Merifluor RSV, Meridian Bioscience Inc., Cincinnati, Ohio)	NA[b]	For culture confirmation	Subgroup differentiation available.
Imagen RSV (Dakocytomation Ltd., United Kingdom)	Sensitivity, 93%; specificity, 98%	Detection of identification in human clinical specimens	Mixture of 3 monoclonal antibodies (17, 54, 59, 132).
PathoDx RSV and Respiratory Virus Panel (Remel Inc., Lenexa, Kans.)	Sensitivity, 77.6–100%; specificity, 98–100%	For clinical specimen detection and culture confirmation	The respiratory panel covers RSV, influenza A/B virus, adenovirus, and parainfluenza virus 1, 2, and 3.
Indirect			
Light Diagnostics Respiratory Virus Panel Screen and/or ID (Chemicon International, Temecula, Calif.)	Sensitivity, 100%; specificity, 100%	For culture confirmation	In a panel format, which covers RSV, influenza A/B virus, adenovirus, and parainfluenza virus 1, 2, and 3.
Bartels Respiratory Virus Antibody Pool (Bartels, a Trinity Biotech Company, Carlsbad, Calif.)	Sensitivity, 91%	For viral respiratory screening and identification	Covers RSV, influenza A/B virus, adenovirus, and parainfluenza virus 1, 2, and 3. Acquired recently by Trinity Biotech.
Imagen Respiratory Screen (DakoCytomation Ltd., United Kingdom)	Sensitivity, 97.8%; specificity, 99.1%	Rapid screen clinical samples or infected cell cultures	Covers RSV, influenza A/B virus, adenovirus, and parainfluenza virus 1, 2, and 3.

[a] Compared to cell culture unless specifically noted. In many cases, the culture used for comparison and validation was suboptimal, making the rapid tests look artificially better. It should be recognized that performances in various laboratories may be different.
[b] NA, not applicable.

the FDA has approved two new antigen detection tests under this category, the Now RSV test by Binax (Portland, Maine) and the Directigen EZ RSV by Becton Dickinson. Several recent parallel validations among Now RSV, Directigen EZ RSV, and Directigen RSV demonstrated that the three antigen assays performed similarly well. Hands-on processing for the two CIA tests (Binax Now and BD Directigen EZ) was significantly reduced, making them more convenient for rapid screening (87, 100, 154). A similar result was achieved when D-IFA and culture were used as the validation standard (5). Another new commercial one-step CIA test, originally manufactured by SA Scientific (San Antonio, Tex.), has been available commercially from SA Scientific (SAS), Remel (Xpect), Fisher Scientific (Sure-Vue), Meridian Bioscience (ImmunoCard), and Wampole (Clearview). The sensitivity and specificity of the kit were 82.5 and 93.3%, respectively, and were equivalent to those yielded by Directigen EZ RSV when a D-IFA and/or a reverse transcriptase (RT)-PCR was used as the "gold standard" (17, 79, 122). In comparison to D-IFA and EIA procedures, these lateral-flow CIA-based procedures require extremely short hands-on time and test turnaround time; some of them require a hands-on time of only 1 to 2 min and only one incubation and are very easy to read.

Some of these rapid detection formats have been considered to be used as point-of-care (POC) tests within clinical laboratories and clinicians' offices by personnel with little formal training in virology techniques (127). There are many such tests commercially available with varying degrees of sensitivity and specificity. One recent study compared the accuracy of the Thermo Electron RSV OIA with D-IFA and viral culture. The sensitivity and specificity were 87.9 and 99.6%, respectively, and the kit is technically easy to use and can be completed within 20 min. As a moderately complex test, it requires minimal oversight and may be used as a rapid POC test (4). Another study favored using the Binax Now RSV test as a POC test to reduce the risk of health care-associated RSV infections in pediatric wards and indicated that it can be used in the field, maintaining consistent vigilance on quality control, due to its simplicity (87). For general screening, the RSV rapid test is found to be a reasonable tool to obtain quick results. However, its lack of specificity for some patients requires confirmation by additional tests, such as culture or molecular assays, to rule out false-positive results and/or detection of other respiratory viruses (1).

