly preserved. Transverse sections may reveal two large uteri and a much smaller intestine in female worms (Fig. 9); a single reproductive tube and intestine are present in the males. The definitive identification of the worm based on internal structures may be difficult to impossible, given the advanced stage of parasite degeneration in many of these specimens. The presence of a parasitic worm in a pulmonary artery and associated with a pulmonary infarct, however, is sufficient for a diagnosis.

Serologic Tests

Serologic tests to detect antibody to *Dirofilaria* are commercially available from several reference laboratories. Although advances have been made to increase specificity without sacrificing sensitivity, cross-reactivity may occur in patients infected with other nematodes, particularly other filarial worms. As with many serologic assays, a positive test is useful, whereas a negative test does not exclude the possibility of infection.

Treatment

The excision of the nodule is curative. Additional antiparasitic therapy is not necessary.

Other Less Common Nematodes

There are a number of additional less commonly occurring nematodes than those described. Some of these and associated important features are included in Table 1.

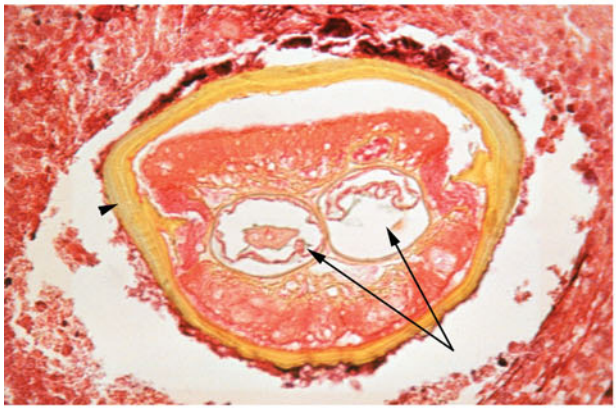

TABLE 1 Other less common nematodes

Organism	Definitive host	Intermediate host(s)/ vectors	Disease(s) produced	Method of diagnosis
Ancylostoma species other than *Ancylostoma duodenale, A. ceylanicum, A. caninum,* and *A. braziliense*	Cats, dogs, and hamsters	Not applicable	Ancylostomiasis, eosinophilic enteritis, cutaneous larva migrans (creeping eruption)	Detection of eggs in stool or adults in histologic sections; rarely, larvae in biopsy sample of skin
Angiostrongylus costaricensis	Rodents, less commonly dogs and monkeys	Mollusks	Infection of the intestinal walls and mesenteric arteries	Identification of parasite in surgically excised tissues; eggs not present in stool. Serologic studies are useful.
Dirofilaria species other than *D. immitis, D. tenuis, D. repens, D. ursi, D. subdermata, D. striata*	Raccoons *(D. tenuis)*, dogs and cats *(D. repens)*, bears *(D. ursi)*, porcupines *(D. subdermata)*, wild cats *(D. striata)*	Mosquitoes, except for *D. ursi,* which is transmitted by blackflies	Usually subcutaneous nodules that contain mature, immature, or degenerated worms	Morphological features of the worm in excised tissues (Fig. 10)

LESS COMMON CESTODES (TABLE 2)

Dipylidium caninum

Description of Agent

D. caninum, a common tapeworm of dogs and cats, also commonly infects children (8, 43).

Epidemiology, Transmission, and Prevention

Dipylidiasis occurs throughout the world (16, 28). This disease, like hymenolepiasis, is transmitted primarily through the ingestion of an infected flea. In the natural cycle, the dog or cat contains the intestinal adult parasite that releases gravid proglottids filled with eggs. The eggs are ingested by fleas or lice, which are the intermediate hosts. The eggs hatch

FIGURE 7 (row 1, left) The immature *A. cantonensis* worm (arrows) in the meninges of this patient is eliciting a marked eosinophilic response. The worm is 200 μm in diameter. Hematoxylin and eosin stain; original magnification, ×50 (AFIP negative no. 73-6862).

FIGURE 8 (row 1, right) The coiled remnants of an immature male *D. immitis* worm are present in this branch of the pulmonary artery. The maximum worm diameter is 250 μm. Movat stain; original magnification, ×15 (AFIP negative no. 71-11563).

FIGURE 9 (row 2, left) The two uteri (arrows), muscle, and trilaminar (arrowhead), smooth cuticle are characteristic of an immature female *D. immitis* worm. The worm diameter is 250 μm. Movat stain; original magnification, ×80 (AFIP negative no. 72-2732).

FIGURE 10 (row 2, right) The *Dirofilaria* species other than *D. immitis* have external longitudinal cuticular ridges, whereas the cuticle of *D. immitis* is smooth. *Dirofilaria tenuis* is pictured here in cross-section; it is 270 μm in diameter and has obvious cuticular ridges (arrows). *Dirofilaria* species other than *D. immitis* are often found in a subcutaneous location rather than in the pulmonary arterial vasculature. Movat stain; original magnification, ×80 (AFIP negative no. 94-5122).

FIGURE 11 (row 3, left) An egg packet of *D. caninum,* which was obtained from a crushed gravid proglottid, is 150 μm in diameter. The eggs within the packet are 40 μm in diameter. Unstained (AFIP negative no. 86-7369).

FIGURE 12 (row 3, right) The thick inner membrane of the egg of *Hymenolepis diminuta* is surrounded by a gelatinous matrix and then by an outer striated shell. The eggs of *H. diminuta* are spherical, whereas those of *Hymenolepis nana* are ovoid. The egg pictured here is 80 μm in diameter. Unstained; original magnification, ×250 (AFIP negative no. 96-5119).

FIGURE 13 (row 4, left) A sparganum superficially resembles an adult tapeworm. Close inspection, however, clarifies its immature form, with a head with only a ventral groove or bothrium (arrow) and a lack of proglottids. The maximum width is 6 mm. Unstained; original magnification, ×0.5 (AFIP negative no. 70-15303).

TABLE 2 Other less common cestodes[a]

Organism	Definitive hosts	Intermediate hosts	Disease produced	Diagnostic method
Hymenolepis diminuta, the rat tapeworm	Rats	Insects	Usually asymptomatic; heavy infections resemble heavy *H. nana* infections	Eggs in the feces (Fig. 12); proglottids disintegrate before fecal passage.
Hymenolepis nana, the dwarf tapeworm[b]	Rats; human-to-human transmission possible	Fleas	This worm, the smallest adult tapeworm that infects humans, produces disease that is usually mild, and patients may be asymptomatic. Massive infections may produce abdominal pain, allergic reactions, anorexia, nausea, diarrhea or constipation, and flatulence.	Identification of characteristic eggs in the stool; proglottids disintegrate and release eggs before they are passed in the stool. The eggs are ovoid, in contrast to those of *H. diminuta,* which are spherical, and have an inner hyaline membrane, a thin egg shell, polar thickenings from which polar filaments arise, and a distinct oncosphere that contains six hooklets.
Less common *Taenia* species				
T. taeniaeformis	Cats	Rodents	Larval stage may infect liver, like cysticercosis.	Demonstration of strobilocercus in histologic sections
T. multiceps	Canids	Sheep, rabbits	Coenurosis, an infection with the coenurus in the CNS,[c] eyes, or subcutaneous tissues (like cysticercosis)	Demonstration of the coenurus in histologic sections
Mesocestoides species	Foxes, dogs, cats, and other mammals	Unknown, possibly reptile or arthropod vectors	Asymptomatic to mild abdominal symptoms	Detection of gravid proglottid with characteristic parauterine organ. Eggs are usually not present in the stool.
Bertia species	Primates	Mites and possibly other insects	Asymptomatic to mild abdominal symptoms	Motile proglottids in the stool, similar to *D. caninum* infection. Eggs within proglottids are not within packets.
Inermicapsifer madagascariensis		Raw sugar cane ingestion has been suggested.	Asymptomatic to symptoms similar to *D. caninum* infections	Motile proglottids in the stool, similar to *D. caninum* infection. Proglottid and egg morphology and number of eggs per packet are used for identification.
Raillietina species	Rodents	Insects	Asymptomatic to symptoms similar to *D. caninum* infections	Motile proglottids in the stool, similar to *D. caninum* infection. Proglottid and egg morphology and number of eggs per packet are used for identification.

[a] Praziquantel is the treatment of choice for infections with adult tapeworms; it is also effective in coenurosis. Effective preventive measures center around controlling disease in the zoonotic host (e.g., cats or dogs) or controlling the zoonotic hosts themselves (e.g., rats). Controlling intermediate hosts is also effective but may prove more difficult.

[b] This parasite is covered in detail in chapter 146.

[c] CNS, central nervous system.

within the intermediate host, releasing larvae that penetrate the body cavity, where they mature into infective cysticercoid larvae. When an infected intermediate host is ingested, the cysticercoid metacestode larva attaches to the small intestine and matures into an adult tapeworm, completing the cycle. Prevention is achieved by deworming animals and controlling fleas and lice.

Clinical Significance

Dipylidiasis is usually an innocuous infection. Larger worm burdens may cause weight loss, abdominal pain, failure to thrive, or the appearance of colic. Disease usually comes to the attention of parents and pediatricians when motile, gravid proglottids are seen in the stool.

Direct Examination/Microscopy

The proglottids of *D. caninum* differ from those of most other cestodes in that they have two genital pores (*dipylos* means two gates), which can be appreciated with the use of a dissecting microscope and compressing the proglottid between two glass slides. The identification may also be achieved by demonstrating the characteristic egg packets (Fig. 11) and/or

characteristic eggs that have distinct morphological features (i.e., four envelopes). A fecal examination will likely be negative for eggs or egg packets, since intact proglottids are usually passed in the stool. Microdissection or histologic examination of the proglottids will reveal the eggs and egg packets. In addition to the egg packets, the histologic examination of the proglottid will reveal other features common to cestodes, such as a tegument, smooth muscle, and calcareous corpuscles.

Serologic Tests

Because the disease is usually subclinical and the diagnosis is achieved when the proglottids are discovered and examined, serologic tests are not necessary.

Treatment

Both praziquantel and niclosamide are effective against *D. caninum*. Upon discovery, examination and treatment of household pets should proceed, as should aggressive flea control.

Spirometra Species

Description of Agent(s)

Sparganosis is the infection of humans by L3 plerocercoid larvae of a pseudophyllidean tapeworm (33). The plerocercoid larva in a human host does not reach maturity and is known as a sparganum. The tapeworms that cause sparganosis are *Spirometra mansoni, Spirometra mansonoides, Spirometra ranarum,* and *Spirometra erinacei*. The precise taxonomic relationship of a cestode known as *Sparganum proliferum* is unclear, but this organism may simply represent a variant of *S. mansonoides* or *S. erinacei*.

Epidemiology, Transmission, and Prevention

Adult *Spirometra* species are widely distributed and are tapeworms of animals, particularly dogs and cats. The parasitic cycle for these worms begins with the passage of eggs from an infected suitable host. The coracidium that emerges from the egg infects the first intermediate host, a copepod. The second intermediate host, which includes snakes, frogs, and fish, becomes infected by ingesting the infected copepod. The cycle is completed when a suitable definite host ingests the second intermediate host. Humans are unsuitable hosts and may become infected by ingesting raw or undercooked meat from a second intermediate host or by drinking contaminated water that contains the infected copepod. Humans have also become infected by using infected animal flesh (e.g., frog flesh) as a poultice.

Clinical Significance

The results of ingesting a plerocercoid larva depend on both the species of the host and the species of the larva. For example, the ingestion of a plerocercoid larva of *Diphyllobothrium* by a human will result in the development of an adult tapeworm, whereas the ingestion of a plerocercoid larva of a *Spirometra* species will result only in the continued existence of the larva in the new host (i.e., the sparganum). This is a situation wherein the human is biologically behaving like a second intermediate or paratenic host. The clinical features of disease are influenced by worm burden (most patients harbor only a single worm), worm location, and worm viability. Spargana migrate, but this migration usually does not cause symptoms. Migration to a subcutaneous location, however, may result in a nodule. This nodule may be excised to exclude the possibility of malignancy. Ocular sparganosis, particularly involving the conjunctiva, may result following the application of a natural poultice that contains raw snake or frog tissues. Inflammation and sometimes calcification ensue following death of the sparganum, and when these occur in the brain they may cause obstructive hydrocephalus (32).

Direct Examination/Microscopy

The spargana of *Spirometra* species are flat, ribbon-like worms that superficially resemble adult tapeworms (Fig. 13). Closer inspection demonstrates an immature anterior end without hooklets; a cleft or ventral groove, termed a bothrium, is present (Fig. 13) (36). Mature proglottids are not produced. Histopathologic examination of the sparganum demonstrates calcareous corpuscles characteristic of a cestode. Developed internal organs are not seen, but rather irregularly scattered muscle fibers and excretory ducts in a loose stroma.

Serologic Tests

If the diagnosis is not suspected, it is usually made on the basis of the unsuspected findings at surgery of a viable sparganum and the findings of the subsequent histopathologic examination. In such instances, serology is not useful. However, if this disease is clinically suspected, the diagnosis may be achieved through the combination of radiology and serology (27).

Treatment

Medical therapy is currently deemed unsuitable for the treatment of sparganosis; the plerocercoid larva is resistant to praziquantel. Complete surgical excision is recommended. An incomplete excision, particularly if the anterior end of the larva remains in the tissue, may result in continued growth of the organism (2).

SUMMARY

There are a wide variety of less commonly encountered helminthic parasites, which may be nematodes, cestodes, or trematodes. The diseases caused by these parasites are interesting and demonstrate their highly evolved life cycles and the complex interactions with their hosts. These diseases range from subclinical, e.g., dipylidiasis, to possibly life-threatening, e.g., angiostrongylosis. In many instances, the disease occurs only in a limited geographic area, which is largely determined by the biological ranges of the definitive and intermediate hosts. The treatment of these parasites varies depending on the infectious agent, but common preventive measures may significantly diminish the transmission of many of these parasitic diseases. These measures include the zoonotic control of parasitic disease in animal hosts and the vectors of transmission, washing of fruits and vegetables, access to clean drinking water, and thorough cooking of meats before consumption.

Arthropods of Medical Importance*

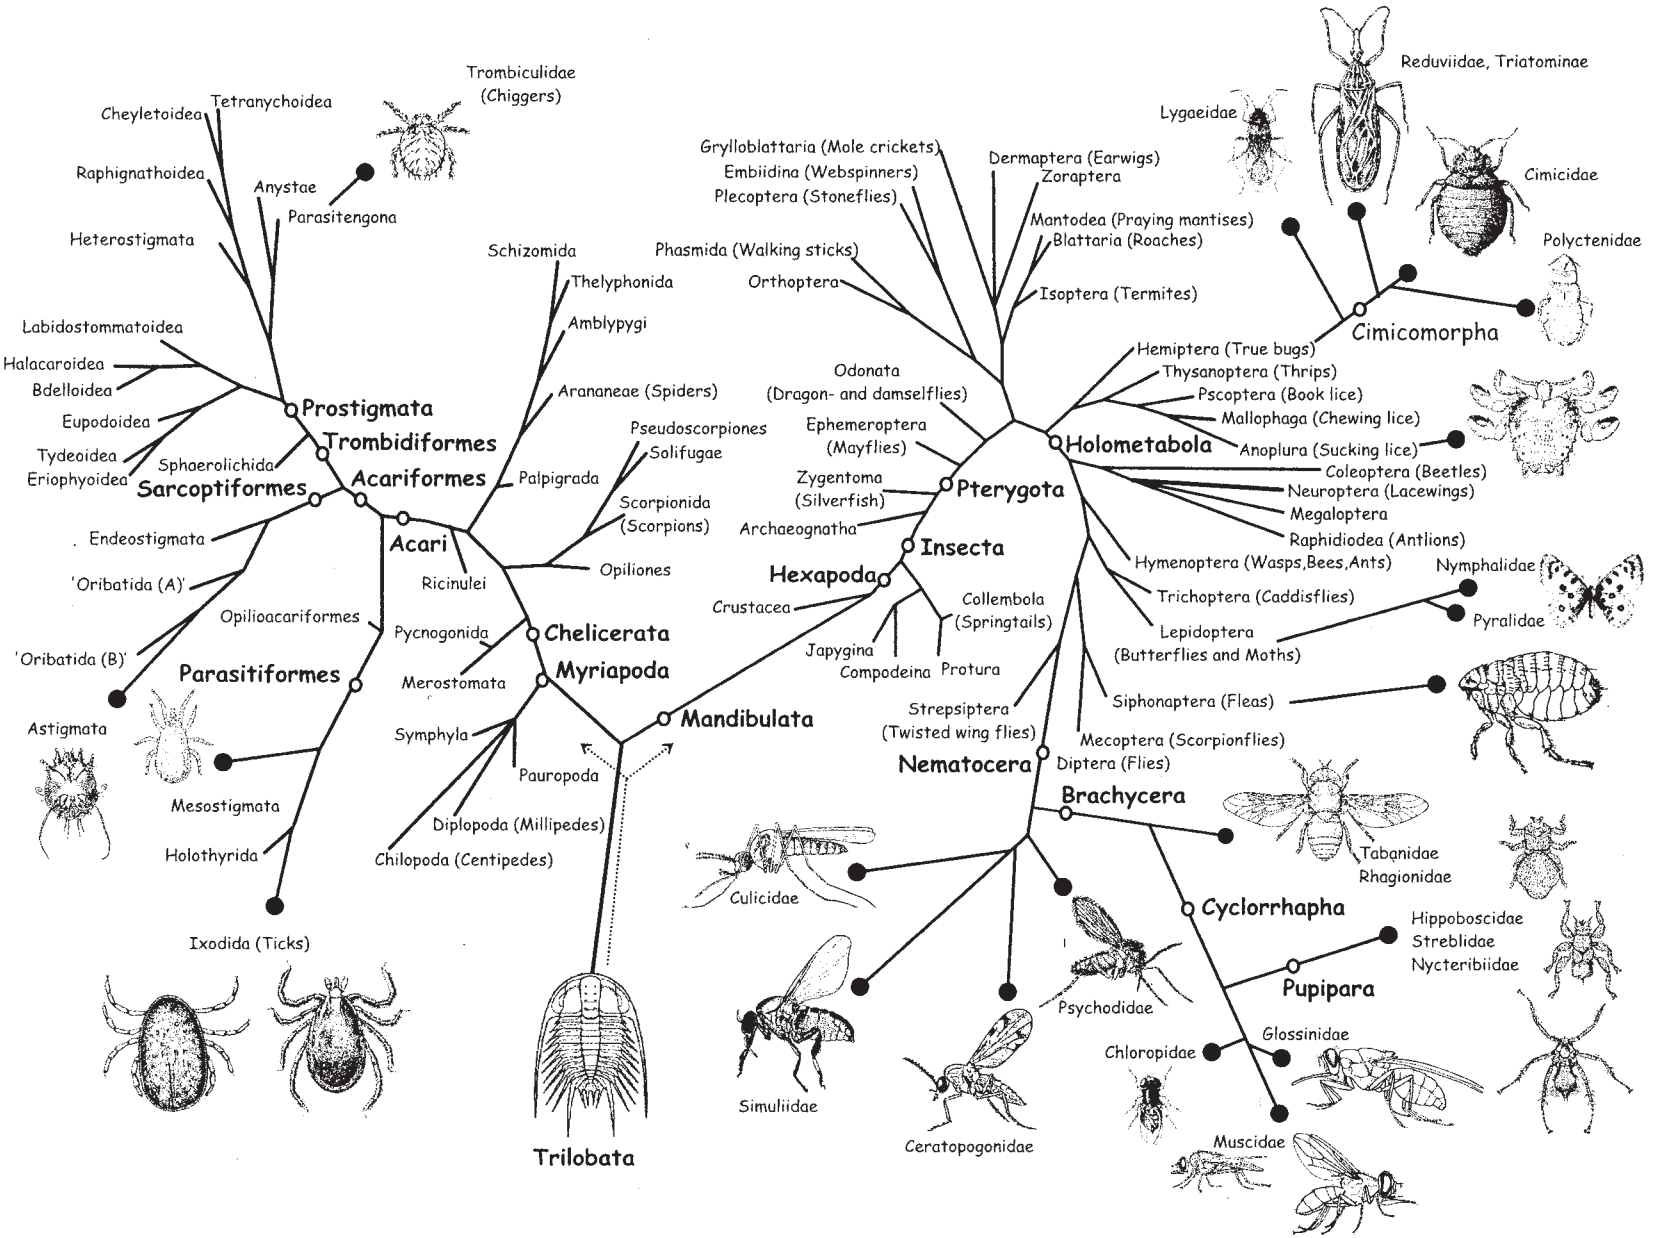
SAM R. TELFORD III

149

Arthropods comprise a diverse group of invertebrate animals (Fig. 1), united in a common body theme (bauplan) of a jointed, chitinous exoskeleton. Four major groupings have classically been recognized: insects, arachnids, crustacea, and millipedes/centipedes; a fifth group contains only the living fossils the horseshoe crabs, which have existed unchanged for hundreds of millions of years. All arthropod classes were extant hundreds of millions of years ago, thereby providing ample opportunity for life history traits such as parasitism to independently evolve, and evolve multiple times, in each class.

Medically important arthropods have long been considered to mainly comprise ectoparasites, parasites that limit their activities to the skin. Parasitism, however, is only one of several associations that comprise the interaction of arthropods of medical importance with humans. Arthropods may actively defend themselves against predation (crushing or swatting) by biting, stinging, piercing, or secreting noxious chemicals. Such defenses would operate regardless of the attacker, be it human or other arthropod. Passive modes of defense may inadvertently affect humans, such as irritation after brushing the urticarial hairs of certain caterpillars. Arthropods may also be medically important due to indirect effects: fear of insects, delusional parasitosis, or allergy due to dust mites. The various modes by which arthropods may affect human health thus reflect the diversity of these animals, but there are very few instances where it may be argued that natural selection favored the offspring of those that focused on causing misery. Accordingly, arthropods should be viewed as a normal part of the environment that under individual circumstances may cause pathology. In addition, because of their ubiquity, spurious associations with pathology are common.

ARTHROPODS AS VECTORS



Arthropods are thought of by many in clinical settings with respect to their role as vectors, transmitters of infectious agents including viruses, bacteria, protozoa, and helminths. Infectious agents may have an obligate relationship with an arthropod (biological transmission) or may simply contaminate an arthropod (mechanical transmission). Malaria parasites undergo a complex developmental cycle within certain mosquitoes and could not perpetuate without them. In contrast, the agent of trachoma *(Chlamydia trachomatis)* is found on the external surfaces of eye gnats and flies (17) and may be transferred between hosts by the act of landing and crawling, but *C. trachomatis* more commonly perpetuates by direct contact of hosts. Mechanical transmission of an infectious agent is dependent on its stability and quantum of infection. Human immunodeficiency virus (HIV), for example, does not survive long outside of the body, and the femtoliter or so of material that may contaminate the mouthparts of a mosquito would not contain enough viable lymphocytes with HIV to initiate infection; thus, mosquitoes have never been epidemiologically linked with HIV transmission even though mosquitoes and other hematophagous arthropods obviously feed on viremic individuals.

There are five major groups of vectors: the diptera (flies and mosquitoes), hemiptera (kissing bugs), siphonaptera (fleas), anoplura (lice), and acarines (ticks and mites). The general life history strategies for each group provide the basis for understanding vectorial capacity, which is the sum of physiological and ecological attributes that allow transmission. Specific vector-pathogen relationships are discussed in detail in chapters focusing on the respective agents but are succinctly summarized here in Table 1.

Diptera

The dipteran vectors are winged insects that include mosquitoes, sand flies, blackflies, gnats, horse/deerflies, and tsetse flies. These range in size from minute (ceratopogonid midges less than 2 mm in length) to large (horseflies more than 2 cm in length). Unlike other winged insects, dipterans have only one pair of wings. Those that take blood meals as adult females may serve as vectors. Blood meals are used as nutrient to produce eggs (anautogeny); once those eggs are laid, another blood meal may be taken and more eggs produced. Thus, unless a mosquito (as an example of a dipteran) inherits its infection (transovarial or vertical transmission), the first blood meal infects it and the second allows the agent to be transmitted; under favorable environmental circumstances, a mosquito may survive for several weeks and take more than two blood meals. Both male and female flies and mosquitoes also require sugar meals (usually from plant nectar), but sugar meals can result in reproduction only in certain species (autogeny).

Trichoptera (Caddisflies)
Lepidoptera (Butterflies and Moths)
Nymphalidae
Pyralidae
Siphonaptera (Fleas)
Mecoptera (Scorpionflies)

Eggs are laid in water or within detritus. Vermiform larvae emerge from the eggs and develop through several stages (instars) in water or detritus, feeding on organic material or bacteria, culminating in pupae from which emerge new adults, thereby undergoing complete metamorphosis (holometabolous development). Depending on the species and the ambient temperature, the duration of the dipteran life cycle may be as short as a week or so. Tsetse flies are an unusual exception to this pattern and produce only one advanced larva for each blood meal, with the larva nourished internally from milk gland analogs during a gestation of several weeks (8). This large maternal investment in offspring makes adulticiding (trapping and spraying) very effective in reducing tsetse fly populations and thereby reducing the transmission of the agents of sleeping sickness.

The diptera are only transiently associated with a blood meal source. Host-seeking cues include body heat, carbon dioxide (exhaled by the host), mechanical vibrations, and lactic acid or other skin-associated compounds. The flies visually seek hosts with their compound eyes, mainly larger, dark-colored objects with movement, but proximal cues associated with a host seem required to initiate feeding (32). Repellants such as DEET (diethyltoluamide) work by disrupting the airborne gradients of chemical cues that allow diptera to home in to their hosts. Once a host has been identified, feeding is initiated and completed within minutes. Sand flies, blackflies, and mosquitoes have a diverse salivary armamentarium of pharmacologically active substances that promote finding and removing blood. During probing, antihemostatic and anti-inflammatory chemicals are secreted into the feeding channel created in the epidermis. Probing lacerates capillaries, and the ADP that is released from damaged endothelial cells would serve to promote platelet activation, but because diptera secrete an apyrase that cleaves ADP into a monophosphate, platelet aggregation is greatly reduced during blood feeding. In addition, local inflammatory processes are temporarily diminished due to secretion of chemicals such as prostaglandin E_2 (29). Thus, the first few bites from a given species remain unnoticed by the host, although factors in the saliva of blackflies may leave an egg-sized lump that is hot to the touch at the site of their bites. Such lumps may persist for several days and may be accompanied by low-grade fever. Such "blackfly fever" should not be misinterpreted as infection; it will resolve on its own without treatment.

The variety of proteins that are deposited within skin during vector feeding are the basis for hypersensitivity reactions, mainly itch, in hosts that are exposed to bites more than once over the course of weeks. Repeated exposure over months may lead to tolerance and a return to failing to react to bites. Although much work remains to be done, there appears to be some cross-reactivity between salivary products from different groups of vectors so that some individuals may equally react to the bites of mosquitoes, bugs, or ticks.

The blood-feeding flies have cruder salivary tools, reflecting their less elegant way of feeding, which usually involves scraping the skin with a roughened maxilla and feeding from the pooled blood or lymph. Accordingly, fly bites are more painful regardless of prior exposure, and few flies successfully engorge to repletion on humans.

Freshly blood-fed diptera seek a resting place for diuresis and digestion, usually the nearest vertical surface. This behavior renders those species that bite within houses susceptible to control by indoor residual insecticide spraying.

The transient nature of infestation by blood-feeding diptera means that few specimens are submitted to clinical laboratories. Other than analyses related to confirming the diagnosis of a vector-borne infection, dipterans would come to the attention of laboratorians for issues related to hypersensitivity, or for myiasis (see below).

Hemiptera

The only hemiptera that serve as vectors are the kissing or reduviid bugs, belonging to a diverse and speciose order of minute to large insects with compound eyes, antennae, sucking mouthparts, two pairs of wings (one delicate pair hidden under an outer pair of more robust ones), and a segmented abdomen. All are easily seen without magnification, adult bedbugs being roughly 1 cm in length and adult triatomines ranging in size from 1 cm to more than 5 cm. Small numbers of eggs are produced by females, from which emerge miniature versions of the adults. These nymphs undergo an incomplete metamorphosis (hemimetabolous development), with development through five nymphal stages, each one requiring a blood meal to proceed. The full duration of the life cycle can be as little as 3 months or as great as 2 years. Reduviid bugs are cryptic, living within cracks of mud walls or other narrow, confined spaces. They serve as vectors of trypanosomes *(Trypanosoma cruzi,* the agent of Chagas' disease, and *Trypanosoma rangeli,* an apparently nonpathogenic trypanosome that is often cotransmitted with *T. cruzi)* in the Nearctic. *Triatoma rubrofasciata* transmits a trypanosome that infects monkeys in Southeast Asia (40), but to date there is no known bug-transmitted trypanosomiasis of humans in the Palearctic. Interestingly, there are good natural cycles of *T. cruzi* transmission within the United States from California through virtually all of the southern-central states, all the way over to Maryland, but there are only rare human cases of autochthonous Chagas' disease reported. Two factors account for this paradox: people live in quality houses that are less likely to have infestations of bugs and, more importantly, the main southern U.S. vector, *Triatoma sanguisuga,* does not defecate on the host while feeding (27). Transmission of *T. cruzi* to humans requires contamination of the site of the bite or mucosa by trypanosomes that are excreted in the bug feces.

As with mosquitoes, salivary products from reduviids contain a variety of pharmacologically active compounds. Unlike those of mosquitoes, repeated reduviid feedings may cause a dangerous anaphylactoid reaction in residents of houses where the bugs are common. Scientists working with reduviid bugs often need to carry an epinephrine injector with them due to their propensity to feeding their colonies upon themselves, thereby receiving large doses of salivary antigens.