It should be noted that the sensitivity and specificity of these tests are applicable to use during the epidemic season, generally the winter in temperate climates. The performance

of these tests is much reduced during periods when the prevalence of virus infection is low, such as the summer months. In addition, the accuracy of these rapid tests can be influenced by the type of specimen obtained and the age of the patient. Rapid antigen detection tests for the diagnosis of RSV respiratory illness in adults are of limited value. A study performed with RSV-infected older adults showed antigen detection in nasal specimens to be very insensitive (46). Two recent studies evaluated the performances of several RSV rapid antigen detection tests including VIDAS RSV, Binax NOW, BD Directigen RSV, and BD Directigen EZ assays. The sensitivity was 0 to 25% for these rapid EIA or CIA antigen tests for adults, a population for which D-IFA remains the rapid method of choice for detecting RSV (24, 46, 100). In general, sensitivity is low when a rapid antigen test is used for the diagnosis of RSV infection in adults (24) and should be replaced by PCR (143). The extremely low sensitivity in adults is due to low and short RSV shedding in respiratory secretions and the problems associated with obtaining nasal washes from frail older adults (18, 62). Because of this relative lack of sensitivity during periods of low virus shedding, disappearance of antigen in nasal secretions during later periods of an acute illness should not be interpreted as an indication that eliminating contact isolation precautions is appropriate. Hospitalized infant patients shed infectious virus at levels that can result in nosocomial transmission far longer than the duration of positive antigen tests.

Nucleic Acid

As is the case with other viral pathogens, in vitro nucleic acid amplification (NAA) tests such as PCR have been implemented gradually in clinical laboratories for RSV detection. Different amplification and identification platforms have been described (Table 3). The NAA tests, in general, have been demonstrated to be superior to routine diagnostic methods in terms of their high sensitivity and specificity. The reported sensitivity of PCR ranges from 93.5 to 100%, and the specificity ranges from 93.9 to 100% (40, 53, 67, 126, 131). The RSV N gene has been used mainly as the target for developing NAA-based assays because (i) nucleotide sequences in the N gene are highly conserved and (ii) the N gene is located nearer the 3′ end of the genome where transcription and replication initiate, and thus this gene is preferentially transcribed. Sequence variations between RSV subgroups A and B have been used to

TABLE 3 Comparison of amplification and identification formats of published NAA tests for RSV detection and quantitation[a]

Amplification and identification format	Procedure design	Sensitivity	Carryover contamination risk	Comments	Reference(s)
RT-PCR; gel electrophoresis	One-step, seminested or nested; monoplex or multiplex	Moderate	Moderate	Earlier applications; subgroup differentiation possible when subgroup-specific primers used	1, 3, 27, 39, 41, 44, 45, 55, 59, 67, 102, 103, 114, 116, 117, 126, 140, 152

design subgroup-specific primers and/or probes for simultaneous RSV subgrouping (1, 10, 39, 47, 49, 53, 57, 59, 69, 70, 75, 83, 101, 102, 107, 108, 126, 131, 137, 143). While cell culture remains the gold standard for RSV diagnosis, the NAA assays have been considered the "platinum" standard to be used as the reference to validate new diagnostic kits in RSV detection (1, 143, 154).

Since Paton et al. first applied RT-PCR in clinical diagnosis of RSV infections (103), numerous NAA techniques have been described in diagnostic applications. Several formats have been used to further confirm and identify the amplicons generated by PCR to further enhance the test sensitivity and specificity (Table 3). In general, diagnostic efficacy of the RT-PCR-based assays was substantially more sensitive than the combination of conventional viral culture and shell vial culture (69, 75, 83, 94, 130, 131, 143). Several new analytic-specific reagent (ASR) kits based on RT-PCR or real-time RT-PCR are commercially available from Roche, Abbott, Cepheid, and Prodesse (47, 69, 75, 83). Targeting RNA molecules, nucleic acid sequence-based amplification (NASBA)-based Nuclisens Easy Q RSV A+B Assay (bioMerieux) incorporated with real-time detection, possesses equivalent or superior sensitivity in comparison to RT-PCR procedures (98).

The mainstream use of RT-PCR in the routine diagnostic laboratories is currently hindered due to the following. First, NAA techniques have a relatively long test turnaround time, from 8 to 48 h (53, 75, 103, 131). Even with the implementation of the real-time PCR format, due to the time needed for specimen processing and nucleic acid extraction, it is still not practical to use the complicated NAA procedures as rapid, POC testing because faster and less expensive alternatives are available (18, 44, 94, 145). Second, there are currently no FDA-approved NAA kits available in the field for RSV detection. Approval requires full validation for ASR kits and user-developed procedures before they can be used for diagnostic purposes. Third, the technical complexities require extensive personnel training to perform such tests correctly, avoiding potential false-positive or false-negative results (120). Finally, the costs of reagents, instruments, and patent royalties have delayed the speed of implementation of NAA techniques in routine diagnostic services. It is predicted that NAA techniques will continue to be used to complement current conventional assays and gradually may replace culture for the detection and identification of respiratory viruses in clinical laboratories.

NAA techniques are especially useful for adult patients when viral shedding is short and low (43, 143). Their application seems efficient when multiplex formats are used for the simultaneous detection of several respiratory viruses in one clinical sample (10, 54, 58, 59, 126, 130). With implementation of the real-time format, rapid RSV viral load quantitation by RT-PCR is possible, which could be helpful to clinicians in some settings. RSV quantitation has been reported using both TaqMan and two-probe hybridization formats by RT-PCR and molecular beacons by NASBA (Table 3). Falsey and Perkins applied a quantitative real-time PCR to volunteers and patients and demonstrated that quantitative PCR has an excellent correlation with viral titers, as measured by quantitative cell culture (43, 107). Several other clinical studies with implementation of quantitative PCR discovered and/or confirmed that RSV viral loads are significantly higher in children than in adults, in acute lower respiratory tract infections than in chronic obstructive pulmonary diseases, and in subgroup A than in subgroup B infections (18, 43, 107). The exact clinical values for the application of RSV quantitative NAA assays merit further investigation.

Isolation Procedures

Isolation of the virus from respiratory secretions by cell culture remains the gold standard method for RSV diagnosis due to its excellent specificity. Appropriate clinical samples for culture include nasal washes, nasopharyngeal aspirates or swabs, tracheal aspirates, BAL fluids, and biopsy materials. Inadequate specimen collection or delays in processing often result in negative culture results. It has been shown that recovery of the virus is highly dependent on the training and interest of the personnel collecting the samples (62). Given the lability of the virus, the samples should be kept cold and should be inoculated as quickly as possible. RSV grows well in several human cell lines and may be adapted to a number of others. For primary isolation, human heteroploid cells, such as HEp-2, HeLa, and A549 cells, are usually preferred. Other cell lines that may be used but are usually less sensitive include human kidney, amnion, and diploid fibroblastic cells and monkey kidney cells (9, 33, 62). The sensitivity of all these cell lines, including the heteroploid human lines, for the growth of RSV is variable and must be monitored. Cell line cultures show characteristic syncytial CPE after 3 to 7 days of incubation (Fig. 2). However, the degree of syncytial formation depends on the type of cell culture, the heaviness of the cell monolayer, the medium, the strain of virus, the multiplicity of infection, and its laboratory adaptation. RSV does not cause syncytia in polarized epithelial cells, such as primary human respiratory tract epithelial cells or MDCK cell line cultures. While cell culture possesses the highest specificity, its sensitivity varies widely, in part due to virus viability, technical expertise required, and cell lines used in the laboratory performing the viral isolation. The reported sensitivities of the conventional tube cell culture compared with various rapid techniques have ranged from 57 to 90% (63, 76).