Although it is possible that a true reduviid bug may be presented by a patient for identification in clinical settings outside of Latin America, it is more likely that such specimens are related heteropterans such as assassin bugs, which are insect predators, or the plant-feeding stinkbugs, chinch bugs, harlequin bugs, or squash bugs. Assassin bugs may

TABLE 1 Summary of the major arthropod genera involved in the biological transmission of infectious diseases

Arthropod(s)	Etiologic agent(s)	Disease
Crustacea		
Decapods	*Paragonimus* spp.	Paragonimiasis
Copepods	*Diphyllobothrium* spp.	Diphyllobothriasis
	Dracunculus medinensis	Guinea worm disease
	Gnathostoma spinigerum	Gnathostomiasis
Insecta		
Anopleura		
Pediculus	*Rickettsia prowazekii*	Epidemic typhus
	Bartonella quintana	Trench fever
	Borrelia recurrentis	Epidemic relapsing fever
Siphonaptera		
Xenopsylla, Nosopsyllus	*Yersinia pestis*	Plague
	Rickettsia typhi	Murine typhus
	Hymenolepis diminuta	Rat tapeworm
Pulex, Oropsylla	*Yersinia pestis*	Plague
Ctenocephalides	*Dipylidium caninum*	Dog tapeworm disease
Hemiptera		
Panstrongylus, Rhodnius, Triatoma	*Trypanosoma cruzi*	Chagas' disease
Diptera		
Aedes	*Wuchereria, Brugia*	Filariasis
	Flaviviruses	Dengue, yellow fever
	Other arboviruses	Encephalitis
Anopheles	*Plasmodium* spp.	Malaria
	Wuchereria, Brugia	Filariasis
	Arboviruses	Encephalitis
Culex	*Wuchereria*	Filariasis
	Arboviruses	Encephalitis
Culicoides	*Mansonella* spp.	Filariasis
Glossina	*Trypanosoma brucei*	African sleeping sickness
Chrysops	*Loa loa*	Loiasis
	Francisella tularensis	Tularemia
Simulium	*Onchocerca volvulus*	Onchocerciasis
	Mansonella ozzardi	Filariasis
Phlebotomus, Lutzomyia	*Leishmania* spp.	Leishmaniasis
	Bartonella bacilliformis	Bartonellosis
	Phlebovirus	Sandfly fever
Arachnida		
Acari (ticks)		
Ixodes	*Borrelia burgdorferi*	Lyme disease
	Anaplasma phagocytophilum	Human granulocytic ehrlichiosis
	Rickettsia conorii	Boutonneuse fever
	Babesia spp.	Babesiosis
Dermacentor	*Rickettsia rickettsii*	Rocky Mountain spotted fever
	Francisella tularensis	Tularemia
	Coltivirus	Colorado tick fever
	Flavivirus	Omsk hemorrhagic fever
Amblyomma	*Rickettsia rickettsii*	Rocky Mountain spotted fever
	Francisella tularensis	Tularemia
	Ehrlichia chaffeensis	Human monocytic ehrlichiosis
Hyalomma	Nairovirus	Crimean-Congo hemorrhagic fever
Rhipicephalus	*Rickettsia conorii*	Boutonneuse fever
	Rickettsia rickettsii	Rocky Mountain spotted fever
Ornithodoros	*Borrelia* spp.	Relapsing fever
Acari (mites)		
Leptotrombidium	*Orientia tsutsugamushi*	Scrub typhus
Liponyssoides	*Rickettsia akari*	Rickettsialpox

inflict extremely painful wounds by their piercing mouthparts, but these would require only typical first aid measures and perhaps a booster of tetanus toxoid given the depth of the puncture wound (proboscises range in length from 3 to 8 mm). The plant feeders may issue noxious secretions, which may taste bad if accidentally ingested (from a bug that infested a fruit or vegetable that was eaten directly from the vine) but would otherwise not be a cause for concern.

Bedbugs *(Cimex lectularius* and *Cimex hemipterus)* are hemipterans but are not known to serve as vectors for any pathogen. These bugs with short broad heads, oval bodies, and four-jointed antennae undergo incomplete metamorphosis, with four nymphal stages, each taking a blood meal in order to develop. The duration of the life cycle is roughly 6 to 8 weeks but may be as long as 11 months, depending on temperature and humidity. These bugs are small, 5 mm or less in length as adults (Fig. 2). They are cryptic and require hiding places such as cracks in walls, mattress foundations, or rattan furniture. At night, bedbugs will emerge and infest sleeping people, taking 10 to 20 min for engorgement. Feeding is often interrupted by the movements of people during their sleep, and so multiple bites may result from a single bedbug (Fig. 2). Blood meals may be taken every week or so, depending on the stage, with batches of 10 to 50 eggs laid; one female may lay 200 to 500 eggs in her life. Various laboratory studies have reported the survival of diverse agents such as HIV (18), hepatitis B virus, *Francisella tularensis,* and West Nile virus within artificially infected bedbugs. Epidemiologically, bedbugs have never been associated with any of these infections. Although one can never say never, the likelihood that a bedbug has served as a vector is infinitesimally small, and a physician may want to question a patient more closely on known risky practices such as intravenous drug abuse.

Siphonaptera

Fleas are bilaterally compressed, heavily chitinized insects with greatly modified hind legs for their characteristic jumping mode of locomotion; they lack wings. They are generally small, no larger than 5 mm in length. Fleas undergo complete metamorphosis, starting from a wormlike larva feeding on organic debris and blood pellets expelled, often with remarkable force and over a long distance, from the anus of the adult flea. The larva develops through three molts (has three instars) and then secretes a silk to form a cocoon, in which it pupates. The female flea requires blood for egg production; one blood meal may serve for the production of several dozen eggs, which are laid on the fur of the host. Eggs become detached from the host's fur, coming to rest within its nest. Most fleas are what are known as "nest parasites." Individual fleas may live as long as a year but usually only for a couple of months, laying eggs daily. As with most arthropods, the duration of the life cycle is affected by temperature and relative humidity, but on average most species take 30 to 75 days to develop from egg to adult.

Of the 2,000 or so flea species that have been described, the vast majority are from rodents and have various degrees of host specificity. Because fleas are generally nest parasites of rodents (and most rodent species are not human commensals), are relatively host specific, and cannot travel long distances (crawling or jumping on the order of a few meters, implying that humans must be directly associated with their habitat for infestation to occur), only a few species are of medical importance. These include the "human" flea *(Pulex irritans),* the dog and cat fleas (*Ctenocephalides canis* and *Ctenocephalides felis),* the main plague vector *(Xenopsylla cheopis),* and the sticktight flea *(Echidnophaga gallinacea).* Of these, *C. felis* is the most notorious pest, feeding voraciously and rapidly developing dense infestations. Chronic infestations of homes are largely due to the presence of a cat or dog (despite its name, this flea will feed on either animal), their bedding, wall-to-wall carpeting, and relatively great humidity within the home. (Cold climates rarely have self-sustaining infestations because winter heating tends to dry out the carpets and molding and other places where the larval fleas tend to be hidden.) Although bites sustained over several weeks will usually induce a typical delayed-type hypersensitivity reaction, with an intensely itching red spot developing at the site of the bite (usually around the ankles), note that not all members of a household will react in the same manner. Some people are more attractive to arthropods than others; others react differently to bites. It is quite possible for only one person to have itchy bites and others in the same house to have none, and thus a diagnosis of flea bite should not depend on the perception that if a household is infested, everyone should demonstrate similar lesions.

The human flea actually feeds on a variety of mammals, including domestic livestock. In tropical sites where homes

FIGURE 2 Bedbugs. (Left) *Cimex lectularius* (bedbug). Scale = 0.5 mm. (Department of Tropical Public Health, Harvard School of Public Health.) (Right) Immediate-type hypersensitivity reaction to bedbug bites acquired in a four-star hotel in Dupont Circle, Washington, D.C., December 2005.

have dirt floors, and livestock share living accommodations, extremely dense infestations may develop. Although this flea is cosmopolitan in its distribution, the cat flea appears to have supplanted it as the major flea pest for humans in many countries.

An unusual flea, the chigoe or jigger *(Tunga penetrans),* will attach to a host and maintain a feeding site. Originally found in Latin America, the chigoe has been carried across to sub-Saharan Africa by humans and may be found anywhere there. This flea will often penetrate under toenails or burrow into skin between toes, or in the soles of feet, an infestation known as tungiasis (Fig. 3). The female *T. penetrans* will swell to 10 times its size, and the host's immune response causes skin to swell up and cover her, with only the end of the abdomen exposed. Through this opening, she will deposit eggs and feces. When the flea dies, the lesion becomes secondarily infected, causing great irritation and pain. Tourists will often become infested by walking barefoot in shady spots around beaches.

Perhaps the most famous flea is the plague vector, the oriental rat flea, *X. cheopis.* Although it prefers rats *(Rattus rattus* and *Rattus norvegicus)* as hosts, in their absence (or when they die) this flea will feed on humans and other animals. These fleas may be found on rats in virtually every tropical or warm temperate port city around the world, having been transported there with their hosts by trade ships. Plague is usually maintained in enzootic foci by wild rodents and their more specific fleas, but in Vietnam, Madagascar, and India, rats and *X. cheopis* appear to be important for perpetuation. Although enzootic plague usually results in sporadic cases, the great fecundity of rats under the right circumstances means that explosive outbreaks of plague may occur in urban areas, with hundreds or thousands of cases. Human exposure in the western United States, where plague is enzootic, may be due to chance contact with ground squirrels or their fleas (often *Diamanus montanus*) in sheds, in disused cabins, in crawl spaces, or by digging around burrows. Domestic cats often serve as an intermediary, hunting moribund rodents and subsequently exposing their owners.

Phthiraptera

Infestation by lice is called pediculosis. Lice are wingless, flat (dorsoventrally), elongate, small (0.4 to 3 mm) insects that are generally characterized by strong host specificity. Classically, two orders were recognized, the Mallophaga (chewing lice) and the Anoplura (the sucking lice); the former now comprises three suborders, and the latter remains as a suborder, all within the order Phthiraptera, which contains about 4,000 species. Of these, the sucking lice are clinically relevant, although the chewing lice may be presented as spurious ectoparasites, or associated with double-pored tapeworm *(Dipylidium caninum)* infection. Most chewing lice are commensals of birds, whereas the sucking lice feed mainly on mammals.

Lice undergo incomplete (hemimetabolous) development, with nymphal forms resembling adult lice, and are often found concurrently with the adults. Thus, size may appear to greatly vary within a single collection of specimens from one host. All lice are delicate and very sensitive to temperature and humidity requirements; all die within days without the host.

Chewing lice usually are found in the feathers of birds, feeding on skin fragments. Virtually all chewing lice lack piercing mouthparts and therefore do not feed on blood. The dog-biting louse *(Trichodectes canis)* may be presented as a specimen because it is a common commensal of dogs and may be spuriously associated with "bites." Dogs serve as definitive hosts for *D. caninum,* the eggs of which are shed in feces; the feces dry on the fur and the louse may then ingest the eggs. The tapeworm eggs hatch and a cysticercoid becomes localized in the hemocoel of the louse. Transmission is effected when the louse is accidentally ingested, usually when the dog is grooming; humans (usually children) are incidentally infected if their hands become contaminated and then touch food or drink or are placed in their mouths.

Book lice (order Psocoptera, also known as psocids) resemble chewing lice and live on molds infesting old books. They are frequently presented as specimens in diagnostic workups for itches of unknown etiology, but do not infest humans or any other animal.

The lice of greatest clinical importance (Fig. 4) are the head louse *(Pediculus humanus capitis),* body louse *(Pediculus humanus corporis),* and pubic louse *(Pthirus pubis).* All of these sucking lice have prominent claws attached to each of their legs, morphologically adapted for grasping the hairs of their host. They feed at least daily and deposit 1 to 10 eggs from each blood meal, gluing one egg at a time onto the shafts of hairs (or in the case of the body louse, onto threads within clothing). The eggs, or nits, are almost cylindrical in shape, and have an anterior operculum. Nits hatch within 4 to 15 days, and each of the three nymphal stages lasts 3 to 8 days. Lice are transferred between hosts by close physical contact, or by sharing clothing in the case of body lice. Schools are excellent sites for the spread of a louse infestation, not only through the sharing of hats and scarves, but by children deliberately infesting others during play. It is possible that transient circumstances, such as a subway headrest recently used by an infested head, could serve as the means

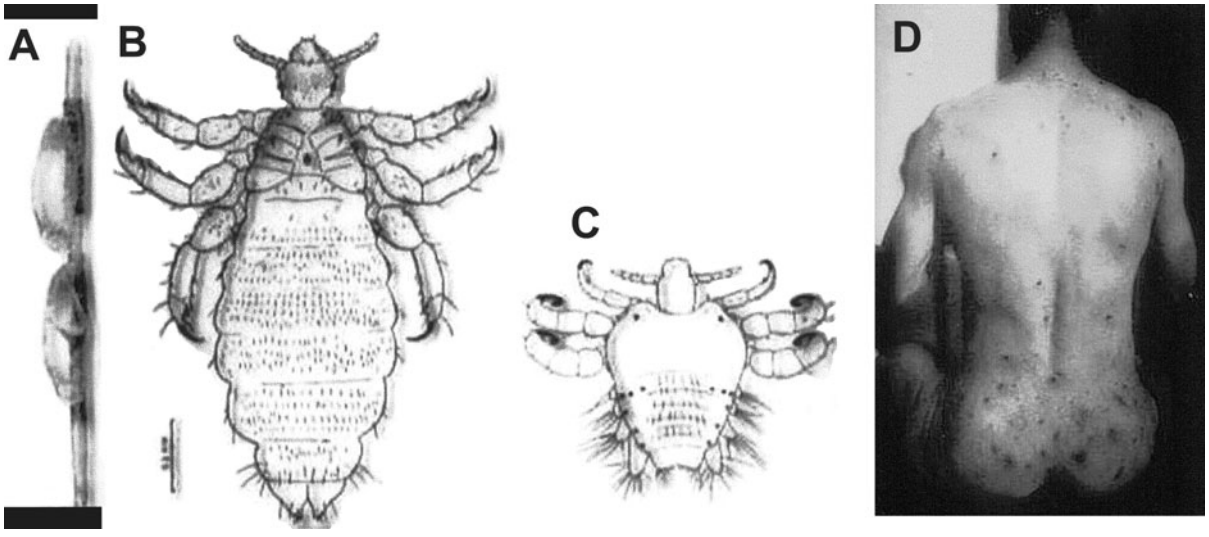

FIGURE 4 Lice. (A) Head louse nits; (B) body louse; (C) pubic louse; (D) vagabond's disease. (Department of Tropical Public Health, Harvard School of Public Health.)

for transfer. The oft-tendered excuse "I got it from a toilet seat" with reference to pubic lice should not be dismissed out of hand, but the probability of acquiring a louse in this manner is far less than by skin-to-skin contact. On the other hand, the presence of pubic lice on the eyebrows usually denotes a sexually transmitted infestation, and pubic louse infestation of a child is cause for an inquiry into the possibility of child abuse.

Body or pubic louse infestation may result in intense irritation for several days, with each bite generating a red papule. Chronically infested individuals may become desensitized, or may develop a nonspecific febrile illness with lymphadenopathy, edema, and arthropathy (although such signs and symptoms should prompt a search for the agent of trench fever). A very few chronically infested individuals may develop "morbus errorum" or vagabond's disease (Fig. 4), with a thickening and dark pigmentation of the skin (14).

Although body louse or pubic louse infestation may be considered evidence of poor hygiene or poor judgement, infestation by head lice should not be a stigma. Nor should head louse infestation be considered to be a public health menace, or even a clinical problem. Very few infestations are dense enough to cause signs or symptoms, and head lice are not vectors. Nonetheless, draconian measures are taken by many school districts, banning an infested child until treatment is thorough enough to remove all nits. Many such schools fail to discriminate between live and dead nits, insisting that all traces of them be absent. Complete removal of all nit remnants can be very difficult, relying mainly on fine-toothed combs, a tool that has been found in the tombs of the Egyptian pharaohs (25).

The sucking lice are both important vectors as well as pests. Among the most notorious vectors in history are the body lice, which may serve as vectors for the agents of epidemic typhus, trench fever, and louse-borne relapsing fever. Napoleon's invasion of Russia in 1812 was probably thwarted by epidemic typhus decimating his troops. It is said that at the end of World War I, a typhus epidemic in Russia and Romania killed 800,000 people (43). Body lice are the product of poor hygiene, with clothes never or rarely being changed, such as in cold weather, by the homeless, or in refugee camps. Trench fever is not uncommon in the homeless, and the most recent large outbreak of typhus was in Burundi, among Rwandan refugees. Oddly, even though the head louse is conspecific and appears vector competent in laboratory experiments, it has not been epidemiologically associated with any of these infections, nor has the pubic louse.

Acarina

The acarines are a subclass within the class Arachnida, which also contains the spiders. Acarina comprise the mites and ticks, tiny to small arthropods with eight legs as nymphs and adults (as opposed to six for insects) and with fused main body segments as opposed to three discrete ones for insects. Acarine bauplane are characterized by two functional body parts, the gnathosoma (or capitulum), which comprises the "head," and the idiosoma, which contains all the remaining functions (reproductive, motility, and digestion). They undergo incomplete metamorphosis, passing through a larval stage and one to several nymphal stages before attaining sexual maturity. The mites are one of the most speciose groups of animals, with 45,000 recognized species. They are among the oldest terrestrial animals, dating in the fossil record to the Devonian (nearly 400 million years ago), and are found in every habitat on earth. There are two major orders of the acarines, the Acariformes and the Parasitiformes. In the former, there are two main groups, the Sarcoptiformes (astigmata) and the Trombidiformes (prostigmata), both of which contain species of clinical significance. The latter comprises three orders, the Holothyrida, the Ixodida, and the Mesostigmata. Of these, only the last two are clinically significant; the holothyrids consist of about 20 species that are found only in Australasia and some neotropical forests, and are unlikely to be encountered (although they are known to secrete a toxin that may incapacitate a human that has ingested such a mite). The mesostigmata (also known as gamasida or dermanyssoidea) include some that infest birds or rodents and that under certain circumstances will infest humans and cause itch. The ixodida consist of the ticks, which are essentially very large mites.

Other than the ticks and some mesostigmatids, mites are generally not considered vectors of agents that infect humans. They are, however, important for their pest potential, causing itch, dermatitis, and allergy.

The house mouse mite *(Liponyssoides sanguineus)* is the vector for rickettsialpox due to infection by *Rickettsia akari*. The relatively mild disease, characterized by fever and exanthema, was first described after a garbage strike in Kew Gardens in the Bronx, New York, N.Y., during the 1940s (16). Garbage piled up, and house mouse populations became dense. When the strike was resolved and the garbage was removed, the mice died or emigrated, leaving behind dense infestations of hungry mites. The prostigmatid trombiculid mites (chiggers) are the vectors for the agent of scrub typhus *(Orientia tsutsugamushi)*, a rickettsiosis of Eurasia and northeastern Australia. Nearly 3 billion people live in countries where scrub typhus is endemic. Scrub typhus is acquired from infestation by tiny (0.2-mm) larval trombiculid mites such as *Leptotrombidium deliense* or *Leptotrombidium akamushi;* an eschar forms at the site of the chigger bite, with proximal lymphadenopathy, fever, headache, exanthema, and myalgia. Case fatality rates can range from 5 to 35% (3). Interestingly, the nymphal and adult stages of this mite feed on detritus or other arthropods and do not take vertebrate blood. Therefore, *O. tsutsugamushi* relies mainly on transovarial or vertical transmission (passage through the egg) for perpetuation, although rodent hosts that are infected may feed noninfected larvae and generate new matrilineages of infected mites. All other vector-borne agents have greater opportunities for horizontal transmission, that is, amplification by infecting a vertebrate host and having multiple blood meals during development.

Mites are extremely difficult to identify, particularly given the likely confusion with dust mites or other ubiquitous free-living forms. All require clearing and mounting on a slide and examination under a compound microscope.

Ticks are prolific vectors, with more recognized transmitted agents than any arthropod other than mosquitoes. All of the nearly 900 known species of ticks require blood for their development and reproduction. Clinically relevant ticks belong to either the Ixodidae (the hard ticks) or the Argasidae (the soft ticks); a third family, the Nuttallielidae, comprises a monotypic genus of soft ticks found in southern Africa and for which an association with a pathogenic agent has yet to be described. Hard ticks are so named because of the hardened sclerotized idiosomal shield, or scutum. In female hard ticks, the scutum is on the anterior third of the idiosoma, with the remainder of the idiosoma consisting of a pleated, leathery cuticle that allows for tremendous expansion during blood feeding. In male hard ticks, which may or may not feed at all, the scutum extends the length of the idiosoma. In contrast, soft ticks have no scutum; their entire idiosoma is leathery.

The "head," or capitulum, consists of the holdfast (hypostome), the chelicerae (which are homologs of insect mandibles), and the palps, which cover the mouthparts (hypostome and chelicerae) and serve a sensory function. Chelicerae act as cutting organs, the two sides sliding past each other, with the cutting teeth at the end gaining a purchase into a host's skin. The hypostome is thereby inserted, allowing anchoring of the entire tick due to recurved, backward-facing teeth or denticles (Fig. 5). Many hard ticks also secrete a cement around the hypostome. Often, when removing an attached dog tick *(Dermacentor variabilis)* from a host, a large piece of skin comes with the hypostome, mostly cement and surrounding epidermis. Thus, by virtue of the cement and denticles, tick hypostomes rarely emerge intact when a tick is removed. "Leaving the head in" is not critical, and most times the remnant will be walled off as a foreign body, or will work itself out, perhaps by the act of scratching. Treatment, therefore, should simply be disinfection of the site of the bite and certainly not excavation of the epidermis looking for the "head." Soft ticks are transient feeders and will only rarely be found attached.

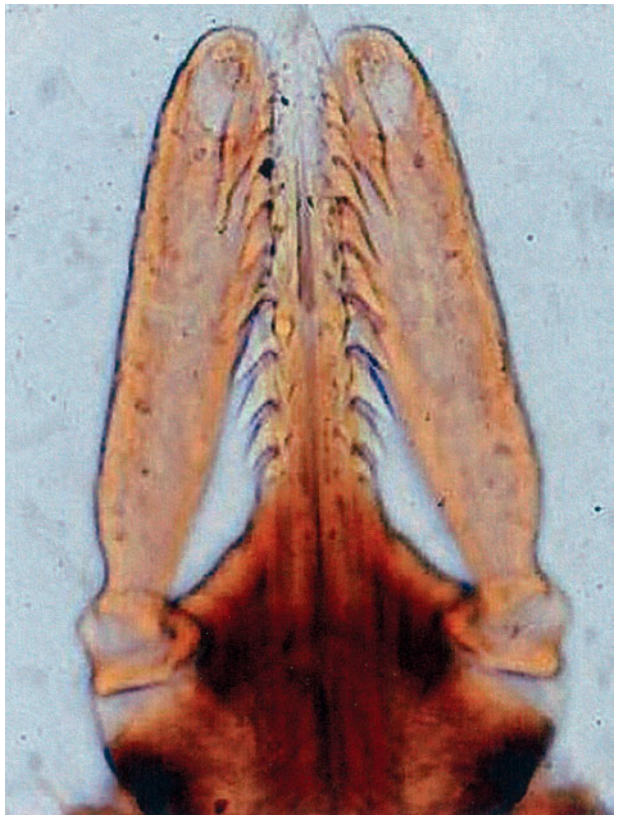

FIGURE 5 Tick hypostome, showing recurved denticles.

Hard ticks require several days to complete their blood meal; the number of days depends on the species and stage of the tick. North American deer ticks (*Ixodes dammini* [30, 35]) will feed for 3 days as a larva, 4 days as a nymph, and 7 days as the female. The closely related European sheep or castor bean tick, *Ixodes ricinus,* feeds for 2 days as a larva, 3 days as a nymph, and 7 days as the female. The duration of feeding depends also on host immune status (previous exposure may induce immediate-type hypersensitivity, which slows down the feeding process) and temperature (*I. dammini* and *I. ricinus* feed twice as long on cold reptiles as on ones that are held at 37°C). The extended duration of feeding is required for the cuticle to soften so that the idiosoma may accommodate 10 to 100 times its weight in blood; also, the site of the bite is prepared so that a pool of lymph and blood is available for removal. During the first 70% of the feeding process, very little blood or lymph appears to be present within ticks, which remain dorsoventrally flat. Hemoglobin is excreted from the anus, lipids are retained, and water from the blood is recycled back into the host as saliva (4). In the last day, usually in the last 3 or 4 h of the blood meal, the tick takes what has been termed "the big sip," removing a large volume of whole blood, and then detaches and drops from the host.

Because they must remain attached for days, hard ticks have evolved means of temporarily disabling a host's local inflammatory response, which might inhibit its feeding. Hard tick saliva is an extremely complex mixture of anticoagulant, anti-inflammatory, and antihemostatic agents (28) that act mainly at the site of the feeding lesion. Tick saliva will also neutralize Th2 responses systemically (42). Hosts that have never been exposed to ticks will not realize that a tick is attached. Indeed, most patients with Lyme disease or spotted fever never knew that they had been "bitten" (34, 41). The most dangerous tick is not necessarily the one that a patient finds and removes, aborting the transmission process, but the one that he or she never knew was there and which was able to complete its feeding.

In contrast, soft ticks are more like mosquitoes in their feeding, spending tens of minutes to no more than a few hours feeding, usually as their host is sleeping. Soft tick saliva does not "need" to be as clever, and in fact some species have painful bites. The pajuello (pajaroello), *Ornithodoros coriaceus,* of California and Mexico is renowned for its "toxic bite," which causes local pain and burning (14).

Tick life cycles have an extended duration, usually months or years. Deer ticks, for example, take 2 years to go from egg to egg. For this reason, there is generally no risk associated with hard ticks engorging and dropping off of a companion animal within a person's home. The engorged tick will not feed again, and will take weeks to molt or lay eggs, and in the interim, usually the relative humidity within the house is too low for extended survival of the tick. On the other hand, cats as opposed to dogs appear to be a risk factor for acquiring Lyme disease, perhaps because deer ticks feed well on dogs but poorly on cats; ticks, particularly nymphs, will detach in mid-feed and readily reattach to the cat's owner (10). The exceptions to the lack of risk associated with ticks engorging and detaching in the household is with the brown dog tick *(Rhipicephalus sanguineus),* which is the vector of Marseille fever (Mediterranean spotted fever, boutonneuse fever) and *Ehrlichia canis* and has also recently been documented as a vector of Rocky Mountain spotted fever. These ticks will hide behind wall molding to molt and indeed are known for dense infestations covering the interior walls of dog kennels.

Ticks can be difficult to identify, depending on their state of engorgement and whether mouthparts are intact. Although tick systematists have recently altered some of the generic epithets, in general the classic Centers for Disease Control and Prevention (CDC) diagrams of the mouthparts and idiosoma (Fig. 6) can be used to at least classify a tick to the genus level. Often, simply knowing the country in which a tick may have been acquired will significantly narrow down the list of possibilities (Table 2).

ARTHROPODS AS "SCALARS"

Vectors impart directionality to a pathogen. In contrast, there are arthropod-pathogen relationships that are not characterized by directionality, and analogous to mathematical terminology, arthropods that inadvertently serve as a source of infection are called scalars (33). Helminths may use an arthropod as an intermediate host, but that arthropod does not deliver the infectious stage of the helminth during an obligate behavior such as blood feeding. Drinking water with copepods (crustacea) containing third-stage larvae of the filarial nematode *Dracunculus medinensis* will initiate infection when the copepods are digested by stomach acids, thereby liberating the nematode larvae, but the copepods do not swim towards a vessel scooping water out for drinking. Accordingly, the patient's history needs to specifically address the possibility of exposure via drinking from natural bodies of water (copepods and *Dracunculus*); the presence of flour beetles, fleas, or roaches (hymenolepidid cestodes, *Dipylidium caninum,* and *Gongylonema* spp.); eating of crabs or crayfish (*Paragonimus* spp.); or being in an environment with dense infestations of houseflies (trachoma). With the exception of houseflies and trachoma (which perpetuates in the absence of flies, spreading by direct contact with ocular exudates), all these are obligate relationships.

Muscoid Flies

The muscoid diptera include the muscids (houseflies and stable flies), the Calliphoridae (blowflies), and the Sarcophagidae (the flesh flies). Egg deposition and larval development occur in characteristic materials, viz., fecal material for houseflies, decaying plant material for stable flies, live flesh for blowflies, and carrion for flesh flies. These flies can be remarkably prolific within short periods: a female housefly, for example, deposits 100 to 150 eggs in moist, decaying organic material, usually excrement, at one time, but may do so 20 or more times (15). Larvae emerge from the eggs within 12 h. Three larval stages develop during a week, and a puparium is formed. The adult fly emerges from the pupa within 4 days, and copulation may occur within 1 day. Thus, a full life cycle may take as few as 12 days.

Houseflies have received much attention for their potential as scalars because of their association with poor hygiene. Flies are strong fliers and move readily from outdoors to indoors. A large fleshy structure at the apex of the proboscis provides a surface for contamination, as do the hairy body and legs of the fly. In addition, flies may regurgitate while feeding, and the vomitus may contain organisms that were acquired in a previous landing. Houseflies commonly feed on human excrement, and virtually every possible enteric pathogen (those causing amebiasis, cholera, typhoid, hepatitis A, and poliomyelitis; even roundworms and *Helicobacter pylori*) has been detected within or upon them. With few exceptions, such findings are epidemiologically irrelevant inasmuch as all of the agents perpetuate in their absence. Poliovirus, for example, was recovered in flies captured from sites where polio was actively being transmitted (38), but use of DDT failed to curtail the epidemic. In contrast, residual DDT treatment of army camps reduced the incidence of shigellosis (39). It is likely that individual cases of enteric disease may derive from fly contamination of food, but whether the risk of such an event merits worry by patients or their health care providers remains unclear. Dense infestations of flies should be reduced (by source reduction, i.e., by preventing flies from getting access to garbage and excrement); a few flies in the house do not warrant setting off a bug bomb.

Cockroaches

Roaches are dorsoventrally flattened, smooth-bodied, winged insects with long antennae, biting-type mouthparts, and abdominal projections (cerci). The outer pair of wings is thick and leathery, and the inner pair is membranous. Roaches may fly, but they usually scuttle about on long, spiny legs. They undergo incomplete metamorphosis, with the immature forms looking like miniature adults, although without wings. Eggs are laid within a hard capsule, the ootheca, which is deposited in a dark crevice. Development is slow, taking about 4 weeks between molts; many roaches have only one generation each year. Roaches can live for months without food, but water seems critical. They are

TABLE 2 Likely human-biting ticks and possible tick-borne infections by global region

Region	Likely tick(s) infesting humans	Possible zoonosis[a]
North America	*Ixodes dammini, Ixodes scapularis, Ixodes pacificus, Ixodes dentatus, Ixodes cookei*	Lyme disease, babesiosis, HGE, Powassan fever
	Dermacentor variabilis, Dermacentor andersoni, Dermacentor occidentalis	RMSF, CTF, tularemia
	Amblyomma americanum, Amblyomma maculatum	Masters' disease/STARI, RMSF, tularemia, HME
	Ornithodoros hermsi, Ornithodoros turicata	Relapsing fever
South America	*Amblyomma cajennense*	RMSF
	Ornithodoros spp.	Relapsing fever
Europe, Russia	*Ixodes ricinus, Ixodes persulcatus*	Lyme disease, babesiosis, HGE, TBE
	Dermacentor marginatus	TIBOLA
	Rhipicephalus sanguineus	Marseille fever, HME?
Japan, China, Korea	*Ixodes ovatus, I. persulcatus*	Lyme disease, babesiosis, HGE, TBE
	Dermacentor spp.	Tick typhus, JSF?
	Haemaphysalis spp.	JSF?
South Asia	*Haemaphysalis* spp.	KFD
	Hyalomma spp.	CCHF
	R. sanguineus	Tick typhus
Southeast Asia	*Ixodes granulatus*	Lyme disease?
	R. sanguineus	Tick typhus? HME?
Australia	*Ixodes holocyclus*	Tick typhus
North Africa	*Hyalomma* spp.	CCHF
	R. sanguineus	Marseille fever, HME?
	I. ricinus	Lyme disease
West Africa	*Hyalomma* spp.	CCHF
	Ornithodoros erraticus	Relapsing fever
	Amblyomma variegatum	ATBF
Sub-Saharan Africa	*A. variegatum, Amblyomma hebraeum, Haemaphysalis leachi*	ATBF
	Hyalomma spp.	CCHF
	Ornithodoros moubata	Relapsing fever

[a] HGE, human granulocytic ehrlichiosis (*Anaplasma phagocytophilum*); HME, human monocytic ehrlichiosis (due to either *Ehrlichia chaffeensis* or *Ehrlichia canis*); RMSF, Rocky Mountain spotted fever; STARI, southern tick-associated rash illness (etiology unknown, possible borrelia); CTF, Colorado tick fever; TIBOLA, tick-borne lymphadenopathy (*Rickettsia slovaca*); JSF, Japanese spotted fever (*Rickettsia japonica*); TBE, tick-borne encephalitis; CCHF, Crimean-Congo hemorrhagic fever; KFD, Kyasanur Forest disease; ATBF, African tickbite fever (*Rickettsia africae*).

omnivorous, feeding on the finest of foods to the vilest of waste, usually at night. Secretions deposited by scent glands (including trail and aggregation pheromones) give rise to a characteristic disagreeable odor that confirms an infestation even when live roaches cannot be found. Common roaches range in size from the small German cockroach (*Blatella germanica*), about half an inch in length, to the American cockroach, nearly 2 in. Much work has been done attempting to incriminate roaches as scalars, even estimating nearly 14,000 CFU of bacteria (mainly *Staphylococcus* spp.) on the surface of the body of one German cockroach (14). Feces laden with *Vibrio,* the agent of cholera, were fed to American cockroaches, with ingestion of as much as 200 μl of material and recovery of live vibrios 30 to 80 h later from roach feces (5). A roundworm (*Gongylonema* spp.) normally infecting ungulates may encyst within roaches and be transmitted to humans when ingested, usually as a contaminant of food. As with flies, the presence of roaches suggests poor environmental hygiene, but only rare instances of enteric disease might be associated with them. Dense infestations may produce large amounts of antigenic material (feces, molted cuticle, or parts from carcasses), which may be implicated in allergic or asthmatic reactions.

Control of roach infestations can be difficult. Boric acid, deposited along walls, behind moldings, and around other sites where they may hide, is effective in killing adults and nymphs by abrading cuticle between abdominal segments, rendering the roach prone to desiccation. Removing standing water (wiping up and getting rid of clutter around sinks) can also reduce infestations by preventing access to water. Roach infestations are most common in apartment buildings serving transient student or immigrant populations, who bring the insects in with their household goods.

DIRECT INJURY DUE TO ARTHROPODS

Arthropods Typically Thought of as Vectors

Vectors such as lice, ticks, bugs, fleas, mosquitoes, and blackflies may directly cause injury by their bites, either by hypersensitivity reactions or toxic effects of their salivary products. Hypersensitivity reactions mainly manifest as itch, with the concomitant potential for secondary infection due to scratching. Bedbug and flea bites may cause immediate-type hypersensitivity reactions with itchy erythema greater than 3 cm in diameter (Fig. 2). Ticks may induce a chronic local granulomatous lesion, persisting for months, perhaps due to remnants of the mouthparts (denticles) left within the epidermis. This phenomenon is particularly pronounced with "seed tick" infestation (stepping into a newly emerged batch of larval *Amblyomma* ticks, often thousands), where dozens or hundreds of ticks may attach at the belt line. Itch

may be immediately relieved by calamine (or Caladryl with Benadryl) lotion, or even holding the affected part under very hot running water, which will induce mast cells to degranulate. Over-the-counter hydrocortisone creams may help mild cases of itch, but severe cases may require prescription strength steroid cream (e.g., betamethasone, 0.05%). Daily application of hydrocortisone should promote a resolution of itch within a week. Tick granulomas may be treated with Retin-A gel (0.05%), which may promote the turnover of epidermis and ejection of remaining antigenic material (personal observation).

As mentioned in the introduction to diptera, blackfly bites may produce blackfly fever, usually as a dose-dependent reaction. Usually, the site of the bite become edematous, with a golf ball-sized lump and an oozing punctate lesion. Fever and myalgia will manifest that night and disappear within 24 h. Such symptoms should not be construed as infection; few pathogens, if any, will have such a short prepatent period. Treatment is symptomatic. Similarly, soft tick bites due to pajaroello or the African tampan *(Ornithodoros moubata)* may immediately cause pain, swelling, and irritation at the site of the bite, with raised hard wheals (24). The effects are said to last several days, with "irritability" of the affected part. Anecdotally, hunters in northern New England and the upper Great Lakes may complain of bites of *Dermacentor albopictus* larvae (a species that usually feeds only on ungulates such as deer or moose) during the early winter; apocrypha indicates that Native Americans called these larvae "bite all same as a piece of fire" (6). The condition has not been studied.

An unusual toxicosis due to tick bite is tick paralysis. The presence of certain feeding ticks induces an acute ascending paralysis. First described for sheep and cattle in Australia in 1843, a similar disease was reported for a child in Oregon in 1912. The Australian *Ixodes holocyclus* attacks cattle, sheep, and dogs but rarely humans, and thus tick paralysis is not a common clinical condition there. However, in the western United States, bites of *Dermacentor andersoni* commonly produce cases of "staggers" in cattle or sheep, which may terminate fatally. Children are the usual victims of tick paralysis, with ticks attached at the nape of the neck. The illness is characterized by fatigue, irritability, distal paresthesias, leg weakness with reduced tendon reflexes, ataxia, and lethargy. Unless the tick is removed, quadriplegia and respiratory failure may result; the case fatality rate without treatment can be 10%. Removal of the tick induces a miraculous recovery within 48 h. (Tick biologists unromantically suggest such an etiology for the tale of Snow White, who awakens after the Prince bends over her and kisses her, probably removing a tick from behind her ear.) A 40- to 60-kDa toxin has been isolated from *I. holocyclus* and has been named holocyclotoxin (21); an antitoxin has been produced for veterinary use. Others with a much lower molecular weight have also been isolated. The toxin has not been isolated from the American tick paralysis ticks. Other ticks (*Amblyomma americanum* and *Ixodes* spp.) have also been reported to induce tick paralysis.

Endoparasitic Arthropods

Arthropods that invade a host's body and cause disease include mites (scabies), fleas (tungiasis), fly larvae (myiasis), and pentastomes (halzoun). Tungiasis was discussed above as part of the general flea section. Pentastomes, or tongue worms, are primitive, elongate arthropods that live as adults in the lungs and air passages of hosts, including fish, amphibians, reptiles, and some mammals. The body, like that of acarines, consists of a cephalothorax and indistinct abdomen, with no legs; often, the cuticle appears ringed or annulated. Chitinous hooks protrude from the head. Their size ranges from 1 to 10 cm. Although long thought to be in its own phylum, recent cladistic analyses based on morphological and molecular characters place it within the Crustacea and most closely related to the branchiurid fish lice (20). Pentastomes undergo a complex life cycle with incomplete development, requiring intermediate hosts in which the nymphal stages may encyst.

Human infestation by *Linguatula serrata* may be due to ingestion of eggs (from contamination by nasal discharges from the dog intermediate host) or ingestion of encysted nymphs within the raw or poorly cooked liver, lungs, or mesentery of an intermediate host such as rabbits, cattle, or sheep (31). A nasopharyngeal syndrome results, known as halzoun in the Middle East and marrara in Sudan. Facial edema, nasal discharge, coughing, and sneezing are due to the migration of nymphal forms into the nasopharynx. Removal of the offending nymphs (by visual inspection and forceps) and symptomatic treatment with antihistamines to reduce edema may be helpful. *Armillifer armillatus* and *Porocephalus crotali* of snakes also cause infections in humans, probably as a result of contaminating drinking water with eggs from their feces and not because of ingestion of poorly cooked snake meat. Usually, human infection is noted only at autopsy or by the presence of calcified abdominal or lung objects in radiographs. Treatment is symptomatic.

The most common of the ectoparasite-caused direct injury is scabies, caused by infestation with the human scabies mite *(Sarcoptes scabiei)*. A number of different populations of *S. scabiei* have been treated as full species based on their tropism for other animals (including dogs, pigs, sheep, cattle, and goats), but all are morphologically identical. Infestation may occur anywhere in the world. Canine sarcoptic mange is commonly associated with scabies infestations in the owners of the dogs. In either animal or human scabies, transmission is by direct personal contact, and infestations often cluster among groups of people, particularly families. There is little evidence that environments become contaminated; fomites for this organism have not been identified.

The female scabies mite burrows beneath the stratum corneum (Fig. 7), leaving behind eggs and feces within a track-like trail. A few dozen eggs are deposited, and these hatch within a week. Larvae form new burrows, but they may also emerge from the skin and move freely about. Nymphs develop from fed larvae, and they in turn develop into the adult male and female. Normal infestations consist of a dozen or two female mites. Nocturnal itching begins within a month of the first infestation but may begin within a day in previously exposed individuals. Thus, newly exposed individuals, prior to their recognizing an infestation by the presence of itching, may contaminate other individuals. Erythematous papules and vesicles first appear on the webs of fingers and spread to the arms, trunk, and buttocks. The burrows contain granular, highly antigenic feces, which cause both delayed- and immediate-type hypersensitivity reactions. Interestingly, in individuals who are immunocompromised, hundreds of female mites may be found, itching is minimal, but a hyperkeratosis is prominent. Such "crusted" or Norwegian scabies are highly infectious to other people.

Scabies infestations can be easily diagnosed by scraping a newly developed papule (not one that has been scratched) with a scalpel coated with mineral oil. The scrapings in oil may be transferred to a slide and examined by bright-field microscopy at ×100 or ×400 for 300- to 400-μm mites or the smaller black fecal granules. Scabies may be treated with 5% permethrin cream or 1% permethrin rinse (Nix; same as is used for head lice). The method of choice until recently

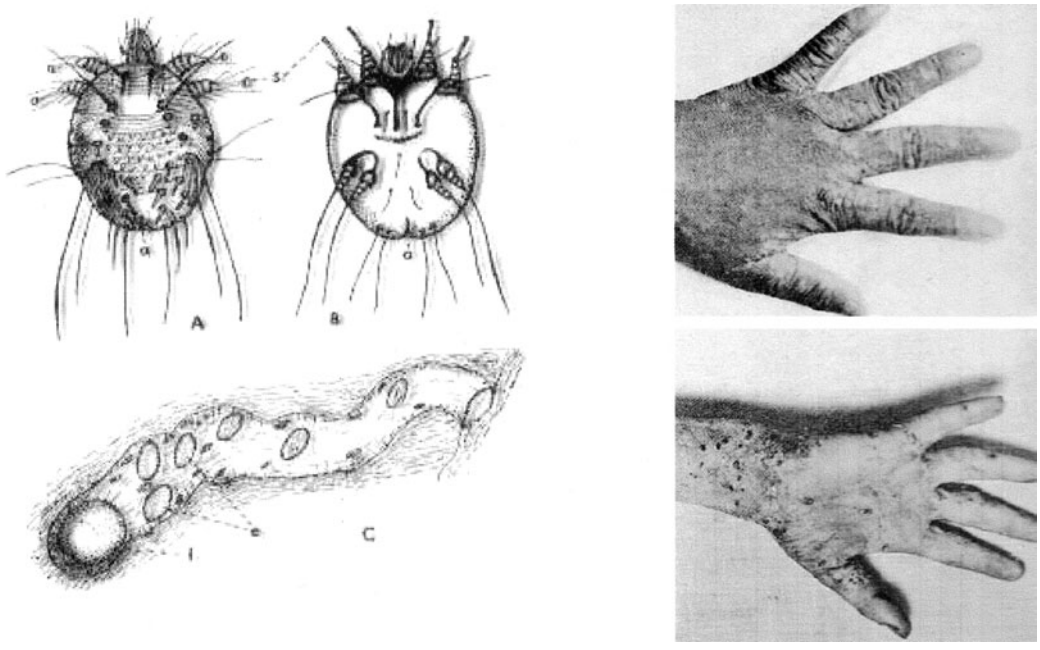

FIGURE 7 Scabies. Diagram of feeding lesion and adult female mite. Chronic scabies affecting the hands. (Reprinted from J. E. Ash and S. Spitz, *Pathology of Tropical Diseases,* W. B. Saunders, Philadelphia, Pa., 1945.)

was topical lindane (Kwell), but the U.S. Food and Drug Administration now suggests the use of permethrin first and lindane only if that fails. Lindane can be neurotoxic to children and small adults.

Demodex folliculorum, the follicle mite, infests virtually everybody. This elongate 500-μm-long mite may be found within follicles on the face, ears, and breast, and it is often brought to the attention of a physician because a tweezed eyelash may have a few mites at the base of the hair shaft. Although they appear to be largely nonpathogenic, the same species causes demodectic mange in dogs and cattle. Pityriasis folliculorum, with small pustules appearing on the forehead, has been attributed to them.

Dust mite allergies (one of many causes of asthma, rhinitis, and atopic dermatitis) are due to inhalation of feces excreted by *Dermatophagoides farinae* or related pyroglyphid mites, which are human commensals that feed on flakes of skin shed from a person. The mites themselves do not infest a person but remain in the environment (usually within bedding or carpets) to feed and develop. About a half gram of skin may be shed from a person each day; one female mite lays one egg a day, for about 2 months; thus, large accumulations of mites may readily develop. The 300- to 400-μm-long mites may be presented by patients as suspects for other nonspecific lesions or sets of signs and symptoms because they may be found in virtually all houses and can be detected if dust is allowed to settle on standing water; the mites float and will move and can be seen at ×20. Humidity less than 60% will greatly reduce dust mite infestations, as will periodic vacuuming and washing of bedding and carpets.

Myiasis is the infestation of human or animal tissue by fly larvae, deposited as eggs or first-stage larvae; the larvae develop by feeding on the surrounding tissue, emerge as third-stage larvae, and pupate in the environment. There are three kinds of myiasis with respect to life cycle patterns: obligate, facultative, and accidental. Obligate myiasis reflects the need for larvae to feed well during development because adult flies do not feed, or they feed poorly. Botflies comprise the main examples of obligate myiasis. Most botflies normally infest animals, and thus human botfly infestation by these species is considered zoonotic. Two flies, *Dermatobia hominis* (human botfly) and *Cordylobia anthropophaga* (tumbu fly), are more adapted to humans, as illustrated by their life cycles. The former fly lays its eggs on a transport (phoretic) host such as a mosquito, and when the mosquito feeds on a human, the eggs hatch during the course of the blood meal and the larvae penetrate the skin at the site of the mosquito bite or burrow in on their own. The latter fly is attracted to sweat, urine, or feces and will oviposit on clothing that has been spread out to dry on the ground or hung up to dry, on areas of cloth that are redolent with such odors, which may remain when primitive clothes washing practices are used. The eggs hatch when placed close to the body and the larvae burrow into the skin. Thus, any clothing washed in tropical countries without the aid of modern soap powders and dryers should be ironed before being worn.

Facultative myiasis is usually due to infestation by blowflies *(Phormia regina),* green bottle flies *(Lucilia sericata)* and related calliphorids, flesh flies (*Wohlfahrtia* spp.), or common houseflies *(Musca domestica).* These flies normally deposit eggs into fecal or other rotting organic material; they will also directly lay eggs into wounds or necrotic tissue, but the larvae may not confine themselves to such resources and move into healthy tissue.

Accidental myiasis includes the incidental findings of fly larvae, often housefly, under wound dressings or within unusual sites such as the gastrointestinal tract. The rat-tailed maggot *(Eristalis tenax)* is actually a hoverfly (syrphid) that breeds in sewage or dirty water. Eggs might be deposited around the anus during defecation, and the larvae may find

their way into the lower gastrointestinal tract or urethra. Drinking unfiltered dirty water might cause temporary infestation of the gut, with larvae surviving into the lower intestine. More often, larvae are found in containers of stool samples that are intended for the clinical laboratory, and are most likely due to oviposition after the sample is taken.

A variety of clinical presentations are evident depending on the site where the larvae are present. Botflies cause furuncular lesions or migratory integumomyiasis (a serpiginous track may be produced in the skin). Wound myiasis comprises shallow or pocketlike initial lesions that become more deeply invasive. Maggots may invade the nose and accompanying structures, causing nasal or oral myiasis. Maggots may get into the ears, producing aural myiasis. Ophthalmomyiasis is due to external or internal infestation. Enteric, vaginal, or vesicomyiasis is due to invasion of the gut or genitalia. In all presentations, pathology may be due to tissue trauma or local destruction, but it is more often associated with secondary bacterial infection. On the other hand, many maggots do not promote bacterial infection, but rather secrete bacteriolytic compounds and have been used as a surgical intervention to debride wounds (9). Sterile *L. sericata* maggots are available by prescription in the United Kingdom, with recommendations for how many "pots" of maggots may be needed for wounds of specific dimensions (http://www.larve.com). Thus, the development of secondary bacterial infection in myiasis may suggest the death of the maggot.

In all cases, treatment is by removal of the maggots, laboriously picking them out using forceps. The maggots causing furuncular myiasis or migratory integumomyiasis will have their posterior end visible within the lesion, exposing the spiracular plates that cover their tracheolar breathing apparatus. Although much lore exists on how to best remove such maggots, including "luring" the maggots with bacon or pork fat, the simplest method is to cover the lesion with petroleum jelly (e.g., Vaseline), thereby preventing the maggot from breathing. (Obstruction of the spiracles is probably the mode of action for bacon or pork rind, not a preference for tasty fat.) It will eventually move out enough in an attempt to get air and so may be grasped with forceps.

Identification of maggots can be difficult. The spiracular plates can be diagnostic (Fig. 8) and should be removed from the posterior end, mounted on slides in an appropriate mounting medium, and compared with pictorial keys. Often, a live maggot can be reared to pupation on raw meat, and the resulting adult fly can be identified. On the other hand, other than academic curiosity, most myiasis cases presenting in developed countries are the result of tourism, and not knowing the specific identity of the fly would not influence further preventive measures; treatment would be sufficient. One important reason for accurately identifying a maggot is for forensic purposes: the developmental rates of the various obligate or facultative myiases have been described as a great aid in assigning time of death for cadavers. The American Board of Forensic Entomology (http://www.research.missouri.edu/entomology/) provides certification for experts in such tasks, and their membership may be consulted should a need for precise identification arise.

Stinging and Biting Resulting in Envenomation

Hymenoptera

Wasps, bees, and ants all belong to the order Hymenoptera, which contains well over 100,000 recognized species. Hymenoptera are minute to medium-sized insects with compound eyes, mandibles, and two pairs of transparent wings (although for the ants, wings may be seen on males or females only at certain times of the year). They undergo complete metamorphosis from a grub-like larva to a pupa. Those of clinical importance are within the Aculeata, particularly the Vespidea (social and solitary wasps), Apoidea (social and solitary bees), and Formicoidea (ants). Most of the Aculeata have a characteristic constriction between the first and second abdominal segments. These insects have a complex social behavior, with males, females, and worker castes. Workers have a stinging organ, which is used for defending the colony or capturing prey.

Most stings by hymenoptera cause localized reactions, sometimes with extreme pain and resulting in a transient induration with hyperemia. By virtue of their living in large colonies, bees and ants may swarm an intruder, and dozens, if not hundreds, of stings may be sustained. Airway obstruction may result should multiple stings be received on the face or neck. Although the honeybee's agricultural value in pollinating plants greatly exceeds any slight risk due to their stings, African honeybees (*Apis mellifera adansoni,* a subspecies of the regular honeybee; also known as "killer bees") which were imported into Brazil in the hope that they would be better pollinators can be dangerous because they are more aggressive than the typical honeybee. Bees differ from wasps and ants in that their stinging apparatus is forcibly torn out during the act of stinging, thereby ensuring the death of the individual bee as a result. Wasps and ants may sting multiple times; some fire ants may hang on by their mandibles and repeatedly insert their posteriorly located stinger.

Bee venom has been well characterized and consists of a large amount of a polypeptide (melittin), phospholipase A2, histamine, hyaluronidase, mast cell discharging peptide, and apamin. Histamine appears to be the cause of the acute pain of bee stings.

Bumblebees, paper wasps, yellow jackets, and hornets may all sting, usually because the victim intrudes too near a nest. The most important clinical manifestation of bee or wasp stings is anaphylaxis. Chest tightness, nausea, vertigo, cyanosis, and urticaria may be seen even in individuals who apparently had never previously been exposed. Dozens of people die each year in the United States due to bee sting anaphylaxis.

Ants, on the other hand, rarely pose a risk for anaphylaxis but produce a reaction that may persist for a longer duration. An induration or wheal may be observed immediately after the sting, and a papule may develop that itches or remains irritated for several days. Secondary bacterial infection may ensue. Fire ants *(Solenopsis invicta)* may bite or sting, both modes accompanied by the injection of a venom, an ethyl ketone for the former and various 2,6-dialkypiperidines in the latter. Other ants (the formicinae) have a venom that is mainly formic acid.

Urticating Caterpillars

Lepidoptera (moths and butterflies) undergo complete development, with the well-known caterpillar and cocoon stages. More than 100,000 species of these familiar insects have been described. Although certain adult moths (in four superfamilies) may imbibe blood or tears, no signs or symptoms are associated with what is evidently an independent evolution of hematophagy. At least eight families of Lepidoptera, however, have caterpillars with urticating hairs, and some of the neotropical species can produce surprisingly severe reactions, including a hemorrhagic syndrome (*Lonomia achelous,* a saturniid moth of the Amazon) due to a fibrinolytic toxin exuding from poison spines (13). More typical are rashes caused by contact with hairs (erucism, or

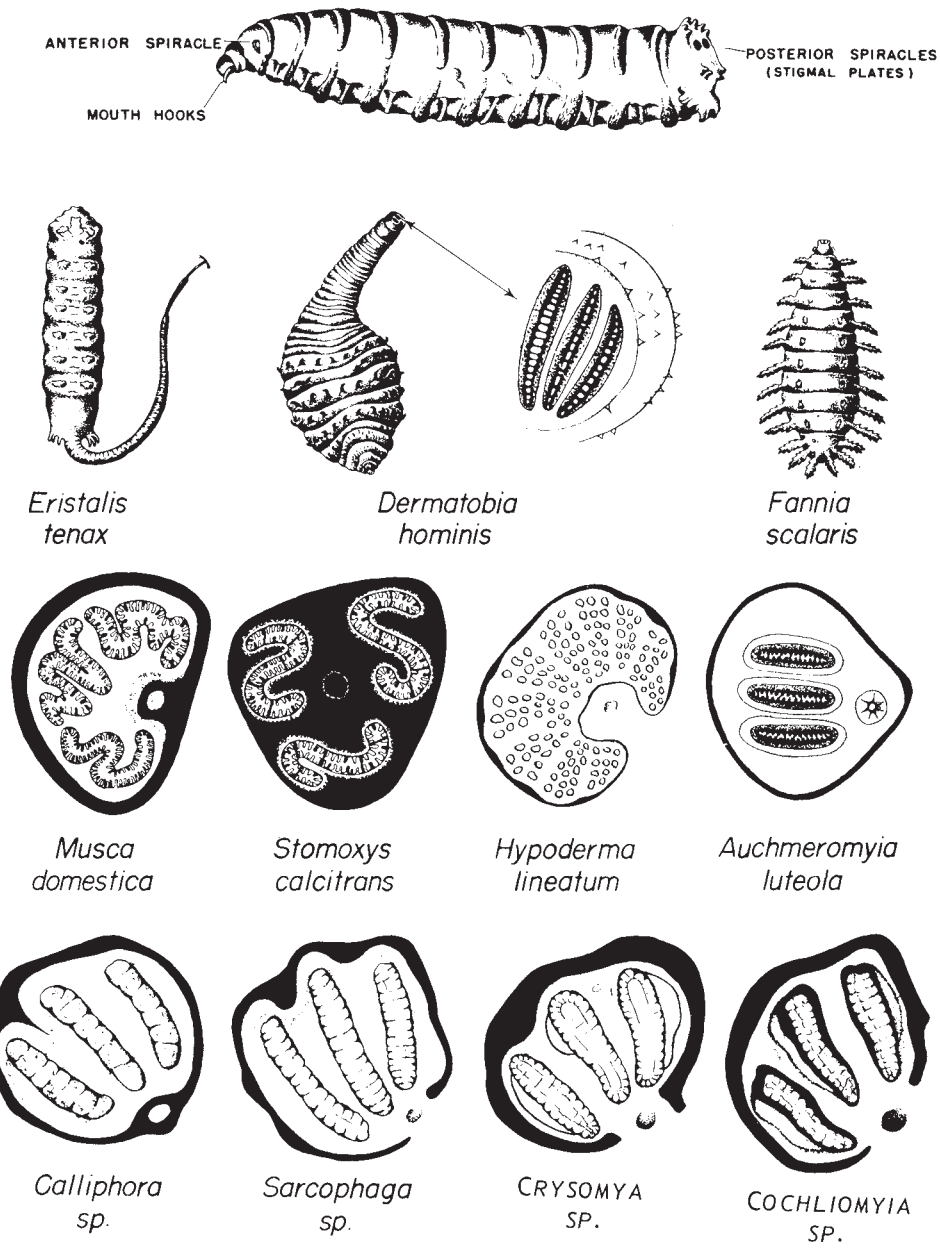

FIGURE 8 Key characters of some myiasis-producing fly larvae. Row 1, mature larva of a muscoid fly (from R. Hegner et al., copyright 1938 by Appleton Century Inc., New York, N.Y.). Row 2, larva of *Eristalis tenax,* the rat-tailed maggot; *Dermatobia hominis,* the human botfly (with an enlarged view of a posterior spiracle); and *Fannia scalaris,* the latrine fly. Rows 3 and 4, appearance of posterior spiracles of some species that produce accidental, facultative, or obligatory myiasis. (CDC, Atlanta, Ga.)

erucic rash). A common shade tree pest, the brown-tailed moth *(Nygmia phaeorrhoea),* in Europe and northeastern North America, liberates tiny barbed hairs when the caterpillar molts. These hairs are blown about by the wind and when skin is exposed, a severe dermatitis results; ingestion or inhalation can also cause significant irritation of the mucosa or bronchospasm. Contact with the eye may induce conjunctivitis. Dermatitis produced by urticating hairs typically comprises itchy, erythematous patches associated with small vesicles and edema. These lesions are only where the hairs have free access to the skin or where contact is made. Use of a masking tape-type lint roller can be very effective in removing urticating hairs, which may or may not be visible.

Scorpions

Scorpions are arachnids with a characteristic crablike appearance. The body consists of the cephalothorax and a segmented abdomen with a segmented tail, which terminates in a prominent stinging apparatus (aculeus). The four pairs of legs include well-defined pincers on the first pair of legs. Scorpions may range in size from 2 to 10 cm. Scorpions undergo incomplete development. Of the 1,000 or so species that are known,

fewer than 50 have been reported to cause illness with their sting. Scorpions are problems mainly in the warmer climates. The bulbous end of the tail contains muscles that force venom through the stinger. All scorpions are predatory on other arthropods, immobilizing their prey with their venom. Humans are stung by walking barefoot at night, by not shaking their shoes out in the morning in an area of endemicity, by lifting rocks or logs, or in bedding that is on the floor. The stings cause local pain (probably due to the great biogenic amine content of the venom), edema, discoloration, and hypesthesia. Systemic signs can include shock, salivation, confusion or anxiety, nausea, tachycardia, and tetany. Venom characteristics differ depending on the genus of scorpion: some stimulate parasympathetic nerves and can lead to secondary stimulation of catecholamines, resulting in sympathetic stimulation, which in turn may contribute to respiratory failure (1). Others affect the central nervous system, are hemolytic, or cause local necrosis. Hypersensitivity and anaphylaxis may occur in individuals who are repeatedly exposed.

Treatment is usually symptomatic, although in areas with known dangerous species (the Middle East [*Leiurus* spp., *Buthacus* spp., and *Buthus* spp.], southern Africa [*Parabuthus* spp., *Buthus* spp., and *Uroplectes* spp.], South and Central America [*Tityus* spp.], and the southern United States [*Centruroides* spp.]), quickly getting a pressure bandage on over the sting and immobilizing the limb (if that is where the sting was) would help to prevent venom from traveling via the lympatics. Lidocaine may be injected directly into the sting to reduce pain. Medical attention should be sought as soon as possible because antivenin, when administered promptly, reduces morbidity. However, antivenin is usually species specific, and without bringing the culprit in for identification, antivenin use would be on a presumptive basis.

Centipedes and Millipedes

The centipedes (class Chilopoda, 2,800 species) and millipedes (class Diplopoda, 8,000 species) are elongate, vermiform arthropods with dozens of segments, each of which bears a pair of legs. Both undergo an incomplete development, with larvae looking like miniature adults. "Centipedes" would suggest having 100 segments (and pairs of legs) or fewer; "millipedes" would suggest more than 100 and up to 1,000. This simplification is not quite correct, but in general, many legs indicate a millipede, and fewer legs (but more than for insects or ticks) indicate a centipede. Other differences are apparent: millipedes are rounded in cross-section, but centipedes are dorsoventrally flattened; millipedes have mouthparts that are ventral and nonpiercing, whereas centipedes have mouthparts that protrude anteriorly and are clearly capable of piercing. Millipedes move slowly, reflecting their mode of life as feeders on detritus. Centipedes are very rapid predators on other arthropods.

The diversity of both millipedes and centipedes is greatest in the tropics, and virtually all those of medical importance are found in warm climates. Millipedes may squirt a noxious, corrosive fluid from pores on their segments. Such fluid may contain benzoquinone, aldehydes, and hydrocyanic acid and cause an immediate burning sensation followed by erythema and edema, even progressing to blistering (2). Most millipedes also have a repugnant smell; both the corrosive fluid and smell tend to protect them from predation. People become exposed when they step on or sleep on millipedes, or provoke them (children playing with them are often victims). Treatment consists of washing the affected site as soon as possible to dilute and remove the corrosive fluids, and is symptomatic for the skin lesions and pain. Centipedes have powerful biting mandibles and small fang-like structures (forcipules) situated between them and derived from the first pair of legs that may inject a venom. This venom is used to immobilize prey, but will be used in defense. Centipede bites occur when people step on or sleep on them or play with them. Envenomation is manifested by local pain and swelling, with proximal lymphadenopathy. Headache, nausea, and anxiety are common. Skin lesions may ulcerate and become necrotic. Death due to centipede bite has been confirmed for only one case, a Filipino child who was bitten on the head by a large *Scolopendra* sp. The common house centipede, *Scutigera coleoptrata* of the eastern United States, is commonly found in bathtubs. This hairy looking, small (5 to 8 cm long) centipede is actually beneficial, preying on roaches and other potential pests within houses. Its strong mandibles can, however, inflict a painful pinch, and it does have a mild venom that produces a bite similar in quality to a bee sting.