The major drawback for cell culture is the length of time necessary to identify viruses in culture. The shell vial assay has significantly lowered the time needed for detection of the virus to 16 h (123). The method combines centrifugation and immunofluorescence to detect expression of viral antigens on infected cells before development of CPE (110). The sensitivity and specificity of shell vial culture range from 67.4 to 92.1% and from 82.9 to 100%, respectively (73, 110, 123). Since HEp-2 cells were abandoned by many clinical laboratories, the sensitivity for routine culture performed with RhMk, MRC-5, and A549 cells can be significantly lower.

The use of Mixed Fresh Cells or R-Mix (Diagnostic Hybrids, Inc., Athens, Ohio), which is a mixture of human lung carcinoma A549 and mink lung Mv1Lu cells, has been shown to be a rapid and sensitive method for the detection and identification of respiratory viruses (8, 36, 51, 125, 142). With significantly decreased costs compared to conventional culture, R-Mix was slightly more sensitive than RMK, HEp-2, and MRC-5 cell lines used in conventional cultures, and it was several days faster (8). Screening of R-Mix cells after overnight incubation was found to be a very sensitive method for the detection of respiratory viruses, including RSV, and was more reliable than direct antigen testing (125). In addition, cell cultures have the major advantage of detection of copathogens and ideally should be used in addition to a rapid technique to diagnose RSV. R-Mix cells are useful to identify the viruses not detected with direct stains (36).

Identification

The appearance of characteristic syncytial CPE in cell culture remains adequate to establish the presence of RSV during the epidemic season. However, since other respiratory viruses such as parainfluenza virus 3 and measles virus can produce similar CPE in certain cell lines, most clinical virology laboratories confirm RSV detection by performing subgroup-specific IFA with infected cells from cell culture vials. Further identification, such as subgrouping and subtyping, can be performed by using RT-PCR followed by nucleotide sequence analysis and/or restriction fragment length polymorphism (RFLP) analysis (49, 106).

Typing Systems

Infections with RSV of subgroup A or B may result in differing clinical manifestations and outcomes; therefore, RSV subgroup information can be useful in clinical patient management (89, 141). RSV subgroup information has been widely used to facilitate epidemiological investigations (22, 50, 117). IFA procedures have been routinely used in the laboratory for subgrouping, and reagents are available from Bartels and/or Remel (Table 1). This technique is very quick but, due to its relative insensitivity, it is usually used only for confirmation and subgroup differentiation on isolates recovered by cell culture. RT-PCR followed by subgroup-specific probe hybridization or RFLP has been used to complement IFA assays by differentiating subgroups directly from the clinical specimens (22, 49, 57, 131, 138). The technique improved significantly when the real-time PCR format was implemented (70, 137).

Further analysis on genomic differences among RSV isolates beyond subgrouping has been used in epidemiologic investigations (22, 128). There was one study using heterogeneous sequences in the RSV G gene to generate subgroups, and it demonstrated that different RSV subgroups were associated with severity of clinical diseases (49). It is worth pointing out that these highly discriminatory typing techniques have been useful in monitoring possible nosocomial RSV infections and facilitating interruption of RSV outbreaks (22, 128).

Serologic Tests

The diagnosis of RSV infections by using serology has no practical application for clinical use. Diagnosis requires several weeks for induction of a serum antibody response and collection of a convalescent-phase serum specimen for identification of recent infection. A fourfold rise of titer between acute- and convalescent-phase specimens by serology is generally accepted as evidence of infection. Young infants, older individuals with repeated infections, and immunocompromised patients may not exhibit a significant rise in antibody titer following infection, depending on the assay used (35, 46). Serologic diagnosis of RSV infection has been more useful for epidemiologic and vaccine studies than for patient management because of the delay required to obtain convalescent-phase sera. Secretory class-specific antibodies to RSV in nasopharyngeal secretions may also be detected. Since these secretory antibodies may be present earlier in infection than serum antibodies, their detection has been used as an adjunct to diagnosis by antigen detection (71). Repeated infections with the same subgroup of RSV occur frequently; therefore, it is usually necessary to test acute- and convalescent-phase sera and observe an increase in titers to confirm the diagnosis. Furthermore, assays that detect immunoglobulin M antibodies to RSV show low sensitivity, particularly for infants less than 6 months of age, precluding a definitive diagnosis in a clinically relevant time frame (95).