Spiders

The Order Araneae comprises nearly 30,000 species, but only a fraction of them have any medical importance. Most are very small (0.5 cm or smaller in length), but a few may be as large as a man's hand. Two major suborders are recognized, the Mygalomorphae, in which the fang-tipped chelicerae operate in parallel using an up-and-down strike, and the Aranaeomorphae, in which the chelicerae operate like insect mandibles, with a side-to-side motion. Spiders have an unsegmented cephalothorax, an abdomen, four pairs of legs, the prominent chelicerae, and spinnerets, specialized organs that secrete silk for making webs. All spiders are predatory on other arthropods and use their venom to immobilize prey, which are stored live. Spiders rend their prey with their chelicerae, and bathe them with a digestion fluid for hours prior to ingestion. Thus, although all spiders have stout chelicerae and can bite, and all spiders have a venom with which to immobilize their prey, most are too small to be noticed by humans even if they were bitten. The spiders of main medical interest belong to four groups (7, 12): the funnel web or trapdoor spiders of Australia (*Atrax* spp., and *Hadronyche* spp.), New World and southern African recluse spiders (*Loxosceles* spp.), South American armed spiders (*Phoneutria* spp.), and the cosmopolitan widow spiders (*Latrodectus* spp.). The recluse and widows have been widely transported by humans.

The clinical manifestations and complications of envenomation may differ among the four main spiders, and the syndromes caused by each have been given names that reflect the identity of the spider. With spider bites in general there are local pain and erythema at the site of the bite, and these may be accompanied by fever, chills, nausea, and joint pains. In loxoscelism, the site of the bite will ulcerate and become necrotic. Skin may slough, and there may be destruction of the adjacent tissues. Hemolysis, thrombocytopenia, and renal failure may ensue. With latrodectism, phoneutrism, and funnel web spider neurotoxicity, the venoms have a strong neurotoxic action. Muscle rigidity and cramping (similar to acute abdomen) are seen with latrodectism; complications include electrocardiogram abnormalities and hypotension. With phoneutrism, visual disturbances, vertigo, and prostration may occur; complications include hypotension and respiratory paralysis (7). Funnel web spiders induce autonomic nervous system excitation, with muscular twitching, salivation, and lachrimation, nausea and vomiting, and diarrhea; fatal respiratory arrest may result from apnea or laryngospasm (23).

Funnel web spider bites require prompt first aid, and the same recommendations could be used for latrodectism or phoneutrism. A compression bandage should be applied over

the site of the bite, and the affected limb should be immobilized by splinting with a compression bandage if a person is bitten on an extremity (standard procedures for snakebite). This may help prevent the venom from moving from the local lymphatics. The patient should seek medical attention as soon as possible for antivenin treatment. Otherwise, treatment is symptomatic with analgesics and antipyretics.

Tarantulas are popular pets and appear fearsome. Fortunately, they are docile and most injuries associated with them are due to their urticating hairs, particularly with respect to conjunctivitis. They do, however, have robust mandibles and venom and should not be provoked; bites are similar in quality to a bee sting.

Necrotic dermal lesions are often classified as loxoscelism even if the appropriate spiders are not known to be present in the area: only 35 of 216 diagnoses of "brown recluse spider bites" proved to be supported by the minimum evidence for assigning such a specific etiology, viz., the known presence of *Loxosceles reclusa* within the geographic area of exposure (37). Severe reactions to tick bite, or even the erythema migrans of Lyme disease, may be confused with recluse spider bites (22).

Miscellaneous Injury Due to Arthropods

Beetles (coleoptera) comprise 40% of all insect species, but even with this great diversity, very few may be harmful. Most injury is related to vesication by secretions containing cantharidin. Hemolymph (blood) of some of these beetles, generally called the blister beetles, also contains this irritant, and thus exposure may be by direct contact with live or dead (crushed) beetles. Cantharidin is the active ingredient of Spanish fly, the alleged aphrodisiac made from pulverized *Lytta vesicatoria.* Ingestion of Spanish fly would irritate the ureter and urethra and cause painful priapism. Overdose or chronic use causes renal tubular necrosis. It is likely that Spanish fly is no longer in demand given the availability of nitric oxide inhibitors.

An unusual group of carabeids, the bombardier beetles, will spray a boiling hot jet of benzoquinone as a defense (11), causing burns and blistering. Blistering is also produced by crushing the staphylinid beetle *Paederus fusca* of Southeast Asia, which contains a toxic alkaloid, pederin.

More commonly, carpet beetles (dermestids), which feed on wool rugs and other animal fur products, are associated with a papulovesicular eruption. In particular, larval dermestids and their hairs or shed skins (exuviae) cause a contact dermatitis.

Water beetles (actually members of the Hemiptera), also known as water skimmers, can inflict strong pinches on unsuspecting toes wading through water.

OTHER INJURY

Delusional or Illusion of Parasitosis

Illusory parasitosis is a condition in which a patient who has a real itch has the mistaken belief that the current itch is due to active infestation by irrelevant arthropods. Often the itch is due to a drug reaction, sunburn, detergents, irritating dusts, poison ivy, or even bona fide arthropod bites (among many other potential sources of itch) that were sustained months in the past. Once a patient has been helped to identify the actual cause of the itch, he or she will not persist in blaming an arthropod. In contrast, in delusory parasitosis the patient cannot be dissuaded that the source of the discomfort is probably not an arthropod. In some patients, there are no objective lesions but simply an insistence that they are infested. Many such cases involve highly educated people who can describe their infestation with great detail. However, they rarely produce a specimen, and when they do, it is usually not an arthropod or part thereof. Delusory parasitosis can be a serious illness which can be treated by experienced mental health professionals.

IDENTIFYING SUBMITTED SPECIMENS

For most purposes, identification to the species level ("this is *Eutrombicula alfreddugesi*") may not provide any more clinically relevant information than identification to a higher taxonomic level ("this is a chigger"). In some cases, simply being able to say "this is definitely an arthropod part, perhaps beetle" may be all the information that is required (in this example, a beetle part may suggest dwarf tapeworm infection or be consistent with urticaria due to the hairs of dermestid beetle larvae, or vesication due to the hot spray of the bombardier beetle). A whole arthropod may be compared with the bauplan diagram to place it within a general group. A classic pictorial key published by the CDC (available from http://www.dpd.cdc.gov/dpdx/HTML/CDProducts.htm) or a simple dichotomous key (Table 3) may be used to narrow the identification down to a known genus of medically important arthropod. Anything more specific will usually require consulting a taxonomic reference or finding an entomologist who will help. Agricultural extension services, university entomology departments, local mosquito or pest control organizations, parasitologists, or local bug-collecting enthusiast clubs may all be of help in identifying a specimen, and usually will not charge out of professional courtesy. (Note that few such entities will be Clinical Laboratory Improvement Amendments certified, and thus fee for service is problematic.)

In some cases, a patient will insist that an arthropod specimen be tested for the presence of an infectious agent. This is particularly common in areas where Lyme disease is endemic. The value of such a practice is dubious, other than for psychologically satisfying the patient's demand. Some commercial laboratories will test for the presence of Lyme disease spirochetes using a PCR assay, but given that the prevalence of infection in the vector may range from 15 to 70%, a positive test is likely. Furthermore, at least with deer ticks, other agents such as those causing granulocytic ehrlichiosis and babesiosis may be present but not revealed by tick testing for Lyme disease spirochetes. Other tick species also are likely to have guilds of microbes as opposed to a sole agent (36). In any event, by the time a PCR result is rendered, the patient may already be experiencing signs and symptoms. For Lyme disease, and likely for ehrlichiosis, postexposure prophylaxis may be provided in the form of two doses of a tetracycline, if the patient remains unconvinced.

The most important variable in determining the riskiness of a tick bite is how long the tick has fed (Fig. 9). If a deer tick is attached for no more than 24 h, regardless of whether it is demonstrated to be infected with Lyme disease spirochetes, *Babesia microti,* or the agent of granulocytic ehrlichiosis, the likelihood of an infectious dose of organisms being transmitted is very small. The biological basis for this "grace period" is a phenomenon known as reactivation, wherein pathogens within ticks require a period of replication after emerging from a period of dormancy that they enter during the long interstadial period between blood meals (19). Reactivation was first described for the agent of Rocky Mountain spotted fever, which attains infectivity within tick salivary glands only after 12 to 18 h of exposure

TABLE 3 Key to the common arthropod classes, subclasses, and orders of medical importance, adult stages[a]

1. Three or four pairs of legs [2]
   Five or more pairs of legs [22]
2. Three pairs of legs with antennae (**insects: class Insecta**) [3]
   Four pairs of legs without antennae (**spiders, ticks, mites, scorpions: class Arachnida**) [20]
3. Wings present, well developed [4]
   Wings absent or rudimentary [12]
4. One pair of wings (**flies, mosquitoes, midges: order Diptera**) [5]
   Two pairs of wings [6]
5. Wings with scales (**mosquitoes: order Diptera**)
   Wings without scales (**other flies: order Diptera**)
6. Mouthparts adapted for sucking, with an elongate proboscis [7]
   Mouthparts adapted for chewing, without an elongate proboscis [8]
7. Wings densely covered with scales, proboscis coiled (**butterflies and moths: order Lepidoptera**)
   Wings not covered with scales, proboscis not coiled, but directed backward (**bedbugs and kissing bugs: order Hemiptera**)
8. Both pairs of wings membranous, similar in structure, although size may vary [9]
   Front pair of wings leathery or shell-like, serving as covers for the second pair [10]
9. Both pairs of wings similar in size (**termites: order Isoptera**)
   Hind wing much smaller than front wing (**wasps, hornets, and bees: order Hymenoptera**)
10. Front wings horny or leathery without distinct veins, meeting in a straight line down the middle [11]
    Front wings leathery or paperlike, with distinct veins, usually overlapping in the middle (**cockroaches: order Dictyoptera**)
11. Abdomen with prominent cerci or forceps; wings shorter than abdomen (**earwigs: order Dermaptera**)
    Abdomen without prominent cerci or forceps; wings covering abdomen (**beetles: order Coleoptera**)
12. Abdomen with three long terminal tails (**silverfish and firebrats: order Thysanura**)
    Abdomen without three long terminal tails [13]
13. Abdomen with narrow waist (**ants: order Hymenoptera**)
    Abdomen without narrow waist [14]
14. Abdomen with prominent pair of cerci or forceps (**earwigs: order Dermaptera**)
    Abdomen without cerci or forceps [15]
15. Body flattened laterally, antennae small, fitting into grooves in side of head (**fleas: order Siphonaptera**)
    Body flattened dorsoventrally, antennae projecting from side of head, not fitting into grooves [16]
16. Antennae with nine or more segments [17]
    Antennae with three to five segments [18]
17. Pronotum covering head (**cockroaches: order Dictyoptera**)
    Pronotum not covering head (**termites: order Isoptera**)
18. Mouthparts consisting of tubular joined beak; tarsi three- to five-segmented (**bedbugs: order Hemiptera**)
    Mouthparts retracted into head or of the chewing type; one- or two-segmented tarsi [19]
19. Mouthparts retracted into the head; adapted for sucking blood (**sucking lice: order Anopleura**)
    Mouthparts of the chewing type (**chewing lice: order Mallophaga**)
20. Body oval, consisting of a single saclike region (**ticks and mites: subclass Acari**)
    Body divided into two distinct regions, a cephalothorax and an abdomen [21]
21. Abdomen joined to the cephalothorax by a slender waist; abdomen with segmentation indistinct or absent; stinger absent (**spiders: subclass Araneae**)
    Abdomen broadly joined to the cephalothorax; abdomen distinctly segmented, ending with a stinger (**scorpions: subclass Scorpiones**)
22. Five to nine pairs of legs or swimmerets; one or two pairs of antennae; principally aquatic organisms (**copepods, crabs, and crayfish: class Crustacea**)
    Ten or more pairs of legs or swimmerets absent; one pair of antennae present; terrestrial organisms [23]
23. Body segments each with only one pair of legs (**centipedes: class Chilopoda**)
    Body segments each with two pairs of legs (**millipedes: class Diplopoda**)

[a] Data from J. Goddard, *Physician's Guide to Arthropods of Medical Importance,* 2nd ed., CRC Press, Inc., Boca Raton, Fla., 1996, and National Communicable Disease Center, *Pictorial Keys: Arthropods, Reptiles, Birds, and Mammals of Public Health Significance,* Communicable Disease Center, Atlanta, Ga., 1969.

to a host. Reactivation is probably a general phenomenon with most ixodid (hard) tick-transmitted agents, the only known exceptions being the viruses causing tick-borne encephalitis and the related Powassan fever, in which transmission is thought to be instantaneous with attachment.

Estimating the degree of engorgement may provide more of an index of individual risk than actual presence or absence of infection. A simple measurement may be made with deer ticks and might be tried for other species of ticks. The scutal index is the ratio of the length of the scutum, the dark shield on the dorsum of the tick, to the length of the tick from tip of the mouthparts to the caudal edge of the tick. A scutal index of >2.5 suggests that a deer tick has been attached for more than 24 h, and therefore transmission is likely (26). Such a finding might prompt a physician to provide prophylactic antibiotics, which would effectively abort Lyme disease or human granulocytic ehlichiosis. Although such prophylaxis would not prevent babesiosis, note that of the agents transmitted by deer ticks, *B. microti* requires the greatest duration of attachment for infectivity, probably relating to the requirement for sporogony during attachment.

Antiparasitic Agents

KARIN LEDER AND PETER F. WELLER

150

There are a number of effective antiprotozoal and anthelminthic drugs currently available. These antiparasitic agents are important both for therapy of individual patients and for control of parasitic infections at a community level. Large-scale chemotherapy is reducing transmission of and morbidity and mortality from certain infections including lymphatic filariasis, onchocerciasis, schistosomiasis, and intestinal nematodes. However, the lack of financial incentives to manufacture existing drugs or to develop new agents is a major limitation to the range of current and future antiparasitic chemotherapies. Emerging resistance among parasites, lack of effective antiparasitic vaccines, and the enormous burden of disease worldwide also pose challenges to the effective management of parasitic infections.

This chapter will focus on the mechanisms of action, pharmacology, clinical utility, and adverse effects of common first-line antiparasitic therapies and newer drug alternatives. Most helminth infections in humans can be treated with one of five drugs, namely, albendazole, mebendazole, praziquantel, ivermectin, and diethylcarbamazine (DEC), so these five drugs will be reviewed in detail. A new agent, nitazoxanide, which has both anthelminthic and antiprotozoal activities, will also be discussed. Other major antiprotozoal drugs, including those used for malaria, gastrointestinal protozoa, leishmaniasis, and trypanosomiasis, will also be reviewed. However, an exhaustive list of all antiparasitic drugs is not included. Specifically, we have excluded discussion regarding agents that do not have a first-line indication or that are recommended only in special situations, such as furazolidone in children or paromomycin in pregnant women. Additionally, most antibacterial and antifungal agents that can also be used for treatment of protozoal infections, such as the 5-nitroimidazoles, trimethoprim-sulfamethoxazole, azithromycin, and amphotericin, will not be discussed in detail here, but their general indications for parasitic infections are shown in Tables 1 and 2. Resistance to antiparasitic agents and drug susceptibility testing are dealt with in chapters 151 and 152.

ANTHELMINTIC AGENTS

Benzimidazoles

The benzimidazoles are antiparasitic agents with a broad spectrum of activity against many helminthic and certain protozoal infections. All members of the benzimidazole class have in common a bicyclic ring system in which benzene has been inserted. Mebendazole and albendazole, both of which are synthetic agents, are the most widely used drugs of this class. Mebendazole is 5-benzoyl-2-benzimidazole carbamic acid, and albendazole is methyl 5-(propylthio)-2-benzimidazole carbamate. The low cost, high efficacy, and ease of administration of these two agents have led to their widespread use for many human parasitic infections. Major indications for their use are shown in Tables 3 and 4. Whereas mebendazole has been approved for treatment of multiple nematode infections by the U.S. Food and Drug Administration (FDA), albendazole is considered investigational for all uses except as treatment for hydatid infections and neurocysticercosis (59b). Other members of this drug class include flubendazole, thiabendazole, and triclabendazole. Flubendazole, a parafluoro analogue of mebendazole, has the same mechanism of action as mebendazole and albendazole and will not be considered separately. It has been licensed in Europe but not in the United States. Thiabendazole is 2-(4-thiazolyl)-1*H*-benzimidazole. Administration of thiabendazole is frequently associated with side effects, and it has now been largely replaced by other anthelmintic agents. Triclabendazole is a new imidazole derivative that has been used as a veterinary agent for many years. It is now considered the drug of choice for fascioliasis (13), but it has not been approved by the FDA and is not widely available.

Mechanism of action. The antiparasitic activity of albendazole and mebendazole results mainly from their ability to bind to a cytoskeletal protein of parasites called β-tubulin, thereby inhibiting the polymerization of tubulin into microtubules (51). The disruption of microtubule synthesis within parasitic intestinal cells results in decreased absorptive function. In addition, mebendazole and albendazole directly inhibit glucose absorption by parasites, leading to a depletion of parasite glycogen stores (32, 34). Parasites therefore have insufficient energy sources for formation of ATP, without which they are unable to reproduce or survive. Although tubulin is also present in mammalian hosts, the benzimidazoles bind to parasite tubulin with an affinity that is hundreds of times greater than the affinity of binding to mammalian tubulin, thereby causing minimal mammalian toxicity.

Thiabendazole has mechanisms of action similar to those of the other benzimidazoles. It blocks glucose uptake, depletes glucose stores, and interferes with microtubule aggregates (32).

TABLE 1 Treatment of major protozoal infections[a]

Organism or disease	Primary agent used for treatment	Alternative agent(s)
Intestinal protozoa		
Entamoeba histolytica	Invasive trophozoites: metronidazole Luminal agent: iodoquinol	Tinidazole Alternative luminal agents: diloxanide furoate, paromomycin
Babesia species	Clindamycin plus quinine	Atovaquone plus azithromycin
Balantidium coli	Tetracycline	Metronidazole, iodoquinol
Crytosporidium parvum	Nitazoxanide	
Cyclospora cayatanensis	Trimethoprim-sulfamethoxazole	
Dientamoeba fragilis	Tetracycline	Iodoquinol, paromomycin, metronidazole
Giardia lamblia	Metronidazole	Tinidazole, nitazoxanide, quinacrine, albendazole, furazolidone, paromomycin
Isospora belli	Trimethoprim-sulfamethoxazole	
Microsporidium species	Albendazole *(Encephalitozoon intestinalis* responds better than *Enterocytozoon bieneusi)*	
Other protozoa		
Amebic meningoencephalitis	Amphotericin B	
Leishmania species	Pentavalent antimonial	Miltefosine, pentamidine, amphotericin B, liposomal amphotericin B
Malaria		
Plasmodium vivax and *P. ovale*	Chloroquine plus primaquine	
Plasmodium falciparum	Quinine sulfate plus doxycycline or plus pyrimethamine-sulfadoxine or quinine plus clindamycin	Mefloquine plus artesunate, Malarone
Plasmodium malariae	Chloroquine	
Toxoplasma gondii	Pyrimethamine plus sulfadiazine	Pyrimethamine plus clindamycin
Trichomonas vaginalis	Metronidazole	Tinidazole
Trypanosoma brucei species (African trypanosomiasis)	Early: Suramin or eflornithine Late: Melarsoprol	Pentamidine
Trypanosoma cruzi (American trypanosomiasis)	Nifurtimox	Benznidazole

[a] Adapted from reference 59b.

In addition, it inhibits the fumarate reductase system of helminths, thereby depriving parasites of their energy source and ultimately resulting in their death (34). The exact mechanism of action of triclabendazole is unknown, but it is thought to act on microtubuli, causing decreased parasite motility.

Pharmacology. Some benzimidazoles are poorly soluble in water and therefore are not well absorbed following oral administration. Although this limits their activity against tissue-dwelling parasites, it contributes to their minimal toxicity and to their efficacy in the treatment of many intestinal helminthic infections (20). None of the benzimidazoles are available as intravenous formulations.

Less than 10% of mebendazole is absorbed after oral administration. It is metabolized in the liver to inactive compounds, eliminated in the bile, and excreted predominantly in the feces. It is 95% protein bound in plasma, and its half-life in serum is 2.5 to 5.5 h. Serum levels are markedly variable between individuals, but tissue and echinococcal cyst concentrations tend to be low (27).

The oral bioavailability of albendazole is also poor, with less than 10% absorption following an oral dose (58). Administration of albendazole with a fatty meal markedly improves bioavailability. It is rapidly metabolized in the liver, and concentrations of the parent drug in plasma are negligible. However, its primary metabolite, albendazole sulfoxide, also has anthelmintic activity (7). This results in a higher efficacy for albendazole than mebendazole for most indications. Albendazole sulfoxide is 70% protein bound and is widely distributed throughout the body. Peak concentrations of albendazole and albendazole sulfoxide in plasma show great intersubject variability but range from 0.24 to 2.96 μg/ml (64). Albendazole induces enzymes of the cytochrome P-450 system which are responsible for its metabolism. Cimetidine and dexamethasone both raise drug levels (44). Albendazole sulfoxide has been detected in urine, bile, liver, cyst fluid, and cerebrospinal fluid (CSF). Plasma levels are 3- to 10-fold and 2- to 4-fold higher than in cyst fluid and CSF, respectively (64, 65). Albendazole sulfoxide has a half-life of approximately 9 h. It is oxidized further to inactive compounds such as albendazole sulfone and is excreted in the urine.

Neither mebendazole nor albendazole is dialyzable. No dosage adjustment is required for individuals with renal impairment, but a reduction in dose should be considered if there is significant hepatic insufficiency.

Thiabendazole is rapidly absorbed from the gastrointestinal tract after oral administration, is metabolized in the liver, and is excreted predominantly in the urine. Its half-life is 1.2 h. It is generally administered after meals to minimize side effects.

Triclabendazole is also rapidly absorbed from the gastrointestinal tract, and absorption is improved further if the drug is given postprandially (52). Its half-life is 12 to 18 h.

TABLE 2 Treatment of major helminthic infections[a]

Organism or disease[b]	Primary agent used for treatment	Alternative agent(s) or treatment
Nematodes		
Ancylostoma caninum (eosinophilic enterocolitis)	Albendazole	Mebendazole, pyrantel pamoate
Angiostrongylus species	Mebendazole	
Ascaris lumbricoides	Albendazole	Mebendazole, pyrantel pamoate, ivermectin, nitazoxanide
Capillaria species	Mebendazole	Albendazole
Cutaneous larva migrans	Albendazole	Ivermectin, topical thiabendazole
Enterobius vermicularis	Albendazole	Mebendazole, pyrantel pamoate
Filariasis (*Wuchereria bancrofti, Brugia malayi*)	Diethylcarbamazine with or without albendazole or ivermectin	
Gnathostoma species	Albendazole	Ivermectin, surgical removal
Hookworm	Albendazole	Mebendazole, pyrantel pamoate
Loa loa	Diethylcarbamazine with or without albendazole or ivermectin	
Onchocerca volvulus	Ivermectin	
Strongyloides stercoralis	Ivermectin	Thiabendazole, albendazole
Toxocara species (visceral larva migrans)	Albendazole	Mebendazole
Trichinella spiralis	Mebendazole	Albendazole
Trichostrongylus species	Albendazole	Mebendazole, pyrantel pamoate
Trichuris trichiura	Mebendazole	Albendazole, ivermectin, nitazoxanide
Cestodes		
Cysticercosis	Albendazole	Praziquantel
Dipylidium caninum	Praziquantel	Niclosamide
Diphyllobothrium latum	Praziquantel	Niclosamide
Echinococcus species	Albendazole	Praziquantel
Hymenolepis nana	Praziquantel	Nitazoxanide
Taenia saginata	Praziquantel	Niclosamide
Taenia solium	Praziquantel	Niclosamide
Trematodes		
Clonorchis sinensis	Praziquantel	Albendazole
Fasciola hepatica	Triclabendazole	Nitazoxanide, bithionol
Intestinal flukes	Praziquantel	
Metorchis conjunctus	Praziquantel	
Opisthorchis viverrini	Praziquantel	
Paragonimus species	Praziquantel	Bithionol
Schistosoma species	Praziquantel	*Schistosoma mansoni:* oxamniquine[c]

[a] Adapted from reference 59b.
[b] This is not an exhaustive list of all possible parasitic infections, but commonly encountered parasites are included.
[c] No longer manufactured and/or problems with availability.

It is metabolized in the liver into an active sulfoxide metabolite and into an inactive sulfone metabolite, both of which are highly protein bound and excreted in the urine.

Spectrum of activity. The benzimidazoles are effective against adult worms and developing helminthic embryos. Mebendazole and albendazole have similar and broad ranges of activity. Both drugs have good efficacy against many common intestinal nematode infections, including ascariasis, trichuriasis, enterobiasis, and hookworm infections. Three-day regimens of both drugs are generally recommended for therapy of individual patients, but a single dose is used for mass or targeted community treatment of intestinal nematodes in areas of endemicity. Albendazole is preferred in most instances, but its efficacy against very heavy infections with *Trichuris trichiura* remains questionable, and mebendazole may be preferable in this circumstance. The reported curative efficacies of the two drugs in different parasitic infections vary according to the baseline intensity of infection in the patient, geographical location, diagnostic tests employed, and duration of follow-up posttreatment.

Mebendazole and albendazole also have activity against other nematode infections, including trichostrongyliasis, capillariasis, trichinellosis, gnathostomiasis, toxocariasis, and cutaneous larva migrans. Additionally, albendazole is being increasingly used in combination with either DEC or ivermectin for treatment of Bancroftian or Brugian filariasis and loiasis; it is particularly useful for these infections as part of a single-dose regimen for mass chemotherapy programs. Although albendazole displays some efficacy against *Strongyloides stercoralis*, ivermectin shows higher cure rates and is the recommended treatment of choice.

TABLE 3 Major indications for albendazole[a]

Indication	Usual dose	Reported efficacy
Echinococcus granulosus	400 mg twice daily, usually minimum of 3–6 mo	Clinical cure, as evidenced by cyst disappearance, in one-third, and improvement in radiological appearance in an additional 30–50%
Cysticercosis	400 mg twice daily, usually for 8 days (8–30 days)	75–95% of parenchymal cysts destroyed and 40–70% of patients show resolution of all active cysts, but unclear if beneficial over placebo
Ascaris lumbricoides	Single 400-mg dose	Median cure rates of 95–97% and egg reduction rates of 99–100%
Cutaneous larva migrans	400 mg daily for 3 days	No large clinical trials, and generally reserved for those with severe or disseminated infection
Enterobius vermicularis	400-mg dose, repeat in 2 wk	Cure rate close to 100%
Hookworm	Single 400-mg dose	70–95% cure rate and 85–100% egg reduction rate
Microsporidiosis	400 mg twice daily, usually for 2–4 wk	Variable efficacy (related to species of pathogen and immune function of host)
Trichuris trichiura	Single 400-mg dose	Cure rate of 35–70% and egg reduction rate of 70–90% (3 days of therapy gives higher cure rates in heavy infections, but mebendazole is the preferred agent for treatment)
Toxocariasis	400 mg twice daily for 5 days	No large clinical trials
Lymphatic filariasis	Single 400-mg dose	Microfilaremia reduced by 98–99% for prolonged periods when administered in combination with DEC or ivermectin; prolonged high doses also have a macrofilaricidal effect
Loa loa	Single 400-mg dose	No microfilaricidal effect, but partial macrofilaricidal effect with sterilization and/or death of adult worms
Giardia lamblia	400 mg daily for 5 days	Cure rate of 97%

[a] From reference 59b.

Both mebendazole and albendazole also show activity in certain cestode infections. Albendazole is again preferred because of its more favorable pharmacokinetics, and it is now considered the drug of choice for medical management or adjunctive treatment of hydatid disease due to *Echinococcus granulosis*. Prolonged albendazole therapy (minimum of 10 years) can also be used in inoperable alveolar echinococcosis or as adjuvant therapy for patients with *Echinococcus multilocularis* infection. In addition, albendazole is used for treatment of parenchymal neurocysticercosis. Note that, despite its anticysticercal activity, not all studies have shown a clear benefit of any form of antiparasitic therapy in this condition, and controversy still exists about the exact indications for therapy.

Neither mebendazole nor albendazole is commonly used in trematode infections, although some activity against opisthorchiasis, chlonorchiasis, and *Echinostoma* species has been reported (41, 54, 82).

Although considered primarily an anthelmintic agent, albendazole is also an alternative agent for giardiasis. Additionally, albendazole has activity in microsporidial infections, particularly those caused by *Encephalitozoon hellem, E. cuniculi,* and *E. intestinalis*.

Thiabendazole kills the adult worms of *Strongyloides stercoralis* and used to be the drug of choice in uncomplicated strongyloidiasis. It also has activity in other nematode infections, including ascariasis, enterobiasis, hookworm, trichuriasis, toxocariasis, trichinellosis, capillariasis, and trichostrongyliasis. It is no longer recommended as first-line therapy for any of these indications because of the high frequency of associated side effects. It is still used topically for treatment of cutaneous larva migrans.

TABLE 4 Major indications for mebendazole[a]

Indication	Usual dose	Reported efficacy
Ascaris lumbricoides	Single 500-mg dose or 100 mg twice daily for 3 days	Median cure rates of 95–98% and egg reduction rates of 99–100%
Enterobius vermicularis	Single 100-mg dose, repeated after 2–3 wk	Mean cure rate of 95%
Hookworm	Single 500-mg dose	Cure rates of 20–80% and egg reduction rates of 60–95% (>95% cure achieved with 3 days of mebendazole, 100 mg twice daily)
Trichuris trichiura	Single 500-mg dose or 100 mg twice daily for 3 days	Cure rate of 40–75% and egg reduction rates of 90–95%; higher cure rates (70–90%) achieved following 3 days of mebendazole (100 mg twice daily)
Toxocariasis	100–200 mg twice daily for 5 days	No large clinical trials

[a] From reference 59b.

Triclabendazole is recommended as the treatment of choice for fascioliasis. It is also considered an alternative to praziquantel for therapy of paragonimiasis and intestinal flukes, although experience with these infections in human trials is more limited.

Adverse effects. Adverse effects following short courses of the benzimidazoles mebendazole and albendazole are infrequent and generally mild. Transient abdominal pain, nausea, and diarrhea may develop. Headache, dizziness, insomnia, and allergic phenomena are also reported. With prolonged high-dose therapy, such as for echinococcosis, transient and reversible elevations of serum transaminases occur in 1 to 5% of recipients. Occasionally, alopecia (<1%) and reversible leukopenia (<1%) are seen. Discontinuation of therapy is infrequently needed, but a recent death related to albendazole-induced pancytopenia has been described (73).

When mebendazole has been used by pregnant women, the incidence of spontaneous abortions or fetal malformations has not been greater than the background population rate. There are also no reports of teratogenicity from albendazole, and women who have received it inadvertently during pregnancy have not experienced adverse fetal outcomes (3). However, studies of benzimidazole drugs performed in animals suggest a possible teratogenic and embryotoxic effect. Since there are no good prospective safety data on either of these agents in humans, it is recommended that neither albendazole nor mebendazole be administered during pregnancy, particularly during the first trimester, unless the potential benefits justify the possible risk to the fetus (110). The amount of albendazole or mebendazole excreted in breast milk has not been well studied, and these drugs should be used with caution in lactating women.

Thiabendazole is associated with side effects in approximately 50% of recipients. The most common adverse reactions are nausea, vomiting, diarrhea, dizziness, anorexia, and malodorous urine. It can also cause rash, pruritis, headache, drowsiness, visual disturbances, hypoglycemia, bradycardia, and hypotension. Severe neuropsychiatric reactions including delirium and disorientation can also occur. It is contraindicated for use during pregnancy.

Triclabendazole is well tolerated, and few significant adverse effects have been described. Occasional side effects include headache, dizziness, and abdominal pain. It is not recommended for use during pregnancy because of insufficient safety data.

Praziquantel

Praziquantel is a synthetic heterocyclic isoquinolone-pyrazine derivative. Major indications for its use are shown in Table 5. It has the unique characteristic of being active against almost all trematodes and cestodes, but it is not useful for treatment of nematode infections. It has been approved for use by the FDA (59b).

Mechanism of action. Praziquantel induces ultrastructural changes in the teguments of parasites, resulting in increased permeability to calcium ions. Calcium ions accumulate in the parasite cytosol, leading to muscular contractions and ultimately to paralysis of adult worms. By damaging the tegument membrane, praziquantel also exposes parasite antigens to host immune responses (8). These effects lead to dislodgment of worms from their intestinal sites and subsequent expulsion by peristalsis.

Pharmacology. Praziquantel is available for oral administration, and over 80% of the drug is absorbed after an oral dose. Coadministration with a high-carbohydrate meal increases serum drug concentrations (90). The drug is biotransformed in the liver, and metabolites are excreted mainly in the urine. The cytochrome P-450 hepatic metabolism of praziquantel is induced by corticosteroids, phenytoin, and phenobarbital. Levels of praziquantel in serum are therefore lowered when any of these drugs are coadministered. Cimetidine, which inhibits P-450-mediated metabolism, can be given concurrently to increase plasma praziquantel levels. Levels in plasma after a single 40-mg/kg dose have been reported as 1.007 to 1.625 μg/ml (45). Praziquantel does not cross the blood-brain barrier well, so levels in CSF are only approximately 20% of plasma levels (20, 90). It is 80% protein bound, and its half-life in serum is 1 to 3 h. It is not dialyzable, and no adjustment in dose is recommended in either renal or hepatic insufficiency.

Spectrum of activity. Praziquantel is active against the larval and adult stages of many trematodes. It is the drug of choice for schistosomiasis and is effective as a single oral dose for all *Schistosoma* species that infect humans. It is used both for treatment of individuals and for mass community chemotherapy programs and leads to decreased transmission and prevalence of infection. Praziquantel is also used for treatment of opisthorchiasis, clonorchiasis, paragonimiasis, and intestinal fluke infections including fasciolopsiasis, heterophyiasis, and metagonimiasis. In contrast to its effect on

TABLE 5 Major indications for praziquantel[a]

Indication	Usual dose	Reported efficacy
Clonorchiasis	75 mg/kg/day in 3 doses for 1 day	Cure rates of 85–100%
Cysticercosis	50–100 mg/kg/day in 3 doses for 1–30 days	Eliminates 50–60% of cysts, but unclear if beneficial over placebo
Opisthorchiasis	75 mg/kg/day in 3 doses for 1 day	Cure rates of >95%
Intestinal flukes	75 mg/kg/day in 3 doses for 1 day	No large clinical trials
Paragonimiasis	75 mg/kg/day in 3 doses for 2 days	>95% cure for pulmonary infections (may be lower in ectopic sites)
Schistosomiasis	40–60 mg/kg/day in 2–3 doses for 1 day	Cure rates of 75–100% and egg reduction rates of 90–95% in those not cured
Tapeworms	Single 10–25-mg/kg dose	Cure rates >95% for *Taenia, Diphyllobothrium,* and *Hymenolepis* species infections

[a] From reference 59b.

other human trematode infections, praziquantel has not proven to be effective in the treatment of *Fasciola hepatica*.

Many cestode infections can also be treated with praziquantel. Most tapeworm infections respond, including those caused by *Taenia*, *Diphyllobothrium*, and *Hymenolepis* species. Because praziquantel does not kill eggs, precautions should be taken to prevent autoinfection, laboratory-acquired infection, or dissemination to others, particularly for *Taenia solium*. Praziquantel is also used in the treatment of neurocysticercosis as an alternative to albendazole, although the overall benefit of therapy in many cases remains unclear.

Praziquantel has also been used in combination with albendazole for treatment of echinococcal infections. Praziquantel has high protoscolicidal activity in vitro, and some reports have suggested that the combination has superior efficacy compared to either drug alone (17, 62).

Adverse effects. Adverse effects of praziquantel are generally mild, but many series suggest that some side effects occur in over 30% of patients. Common reactions include dizziness, lethargy, headache, nausea, and abdominal pain. Severe adverse reactions are uncommon, although administration to individuals with neurocysticercosis can result in seizures and neurological sequelae related to precipitation of an inflammatory response.

Animal studies do not suggest a teratogenic effect of praziquantel, but an increased abortion rate has been seen in rats. There are minimal data on its safety in humans, so it should be avoided during pregnancy when possible (20). No adverse effects of praziquantel administration during lactation have been reported, but it is excreted in human breast milk, and discontinuation of breast-feeding on the day of therapy and for the following 72 h is recommended.

Ivermectin

Ivermectin is a semisynthetic macrocyclic lactone derivative of avermectins, which are natural substances derived from the actinomycete *Streptomyces avermitilis*. Major indications for its use are shown in Table 6. It was initially developed as an agent for veterinary use but is now used widely in humans. Ivermectin is a potent oral agent with relatively broad-spectrum anthelmintic activity. It has been approved by the FDA for therapy of onchocerciasis and uncomplicated strongyloidiasis (59b).

Mechanism of action. The exact mechanism of action of ivermectin is unclear. It causes an influx of chloride ions across glutamate-gated chloride channels in nerve and muscle cell membranes, resulting in hyperpolarization of the affected cells and consequent paralysis and death of parasites (14, 98). It was postulated that ivermectin may act as an antagonist of the neurotransmitter γ-aminobutyric acid, but this has now been disproven (76). Although specific ivermectin binding sites have been identified in mammalian brain tissue, the affinity of ivermectin for sites within parasites is about 100 times greater than for mammalian tissue.

Pharmacology. Ivermectin is available only as an oral preparation and is rapidly absorbed after oral administration. The effect of food on the bioavailability of the drug has not been well studied. Ivermectin is metabolized in the liver and excreted almost entirely in the feces. Peak levels in serum of approximately 46 ng/ml have been reported after a single 12-mg dose (27). It is highly protein bound in plasma, and it has a half-life of 10 to 16 h. The drug accumulates in fat tissue and does not readily cross the blood-brain barrier (4).

Spectrum of activity. Ivermectin is the drug of choice for onchocerciasis and nondisseminated strongyloidiasis. In onchocercal infections, ivermectin does not have a significant effect on the viability of adult worms, but it is thought to impair release of microfilariae. In addition, it is a potent microfilaricide and leads to a sustained reduction in microfilaremia for many months (14). It can be used both for the treatment of individual patients and for mass chemotherapy programs in areas where onchocerciasis is endemic. In uncomplicated strongyloidiasis, ivermectin has excellent efficacy in normal and immunocompromised patients, although experience with its use in disseminated infection is more limited (76).

In addition to the above indications, ivermectin also has activity against microfilariae of *Wuchereria bancrofti*, *Brugia malayi*, and *Loa loa*. It does not have a significant effect on adult worm viability in these infections, so reduced microfilaremia is sustained only with repeated doses, and it has not replaced DEC as first-line therapy for these infections. Ivermectin also has some activity against *Mansonella ozzardi* and *Mansonella streptocerca* microfilariae.

Ivermectin also has efficacy against many intestinal helminths, including *Ascaris lumbricoides*, *Trichuris trichiura*, *Enterobius vermicularis*, and cutaneous larva migrans (67).

TABLE 6 Major indications for ivermectin[a]

Indication	Usual dose	Reported efficacy
Ascaris lumbricoides	Single 200-μg/kg dose	Cure rates of 78–99%
Cutaneous larva migrans	200 μg/kg daily (usually 12 mg) for 1–2 days	Cure rates of 77–100%
Gnathostoma spinigerum	200 μg/kg daily for 2 days	Cure rates of 76–95%
Onchocerca volvulus	Single 150-μg/kg dose; repeat every 6–12 mo until asymptomatic	Skin microfilarial counts reduced by 85–95%, and levels remain suppressed by >90% at 1 yr
Strongyloides stercoralis	200 μg/kg daily for 1–2 doses	Cure rates of 85–97% in uncomplicated infection (normal or immunocompromised hosts)
Trichuris trichiura	200 μg/kg daily for 3 days	Cure rates of 35–84%
Ectoparasites: scabies and lice	Single 200-μg/kg dose	Almost 100% efficacy, particularly if repeat dose given in severe infestations after 2 wk

[a] From reference 59b.

However, it is not generally used as first-line treatment for these indications due to the widespread availability and excellent efficacy of albendazole. It also can be used for treatment of gnathostomiasis (49). It is not active against trematodes or cestodes.

In addition to its anthelmintic activity, ivermectin is the drug of choice for ectoparasitic infestations, including scabies and lice.

Adverse effects. Ivermectin is generally well tolerated. Most of the adverse effects that occur following its administration are a result of the host's immune response to destruction of parasites rather than toxic effects of the drug per se. Adverse effects include fever, rash, dizziness, pruritis, myalgia, arthralgia, and tender lymphadenopathy, but the severity of these symptoms relates to the pretreatment intensity of infection rather than to serum ivermectin concentrations (69). Severe reactions occasionally occur following its use, including a hypersensitivity response to dying microfilarial parasites known as the Mazzotti reaction. This anaphylactoid response is characterized by allergic manifestations including pruritis, edema, fever, and systemic hypotension. However, these severe reactions are primarily restricted to individuals with high parasite loads. In patients infected with *Loa loa* who have elevated levels of microfilaremia, ivermectin has been associated with the development of fatal encephalopathy (101).

Ivermectin has not been reported to be teratogenic in rats or rabbits, but it has been associated with cleft palate and occasional unexplained maternal deaths in mice (14, 20). There are insufficient data to recommend its use in pregnant women, although the risk of fetal damage in 203 pregnant women inadvertently treated with ivermectin was no greater than in controls, and it has been suggested that ivermectin can be given safely after the first trimester (35, 77, 110). It is excreted in breast milk in low concentrations, so its administration to lactating women should be avoided when possible.

DEC

DEC is a piperazine derivative. Its main use is in filarial infections. Major indications for its use are shown in Table 7. DEC is not licensed for use in the United States but can be obtained from the Centers for Disease Control and Prevention (CDC) under an Investigational New Drug protocol (phone no., 404-639-3311; website, http://www.cdc.gov/).

Mechanism of action. The mode of action of DEC is uncertain. It is predominantly a microfilaricidal agent, and it is thought that its main effect is to alter the surface membrane of microfilariae, thereby enhancing destruction via host immune responses (32, 34). It also has some macrofilaricidal activity in certain conditions, likely via hyperpolarization and immobilization of adult worms (48).

Pharmacology. DEC is available only in tablet form. It is freely soluble in water and is almost completely absorbed after oral administration. The drug is metabolized in the liver, although over 50% is excreted unchanged in the urine. There is negligible protein binding, and it is widely distributed in tissues. It readily crosses the blood-brain barrier. Peak levels in plasma of 100 to 150 ng/ml have been reported after a single 0.5-mg/kg dose (26). The half-life of DEC is 2 to 17 h. Renal excretion is reduced in the presence of an alkaline urinary pH, and dose reductions are required in patients with renal impairment.

Spectrum of activity. DEC is an effective microfilaricidal drug against *W. bancrofti, B. malayi, Brugia timori, Onchocerca volvulus, L. loa,* and *M. streptocerca*, but it has little or no effect on *Mansonella perstans* or *M. ozzardi* microfilariae. It has been the drug of choice for lymphatic filariasis for the last 50 years. It is used both for individual therapy for filarial infections and for mass community chemotherapy programs, either alone or in combination with ivermectin or albendazole. It is predominantly a microfilaricidal agent, although it has some macrofilaricidal activity in *W. bancrofti, B. malayi, B. timori,* and *L. loa* infections (68, 70, 75). DEC has also been used in the treatment of toxocaral visceral larva migrans, but albendazole is now the preferred agent because of its better safety profile.

Adverse effects. The side effects of DEC include mild headache, dizziness, anorexia, nausea, and arthralgias. Administration of the drug to individuals with filarial infections can induce adverse results that are not due to the drug itself but instead are related to host responses, in part to release of *Wolbachia* endosymbionts from filariae, following damage to adult worms (local reactions) and death of microfilariae (systemic reactions). These allergic reactions tend to be relatively mild with lymphatic filariasis and infrequent with loiasis but can be severe with onchocerciasis or with heavy *L. loa* infections. Reactions include intense pruritis, rash, fever, hypotension, and encephalopathy. The potentially fatal Mazzotti reaction and serious ophthalmic adverse effects can occur following treatment of *O. volvulus* with DEC, and this has led to DEC being contraindicated for onchocercal infections.

Animal studies have not shown DEC to be teratogenic, but it may increase the risk of abortion, so its administration should be avoided in pregnancy when possible (20, 43). It is not excreted in breast milk and is safe during lactation.

Pyrantel Pamoate

Pyrantel, a tetrahydropyrimidine, is a relatively broad-spectrum agent against nematodes. It is associated with more side effects and lower efficacy than the benzimidazoles, so it is largely being replaced. It is approved by the FDA but is considered investigational for most indications except enterobiasis.

TABLE 7 Major indications for DEC[a]

Indication	Usual dose	Reported efficacy
Loa loa	Up to 9 mg/kg/day in 3 doses for 21 days	Few large trials, but single course is curative in <50% of patients
Wuchereria bancrofti and *Brugia malayi*	Up to 6 mg/kg/day in 3 doses for 14 days or single dose	>90–99% reduction in microfilaremia, but may need additional courses to eradicate adult worms

[a] From reference 59b.

Mechanism of action. Pyrantel is a depolarizing neuromuscular blocking agent. It exerts its anthelmintic effect via release of acetylcholine and inhibition of helminthic acetylcholinesterase. This results in stimulation of ganglionic receptors and spastic paralysis of adult worms. The worms become dislodged from the intestinal wall and are expelled in the feces by normal peristalsis.

Pharmacology. Pyrantel is administered orally but is almost insoluble in water and is therefore poorly absorbed from the gastrointestinal tract. More than 50% is excreted unchanged in the feces. The absorbed drug is partially metabolized in the liver. There is no significant interaction with food.

Spectrum of activity. Pyrantel has excellent efficacy in the treatment of ascariasis and hookworm and pinworm infections. It also has some activity against hookworm and *Trichostrongylus*. It is not active against *Trichuris trichiura*.

Adverse effects. Although pyrantel is generally well tolerated, it can lead to adverse reactions including anorexia, nausea, vomiting, abdominal cramps, and diarrhea. It has also been associated with neurotoxic effects including headache, dizziness, drowsiness, and insomnia. Transient increases in hepatic enzymes have also been reported.

Animal studies have not shown adverse effects in the fetus, and it has been used during pregnancy in humans without harmful fetal effects (100). It is not recommended for children under 2 years of age.

NEW AGENT WITH ANTHELMINTIC AND ANTIPROTOZOAL ACTIVITY: NITAZOXANIDE

Nitazoxanide is a new 5-nitrothiazole derivative with broad-spectrum activity against numerous intestinal protozoa, helminths, and anaerobic bacteria. Major indications for its use are shown in Table 8. It was initially developed as a veterinary anthelmintic with activity against intestinal nematodes, cestodes, and liver trematodes (30). In 2002, the FDA approved oral-suspension nitazoxanide for the treatment of diarrhea caused by *Cryptosporidium* species and *Giardia lamblia* in pediatric patients 1 to 11 years of age, and in 2004, nitazoxanide was approved for treatment of diarrhea caused by *G. lamblia* in adults (30, 59a). At present, it is pending licensure for treatment of infection due to *Cryptosporidium* species in adults and for use in treating immunocompromised hosts.

Mechanism of action. Nitazoxanide inhibits pyruvate ferredoxin oxidoreductase, an enzyme essential to anaerobic energy metabolism. This is its mechanism of action against anaerobic bacteria (e.g., *Trichomonas vaginalis*, *Entamoeba histolytica,* and *Clostridium perfringens*) and protozoa, although for protozoa additional mechanisms may also be involved (33). The mechanism of nitazoxanide's activity against helminths has not yet been determined.

Pharmacology. Nitazoxanide is given by the oral route and is available as a suspension or a tablet. Bioavailability is nearly doubled by administration with food (94). It is absorbed from the gastrointestinal tract, with approximately

TABLE 8 Major indications for nitazoxanide[a]

Indication	Usual dose[b]	Reported efficacy
Cryptosporidium parvum	Immunocompetent children 1–11 yr[c] and adults: b.i.d. treatment for 3 days	Cure rates of 52–80%
	Immunocompromised patients: 1,000 mg b.i.d. for 2–8 wk	Cure rates of 18–67% (efficacy varies with CD4 count in human immunodeficiency virus-positive patients)
Giardia lamblia	b.i.d. treatment for 3 days[c]	Cure rates of 71–94%
Ancylostoma duodenale	b.i.d. treatment for 3 days	Cure rate of 96%
Ascaris lumbricoides	b.i.d. treatment for 3 days	Cure rates of 69–100% (in heavy infections of >10,000 eggs/g, lower egg clearance rates of 48%, but egg reduction rates of >99%)
Balantidum coli	b.i.d. treatment for 3 days	Cure rate of 77%
Blastocystis hominis	b.i.d. treatment for 3 days	Cure rates of 97–100%
Cyclospora cayetanensis	b.i.d. treatment for 3 days	Cure rate of 71%
Entamoeba histolytica	b.i.d. treatment for 3 days	Cure rates of 69–96%
Enterobiasis vermicularis	b.i.d. treatment for 3 days	Cure rates of 80–100%
Fasciola hepatica	b.i.d. treatment for 7 days (daily dose as shown below)	Cure rates of 40–97%
Hymenolepis nana	Single oral dose of 50 mg/kg or b.i.d. treatment for 3 days	Cure rates of 80–97%
Isospora belli	b.i.d. treatment for 3 days	Cure rate of 100%
Strongyloides stercoralis	b.i.d. treatment for 3 days	Cure rate of 94%
Taenia saginata	Single 25-mg/kg dose or b.i.d. treatment for 3 days	Cure rates of 95–100%
Trichuris trichiura	b.i.d. treatment for 3 days	Cure rates of 76–100% (in moderate infections with 2,000–5,000 eggs/g, lower egg clearance rates of 56%, but egg reduction rates of >99%)

[a] Adapted from reference 30.

[b] The dosing schedule of nitazoxanide when given twice a day (b.i.d.) for 3 days is as follows: children 1 to 3 years old, 100 mg b.i.d. for 3 days; children 4 to 11 years, 200 mg b.i.d. for 3 days; and adults, 500 mg b.i.d. for 3 days.

[c] Licensed for this use by the FDA.

one-third of the oral dose excreted in urine and two-thirds excreted in feces (9, 74). In blood, nitazoxanide is rapidly hydrolyzed to form an active metabolite, tizoxanide. The maximum concentration of tizoxanide in plasma following an oral dose of 500 mg of nitazoxanide is 2 mg/liter (6.5 μM), and its half-life in plasma is 1 to 2 h (1). Tizoxanide is extensively bound to plasma proteins (>99%), and its urinary elimination half-life is 7.3 h (95). Tizoxanide then undergoes glucuronidation to form tizoxanide glucuronide. Nitazoxanide is not detected in plasma, urine, bile, or feces, but tizoxanide is found in plasma, urine, bile, and feces and tizoxanide glucuronide is found in plasma, bile, and urine (74).

The pharmacokinetics of nitazoxanide in patients with impaired liver or renal function has not been studied, and the drug must be administered to these patients with caution (30).

Spectrum of activity. Nitazoxanide is a broad-spectrum antimicrobial agent with activity against protozoa, nematodes, cestodes, trematodes, and bacteria. Although it is currently licensed in the United States only for treatment of *Cryptosporidium parvum* in immunocompetent children and *Giardia lamblia* in children and adults, it has been shown to be effective in vitro and/or in vivo against infections caused by many enteric protozoa and helminths, including *Ascaris lumbricoides, Balantidium coli, Blastocystis hominis, Cyclospora cayetanensis, Echinococcus multilocularis, Echinococcus granulosus, Entamoeba histolytica, Fasciola hepatica,* hookworms, *Hymenolepis nana, Isospora belli*, microsporidial species (*Enterocytozoon bieneusi* and *Encephalitozoon intestinalis*), *Taenia saginata, Trichomonas vaginalis, Trichuris trichiura,* and *Vittaforma corneae* (30). Nitazoxanide also has in vitro and in vivo activity against *Bacteroides* species, *Clostridium difficile,* and both metronidazole-susceptible and metronidazole-resistant strains of *Helicobacter pylori* (30, 74).

Adverse effects. Nitazoxanide is very well tolerated, with adverse effects similar to those of a placebo. Mild and transient side effects have been seen in only 3 to 4% of patients, principally related to the gastrointestinal tract (abdominal pain, diarrhea, and nausea) (22). No significant adverse effects on electrocardiography, hematology, clinical chemistry, or urinalysis parameters have been noted (33).

There are minimal data on the safety of nitazoxanide in pregnant or lactating women (30).

ANTIMALARIALS

Quinoline Derivatives

The quinoline derivatives can be divided into four groups: the 4-aminoquinolines, the cinchona alkaloids, synthetic compounds such as mefloquine and halofantrine, and the 8-aminoquinolines.

4-Aminoquinolines

The 4-aminoquinolines include chloroquine, hydroxychloroquine, and amodiaquine. Chloroquine is the most widely used of these agents. It is a cheap, safe drug that has been used extensively for treatment and prophylaxis of all four *Plasmodium* species that infect humans. Hydroxychloroquine is a related synthetic compound with an identical clinical spectrum, similar pharmacokinetics, and similar adverse effects. Amodiaquine is another related agent which also has the same mechanism of action and spectrum of activity. It is reported to be more effective than chloroquine for parasite clearance, but its utility is limited by toxicity. It has not been approved by the FDA (59b).

Mechanism of action. The main mechanism of action of the 4-aminoquinolines is thought to be via nonenzymatic inhibition of heme polymerization. The 4-aminoquinolines act specifically against intraerythrocytic stages of malaria parasites. Asexual intraerythrocytic malaria parasites actively concentrate quinoline ring compounds within hemoglobin-containing vesicles. In the absence of drug, *Plasmodium* organisms degrade host erythrocyte hemoglobin to provide amino acid nutrients essential for parasite growth. The degradation of hemoglobin produces free heme, which is stored as ferriporoporphyrin IX within the red blood cell. Ferriporoporphyrin IX is toxic to the parasite and is usually polymerized into nontoxic malaria pigment (hemozoin). In the presence of drug, there is inhibition of the conversion of heme into hemozoin, leading to the accumulation of products toxic to the parasite and resulting in parasite death (89). These agents also inhibit protein synthesis by inhibiting incorporation of phosphate into DNA and RNA and by inhibiting DNA and RNA polymerases (32).

Pharmacology. The 4-aminoquinolines are extensively distributed in tissues and are characterized by a long elimination half-life. Despite similarities in their chemical structures, these drugs show differences in their biotransformation and routes of elimination (83).

Chloroquine is available in oral and parenteral forms. Many different formulations of chloroquine are manufactured worldwide. Chloroquine is rapidly absorbed from the gastrointestinal tract after oral administration and has oral bioavailability exceeding 75%. Food has variable effects on absorption. The drug is extensively distributed in body tissues and reaches high levels within the brain (50). Chloroquine binds to melanin-containing cells in the skin and eye, so it can also reach high levels in these sites. There is marked variability in peak concentrations in plasma between individuals, but oral administration at standard treatment doses results in blood concentrations above 1 mmol/liter for at least 4 days (85). It is approximately 60% protein bound and has a half-life of about 4 to 6 days. Approximately 30 to 50% of the drug is metabolized in the liver to inactive compounds, and the remainder is excreted in the urine. Treatment reduction (usually 50% of the normal dose) is required in patients with severe renal or hepatic failure. It is not dialyzable.

In contrast, amodiaquine is a prodrug and is almost entirely metabolized to a biologically active metabolite, desethylamodiaquine, following oral administration. Otherwise, it has pharmacokinetic properties similar to those of chloroquine but has a smaller volume of distribution.

Spectrum of activity. The 4-aminoquinolines are efficient and rapidly acting blood schizonticides. They can be used in both the treatment and the prophylaxis of susceptible strains of all four *Plasmodium* species. They have no effect on tissue schizonts or exoerythrocytic stages. They are gametocytocidal for *Plasmodium vivax* and *P. malariae* but have minimal effect on *P. falciparum* gametocytes. Following infections with *P. vivax* or *P. ovale*, primaquine is also needed to eradicate liver hypnozoites and prevent relapses of infection.

Despite emerging resistance among *P. vivax* parasites, chloroquine remains first-line therapy for *P. vivax, P. malariae,* and *P. ovale* infections. It also remains the treatment of choice for susceptible *P. falciparum* strains, although *P. falciparum* strains from most areas of the world are now resistant to it.

Because of its potential toxicity, amodiaquine is not recommended for prophylaxis of malaria and is generally not used as first-line treatment. However, it results in faster parasite clearance and more rapid resolution of symptoms than chloroquine, and it may be effective in some cases of chloroquine-resistant malaria, so it is used as an alternative treatment regimen in some areas.

Chloroquine is also active against *E. histolytica* trophozoites but is rarely used for this indication since the nitro-5-imidazoles are the drugs of choice.

Adverse effects. Chloroquine has a bitter taste. It is generally well tolerated at the doses required for malaria prevention or treatment, even when taken for prolonged periods. However, it can lead to nausea, abdominal discomfort, dizziness, retinal pigmentation, blurred vision, electrocardiographic changes, muscular weakness, and, rarely, transient psychiatric symptoms. It can also cause severe pruritis, particularly in African blacks. Irreversible neuroretinitis can result if it is taken at high doses for prolonged periods. If an overdose is taken, it can cause shock, arrhythmia, and death.

At the doses used for malaria treatment or prophylaxis, chloroquine has rarely been reported to cause adverse congenital effects (53). However, affinity for melanin-containing tissues such as the retina, iris, and choroid of the eye has been reported, and definitive delineation of fetal risk remains undefined. It is used commonly for treatment and prophylaxis of malaria in pregnant women without evidence of teratogenicity, and it is generally agreed that the benefits of preventing and treating malaria in pregnant women outweigh the potential fetal risks. Chloroquine is excreted in breast milk in small amounts.

Amodiaquine is more palatable than chloroquine and seems to cause less itching. However, serious adverse events including agranulocytosis, aplastic anemia, and drug-induced hepatitis have been reported. These have occurred predominantly following long-term amodiaquine use (mean, 7 to 8 weeks) for malaria prophylaxis, and short-term treatment regimens are thought to be safe (72).

Cinchona Alkaloids

The cinchona alkaloids, quinine and quinidine, contain a quinoline ring. Quinidine is the diastereoisomer of quinine. Quinine was originally extracted from the bark of the South American cinchona tree, but a synthetic form is now available, usually as a quinine sulfate salt. Quinidine is more active than quinine, but it is also more cardiotoxic.

Mechanism of action. The exact target of cinchona alkaloids is unknown. They are thought to act by forming complexes with ferriprotoporphyrin IX, thereby interfering with hemoglobin digestion and resulting in cell lysis and death of schizonts (29). They are also thought to interfere with the function of plasmodial DNA and inhibit the synthesis of parasite nucleic acids and proteins. Quinine also interacts with certain fatty acids present in parasitized erythrocytes, preventing red blood cell lysis and interrupting schizont maturation (32). Additionally, it increases intracellular pH, resulting in lethal effects on the parasite.

Pharmacokinetics. Quinine is available for oral administration as a sulfate salt and for parenteral administration as quinine dihydrochloride. It is >80% absorbed from the gastrointestinal tract following oral doses. It is widely distributed in body tissues, but the concentrations in CSF are <10% of concurrent levels in plasma. It is over 90% protein bound. Quinine is metabolized in the liver, and the native drug and its metabolites are excreted in the urine (50). It has a short half-life, 8 to 12 h, necessitating multiple daily doses. After daily dosing, average concentrations in serum are approximately 7 μg/ml. Intravenous quinine is used in many countries when oral therapy cannot be tolerated, but quinidine gluconate is considered the parenteral drug of choice in the United States (59b). Quinidine has similar pharmacokinetic properties.

The pharmacokinetic properties of the cinchona alkaloids are considerably altered in malaria, with a reduction in clearance that is proportional to the severity of disease. Consequently, doses should be decreased by 30 to 50% after the third day of treatment to avoid accumulation of the drug in seriously ill patients (108). Drug levels may also be increased by administration with foods that alkalinize the urine, because increased tubular reabsorption results. Caution is recommended for use in patients with significant renal or liver impairment, but there are no specific dose adjustment guidelines. Both agents are partially dialyzable.

Spectrum of activity. The cinchona alkaloids can be used in the treatment of all four species of *Plasmodium* that infect humans. Their main indication is in chloroquine-resistant *P. falciparum*. Oral therapy is indicated in uncomplicated malaria, but intravenous formulations of quinine dihydrochloride or quinidine gluconate are used in severe infections.

Quinine and quinidine are blood schizonticides but have little effect on sporozoites or preerythrocytic forms of the parasite. Consequently, they do not eradicate *P. vivax* or *P. ovale* hypnozoites in the liver. They also are not gametocytocidal against *P. falciparum*. They are generally given in combination with other agents. Although relative resistance to these agents has emerged, they remain useful drugs for the treatment of malaria worldwide.

Quinine is also used for the treatment of babesiosis. It is ineffective when used as a single agent but can be given together with clindamycin or azithromycin (36).