Current means of serologic diagnosis for RSV infections include IFA, EIA, complement fixation test, and neutralization assays (62, 66, 95, 121, 144). Virus neutralization tests have been developed as plaque reduction assays or in a microneutralization format. Other test formats, including immunoprecipitation, fusion inhibition, and immunoblot assays, can be used to detect class-specific antibodies directed to specific viral proteins (56, 93). I-IFA has been used widely for RSV antibody detection (62, 144). Reagents for RSV antibody detection by I-IFA are commercially available from Bion Enterprises, Ltd. (Des Plaines, Ill.), Diagnostic Products Corporation (Los Angeles, Calif.), Globalemed, LLC (Alexandria, Va.), Hemagen Diagnostics, Inc. (Columbia, Md.), Meridian Bioscience Inc. (Cincinnati, Ohio), and PanBio Inc. (Columbia, Md.).

Antiviral Susceptibilities

Ribavirin has been used to treat severe RSV infections, although its efficacy has been questioned in recent studies. Resistance to ribavirin has not been recognized. Palivizumab prophylactic treatment of high-risk infants prevents about one-half of the hospitalizations in this group. The cause of prophylactic failure in the other patients is not clear but does not appear to be viral resistance. Several RSV escape mutants derived in the laboratory have been shown to be resistant to palivizumab prophylaxis in cell culture and cotton rats (153). An immunofluorescence binding assay that predicts palivizumab neutralization of RSV was developed, and a total of 458 RSV isolates recovered during 1998 to 2002 were tested. The results indicated that, at present, the development of palivizumab-resistant mutants does not appear to play a significant role in hospitalizations for breakthrough RSV disease occurring in infants receiving palivizumab prophylaxis. The nucleotide and amino acid sequences of the F protein epitope to which palivizumab binds were highly conserved among the clinical isolates evaluated in the present multicenter study, even in those from children receiving palivizumab prophylaxis (31).

Evaluation, Interpretation, and Reporting of Results

The availability of rapid antigen assays with a turnaround time as short as 15 min makes it possible for clinicians to receive results in a timely fashion. The potential benefits of rapid diagnosis include discontinuation or avoidance of unnecessary antibiotics, occasional indication for ribavirin as an antiviral medication, and a shortened hospital stay. Rapid detection of RSV also can be used as part of an infection control program to decrease nosocomial RSV transmission through proper isolation or cohorting of infected patients (74, 78, 84). However, due to their relatively low sensitivity, false-negative results can be expected in a small percentage of cases, and negative results should never be interpreted as excluding the possibility of RSV infection. In particular, ill children with highly characteristic illnesses in the peak period of RSV epidemics should be placed in proper isolation. In the laboratory, it is important to use culture and RT-PCR assays as backup tests, especially for those specimens that have yielded negative antigen results.

Cell culture is considered to have the highest specificity, followed by antigen tests and NAA assays. NAA assays, which have been demonstrated to be the most sensitive test for detection of RSV, are particularly useful for testing respiratory specimens collected from adults since viral shedding is

short and low (43, 137, 143). NAA assays, including RT-PCR and NASBA, will gradually be used more frequently in routine diagnostic laboratories as the techniques become more user friendly and test turnaround becomes more rapid; however, a small number of false-positive results can occur due to contamination during specimen processing or to carryover contamination. Quantitative PCR rapidly determines the viral RNA level when a real-time format is incorporated. Although the viral RNA level is correlated to the viral load measured by quantitative culture, clinical application of quantitative PCR awaits further investigation (18, 107). Before interlaboratory standardization is implemented, quantitation generated from PCR assays should be interpreted cautiously.