Adverse effects. Quinine has an extremely bitter taste and can be associated with nausea, vomiting, and epigastric pain. It also often leads to the symptom complex of cinchonism (nausea, tinnitus, dysphoria, and reversible high-tone deafness). Quinine can also cause hyperinsulinemic hypoglycemia, especially in children and pregnant women with severe malaria, as it increases release of insulin from the pancreas. It has also been associated with massive hemolysis in patients with heavy *P. falciparum* infections. Agranulocytosis, thrombocytopenia, retinopathy, and tongue discoloration are additional adverse effects described. Overdose of quinine can lead to ataxia, convulsions, and coma.

When used as treatment for severe malaria, intravenous quinidine is associated with cardiac arrhythmias. It prolongs the QT interval, widens the QRS complex, and prolongs the PR interval. It can therefore lead to hypotension and ventricular arrhythmias including torsade de pointes. Consequently, it should be administered only in an intensive care setting with cardiac monitoring. As with quinine, administration can also result in blood dyscrasias and cinchonism.

Despite reports of congenital defects following administration of quinine during pregnancy, it can be administered during pregnancy when the benefits of maternal treatment outweigh the potential fetal risks (56, 87). Quinidine has not been reported to be teratogenic. Quinine can have an abortificient effect and lead to induction of labor. It is excreted in small amounts in breast milk but can be administered during breast-feeding when necessary.

Synthetic Quinoline Compounds

Mefloquine

Mefloquine is a synthetic 4-quinoline methanol compound structurally related to quinine.

Pharmacokinetics. Mefloquine is available for oral administration only. Food enhances bioavailability, and it should not be taken on an empty stomach. It is >85% absorbed following oral administration and is concentrated within red blood cells (46). It is >95% protein bound and has a half-life of 2 to 3 weeks. Because of its long half-life, mefloquine is frequently used for prophylaxis of malaria as a once-weekly dose. However, when mefloquine is administered weekly, it requires about 8 weeks before steady drug levels are reached, so a loading dose is often recommended. Peak concentrations in plasma following 500- and 1,000-mg oral doses are 430 and 965 ng/ml, respectively. It is highly lipophilic and widely distributed throughout the body and can cross the blood-brain barrier. Mefloquine is metabolized in the liver and excreted in the bile and feces. There are no specific recommendations regarding the need for dosage adjustment in patients with renal or hepatic failure. It is not dialyzable.

Mechanism of action. Mefloquine interacts both with host cell phospholipids and with the ferriprotoporphyrin IX of the parasitized erythrocyte (32). The precise mechanism of action is not known, but it is thought to act by interfering with the digestion of hemoglobin during the blood stages of the malaria life cycle, likely via a mechanism similar to that of quinine (29). It does not inhibit protein synthesis.

Spectrum of activity. Mefloquine is active against the erythrocytic schizonts of all four species of human malaria parasites, and it is used for both chemoprophylaxis and therapy. Since weekly administration is sufficient for chemoprophylaxis, it is convenient for use in travelers to malaria-endemic areas. Its main utility in malaria treatment results from its activity against most chloroquine-resistant *P. falciparum* strains, although resistance has been recognized, particularly in some areas of Southeast Asia. When used for therapy, it is frequently combined with another agent, usually an artemisinin derivative. Mefloquine does not kill tissue schizonts, so patients with *P. vivax* should be subsequently treated with an 8-aminoquinoline. It also has no effect on gametocytes.

Adverse reactions. Adverse reactions to mefloquine include nausea and vomiting, as well as central nervous system effects such as dysphoria, dizziness, disturbed sleep, nightmares, and ataxia. Severe neuropsychiatric reactions including delirium and seizures have been reported occasionally and are thought to occur in approximately 1:200 to 1:1,300 patients treated for acute falciparum malaria (5, 39, 103). Mefloquine can also potentiate dysrhythmias in individuals on beta blockers. It is quite expensive and is unaffordable for general use throughout areas such as tropical Africa.

Mefloquine is teratogenic in high doses in animals, but reports of studies in humans do not support teratogenic effects (102). A possible higher rate of spontaneous abortion has been suggested, so it is generally avoided in the first trimester of pregnancy. It can be used in later stages of pregnancy if the benefits outweigh the potential risks (71). It is excreted in low concentrations in breast milk but can be used in lactating women when necessary.

Halofantrine

Halofantrine is a synthetic phenanthrene-methanol compound. It has not been approved by the FDA (59b).

Pharmacokinetics. Halofantrine is available only for oral administration but has variable bioavailability. Absorption is enhanced by administration with fatty food, but because high levels in blood enhance toxicity, it is recommended for administration on an empty stomach. It is metabolized in the liver to an active metabolite, *N*-desbutylhalofantrine. The half-lives of halofantrine and its metabolite are 6 to 10 and 3 to 4 days, respectively. It is excreted mainly in the feces.

Mechanism of action. Halofantrine has activity against the asexual erythrocytic stages of malaria parasites, although the exact mechanism of action is unclear.

Spectrum of activity. Halofantrine is efficacious in the treatment of *P. vivax* and *P. falciparum* malaria, but data concerning *P. ovale* and *P. malariae* are limited (11). It is not recommended for prophylaxis of malaria because of toxicity. It is active against blood schizonts only and appears to have no effect against sporozoites, gametocytes, or tissue stages. Halofantrine is more active than mefloquine; however, cross-resistance between these drugs occurs. Its expense and potential toxicity also limit its use, so it is not recommended as a first-line agent.

Adverse effects. Halofantrine leads to gastrointestinal adverse effects including nausea, vomiting, diarrhea, and abdominal pain. It also has potential cardiovascular toxicity and causes concentration-dependent prolongation of the QT interval. It is therefore contraindicated in patients with long-QT syndrome as it can lead to cardiac arrest. It can also lead to pruritis and hepatic enzyme elevations.

Halofantrine is contraindicated in pregnancy. The degree of excretion in breast milk is unknown, and it is not advised for use in lactating women.

8-Aminoquinolines

The 8-aminoquinolines are primaquine and tafenoquine (WR 238,605). Tafenoquine is not yet licensed for malaria prophylaxis or treatment and has not been approved by the FDA (59b).

Mechanism of action. The 8-aminoquinolines interfere with parasite mitochondrial enzymes involved in energy production. They also have an inhibitory action against DNA, although the exact mechanism by which this occurs is unclear (32). An active metabolite of the drug is thought to interrupt the mitochondrial transport system and pyrimidine synthesis in hypnozoites (107).

Pharmacokinetics. The 8-aminoquinolines are well absorbed after oral administration with >90% bioavailability. Primaquine is rapidly metabolized in the liver and its half-life is 4 to 7 h, so it needs to be administered daily. Following a 15- or 45-mg oral dose, peak levels in serum are 53 and 107 ng/ml, respectively (60). Detailed information regarding distribution in body tissues is not available, but primaquine is found at relatively low concentrations in most body sites.

Tafenoquine has a longer half-life, 2 to 4 weeks. Weekly or possibly monthly doses seem to be sufficient when used for prophylaxis, thus making it better tolerated than primaquine. A single dose of tafenoquine may be sufficient for

prevention of relapse following *P. vivax* infections (106). Optimal dose-finding studies are being performed.

Clinical indications. Primaquine and tafenoquine are less active against blood-stage malarial forms than most other antimalarial agents but instead are very active against preerythrocytic sporozoites and exoerythrocytic tissue schizonts of all four malarial species. Their main use is to prevent relapse of *P. vivax* and *P. ovale* infections from latent hypnozoites following treatment with chloroquine. Additionally, they are gametocytocidal against *Plasmodium* organisms, especially *P. falciparum*, and can interrupt transmission of malaria. They are also effective causal prophylactic agents but are not generally recommended for routine use in travelers. Tafenoquine is reported to be more active than primaquine and has higher schizonticidal activity (10).

Adverse effects. Mild gastrointestinal side effects including nausea and abdominal pain are common following 8-aminoquinoline administration. These drugs should not be used in people with glucose-6-phosphate dehydrogenase deficiency as they can induce hemolysis. Patients with NADH methemoglobin reductase deficiency are at risk of developing methemoglobinemia. Primaquine also occasionally causes arrhythmias. These agents should also not be used during pregnancy or lactation because of the potential risk of hemolytic effects in the fetus.

Artemisinin (Qinghasou) Derivatives

Artemisinin is an extract from the Chinese herbal plant *Artemisia annua*, also known as qinghasou. It is a sesquiterpene lactone peroxide. Synthetic derivatives include artemether, dihydroartemisinin, arteether, and artesunate. They have not yet been approved for use by the FDA (59b).

Mechanism of action. Artemisinin and its derivatives act mainly against the asexual erythrocytic stages of malaria. They have an antiparasitic effect, particularly on young, ring-form parasites, leading to their clearance and preventing development of more mature pathogenic forms. They bind to the parasite membrane and to ferriprotoporphyrin IX, so the drugs are highly concentrated within parasites and reach 100 to 300 times higher concentrations in *P. falciparum*-infected red blood cells than in uninfected cells (37). By binding iron in the malarial pigment, they lead to production of toxic oxidative free radicals which damage parasite organelles and alkylate parasitic proteins. This leads to the inhibition of protein synthesis and ultimately to parasite death.

Pharmacology. The derivatives of artemisinin have greater solubility and consequently have been developed for easier administration by a variety of routes. Artesunate is water soluble and can be given intravenously, intramuscularly, orally, or by suppository. Artemether and arteether are oil soluble and available in tablet, capsule, or intramuscular injection forms. Although artesunate is the most potent in vitro, there is no apparent clinical difference in efficacy between the formulations. The artemisinin derivatives have a short half-life, less than 1 to 2 h. They are usually administered once daily for a minimum of 3 days. All are metabolized to the active compound dihydroartemisinin. They should be used with caution in individuals with hepatic or renal impairment.

Spectrum of activity. The artemisinin derivatives are effective against *P. falciparum* and *P. vivax* and are the most potent and rapidly acting parasiticidal drugs. They act specifically against the erythrocytic stages of *Plasmodium*. They are also active against gametocytes, reducing gametocyte carriage by about 90%, and therefore decrease malaria transmission in areas where they are widely used (15, 81). They are not effective against the intrahepatic stage of *P. vivax* or *P. ovale* infections. These drugs are effective against multidrug-resistant *P. falciparum* and are now the drugs of choice against mefloquine- and/or quinine-resistant isolates. No clinically significant resistance has been reported. However, late recrudescence is common unless these agents are combined with another drug, so they are usually administered with a second agent such as mefloquine or doxycycline. Despite the quicker clearance of parasitemia with artemisinin derivatives, randomized trials comparing them with quinine have not shown a benefit in terms of mortality.

There is minimal information available regarding the efficacy of the artemisinin derivatives in *P. ovale* and *P. malariae* infections. The artemisinin derivatives also have activity against schistosomiasis but have not been widely used for this indication (2).

Adverse effects. The artemisinin derivatives are very well tolerated with no serious toxicity or subjective adverse effects. They have been associated with adverse neurological effects in animal models, but there is no evidence that this occurs in humans. It is recommended that they be avoided in pregnancy because of insufficient safety data. The amount excreted in breast milk is unknown.

Antifolates

Pyrimethamine-sulfadoxine, also known as Fansidar, is still commonly used for treatment of malaria in some countries. Pyrimethamine is a synthetic aminopyrimidine antimalarial agent, and sulfadoxine is a long-acting sulfonamide agent.

Pharmacology. Fansidar tablets are composed of 25 mg of pyrimethamine and 500 mg of sulfadoxine. Both drugs are well absorbed orally. After oral administration of a single tablet, peak concentrations of pyrimethamine and sulfadoxine in plasma are 0.13 to 0.4 and 51 to 76 μg/ml, respectively. The half-life of pyrimethamine is 80 to 95 h, and the half-life of sulfadoxine is 150 to 200 h (108). Both components are approximately 90% protein bound. Sulfadoxine is metabolized in the liver, and both agents are excreted mainly in the urine.

Mechanism of action. Pyrimethamine acts against the asexual erythrocytic stage of *Plasmodium* by inhibiting the plasmodial enzyme dihydrofolate reductase. Although it is active against *P. falciparum*, rapid development of resistance occurs and is a major factor limiting its use as a single agent. Combining pyrimethamine with a sulfonamide or sulfone provides sequential, synergistic inhibition of the folate biosynthesis pathway. Malaria parasites are unable to utilize host-derived folic acid, so inhibition of folic acid biosynthesis prevents malarial DNA replication, ultimately leading to cell death.

Spectrum of activity. Pyrimethamine-sulfadoxine is effective for both treatment and chemoprophylaxis of *P. falciparum* malaria. It is no longer recommended for routine prophylaxis because of the potential for severe adverse effects. It acts mainly against blood schizonts and does not have significant gametocytocidal activity. Emerging resistance is limiting its use in treatment; however, its low cost means that it remains first-line therapy for *P. falciparum* in many African countries. Pyrimethamine-sulfadoxine also has some efficacy in the treatment of *P. vivax*, but it has

longer parasite and fever clearance times than chloroquine and higher failure rates (30 to 40%), so it is not recommended. The efficacy of Fansidar against *P. ovale* and *P. malariae* has not been adequately evaluated.

Pyrimethamine is also used in combination with sulfadiazine for the treatment of toxoplasmosis.

Adverse effects. Pyrimethamine-sulfadoxine can result in adverse effects including rash, nausea, vomiting, headache, and peripheral neuritis. It can also be associated with more serious and occasionally fatal reactions, including the Stevens-Johnson syndrome and blood dyscrasias (particularly agranulocytosis and megaloblastic anemia). Other reported adverse effects include hepatitis, toxic nephrosis, exfoliative dermatitis, and erythema multiforme. The long half-life of the sulfa component means that sensitivity reactions can be sustained for prolonged periods even after the drug is discontinued.

Pyrimethamine has been associated with teratogenic effects in animals. There are no controlled human studies; however, it has been used frequently during pregnancy, particularly in African countries, and has been associated with good fetal outcome. It is officially recommended for use during pregnancy only when potential benefits outweigh the possible risks to the fetus. Fansidar can cause kernicterus in infants, so it should be used with caution in pregnant women late in the third trimester. Both pyrimethamine and sulfadoxine are excreted into the breast milk and are preferably avoided during lactation.

Atovaquone-Proguanil (Malarone)

Malarone is a tablet combination of 250 mg of atovaquone and 100 mg of proguanil. Atovaquone is a hydroxynaphthoquinone, and proguanil is an antifolate. Malarone has been approved for use by the FDA for prophylaxis and treatment of malaria.

Pharmacokinetics. Atovaquone is a highly lipophilic compound with low aqueous solubility and poor and variable oral availability. Its absorption is increased if it is administered with fatty foods or a milky drink. It is not metabolized and is excreted almost exclusively in the feces. It is 99% plasma protein bound, and its half-life is 2 to 3 days. Proguanil is rapidly and extensively absorbed after oral administration. It is metabolized by the cytochrome P-450 in the liver to the active cyclic triazine metabolite, cycloguanil. It is 75% protein bound and is excreted mainly in the urine. Its half-life is 12 to 21 h. After two malarone tablets twice daily for 3 days, mean levels of proguanil and atovaquone in plasma have been reported as 170 and 908 ng/ml, respectively (25).

There are no official guidelines regarding dose reductions for malarone in hepatic or renal insufficiency.

Mechanism of action. Atovaquone has a novel mechanism of action. *Plasmodium* species are dependent on de novo pyrimidine biosynthesis, which is selectively coupled with electron transport. Atovaquone inhibits the electron transport system in the mitochondria of parasites, thereby blocking nucleic acid synthesis and inhibiting replication (55). When used as monotherapy, atovaquone is associated with high recrudescence rates. Proguanil also acts against the asexual erythrocytic stage of the parasite by selectively inhibiting plasmodial dihydrofolate reductase. However, in combination with atovaquone, it acts via a different mechanism and directly lowers the effective concentration at which atovaquone causes collapse of the mitochondrial membrane potential (93).

Spectrum of activity. Malarone is effective against asexual and sexual forms of the *P. falciparum* parasite and is recommended for treatment and prophylaxis of falciparum malaria. It is becoming an increasingly utilized alternative to mefloquine for chemoprophylaxis in travelers to malaria-endemic areas. Malarone is also effective for treating *P. vivax* and *P. ovale*, but neither drug is effective against hypnozoites so primaquine is additionally required to prevent relapses after drug discontinuation. Malarone also shows good efficacy against *P. malariae* in limited studies (84). Reports of clinical failures and resistance of *P. falciparum* isolates to malarone via a single mutation are emerging.

Adverse effects. Malarone is generally very well tolerated. Side effects are mild and include anorexia, nausea, vomiting, abdominal pain, diarrhea, pruritis, and headache. Between 5 and 10% of recipients develop transient asymptomatic elevations in transaminase and amylase levels. Because of inadequate safety data, it is not recommended for use during pregnancy or lactation.

OTHER ANTIPROTOZOAL AGENTS

Diloxanide Furoate

Diloxanide furoate, also known as Furamide, is a substituted acetanilide. Its main use is as a luminal amebicidal agent. It is not widely available in the United States and can be obtained only from specific pharmacies (59b).

Mechanism of action. The mechanism of action of diloxanide furoate is unknown.

Pharmacology. Diloxanide furoate is available in tablet form. The parent drug is poorly absorbed following oral administration, but it is hydrolyzed in the bowel lumen to an active compound, diloxanide, which is >90% absorbed. Metabolites are excreted primarily in the urine.

Spectrum of activity. Diloxanide furoate acts primarily as a luminal agent and helps clear the bowel of *E. histolytica* cysts, thereby preventing relapse in cyst carriers (59). It is not effective for amebas in the bowel wall or in other tissues such as the liver, so it is generally given with a 5-nitroimidazole.

Adverse effects. Side effects are generally not severe but include rash, nausea, abdominal pain, diarrhea, and flatulence. It is not recommended for use in pregnancy or during lactation.

Iodoquinol

Iodoquinol is a halogenated 8-hydroxyquinoline derivative, diodohydroxyquin.

Mechanism of action. Iodoquinol is thought to act by inactivating essential parasitic enzymes and inhibiting parasite multiplication (32).

Pharmacology. Iodoquinol is available for oral administration but is very poorly absorbed, with 8% reaching the systemic circulation. It is excreted primarily in the feces, but small quantities of glucuronic acid metabolites are excreted in the urine. It should not be used in individuals with renal or hepatic insufficiency and should be used with caution in patients with thyroid or neurologic disease.

Spectrum of activity. Iodoquinol is a potent amebicidal drug. It is effective against trophozoites and cysts of *E. histolytica* located within the lumen of the intestine and is used to eradicate amebic cysts to help prevent relapse of infection (59). Because it is poorly absorbed systemically, it is not effective for invasive intestinal or extraintestinal *E. histolytica* infections and is therefore frequently combined with a 5-nitroimidazole.

Iodoquinol also has activity against *Balantidum coli*, *Dientamoeba fragilis,* and *Giardia lamblia*. It has also been used for *Blastocystis hominis*, although the significance of this agent as a true pathogen remains controversial (57).

Adverse effects. The main side effects of iodoquinol include nausea, abdominal cramps, diarrhea, headache, pruritis, and rash. Skin and hair may be temporarily stained yellow-brown following exposure. In high doses or with prolonged use, it can cause optic neuritis, optic atrophy, peripheral neuropathy, ataxia, and seizures. It is also associated with nephrotoxicity. It should be avoided in individuals who are sensitive to iodine. The degree of safety associated with its use in pregnancy or lactation is uncertain, so it is recommended that it be avoided.

Pentavalent Antimonial Compounds

The pentavalent antimony derivatives are used for treatment of leishmaniasis. They include sodium antimonylgluconate (or stibogluconate), also known as Pentostam, and *N*-methylglucamine antimoniate (or meglumine antimoniate), also known as Glucantime. Selection of one drug over the other is based primarily on cost and availability. Neither drug is licensed for use in the United States, but sodium stibogluconate is available from the CDC for individual patient use (59b).

Mechanism of action. The precise mechanism of action of the pentavalent antimony derivatives remains unclear. They are thought to inhibit enzymes of glycolysis within parasites. Because glycolysis is the major source of parasitic ATP, the blockade of this source of energy is fatal to parasites (32).

Pharmacology. The pentavalent antimonials are administered parenterally (intramuscularly or intravenously) or via intralesional injection. They remain in plasma and are excreted predominantly by the kidneys. Small amounts are metabolized in the liver to trivalent antimony, which contributes to the toxicity associated with their use. Following intramuscular administration, mean peak antimony concentrations in blood of 10.5 to 12 μg/ml have been reported (16). There are no specific guidelines regarding dose adjustment in renal impairment.

Spectrum of activity. Antimony preparations are efficient in killing many protozoan and helminthic parasites but are no longer recommended for most parasitic infections because of their toxicity. However, they are still used for the treatment of visceral, mucocutaneous, and cutaneous leishmaniasis, as few effective alternatives exist. Various treatment regimens are used, but the exact duration and efficacy vary depending on the type of leishmaniasis, the severity of the lesion, and the area of endemic infection.

Adverse effects. Minor adverse effects from the pentavalent antimonials are common and include nausea, vomiting, headache, and malaise. More severe reactions such as leukopenia, agranulocytosis, and electrocardiographic changes (prolongation of the QT interval and ventricular arrhythmias) can also occur. Renal insufficiency, proteinuria, and elevation of hepatic and pancreatic enzyme levels have also been described.

Miltefosine

Miltefosine is a phosphocholine analogue that was originally developed as an anticancer compound. It is the first effective oral agent for visceral leishmaniasis and is becoming increasingly important because of growing resistance of leishmaniasis strains to pentavalent antimonials. Miltefosine was registered in 2002 for the oral treatment of visceral leishmaniasis in India and has recently been approved in Germany, but it is not available in the United States.

Mechanism of action. The mechanism of action of miltefosine is not well understood. The drug interferes with cell signaling pathways and membrane synthesis (42). Miltefosine has a direct antiparasitic activity and appears to act on key enzymes involved in the metabolism of ether lipids present on the surface of parasites, but the exact mechanisms of its cytotoxicity are unknown (42, 63). Miltefosine does not appear to have a direct immunostimulatory effect, but it does induce apoptotic cell death (80). It has been shown to be active against both the extracellular promastigote form and the intracellular amastigote form of *Leishmania* parasites both in vitro and in vivo (88).

Pharmacology. Miltefosine is well absorbed after oral administration and is widely distributed. Minimal pharmacokinetic data are available for humans, but in rats the drug is rapidly taken up and accumulates in the kidney, liver, lung, spleen, and adrenal glands (63). On oral administration of 30 mg of miltefosine per kg of body weight twice per day, concentrations of 155 to 189 nmol/g of tissue are achieved (42). Miltefosine has a long half-life, about 8 days, and is slowly metabolized by phospholipase.

Spectrum of activity. Miltefosine has activity against *Leishmania* spp. and *Trypanosoma cruzi* both in vitro and in vivo, but clinical studies to date have been limited to leishmaniasis. In vitro activity of miltefosine against *Trypanosoma brucei, Entamoeba histolytica,* and *Acanthamoeba* spp. has also been demonstrated (19).

The majority of studies using miltefosine have examined its role against visceral leishmaniasis in India. In clinical trials, miltefosine has been found to have a cure rate of 94 to 97% at 6 months in both adults and children (6, 97). It is generally given at 2.5 mg/kg per day for 4 weeks (6, 28, 42, 96, 97). Recent studies have also examined its efficacy in New World cutaneous leishmaniasis and have found 82 to 94% efficacy against *Leishmania (Viannia) panamensis*, 60% cure for *Leishmania mexicana*, and 33% cure for *L. v. braziliensis* (91, 92).

Adverse effects. In various clinical trials, toxic effects associated with miltefosine have usually been found to be tolerable and reversible, although the therapeutic window appears to be narrow (80). Mild to moderate gastrointestinal side effects, including nausea, vomiting, and diarrhea, occur in up to 60% of patients. Dose-related motion sickness is also reported in up to 40% of patients (92). A mild increase in aspartate aminotransferase and creatinine and/or blood urea nitrogen levels has been reported, with reversible hepatotoxicity and renal damage in a few cases (6, 63).

Miltefosine is abortifacient and teratogenic in animals and should not be used in pregnancy.

Pentamidine

Pentamidine is an aromatic diamidine compound that is used as an antiprotozoal agent in the treatment of leishmaniasis and African trypanosomiasis. Its use has been approved by the FDA (59b).

Mechanism of action. Pentamidine is chemically related to guanidine. Its mechanism of action has not been clearly defined and may not be uniform against different organisms. It is possible that it inhibits dihydrofolate reductase and interferes with aerobic glycolysis in protozoa. It may also interfere with amino acid transport, precipitate nucleotides and nucleotide-containing coenzymes, and inhibit DNA, RNA, and protein synthesis (86).

Pharmacology. Pentamidine is currently available as an isothionate salt. It is poorly absorbed from the gastrointestinal tract. When used for protozoal infections, it must therefore be administered intramuscularly or intravenously, but it can be given via inhalation for prevention of *Pneumocystis carinii* pneumonia. Following intravenous administration of a 4-mg/kg dose, concentrations of 0.3 to 1.4 μg/ml in plasma have been reported (105). The highest concentrations of the drug are found in the kidney, liver, and spleen, and pentamidine penetrates poorly into the central nervous system. It has a short serum half-life of 6.5 to 9 h because it is rapidly and extensively taken up by tissues. Its extensive tissue binding results in prolonged excretion over a period of 6 to 8 weeks, and it is eliminated via the kidneys. Pentamidine should be used cautiously in the presence of renal or hepatic failure, but no dosage adjustment is recommended.

Spectrum of activity. The antiparasitic indications for pentamidine include leishmaniasis and African trypanosomiasis, but its main use is as an antifungal agent for treatment and prophylaxis of *Pneumocystis carinii* pneumonia.

Despite its leishmanicidal activity, pentamidine's toxicity means it is not first-line therapy for leishmaniasis, and it is used predominantly in individuals intolerant of antimonial compounds or in those whose disease is refractory to other treatment. *Leishmania donovani* infections in particular are increasingly resistant to antimonials, and pentamidine can be used as an alternative agent.

Pentamidine is also active against African trypanosomes, but its utility is restricted to trypanosomiasis without central nervous system involvement. Because central nervous system involvement occurs early with *Trypanosoma brucei rhodesiense*, it is used more frequently for *T. b. gambiense* infections.

Adverse effects. Over half of parenteral pentamidine recipients experience some adverse effect from therapy. Administration is associated with a variety of reactions that appear to be unrelated to drug concentrations in plasma (86). Immediate reactions include nausea, anorexia, dizziness, pruritis, and hypotension. Pentamidine can also produce local effects including pain and necrosis at the site of injection. In addition, pentamidine administration is associated with hematologic effects, particularly leukopenia (up to 10% of recipients) and thrombocytopenia (approximately 5%), as well as with electrolyte abnormalities including hyperkalemia, hypomagnesemia, and hypocalcemia. Other severe adverse effects include ventricular arrhythmias, pancreatitis, hypo- or hyperglycemia, hepatotoxicity, and acute renal failure. Pentamidine has also been associated with Stevens-Johnson syndrome. Finally, occasional seizures and hallucinations have been reported.

There are minimal available safety data regarding the use of pentamidine in pregnancy or lactation, and its use is therefore not recommended unless the benefits outweigh potential risks.

Suramin

Suramin is a polysulfonated naphthylamine derivative of urea. Its main indication is in the treatment of African trypanosomiasis. It is not licensed for use in the United States but is available from the CDC via a compassionate-use drug protocol (59b).

Mechanism of action. The mechanism of action of suramin is not fully understood but is thought to be via inhibition of enzymes associated with DNA metabolism and protein synthesis of the trypanosomal parasites (78).

Pharmacology. Suramin is dispensed as a sodium salt and is soluble in water. It is not absorbed when given orally and is usually administered as a 10% solution by slow intravenous infusion. Following intravenous injection, it is rapidly distributed and >99% becomes bound to plasma proteins. It does not cross the blood-brain barrier. Its half-life is 41 to 78 days. It is excreted in the urine. It should not be used in the presence of renal failure or significant hepatic dysfunction.

Spectrum of activity. Suramin is an effective drug for early hemolymphatic stages of *T. b. gambiense* infections. It also has some effect in early *T. b. rhodesiense*, provided that there is no central nervous system involvement (24).

Suramin was used to treat onchocerciasis prior to the development of ivermectin. An advantage of suramin is that it has macrofilaricidal activity, damaging the intestinal epithelium of adult *O. volvulus* worms and resulting in their death (99). However, it is associated with frequent toxic effects at required doses, so it has therefore been replaced by ivermectin. Suramin also has activity against adult *W. bancrofti* worms but is not recommended for this indication (32).

Adverse effects. Potential side effects include an immediate reaction with nausea, vomiting, shock, and loss of consciousness following suramin injection. Other adverse effects include renal impairment, exfoliative dermatitis, and neurological toxicity. It has also been associated with pancytopenia.

Suramin has been reported to be teratogenic in rodents (104). No case of infant malformation in humans has been described, but it is not recommended for use during pregnancy except in circumstances where there is no suitable alternative.

Melarsoprol

Melarsoprol is a trivalent arsenical compound. Its main use is in the treatment of African trypanosomiasis. It is not licensed for use in the United States but is available from the CDC via a compassionate-use drug protocol (59b).

Mechanism of action. Melarsoprol appears to act by binding to essential thiol groups of trypanosomes, and it has a particularly high affinity for the active site for pyruvate kinase. This results in interference with energy generation within parasites, thereby preventing trophozoite multiplication.

Pharmacology. Melarsoprol is absorbed if given orally but is generally administered by the intravenous route. It is prepared as a solution in propylene glycol and is given by slow intravenous infusion. It is estimated that <1% penetrates the central nervous system, and concentrations in CSF are up to

50-fold lower than concentrations in serum (12, 34). However, it is so efficacious as a trypanocidal agent that it can be used for late stages of trypanosomal disease. Melarsoprol has a half-life of approximately 35 h. Its metabolism has not been well studied, but it is excreted predominantly in the urine.

Spectrum of activity. Melarsoprol is active in the treatment of all stages of African trypanosomiasis due to *T. b. gambiense* and *T. b. rhodesiense*. Because of its toxicity, it is generally reserved for use in late stages of disease involving the central nervous system.

Adverse effects. Malarsoprol is commonly associated with significant toxicity. It causes vomiting, abdominal pain, hepatotoxicity, peripheral neuropathy, cardiac arrhythmias, and albuminuria. Administration can also lead to a reactive encephalopathy in up to 10% of patients, and this is associated with significant mortality. Hypersensitivity reactions are also relatively frequent. The injection is very irritating, and extravasation during intravenous administration should be avoided. There are minimal data available regarding potential teratogenic effects.

Eflornithine

Eflornithine is also known as DFMO. Its main indication is for treatment of African trypanosomiasis. Its manufacture was ceased temporarily; although it has been resumed, drug availability is still limited, and it is not available in the United States for systemic use.

Mechanism of action. Eflornithine selectively and irreversibly inhibits ornithine decarboxylase, an enzyme required for the formation of polyamines needed for cellular proliferation and differentiation in parasites. It therefore leads to inhibition of parasite growth (47).

Pharmacology. Eflornithine can be administered by mouth and has >50% oral bioavailability, but significant diarrhea frequently results so it is usually given intravenously. No protein binding of the drug occurs following intravenous administration. It crosses the blood-brain barrier and produces CSF-to-blood ratios between 0.13 and 0.5 (40, 61). The half-life is 3 to 3.5 h, and approximately 80% of the dose is excreted unchanged by the kidneys. Dose reduction is required in patients with significant renal impairment.

Spectrum of activity. Eflornithine is used for treatment of *T. b. gambiense* infection when there is central nervous system involvement. It is ineffective as monotherapy against *T. b. rhodesiense* (18). It also displays some activity against other parasites, including *Plasmodium* species, *Cryptosporidium parvum,* and *Trichomonas vaginalis*, but it is not used for these indications because of toxicity.

Adverse effects. Side effects of eflornithine occur in up to 40% of patients. Common adverse reactions include vomiting, abdominal pain, dizziness, arthralgias, hearing loss, and rash. Bone marrow toxicity resulting in thrombocytopenia and leukopenia has also been described.

Eflornithine has been shown to arrest embryonic development in animals (31). There are no good studies of its safety in pregnancy or lactation, so it should be used only when the potential maternal benefits outweigh the possible risks to the fetus.

Agents for American Trypanosomiasis: Nifurtimox and Benznidazole

The two agents used for treatment of American trypanosomiasis are nifurtimox and benznidazole. Nifurtimox is a nitrofuran, and benznidazole is a 2-nitroimidazole derivative. Neither is approved for use by the FDA, but nifurtimox is available from the CDC for compassionate use (59b).

Mechanism of action. Benznidazole has an inhibitory effect on protein and RNA synthesis in *Trypanosoma cruzi* cells (79). It is thought to cause increased phagocytosis, cytokine release, and production of reactive mitogen intermediates that result in destruction of intracellular parasites (66).

The mechanism of action of nifurtimox seems to be related to its metabolism to chemically reactive radicals that cause production of toxic reduced products of oxygen, such as superoxide, hydrogen peroxide, and hydroxyl radicals (23, 34). These compounds accumulate within trypanosomes, leading to toxic effects including membrane damage and enzyme inactivation. It may also cause direct inhibition of protein synthesis via damage to parasite DNA (38).

Pharmacology. Benznidazole is available for oral administration and has a bioavailability of over 90%. It is approximately 40% protein bound. It has a half-life of approximately 12 h and has good tissue penetration (109).

Nifurtimox is administered orally but has poor oral bioavailability. It is metabolized in the liver and has a half-life of approximately 3 h. Dose reduction is advised for patients with significant hepatic or renal impairment, but no specific guidelines exist.

Spectrum of activity. Both benznidazole and nifurtimox are used for the treatment of acute *Trypanosoma cruzi* infection (Chagas' disease). Neither agent has demonstrated efficacy in late stages of disease. Nifurtimox also has been shown to have some activity in leishmaniasis and African trypanosomiasis, but it is not generally used for these indications.

Adverse effects. Side effects are common with benznidazole and are seen in up to 40% of treated individuals. Common adverse effects include vomiting, abdominal pain, peripheral neuropathy, rash, and pruritis. Bone marrow suppression and neuropsychiatric reactions have also been reported. Nifurtimox has significant side effects that preclude the completion of therapy in many patients. Adverse effects include anorexia, nausea, rash, headache, sleep disturbance, peripheral neuropathy, and myalgias. Less frequent but more severe toxicity includes psychosis and convulsions.

Benznidazole crosses the placenta, but there are minimal data regarding teratogenic effects for either agent in animals or humans (21).

Mechanisms of Resistance to Antiparasitic Agents

W. EVAN SECOR AND PHUC NGUYEN-DINH

151

Parasitic diseases rank among the most prevalent and severe diseases worldwide, and yet their control relies heavily on a single tool: the drugs used for chemotherapy or prophylaxis. This situation exists because no effective antiparasitic vaccines are available and implementation of other control measures often proves to be difficult in countries where parasitic diseases are endemic. This dependence on drugs is compounded by the relative paucity of the current armamentarium of antiparasitic products, a situation attributable largely to a lack of economic incentives for research and development. Furthermore, those drugs that are available are too often used incorrectly in communities and in control programs, a practice that encourages the selection of drug-resistant parasites.

The complex biologic interactions between parasites and their hosts (and at times vectors) influence significantly the emergence and expression of drug resistance. In many cases the observed resistance is true resistance, attributable to biologic characteristics of the parasites that enable them to survive drug concentrations that are lethal to susceptible members of the species. Mechanisms for such true resistance are varied and include a decrease in parasite drug accumulation or modifications in enzyme structure or metabolic pathways. However, various host factors modulate the clinical and parasitologic responses to drug treatment, and the observed responses do not necessarily reflect true parasite resistance or susceptibility. For example, in populations with high rates of exposure to parasitic infections, the resulting high rates of immunity might suffice to eliminate an infection treated with an ineffective drug. Conversely, treatment with a drug to which the parasite is biologically susceptible will not necessarily result in therapeutic success if the host takes an inadequate dose of the drug, absorbs it poorly, or lacks the immune response that might be needed for a successful antiparasitic synergism with the drug. Such host factors may be especially important in the areas where most parasitic diseases prevail, where high rates of parasite transmission result in high rates of immunity in most of the population, and where, conversely, malnutrition and human immunodeficiency virus (HIV) infection frequently decrease the patient's immune status.

Greater understanding of the epidemiology and mechanisms of drug resistance can provide valuable guidance for a better use of existing compounds and for the development of novel products. A selective review of drug resistance in five diseases will illustrate the existing problems and their potential solutions. A summary of the proposed mechanisms of resistance is provided in Table 1.

MALARIA

Overview

Malaria, the parasitic disease with the most visible public health impact, also presents the greatest problem of drug resistance (133, 136). Furthermore, resistance is found mainly in *Plasmodium falciparum,* the most pathogenic of the four species that cause human malaria, responsible for at least one million deaths annually. The 4-aminoquinoline drug chloroquine, a cornerstone of antimalarial chemotherapy since the 1940s due to its low cost, safety, and rapid action, has seen its usefulness seriously eroded by the widespread occurrence of resistant strains of *P. falciparum*. From the original foci in Southeast Asia and South America, resistance has spread relentlessly and is now found in most areas of the world, including Africa, the continent with the heaviest malaria burden. Chloroquine no longer constitutes an appropriate treatment option in most countries where malaria is endemic. Among alternate drugs for use against chloroquine-resistant *P. falciparum,* synergistic combinations of inhibitors of the parasite folate biosynthetic pathway are relatively inexpensive and safe. An antifolate combination often used until recently consists of sulfadoxine and pyrimethamine (S-P), two compounds which sequentially block the parasite dihydropteroate synthase (DHPS) and dihydrofolate reductase (DHFR), respectively. However, resistance to S-P has emerged and is found in Asia and South America, often at high prevalence, and in many African countries. *P. falciparum* resistant to both chloroquine and S-P can be treated with several other drugs, which include quinine and mefloquine (two quinoline methanols), the tetracyclines, the artemisinin derivatives (a sesquiterpene lactone class of compounds), and the recently introduced combination atovaquone-proguanil. However, resistance against some of these drugs has now been observed, especially in Southeast Asia and South America. This precarious situation is of great concern and is addressed by the recommended use of combination therapies, often containing artemisinin derivatives, that aim at delaying the emergence of resistance (133). The newer drugs or drug combinations might, however, prove too costly

TABLE 1 Summary of proposed mechanisms of resistance to selected antiparasitic drugs

Disease	Drug(s)	Mechanism(s) of resistance
Malaria	Chloroquine	Decreased accumulation of the drug by the parasite, resulting from multifactorial, multigenic mechanisms
	Pyrimethamine	Alteration in binding affinities between the drug and the parasite dihydrofolate reductase-thymidylate synthase, resulting from mutations on the corresponding gene
	Sulfadoxine	Alteration in binding affinities between the drug and the parasite dihydropteroate synthase, resulting from mutations on the corresponding gene
	Atovaquone	Alteration in binding affinities between the drug and the parasite cytochrome *b*
Trichomoniasis	Metronidazole Tinidazole	Aerobic: decreased oxygen scavenging Anaerobic: reduced concentration of enzyme(s)necessary to activate nitro group
Leishmaniasis	Pentavalent antimonials	Decreased active intracellular drug concentration through increased efflux or decreased conversion to active trivalent form
	Amphotericin B, paromomycin, miltefosine	Widespread clinical resistance not currently documented; resistance has been produced in laboratory strains
African trypanosomiasis	Melarsoprol, pentamidine	Mutation/loss of P2 adenosine transporters that facilitate drug uptake
Schistosomiasis	Oxamniquine	Lack of esterase necessary for drug activation
	Praziquantel	Widespread clinical resistance not currently recognized as important problem for public health; resistance documented in laboratory strains
	Artemether	Effective against immature worms; no resistance as yet documented

for many areas, particularly in Africa, where the malaria problem is the worst but where drug resistance has not yet reached the nearly untenable proportions found in Southeast Asia. This situation underlines the importance of using rationally those drugs that are still effective.

In *P. vivax,* the most prevalent species, chloroquine-resistant strains were first reported in 1989 in Papua New Guinea (109) and are now found in other areas where *P. vivax* is endemic. In addition, *P. vivax* infections have been described with decreased sensitivity to primaquine, an 8-aminoquinoline that prevents relapses in this species by destroying dormant liver-stage parasites (hypnozoites) (115).

Mechanisms of Resistance to Selected Antimalarials

Chloroquine resistance in *P. falciparum* appears to have a multifactorial, multigenic basis (132). Epidemiologically, the long delay between the introduction of chloroquine and the emergence of resistance, despite massive use of the drug, suggests that several genetic changes are necessary before chloroquine resistance becomes manifest. Clinically and parasitologically, the existence of different degrees of in vivo and in vitro resistance also suggests the intervention of multiple factors. Chloroquine-susceptible parasites accumulate the drug in their digestive vacuole, where the drug appears to interfere with the polymerization and detoxification of heme (a by-product of the digestion of host cell hemoglobin by the parasite), resulting in the accumulation of heme-chloroquine complexes that are toxic to the parasites (120). In resistant parasites this accumulation is decreased (51). Furthermore, chloroquine resistance can be reversed in vitro by various compounds, including the calcium channel blocker verapamil (81) and the tricyclic antidepressant desipramine (7), apparently through increased accumulation of the drug in the resistant parasites (7, 69). Several mechanisms have been proposed for these hallmark manifestations of chloroquine resistance, including (i) a decreased uptake of chloroquine by alterations in a chloroquine importer (possibly an Na^+/H^+ exchanger) found in the parasite plasma membrane (39, 110); (ii) an alteration in pH in the parasite digestive vacuole, which decreases the interactions between the drug and its heme target (43); (iii) a reduced accessibility of heme for binding with chloroquine (13); or (iv) an increased efflux of chloroquine from the acid digestive vacuole (69).

Chloroquine resistance is linked most closely to point mutations in the *pfcrt* gene found on the parasite's chromosome 7. This gene encodes pfCRT, a transmembrane transporter protein found on the parasite digestive vacuole, which may be involved in efflux of drug/metabolites or pH regulation (50). Laboratory investigations using genetic crosses and field studies with chloroquine-resistant parasites from Asia, Africa, and South America have identified the key role of a mutation affecting codon 76, most often Lys→Thr (K76T) (12, 36, 132). This central mutation is accompanied by additional polymorphisms on the *pfcrt* gene, particularly in the neighboring residues 72 to 75 and residue 220, in variant patterns that reflect the geographic origin of the parasites (84, 126, 132). These additional mutations possibly compensate for a loss of transporter function, derived from the K76T mutation, or they may play an additional role in resistance. The K76T mutation is now a valuable molecular marker used in epidemiologic surveys of chloroquine resistance (1, 35, 85). Its measured prevalence may offer a useful predictor of the clinical efficacy of chloroquine in a given area, provided that appropriate adjustments are made for host factors, particularly immunity, that may result in parasite clearance in spite of treatment with an ineffective drug (36, 37).

Another gene has also been linked, albeit less consistently, to chloroquine resistance. The *pfmdr1* gene, on chromosome 5,

encodes the P-glycoprotein homolog-1 (PGH-1), a *P. falciparum* homologue of the mammalian multidrug resistance gene which increases outflux of drugs. Current evidence indicates that *pfmdr1* does not play a primary, causal role in chloroquine resistance. Initial studies that associated amplification of *pfmdr1* with chloroquine resistance have not been confirmed. In genetic cross experiments, chloroquine resistance has not cosegregated with *pfmdr1* (131). However, field assessments have found associations, albeit variable, between *pfmdr1* polymorphisms and chloroquine resistance (136), thus suggesting that *pfmdr1* may play an adjunct function in resistance. Indeed, transfection experiments have shown that selected mutations in *pfmdr1* can modulate chloroquine resistance in vitro, in concert with mutations in other genes such as *pfcrt* (108).

The *pfmdr1* gene also appears to be involved in resistance to other antimalarial drugs. Experiments using transfection (108) or genetic crosses (42) and field investigations (99, 136) have found that mutations at specific positions of *pfmdr1* alter responses not only to chloroquine but also to quinine, mefloquine, and the unrelated artemisinin derivatives (often in the reverse direction). Selection of mefloquine-resistant *P. falciparum* through drug pressure in continuous culture have resulted in amplification of the *pfmdr1* gene, concomitantly with an increase in resistance to quinine and a decrease in resistance to choloroquine in the selected parasites (25). Field investigations have linked *pfmdr1* amplification with in vitro resistance to mefloquine and artesunate (104) and with in vitro resistance to mefloquine, quinine, and artesunate and increased sensitivity to chloroquine (99). These associations are not absolute, indicating that transporter molecules other than PfCRT and PGH-1 may be involved in resistance to these antimalarial drugs (86).

Pyrimethamine-resistant *P. falciparum* appeared quite rapidly in several locations after the introduction of the drug in the early 1950s (94), suggesting that in contrast to chloroquine, a single gene is involved in pyrimethamine resistance. Differently from bacteria and human tumor cells, gene amplification is not involved in *P. falciparum* resistance to DHFR inhibitors (26). Resistance to DHFR inhibitors has indeed been linked to point mutations in the parasite dihydrofolate reductase-thymidylate synthase gene on chromosome 4 of *P. falciparum* in studies of culture-adapted *P. falciparum* (26, 52, 95) and of field-collected parasites (31, 136) and in transfection experiments (137). These mutations result in alterations of the enzyme binding affinities with the drugs and occur in a sequential pattern, the primary event being an S108N mutation, with subsequent mutations (particularly N51I and C59R) allowing increasing levels of resistance in vitro while maintaining the functionality of the enzyme (101). In vitro resistance to cycloguanil, the active metabolite of proguanil (another DHFR inhibitor), is also linked to various *dhfr* mutations. However, these mutations differ from those associated with resistance to pyrimethamine (52, 95). In similar studies with sulfadoxine using culture-adapted *P. falciparum* and transfection experiments, resistance to sulfonamides/sulfone has been traced to a set of sequential mutations in the gene for dihydropteroate synthase (which also encodes dihydrohydroxymethylpterin pyrophosphokinase) on chromosome 8 (121, 129). The likely initial event consists of an A437G mutation, with subsequent additional mutations conferring increasing degrees of resistance (101). Resistance to the S-P combination appears to require a minimum of three mutations on the *dhfr* gene, accompanied by two additional mutations on the *dhps* gene ("quintuple mutant"), with the clinical outcome being subject to additional host factors such as folate levels, immunity, and absorption and drug metabolism (29, 44, 70, 101, 103). The I164L mutation in *dhfr,* associated to high levels of S-P resistance as well as to decreased sensitivity to chlorproguanil-dapsone, a new antifolate combination similar to S-P, has not been yet reported from Africa (92). Surveys of mutations in the *dhfr* and *dhps* genes in *P. falciparum* now offer a useful tool for monitoring of resistance to S-P and other antifolates and are potentially valuable for assessing the risk of emergence of resistance by detection of prerequisite mutations as they appear in local parasite populations (6, 53, 102, 136).

The recently introduced drug combination Malarone consists of a synergistic association of proguanil (a DHFR inhibitor) and atovaquone (a mitochondrial inhibitor of *P. falciparum*). While resistance develops readily to either compound used alone, their combination aims to overcome this problem. Investigations using in vivo and in vitro resistant *P. falciparum* have linked resistance to avovaquone to mutations in the parasite cytochrome *b* gene, that may decrease the binding affinity of cytochrome *b* for atovaquone (67). Further investigations of atovaquone-proguanil treatment failures in cases of *P. falciparum* infections have associated these failures with mutations at codon 268 of the cytochrome *b* gene (71).

While drug resistance in *P. vivax* has not reached the same magnitude as in *P. falciparum,* investigations on mechanisms of resistance in this species currently examine the potential role of *P. vivax* homologues of *pfcrt* (90), *mdr1* (14), *dhfr* (54), and *dhps* (68).

TRICHOMONIASIS

Infection with *Trichomonas vaginalis* is one of the most common causes of human vaginitis. In addition, recent data have linked *T. vaginalis* infections with preterm delivery, low birth weight, greater susceptibility to infection with HIV, and an increased risk of cervical neoplasia (24, 73, 127). As a result, expedient treatment of this infection has become an important public health measure.

T. vaginalis is a facultative anaerobe, and *T. vaginalis* infections are most commonly treated with 5-nitroimidazoles. Metronidazole, and more recently tinidazole, are the only drugs licensed for treatment of trichomoniasis in the United States. Tinidazole functions in a manner analogous to that of metronidazole and is more active at equimolar concentrations (28). However, strains clinically resistant to metronidazole often have cross-resistance to tinidazole.

Most studies on the mechanism of action of 5-nitroimidazoles and resistance to them have been performed with metronidazole. The drug enters parasites in an inactive form by passive diffusion. Once inside, the low intracellular redox potential generated by trichomonad energy production results in reduction of the nitro group, forming a nitro radical that damages the parasite (61). *T. vaginalis* resistance to metronidazole occurs in two forms, designated according to the oxygen environment under which they can be observed. Anaerobic resistance is the more extreme form and has been associated with reduced activity of ferredoxin, pyruvate:ferredoxin oxidoreductase (PFOR), malic enzyme, and hydrogenase, enzymes in the metabolic pathway responsible for activation of metronidazole to its toxic form (15, 41, 72, 74, 107). Transfection of a drug-resistant trichomonad with ferredoxin increased its susceptibility to metronidazole (75). In contrast, targeted disruption of the ferredoxin gene in *T. vaginalis,* which also resulted in a 95% decrease in PFOR

activity, failed to confer resistance (76). Together, these studies suggest that ferredoxin and PFOR are capable of, but not necessary for, 5-nitroimidazole activation.

Anaerobic resistance is usually seen only in laboratory-derived strains, although one clinical isolate with anaerobic resistance has been described (128). Most isolates from patients who cannot be cured with metronidazole display resistance that is detectable only under aerobic conditions. While the mechanism for aerobic resistance is less well understood, the enzymes responsible for oxygen scavenging in these parasites appear to have lower substrate affinities (139). This results in more free oxygen in the cytosol that accepts electrons from, or in lieu of, metronidazole and decreases the intracellular concentration of active drug (72, 106). Isolates with laboratory-induced aerobic resistance and some clinical isolates also have decreased mRNA levels and lowered protein expression of enzymes involved in trichomonad metabolism (105, 107). However, assessment of ferredoxin, PFOR, malic enzyme, and hydrogenase in 28 clinical isolates revealed no correlations between mRNA levels of these enzymes and resistance to metronidazole under either aerobic or anaerobic conditions (83).

The molecular epidemiology of *T. vaginalis* suggests that clinically resistant isolates are genetically related and stable over time (57, 116, 125). However, despite increasing recognition of metronidazole treatment failures (96, 117), no epidemics of resistant trichomoniasis have occurred. To explain this observation, it has been hypothesized that resistant isolates are less transmittable between sexual partners (122). Support for this hypothesis comes from findings that clinical isolates with resistance to metronidazole have decreased aerotolerance (106).

Treatment of patients who have metronidazole-resistant trichomoniasis often results in an immediate resolution of symptoms and a negative wet mount. However, within 3 to 4 weeks, in the absence of further exposure, symptoms may recur as the number of organisms rises. Thus, it is important to monitor the efficacy of treatment for up to a month and to encourage patients to avoid unprotected intercourse during this time. When metronidazole resistance is encountered, patients are often treated with increased doses for a longer time (80). However, many patients cannot tolerate high doses of metronidazole and such practices may only exacerbate the development of drug resistance. Clearly, alternatives to metronidazole for treatment of *T. vaginalis* are needed. Furazolidone is active in vitro against isolates of *T. vaginalis* that are resistant to metronidazole and tinidazole (88), but it is poorly absorbed from the digestive tract and would require topical application, thus somewhat limiting its efficacy. Nitazoxanide and disulfiram kill metronidazole-resistant trichomonads in vitro but have not been evaluated in treatment trials (2, 10, 19). Alternative topical therapies that may have some benefit for patients with metronidazole-resistant *T. vaginalis* infections are paromomycin sulfate and povidone-iodine (91, 130, 135, 140). Non-5-nitroimidazole treatments are also important for persons who demonstrate hypersensitivity to metronidazole and tinidazole.

LEISHMANIASIS

Leishmaniasis is transmitted to humans by phlebotomine sandfly vectors and manifests itself in a variety of syndromes. Depending in part on the infecting *Leishmania* species, the pathology ranges from a cutaneous lesion that may be self-limiting to the more severe mucosal or visceral forms. The identification of leishmaniasis as an important opportunistic infection in patients with AIDS has presented new challenges for treatment of this disease, with treatment failures occurring in up to 50% of HIV type 1-positive individuals (3). Use of antileishmanial drugs is limited by their high cost, the difficulty of their administration (injection for several weeks), and their associated toxicity. These factors are even more consequential in the developing countries where leishmaniasis is endemic and can lead to premature self-termination of therapy, which in turn may promote increased levels of resistance (48, 55). While true drug resistance has been described for isolates of some *Leishmania* spp., other species or isolates may just differ in their intrinsic sensitivity to certain compounds. True resistance is more likely in anthroponotic forms of leishmaniaisis, such as *Leishmania donovani* and *Leishmania tropica* (27).

Leishmania infections caused by all species and of all clinical forms are most commonly treated with the pentavalent antimonial compounds sodium stibogluconate and meglumine antimoniate (5, 87, 93). Consequently, they are also the only antileishmanial compounds to which widespread clinical drug resistance has been described. In some regions of India, treatment failure is as high as 65%. Development of resistance has been attributed both to the substandard quality of drug produced by some manufacturers and to inappropriate administration of treatment by some caregivers (87, 119). Evidence for true drug resistance in this setting comes from observations that isolates from clinically resistant patients require higher in vitro concentrations of drug to kill the parasites than do isolates from patients who responded to treatment (119). Furthermore, these differences persist when the putatively resistant isolates are maintained in vitro in the absence of drug pressure, suggesting that a stable genetic change confers resistance (40). The mode of action for pentavalent antimonials, as well as the development of drug resistance, is still poorly defined. In vitro studies have suggested that the pentavalent antimonials are reduced to an active trivalent form that disrupts the parasite's metabolism (8, 93). One hypothesized resistance mechanism is a loss in the parasite's reductase activity, resulting in lower concentrations of effective drug (93, 113). Resistance has also been associated with increased production of trypanothione or glutathione that bind with the trivalent antimonials and extrusion of the resulting thiol-drug conjugates by ATP-binding cassette (ABC) transporters (65, 93). Increased expression of the enzymes involved in thiol synthesis or of the ABC transporter promotes resistance to pentavalent antimonials; inhibition of these pathways in resistant strains increases susceptibility to drug (16, 45, 56, 77, 93). Because of the high level of pentavalent antimonial resistance, this treatment is no longer considered useful in India and other drugs are used for primary treatment of visceral leishmaniasis (5, 87, 119). One of these other drugs, amphotericin B, interacts with parasite-specific 24-alkyl sterols and induces pore formation in the parasite plasma membranes (20). The use of amphotericin B has been limited in the past due to its high cost and toxicity; however, new lipid-associated formulations of amphotericin B have greatly reduced toxicities and retain good efficacy even when administered in lower dosages (5, 87). Like the pentavalent antimonials, optimal activity of amphotericin B may require competent host immune responses (33). Lipid-associated formulations of amphotericin B are phagocytized by host monocytes and accumulate in the phagocytic lysosomes where *Leishmania* amastigotes reside (138). Although the ABC transporter associated with resistance to pentavalent antimonials shares the characteristics of membrane transporters that confer multidrug resistance, in vitro studies demonstrate that

antimonial-resistant parasite strains do not display cross-resistance to amphotericin B (16, 34, 40). Similarly, laboratory or field isolates with resistance to pentivalent antimonials are killed effectively by paromomycin and miltefosine, two other drugs in development for treating leishmaniasis (5, 16, 27, 40). Miltefosine is particularly promising, as it can be taken orally and has fewer side effects than most of the parenteral treatments for leishmaniasis. As a result, although the drug is more expensive than other therapies, it can be administered on an outpatient basis and the overall cost for treatment is lower than less costly drugs that require hospitalization (87). It has also shown efficacy for a severely immunocompromised leishmaniasis patient coinfected with HIV-1 (111). Enthusiasm is tempered, however, both because it is teratogenic, thereby limiting its unregulated use in women of childbearing age, and because it has been observed that leishmanial resistance to miltefosine develops easily in vitro (112, 119).

AFRICAN TRYPANOSOMIASIS

Trypanosoma brucei rhodesiense and *Trypanosoma brucei gambiense* are the etiologic agents of sleeping sickness. They are endemic in east and west central Africa, respectively, and are transmitted by tsetse fly bites. Because these parasites possess antigenic switching mechanisms, host immune responses are ineffective and the prospects for the development of vaccines against these organisms are meager. As a result, drug treatment is the only medical intervention available to combat sleeping sickness for the foreseeable future. Recent political unrest with subsequent loss of an effective public health infrastructure in parts of Africa has caused a resurgence of this disease, a situation that has been compounded by increased resistance to the limited armamentarium of efficacious drugs.

Pentamidine and suramin are useful for treatment only of early stages of infection because they are highly ionic and do not cross the blood-brain barrier. Late-stage, central nervous system disease is treated with melarsoprol B. Eflornithine is effective against late-stage *T. b. gambiense* infections that are resistant to melarsoprol, but *T. b. rhodesiense* is not susceptible to this drug (4). Data are somewhat limited but suggest that patients coinfected with HIV are more likely to relapse following treatment with melarsoprol or eflornithine than individuals with trypanosome infection alone (58).

The efficacies of pentamidine and melarsoprol are dependent on their selective accumulation inside the parasite rather than in the host's cells (11). These two drugs share an amidinium-like moiety with amino purines that is recognized and actively taken up by nucleoside transporters in the trypanosome membrane, resulting in a concentration of these compounds within the parasite. Thus, although pentamidine and melarsoprol have different modes of action, resistance to these drugs seems to occur through a similar mechanism due to shared structural motifs (46, 89). Resistance to both drugs has been associated with the loss of the adenosine transporter P2 and accumulation of less drug (8, 11, 18, 89). Other transporters permit parasite uptake of purines and confer survival in the absence of this transporter (17). The P2 transporter has been cloned and expressed in yeast, where it enabled uptake of adenosine and was inhibited by melarsoprol but not pentamidine (82). Sequencing of the P2 transporter from drug-resistant parasites revealed six amino acid changes, at least one of which was shared with a field isolate from a patient with a melarsoprol-resistant infection (82). Two additional transporters have now been shown to contribute to pentamidine uptake, explaining at least in part the high rate of clinical resistance to melarsoprol compared to that of pentamidine (11, 30, 38, 62). Mechanisms of resistance to suramin or eflornithine are unknown but are thought to similarly reflect decreased intraparasite levels of drug accumulation. However, it is likely that uptake of suramin uses other transporters or is based on an alternative mechanism, as trypanosomes that have undergone genetic manipulation of their transporters that renders them 10-fold more resistant to pentamidine are still susceptible to suramin (65).

SCHISTOSOMIASIS

Drug resistance in human helminths is rare, a fact attributed to their long reproduction cycles and to their lack of multiplication inside the human host (the exception being *Strongyloides stercoralis*). Thus, when considering treatment failures in schistosomiasis, it is important to distinguish characteristics leading to reduced drug efficacy from those of true drug resistance. For example, persons with very high levels of infection are less likely to be cured with single-dose therapy than individuals with lower worm burdens (63, 100, 123). This is in part related to the fact that the standard drugs used to treat schistosomiasis, oxamniquine and praziquantel, are effective only against the adult stage of the parasite. Immature worms that may be present at the time of drug treatment, especially in areas of high transmission, are not susceptible to the initial treatment and subsequently develop into patent infections that give the impression of drug resistance. As a result, a minimum of two treatments spaced 4 to 6 weeks apart should be attempted when drug resistance is suspected (100, 123).

Nevertheless, *Schistosoma mansoni* infections that have true oxamniquine resistance have been reported in Brazil and Kenya (23, 32) and praziquantel-resistant infections have been described in Egypt and Senegal (60, 118). While alternative explanations to drug resistance have been offered for the praziquantel treatment failure, eggs obtained from the feces of individuals who could not be successfully treated have been used to establish infections in mice for confirmation of the drug resistance phenotype (47, 59, 60, 79). Nevertheless, despite continued treatment pressure, widespread clinical resistance has not been observed since these foci were described (9).

Oxamniquine is activated by a schistosome esterase, binds the parasite's DNA, and irreversibly inhibits RNA and DNA synthesis (21). This enzymatic activity is not present in *Schistosoma haematobium* (a species not susceptible to oxamniquine) or oxamniquine-resistant strains of *S. mansoni* (21, 98). Classical genetic studies on oxamniquine-resistant strains demonstrate that this resistance is controlled by a single autosomal recessive gene that also confers resistance to hycanthone, an older antischistosome drug that is no longer used clinically (22, 97). Production of oxamniquine has now ceased, and it is no longer available commercially (49).

Resistance to praziquantel is manifested by a reduced effect of the drugs on the tegument of adult schistosomes (59, 78, 134). In drug-susceptible parasites, this damage makes the worms susceptible to attack and killing by the host's immune response. Interestingly, although immature worms are not susceptible to praziquantel treatment, eggs, miracidia, and cercariae from praziquantel-susceptible strains of *S. mansoni* show decreased hatching, drastic morphologic changes, and increased tail shedding, respectively, when exposed to drug in vitro than do these life cycle stages from praziquantel-resistant strains (79). The unique beta subunit of the schistosome calcium ion channel has been proposed as a molecular

target for praziquantel (66). However, no differences in this gene's sequence or expression were observed among a limited number of praziquantel-resistant and -susceptible parasite strains (124). While mathematical models predict that widespread resistance to praziquantel is not imminent, they do anticipate that it will emerge in 10 to 20 years (64). This finding reiterates the need for ongoing drug discovery and testing even for parasites less prone to the development of drug resistance.