Immunity to RSV is short-lived, and repeated infections with RSV as well as subclinical RSV infections are common. The likelihood of identifying RSV as the etiology of a patient's infection is greatest when a specimen is obtained within the first 3 days of illness, especially when culture is used. Repeat viral cultures or viral antigen detection by several antigen assays performed serially after the initial confirmation of RSV infection usually become negative 1 week after onset of illness in about 50% of patients. However, excretion of live virus in immunocompromised infants has been documented up to 3 weeks after onset of illness (62, 77). When interpreting laboratory test results for RSV detection, it is also important to take into account the probability that RSV is associated with the patient's illness. Physicians should be aware of specific regional patterns of RSV activity when considering laboratory confirmation for infection. The positive and negative predictive values vary according to the prevalence of the disease in a particular population during certain seasons.

Effective exchange of relevant information between clinicians and the laboratory is essential to good patient care. RSV is extremely labile. Even when sensitive methods such as RT-PCR are used, false-negative results are possible, mainly due to improper specimen collection, transport, and processing. The importance of correct specimen collection and prompt specimen transport cannot be overemphasized. Prompt reporting of test results may assist clinicians in discontinuing unnecessary forms of therapy or in cohorting infected individuals, thereby preventing nosocomial spread of infection.

HUMAN METAPNEUMOVIRUS

Taxonomy

Human metapneumovirus (hMPV) is an RNA virus of the *Paramyxoviridae* family, and part of the *Pneumovirinae* subfamily along with RSV. The virus was discovered in 2001 (135). The *Paramyxoviridae* family is divided into two subfamilies, *Pneumovirinae* and *Paramyxovirinae*. The *Pneumovirinae* subfamily includes the two genera *Pneumovirus* and *Metapneumovirus*. The avian pneumoviruses (APV) are highly related to hMPV. APV and hMPV were separated by taxonomists into the separate genus *Metapneumovirus* because they can be distinguished from members of the *Pneumovirus* genus by their lack of genes encoding the nonstructural proteins NS1 and NS2 and by a different gene order in the RNA genome. APVs have been classified into four subgroups (A through D). hMPV is related most closely by sequence homology to subgroup C APV. hMPV does not infect turkeys or chickens; the only known natural host is humans.

Description of the Agent

hMPV is an enveloped respiratory virus with a single-stranded, nonsegmented, negative-sense RNA genome. Although APV and hMPV are related to the human and animal RSV viruses, they differ in that the gene order in the nonsegmented genome is slightly altered and APV and hMPV are lacking the two nonstructural proteins NS1 and NS2 that are located at the 3′ end of RSV genomes (Fig. 1). These RSV proteins are thought to counteract host alpha, beta, and lambda interferons (124). The absence of NS1 and NS2 in the metapneumoviruses may contribute to decreased pathogenicity of these viruses relative to RSV strains. Full-length sequences of a number of hMPV genomes have been reported (11, 68, 134). The genome is predicted to encode nine proteins in the order 3′-N-P-M-F-M2-SH-G-L-5′ (the M2 gene is predicted to encode two proteins, M2-1 and M2-2, using overlapping open reading frames, as in RSV) (134). The genome also contains noncoding 3′ leader, 5′ trailer, and intergenic regions, consistent with the organization of most paramyxoviruses (68). The viral promoter is contained within the 3′-terminal 57 nucleotides of the genome (12). The F, G, and SH proteins are integral membrane proteins on the surface of infected cells and virion particles. The F protein is a classic Type I integral membrane viral fusion protein containing two heptad repeats in the extracellular domain that facilitate membrane fusion. There is a predicted non-furin F1/F2 cleavage site near a hydrophobic fusion peptide, which contrasts with the furin cleavage site in RSV. The predicted attachment (G or glycosylated) protein of hMPV exhibits the basic features of a glycosylated type II mucin-like protein. The hMPV G protein differs from the RSV and APV G proteins in that it lacks a predicted cysteine noose structure. The N (nucleoprotein), P (phosphoprotein), and L (polymerase or large) proteins are replication proteins in the nucleocapsid; the M2-1 and M2-2 proteins likely are regulatory proteins. The M (matrix) protein is thought to coordinate viral assembly by interfacing viral nucleocapsids with the surface membrane proteins.