One new compound being investigated for the treatment of schistosomiasis is artemether, a derivative of the antimalarial drug, artemesinin. Unlike oxamniquine and praziquantel, artemether is most effective against juvenile worms (114). Thus, it could be used as a prophylactic against patent schistosomiasis for persons with a known exposure or in combination with praziquantel to kill all worms in the human host. Caution about its use, however, has been raised as there is concern that treatment of schistosomiasis with this drug will hasten the occurrence of malarial resistance to it (49).

FUTURE PERSPECTIVES

Several factors contribute to the emergence of drug-resistant parasites. Those parasite species with short life cycles and high multiplication rates that occur in areas of intense transmission are most likely to develop resistant subpopulations. The selection of such populations is encouraged when the parasites are repeatedly exposed to suboptimal drug concentrations. This pattern can result from the use of drugs with long half-lives, or more typically from the frequent, often unjustified use of inadequate doses of drugs, a common occurrence in countries where parasite infections are endemic. Public health interventions to correct these factors have not always been successful and would benefit from a better understanding of the drug resistance mechanisms used by parasites. These mechanisms are very diverse and have been difficult to study, but recent technological advances now provide long-awaited tools that will facilitate the task. The genome sequences for *Plasmodium falciparum, Trichomonas vaginalis, Leishmania major,* and *Trypanosoma brucei* have recently been completed, and sequencing of the *Schistosoma mansoni* genome is ongoing. When these data are used, for example, in combination with microarray technology, where the DNA of drug-resistant parasite strains is compared to that of drug-susceptible strains, identification of the genes that confer resistance should proceed even more rapidly than in the last few years. In addition, genomic data may also be useful in the design of new chemotherapeutic agents as they help researchers identify metabolic processes of parasites that are sufficiently different from those of their human hosts to allow specific attack.

Susceptibility Test Methods: Parasites

PHUC NGUYEN-DINH AND W. EVAN SECOR

152

OVERVIEW

Accurate methods for ascertaining the responses of parasites to antiparasitic drugs can prove useful at several levels. They can assist in the clinical management of individual patients, they can yield epidemiologic information that may guide drug use policies and public health interventions, and they offer crucial research tools for the development of new and better drugs. Drug susceptibility tests fall into four broad categories: in vivo tests, in vitro tests, tests with experimental animals, and molecular tests.

In vivo tests with patients directly assess the clinical efficacies of existing compounds. These tests are performed in actual epidemiologic investigations, and their modest technical requirements make them suitable for use under field conditions in developing countries. The interpretation of in vivo tests is limited by potential interferences by factors related to the host (e.g., immunity or variations in drug intake or metabolism) or to the environment (e.g., reinfections). However, such tests have proven instrumental in guiding drug use policies, particularly for malaria.

In vitro tests circumvent these interferences by isolating the parasites from their hosts and investigating them in culture under controlled laboratory conditions, with opportunities for repeated assessments against multiple compounds (including experimental compounds). In vitro tests, however, are technically more demanding and therefore less amenable to performance under field conditions. They are most informative if they are used to investigate parasites that multiply rapidly in culture, a select group consisting mostly of protozoa. They are of limited use for assessing inactive drug precursors that must be activated by the host or drugs whose antiparasitic activity necessitates the synergistic effect of the host's immune defenses.

Tests with experimental animal models permit investigations of parasites that cannot be grown in culture or of drugs not yet approved for use in humans.

Molecular tests detect genetic variations that are potentially linked with resistance. Such tests offer unique advantages. PCRs can be performed with minute amounts of nonviable parasite genetic material. They can be run in batches, allowing large-scale epidemiologic studies. Molecular analysis at the single-organism level circumvents potential ambiguities associated with the heterologous parasite populations occasionally encountered in in vivo or in vitro tests and allows the dissection of such populations. Because of their short duration (hours), molecular diagnostic procedures can potentially be used to guide patient management. The other categories of tests usually require more time (days to weeks) and yield results that are used mainly for epidemiologic surveillance and experimental chemotherapy studies. Drawbacks of molecular tests reside in their technical requirements and in the need to be certain that the genes evaluated correlate with functional resistance. However, thanks to the development of more practical protocols and more robust automated equipment, as well as a better understanding of the genes that confer resistance, molecular techniques are used in an increasing number of laboratories, including field facilities.

These different categories of tests provide complementary information. At one end of the spectrum, molecular tests analyze parasites at their most basic biologic level, without any outside interference. At the other end, in vivo tests with patients reflect complex interactions between host and parasite, yet are most relevant for clinicians and public health practitioners. While a good correlation between results of various test methods is desirable, some degree of discrepancy should be expected to result from factors linked to the host or the culture conditions. Indeed, a judicious analysis of such discrepancies might provide valuable insights into the mechanisms of drug action and resistance.

These points are illustrated in the following discussions of five parasitic diseases, selected for their particular chemotherapeutic challenges. A summary is provided in Table 1.

MALARIA

Most drug resistance tests in malaria concern *Plasmodium falciparum,* which is, among the four species that infect humans, the most virulent and the most prone to the development of resistance.

Initial observations of drug-resistant malaria occur most often in a clinical context, and their confirmation is frequently sought by in vivo tests. These aim at documenting the parasitologic and clinical response of a malaria infection in a patient treated with a standard dose of the test drug and monitored under controlled conditions. Initially standardized by the World Health Organization (WHO) for the response of *P. falciparum* to chloroquine, in vivo tests have been variously modified for simpler performance

TABLE 1 Selected antiparasitic agents and susceptibility testing methods[a]

Disease and drugs	Testing methods	Remarks
Malaria Chloroquine, sulfadoxine-pyrimethamine, quinine, mefloquine, artemisinin, atovaquone-proguanil, tetracycline, primaquine, others	In vivo tests in patients with *P. falciparum* or *P. vivax* malaria Culture of erythrocytic stages of *P. falciparum;* criteria for assessment: • Microscopic examination: maturation from rings to schizonts; parasite multiplication • Metabolic activity: incorporation of [^{3}H] hypoxanthine; production of pLDH, HRP2 • DNA quantitation PCR-based genetic analysis (mostly, *P. falciparum*) of mutations/amplification in genes putatively involved in resistance to chloroquine *(pfcrt, pfmdr1),* antifolates (*dhfr, dhps* genes), atovaquone (cytochrome B gene), and others	Drug resistance is a major problem, especially in *P. falciparum;* it also occurs in *P. vivax.* Tests are used for epidemiologic assessment as well as for laboratory investigations. Short-term culture tests are also described for erythrocytic stages of *P. vivax.* On an experimental basis, in vitro tests for drug effect on liver stages and sexual stages (gametocytes)
Trichomoniasis Metronidazole, tinidazole	Culture under aerobic and anaerobic conditions; criterion for assessment: parasite mobility	Resistance to metronidazole is relative; testing is performed over a wide range of concentrations.
Leishmaniasis Sodium stibogluconate, meglumine antimoniate, pentamidine, amphotericin B, paromomycin, miltefosine	Culture of promastigotes; criteria for assessment: • Microscopic examination and parasite count • Metabolic activity: incorporation of [^{3}H] thymidine; hydrolysis of *p*-nitrophenyl phosphate; conversion of MTT or Alamar Blue Culture of amastigotes (intracellular or axenic); criteria for assessment: • Microscopic examination and counting of stained intracellular parasites • Luciferase activity of transfected parasites • Flow cytometry using GFP-transfected parasites or intracellular staining with anti-*Leishmania* monoclonal antibody • Flow cytometry based on alterations in membrane potentials (amphotericin B)	Problems with most drugs: high cost, difficulty in administration, and toxicity High level of failure of pentavalent antimonials in some areas Coinfection with human immunodeficiency virus type 1 can compromise therapy results. Tests with intracellular or axenic amastigotes show better correlation with clinical drug efficacy.
African trypanosomiasis Pentamidine, suramin, melarsoprol, eflornithine	Culture of trypomastigotes; criteria for assessment: • Microscopic examination and parasite count • Metabolic activity: hydrolysis of *p*-nitrophenyl phosphate, reduction of Alamar Blue	In vitro tests used mainly for laboratory investigations Ability to detect mutations in transporter responsible for drug uptake may soon allow tests applicable in the field.
Schistosomiasis Oxamniquine, praziquantel	Damage to adult worms from experimental infections with suspected resistant strains (praziquantel) Egg hatching efficiency, miracidial morphology, and cercarial tail shedding (praziquantel)	In vivo animal tests needed for confirmation due to dependence of drug effect on host immune response

[a] See text for details.

and assessments of other drugs and are used in epidemiologic investigations or for monitoring drug resistance (23, 61).

In vitro drug studies of the activities of drugs against the malaria parasite have focused on the asexual erythrocytic stages of *P. falciparum,* for which long-term cultivation techniques are available (53). The microtechnique originally described by Rieckmann et al. (41) offers the simplest test format and has been standardized and adapted to field work by WHO for use with various antimalarial drugs (60). By this technique, a 100-μl fingerprick capillary blood sample is collected from an infected individual and diluted 10-fold in culture medium (RPMI 1640 supplemented with 25 mM HEPES buffer). This blood-medium mixture containing synchronous *P. falciparum* ring stage parasites (the only asexual stage found in patient peripheral blood) is cultured in the wells of a 96-well microtiter plate. The wells are predosed with various concentrations of test drug (including a non-drug control), and the plates are incubated in a candle jar at

37°C. After 24 to 30 h of incubation, thick smears of the wells' contents are made and the smears are stained with Giemsa stain; the maturation of parasites to multinucleated schizonts in drug-containing wells is compared with the maturation of parasites in the control well, and the inhibition of parasite maturation by various concentrations of the antimalarial compound is assessed. In the case of chloroquine, the presence of schizonts in the wells containing 8 pmol of chloroquine indicates in vitro resistance. The results can be alternately expressed as a dose-response curve, and results from several isolates can be pooled to reflect the overall status of malaria parasites in an area.

Beyond this simplest format, other in vitro tests that are not as widely available as the microtechnique but offer valuable advantages have been developed. These more versatile tests are applicable both to field-collected parasites and to the parasites growing asynchronously in long-term laboratory cultures and can also be used for screening potential new antimalarials and for investigations on drug modes of action. Parasites are cultured in suspensions containing fewer cells for a longer period, often 48 to 72 h, allowing the drug to exert its inhibitory effect on all phases of the parasite's full cycle of asexual multiplication. Parasite growth and inhibition can be assessed using different methods. Parasite counts by microscopic examination are simple to perform but cumbersome (33). Measurement of uptake of [^{3}H]hypoxanthine (10) offers a semiautomated, quantitative, high-output approach but necessitates the use of radioactive material and specialized equipment. Measurement of *Plasmodium*-specific products such as histidine-rich protein 2 (HRP2) (34) or parasite lactate dehydrogenase (pLDH) (31) by enzyme-linked immunosorbent assay circumvents the use of radioisotopes but still requires a spectrophotometer. Quantification of parasite DNA by real-time PCR is an additional approach (9).

The successful completion and interpretation of all malaria in vitro tests depend on several factors. Such factors include a recent intake of antimalarial drugs by the patient, which may decrease the test success rates; high parasite inoculums, which can lead to an overestimation of resistance to some drugs (14); and folate and *para*-aminobenzoic acid in the culture medium, which will antagonize the in vitro effect of antifolate drugs (57).

While the great majority of tests assess asexual stages of *P. falciparum*, in vitro drug studies on other species and stages are also possible, albeit substantially more cumbersome. The microtechnique has been adapted for testing of erythrocytic stages of *P. vivax* (52), and progress in continuous culture techniques (17) might allow further improvements. In vitro cultures of the sexual blood stages (gametocytes) and the liver (exoerythrocytic) stages of *P. falciparum* can also be used to assess the antimalarial activity of various compounds on these stages (7, 49).

Potential genetic markers for drug resistance that now offer promising tools for assessing drug resistance have been identified (59). Chloroquine resistance has been linked to point mutations in the *pfcrt* gene of *P. falciparum*, which encodes PfCRT, a transmembrane transporter found on the parasite digestive vacuole, with a Lys→Thr mutation on codon 76 (K76T) playing a central role (13). *P. falciparum* and *P. vivax* resistance to antifolates, such as sulfadoxine-pyrimethamine, has been associated with mutations in the genes encoding parasite dihydrofolate reductase *(dhfr)* and dihydropteroate synthetase *(dhps)* (20, 39). Point mutations and gene amplification of the *pfmdr1* gene encoding Pgh1, the P glycoprotein homologue 1, have been linked to varying extents with *P. falciparum* responses to chloroquine and other drugs such as quinine, mefloquine, and artemisinin derivatives (38). Resistance to atovaquone (a component of the recently introduced drug combination atovaquone-proguanil) has been linked to point mutations in the *P. falciparum* cytochrome B gene (24). Such genetic polymorphisms can be identified through standard techniques, which include mutation-specific nested PCR (13) or nested PCR followed by sequencing (2), restriction fragment length polymorphism analysis (51), or detection with molecular beacons (15). High-throughput methods using real-time PCR (56) or sequence-specific oligonucleotide probes (1) permit the rapid analysis of large numbers of samples and are thus particularly suitable for molecular surveillance. Using these techniques, a large number of field investigations have been conducted to assess linkage between parasite genotypes and resistance; to measure the prevalence of putative molecular markers for resistance; and to predict the risk of future emergence of resistance, based on the number and nature of polymorphisms observed in existing parasite populations.

The judicious use of in vivo, in vitro, and molecular tests can yield valuable information to address drug resistance in malaria (35).

TRICHOMONIASIS

While failures of treatment for *Trichomonas vaginalis* infections have often been regarded as being due to poor patient compliance or rapid reinfection, there is an increasing recognition that true clinical resistance exists and may be increasing (36, 48), thus necessitating accurate drug susceptibility testing of patient isolates. In vitro testing for resistance to 5-nitroimidazoles is indicated following failure of two standard treatments to cure the patient's infection. Metronidazole and tinidazole susceptibility testing for *T. vaginalis* is a simple assay of parasite motility in the presence of drug (29). It is performed under both aerobic and anaerobic conditions to determine which type of resistance is present. Also, differences in in vitro drug sensitivity between clinically resistant strains are more pronounced when the assay is performed under aerobic conditions. Axenic trichomonads are cultured in Diamond's trypticase-yeast-maltose media with serial dilutions (400 to 0.2 μg/ml) of metronidazole or tinidazole dissolved in dimethyl sulfoxide (DMSO) and the appropriate parallel concentrations of DMSO in U-bottom microtiter plates. Plates are incubated at 37°C for 48 h and are then examined microscopically with an inverted phase-contrast microscope. The lowest concentration of drug in which no motile organisms are observed is defined as the minimum lethal concentration (MLC). Aerobic MLCs greater than 100 μg of metronidazole per ml and anaerobic MLCs greater than 3.1 μg of metronidazole per ml have been associated with clinical resistance (32). This assay has been adapted to determine 50% inhibitory concentrations and screen novel compounds for antitrichomonad activity by measuring incorporation of [^{3}H]thymidine (8) or acid phosphatase activity (27). These modifications have not yet been adapted to identify clinically resistant isolates, but theoretically this could be accomplished rather easily.

One difficulty of the in vitro culture method for assessing resistance of *T. vaginalis* isolates is the need to derive axenic cultures from clinical specimens. As individuals with trichomoniasis are often infected with other sexually transmitted disease organisms that grow in Diamond's media, this may require an extended time. Recent studies on the molecular epidemiology of *T. vaginalis* suggest that genetic markers of

metronidazole resistance exist (19, 47, 55). While other studies fail to corroborate this finding (50), the prospect of a molecular marker for resistant *T. vaginalis* is exciting, as it may make possible a PCR-based assay for resistance. This would obviate the need for establishing axenic cultures and may allow direct testing of specimens from patients suspected of harboring a resistant isolate.

LEISHMANIASIS

Treatment failure in leishmaniasis may result from either true drug resistance or patient immunodeficiencies that preclude effective chemotherapeutic action. Differentiation of these two possibilities is important for both individual patient care and general public health. Traditional testing for drug resistance in *Leishmania* is performed by culturing the promastigote form of the parasite with drug in standard cell culture media (Schneider's, RPMI, or M199) supplemented with bovine sera for 42 to 72 h at 26 to 37°C and assessing viability by direct counting (4), [^{3}H]thymidine incorporation (18), enzymatic hydrolysis of *p*-nitrophenyl phosphate (3), conversion of 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) (43), or reduction of Alamar Blue (30). [^{3}H]thymidine incorporation is perhaps the most sensitive method, but it requires access to radioactive materials and a scintillation counter. Hydrolysis of *p*-nitrophenyl phosphate and conversion of MTT are colorimetric assays, but *p*-nitrophenyl phosphate hydrolysis has high backgrounds caused by medium components and MTT may interact with certain drugs (e.g., meglumine antimoniate). An advantage of Alamar Blue is that it is not necessary to further manipulate the parasites in order to read the assay. Thus, drug activities can be monitored at different time points after initiation of cultures.

Recently, amastigotes have been adapted to in vitro drug testing in both axenic and intracellular assays. Intracellular assays bear the closest resemblance to the in vivo situation, and their results correlate better with the in vivo response to treatment than the results of assays that use promastigotes do (26). Previously, intracellular assays were very labor-intensive, as each condition necessitated preparation of slides, staining of macrophages, and manual counting of infected cells. Stable transformation of isolates with firefly luciferase has facilitated this process and provides an added advantage in that efficacy of drugs can be compared for promastigotes, axenic amastigotes, and intracellular amastigotes (44). Cells are simply lysed, the substrate luciferin is added, and activity is measured on a luminometer.

Assays that use a flow cytometer to evaluate drug efficacy have also been developed. In one of these assays, laboratory or field isolates are transfected with the gene encoding green fluorescent protein (GFP) (45). Promastigotes or amastigotes are then incubated with drug and enumerated on a flow cytometer. In this assay, there is no need for addition of substrates or staining with antibodies because GFP is intrinsically fluorescent.

If transfection with exogenous genes is undesirable, mammalian cells that have been infected with parasites and treated with drug can be fixed and permeabilized. Intracellular amastigotes are then detected with anti-*Leishmania* lipophosphoglycan monoclonal antibody followed by a fluorescence labeled anti-mouse immunoglobulin antibody (12). This assay can be used for assessing drug sensitivity of a variety of *Leishmania* species, and it is more adaptable to use with individual patient isolates. A third flow cytometer-based test that works by measuring parasite membrane potentials has been developed (11). However, this test is useful only for evaluating resistance to amphotericin B. A drawback of tests that employ luminescent or flow cytometric detection is that they require specialized equipment.

Recently, clinical isolates of *Leishmania donovani* with resistance to a pentavalent antimonial (sodium antimony gluconate) were identified by PCR amplification of a novel parasite sequence (46). This assay is of interest, as no manipulation beyond growing parasites is needed. However, it is likely that its applicability is species and drug restricted.

AFRICAN TRYPANOSOMIASIS

As in leishmania drug sensitivity testing, trypanosomes can be cultured in vitro with drug and monitored for viability by enzymatic hydrolysis of *p*-nitrophenyl phosphate (3) or by direct counting (22). Parasites are cultured at 37°C for 24 h in 4 to 5% CO_2 in phenol red-free Iscove's medium containing hypoxanthine, thymidine, glutamine, L-cysteine, pyruvate, β-mercaptoethanol, and heat-inactivated bovine or horse sera. An in vitro lysis assay has been developed for testing sensitivity of *Trypanosoma brucei* subspecies to melarsoprol (62). It requires the ability to culture trypanosomes and a thermostatically controlled recording spectrophotometer. As susceptible organisms die, their absorbance at 500 nm is reduced over the course of 30 min. If control drug-susceptible and drug-resistant strains are available to use as controls, this technique could perhaps be adapted to field use because differences in intensity at this wavelength can be distinguished by the unaided eye. Visible color change can also be observed when trypanosomes are incubated with Alamar Blue (40). However, in contrast to assays for *Leishmania* drug sensitivity, the dye is added after parasites are incubated with drugs for 66 to 72 h, depending on the parasite subspecies.

With the identification of the purine transporter responsible for melarsoprol uptake and the identification of the genetic mutations that confer resistance, it may soon be possible to utilize molecular tools to identify trypanosome isolates that are resistant to melarsoprol. One of the genetic mutations leading to an amino acid change in the transporter abrogates a restriction endonuclease site, while a different mutation creates another one (28). Thus, PCR amplification of the appropriate gene followed by enzymatic digestion and gel electrophoresis results in different DNA banding patterns that could be used to distinguish melarsoprol-susceptible and -resistant isolates. While more clinical drug-resistant isolates must be evaluated to confirm the utility of this test, a similar banding pattern between melarsoprol-resistant laboratory-derived and field isolates (28) suggests that this tool could be useful for both management of individual patients' infections and tracking the spread of resistance in a population (5).

SCHISTOSOMIASIS

Investigation of drug resistance mechanisms of schistosomes is more difficult and time-consuming than those associated with protozoan infections. This is because the parasites are extremely difficult to grow in vitro and the efficacies of the two drugs most commonly used for the treatment of schistosomiasis, praziquantel and oxamniquine, are dependent upon components of the immune system (16, 42). Thus, tests for drug sensitivity generally require investigators to obtain eggs from an unsuccessfully treated mammalian host, infect the snail intermediate host, obtain cercariae from the infected snail, and infect and treat experimental animals.

A protocol to determine 50% effective dose (ED_{50}) values for mice has been developed and demonstrates good reproducibility among different laboratories (6). ED_{50}s can also be estimated in an in vitro assay by assessing contraction of worms following perfusion and incubation with praziquantel (37). Recently, praziquantel-resistant worms obtained from infected mice were shown to suffer less tegumental damage when exposed to praziquantel in vitro than did adult worms from isolates susceptible to praziquantel (21, 58). Although immature worms are relatively invulnerable to praziquantel, differences in egg hatching efficiency, miracidial morphology, and cercarial tail shedding can be observed between praziquantel-resistant and praziquantel-susceptible strains in the presence of drug (25). In theory, because these assays are simple and do not require sophisticated equipment, they should be readily adaptable to field use to assess parasite resistance in infected humans (utilizing eggs or miracidia hatched from eggs obtained from fecal material) or snails. Random amplified polymorphic DNA PCR analysis of praziquantel-susceptible and -resistant *Schistosoma mansoni* strains yields different banding patterns following electrophoresis of PCR products (54). These results suggest that specific primers that will be useful for rapid differentiation of drug-susceptible and -resistant isolates could be designed.

FUTURE PERSPECTIVES

Most susceptibility tests for antiparasitic drugs are not routinely available in clinical diagnostic laboratories, because these procedures are not in frequent demand and present special technical requirements. Such tests are performed mainly in reference or research laboratories or during epidemiologic investigations in areas of endemicity. Thanks to recent advances in laboratory technology and genetic analysis of parasites, available tests are increasingly sophisticated and informative. The development of tests that are robust and simple to use will facilitate field studies that aim at optimizing the deployment of currently available drugs. These field tests usefully complement the more sophisticated procedures used in research laboratories whose main orientation is toward the development of novel antiparasitic compounds.

  encephalitis, 2083
  endosymbiont-bearing, 835, 2082
  identification, 345, 2018, 2030–2033, 2035
  keratitis, 2083–2085
  preservation, 59
  specimen collection, 1996
  treatment, 2234
Acanthamoeba astronyxis, 2082–2083
Acanthamoeba castellanii, 1991, 2082–2083, 2086
Acanthamoeba culbertsoni, 2017, 2082–2085
Acanthamoeba divionensis, 2082–2083
Acanthamoeba hatchetti, 2082
Acanthamoeba healyi, 2082–2083
Acanthamoeba polyphaga, 2082–2083, 2089
Acanthamoeba rhysodes, 2082
Acanthoma, large cell, 1602
Acarina (subclass), 2205–2207
Acedapsone, 1227
Acervuli, 1725
Acetamide hydrolysis test, 339
  actinomycetes, 530
Acetohydroxamic acid, 1100
Acetoin, *see* Voges-Proskauer test
Acetoin production, *Staphylococcus*, 399–400
N-Acetyl-L-cysteine (NALC), 1737, 1773
N-Acetyl-L-cysteine (NALC)-NaOH digestion-decontamination method, 334, 554, 563
Acetyl-methyl-carbinol, *see* Voges-Proskauer test
Acetyltransferase, aminoglycoside-modifying, 1122
Achaetomium strumarium, 1808, 1824–1825, 1900, 1906–1907
Acholeplasma, 1004–1006
Acholeplasma laidawii, 1005–1006
Acholeplasma oculi, 1006
Acholeplasmataceae (family), 1005
Achromobacter
  asaccharolytic, 777–778
  identification, 373–374
Achromobacter denitrificans, 374, 777, 779
Achromobacter group B, 781–782
Achromobacter group E, 781–782
Achromobacter group F, 781–782
Achromobacter piechaudii, 374, 777, 779
Achromobacter putrefaciens, *see Shewanella putrefaciens*
Achromobacter ruhlandii, 777
Achromobacter xylosoxidans, 373, 777, 781–782, 1128
Acid fuchsin, 336
Acid production from carbohydrates
  actinomycetes, 530
  Listeria, 478
  Neisseria, 609
  Staphylococcus, 400
"*Acidaminococcaceae*" (family), 862
Acidaminococcus, 378, 862–863, 867–868
Acidaminococcus fermentans, 868
Acid-fast stain, 184–185, 344–345
  modified, 344–345
    actinomycetes, 527–528

Acid-fast stain *(continued)*
Mycobacterium, 344–345, 545, 555–557, 561–562
parasites, 2014–2015, 2021–2022
quality control, 561–562
Acid-fast trichrome stain, 2018
Acidic dyes, 182–183
Acidovorax, 749–769
clinical significance, 753
culture, 754–755
description of genus, 750
direct examination of specimen, 753
epidemiology and transmission, 750–751
evaluation and reporting of results, 761
identification, 759–760
isolation, 754–755
specimen handling, 753
taxonomy, 276, 749–750
Acidovorax delafieldii, 750, 759
Acidovorax facilis, 750, 759
Acidovorax temperans, 750, 759
Acinetobacter, 771–773, 794
antimicrobial susceptibility, 252, 773, 1080–1086, 1133, 1154–1155, 1257
asaccharolytic, 772, 774
clinical significance and treatment, 311, 771, 773–774
description of genus, 771, 817
genomospecies, 771
hand hygiene, 81
identification, 375, 608, 692, 772, 774, 821, 827
natural habitats, 771, 773
nosocomial infections, 771, 773
saccharolytic, 772, 774
taxonomy, 771
Acinetobacter baumannii, 251, 375, 771, 773, 1090, 1122, 1126, 1128–1129
Acinetobacter calcoaceticus-A. baumannii complex, 771
Acinetobacter haemolyticus, 771
Acinetobacter johnsonii, 773
Acinetobacter junii, 773
Acinetobacter lwoffii, 375, 771, 773
Acinetobacter radioresistens, 773
Acinetobacter schindleri, 773
Acinetobacter ursingii, 773
Acne vulgaris
anaerobic non-spore-forming rods, 876
Propionibacterium, 875
Acremonium
description of genus, 1808, 1828
direct examination of specimen, 1745, 1748
geographic distribution, 1748
taxonomy, 1725
Acremonium alabamense, 1808
Acremonium curvulum, 1808
Acremonium falciforme, *see Fusarium falciforme*
Acremonium kiliense, 1808, 1828, 1923
Acremonium potronii, 1808
Acremonium recifei, 1808, 1828
Acremonium strictum, 1808
Acridine orange stain, 177–178, 188, 345, 2045, 2050
Acrodermatitis chronica atrophicans, 974
Acrophialophora, 1808
Acrophialophora fusispora, 1808
Actinic keratosis, human papillomavirus, 1602
Actinobacillus, 372, 622–624
Actinobacillus actinomycetemcomitans, 372, 621–624, 636, 643–644
Actinobacillus equuli, 622–624
Actinobacillus hominis, 622–624
Actinobacillus lignieresii, 622–624
Actinobacillus suis, 622–624
Actinobacillus ureae, 622–624
Actinobacteria (class), 485
Actinobacteria (phylum), 277, 872–873
Actinobaculum, 485, 872–874, 876, 879–880
"*Actinobaculum massiliae*," 874, 879–880
Actinobaculum schaalii, 872, 875, 880
Actinobaculum suis, 872
Actinobaculum urinale, 872, 874–875, 879–880
Actinomadura, 515–542
aerial hyphae, 529
antimicrobial susceptibility, 534, 1241–1242
clinical significance, 520–521
description of genus, 516
direct examination of specimen, 527
evaluation and reporting of results, 535
identification, 370, 528–534
isolation, 527–528
natural habitats, 520
specimen handling, 526–527
taxonomy, 515–516
Actinomadura dassonvillei, *see Nocardiopsis dassonvillei*
Actinomadura latina, 517–521
Actinomadura madurae, 520–521, 532
Actinomadura pelletieri, 517, 520–521
Actinomucor elegans, 1852
Actinomyces, 872–888
antimicrobial susceptibility, 881–882, 1078, 1089–1094, 1097, 1216
clinical significance, 875–876
culture, 319, 878
direct examination of specimen, 877–878
epidemiology and transmission, 875
identification, 368–369, 377–378, 873, 878–881
interpretation and reporting of results, 882–883
isolation, 878
specimen handling, 877
taxonomy, 281, 485, 872, 874
Actinomyces bernardiae, *see Arcanobacterium bernardiae*
Actinomyces cardiffensis, 874–875, 880
Actinomyces dentalis, 874, 879–880
Actinomyces europaeus, 485, 880
Actinomyces funkei, 875, 880
Actinomyces georgiae, 880
Actinomyces gerencseriae, 875, 878, 880
Actinomyces graevenitzii, 875, 878, 880
Actinomyces hongkongensis, 874, 879–880
Actinomyces israelii, 875, 878–880, 1087
Actinomyces meyeri, 875, 880
Actinomyces naeslundii, 875, 879–880
Actinomyces nasicola, 874, 879–880
Actinomyces neuii, 485, 872, 880
Actinomyces odontolyticus, 875, 878, 880
Actinomyces oricola, 874, 879–880
Actinomyces pyogenes, *see Arcanobacterium pyogenes*
Actinomyces radicidentis, 878, 880
Actinomyces radingae, 485, 875
Actinomyces turicensis, 485, 509, 875, 880
Actinomyces urogenitalis, 880
Actinomyces viscosus, 880
Actinomycetes
aerobic, 515–542
antimicrobial susceptibility, 529–530, 534, 1241–1242
cell membrane, 531–532
cell wall, 531–532
clinical significance, 520–526, 1241