Epidemiology and Transmission

hMPV outbreaks occur in annual epidemics during late winter and early spring in temperate climates, often overlapping in part or in whole with the annual RSV epidemic. Long-term studies have shown that sporadic infection does occur year-round (147). The usual period of viral shedding has not been defined but is likely to be weeks following primary infection in infants. The incubation period is thought to be about 3 to 5 days. Humans are the only source of infection. Formal transmission studies have not been reported, but experts believe that transmission occurs by close or direct contact with contaminated secretions involving large-particle aerosols, droplets, or contaminated surfaces. Nosocomial infections have been reported, and contact isolation with excellent hand washing for health care providers is appropriate.

Clinical Significance

The virus causes upper and lower respiratory tract illnesses. A study of the association of the virus with respiratory disease was performed using prospectively collected data in a cohort of over 2,000 subjects aged 0 to 5 years, monitored during a 25-year period at Vanderbilt University Medical Center (147). This study showed that hMPV is associated with the common cold (complicated by otitis media in about one-third of cases) and with lower respiratory tract illnesses such as bronchiolitis, pneumonia, croup, and exacerbation

of reactive airways disease. The profile of signs and symptoms caused by hMPV is very similar to that caused by the related pneumovirus RSV. Approximately 12% of outpatient lower respiratory tract illness was associated with hMPV infection, which was second only to RSV in this regard. A prospective study of all infant hospitalizations for acute respiratory illness or fever without localizing symptoms in Nashville, Tenn., and Rochester, N.Y., organized by the Centers for Disease Control and Prevention found that 3.9% of 668 such child hospitalizations were associated with hMPV (99). Children with RSV or hMPV infection required supplemental oxygen and medical intensive care at similar frequencies. Many other studies at referral hospitals, most performed as retrospective studies using samples referred to a diagnostic virology laboratory, suggested that approximately 5 to 10% of such patient specimens contain the hMPV genome. hMPV has been found in association with respiratory tract disease in every continent; dozens of country-specific case series have been reported.

About one-half of the cases of lower respiratory tract illness in children occur in the first 6 months of life, suggesting that young age is a major risk factor for severe disease (147). Both young adults and the elderly can suffer hMPV infection that leads to medically attended illnesses including hospitalization, but severe disease occurs at much lower frequencies in adults than in young children (41, 42). Severe disease in older subjects is more common in immunocompromised patients (104, 136) and can be fatal in these subjects (23). A large proportion of respiratory tract secretion samples submitted to diagnostic virology laboratories are obtained from immunocompromised patients. hMPV infection is associated with wheezing more commonly in patients with underlying pulmonary disease, especially asthma (148). Although a significant number of patients with asthmatic exacerbation have hMPV infection, it is not yet clear whether there is a particular association of the virus with long-term wheezing. RSV and hMPV coinfections have been reported, which is not surprising given the overlapping seasons. Studies that identify coinfections solely on the basis of amplification of viral genome by RT-PCR, however, should be interpreted with caution for several reasons. PCR is susceptible to false-positive tests due to cross-contamination in some laboratories that perform frequent amplifications. Ideally, amplified PCR products should be confirmed by hybridization or preferably nucleotide sequence analysis to demonstrate diversity of isolates and lack of contamination by laboratory isolates. Second, viral genome can be detected by RT-PCR in respiratory secretions for several weeks or more, even after live virus shedding has ceased. It is difficult to know in this situation if the presence of a positive RT-PCR test signifies active infection or simply a recent acute infection. Coinfection with bacteria is not common, except for the local complication of otitis media, which is frequent (119, 129, 147).

Collection, Transport, and Storage of Specimens

Reports in the literature suggest that the virus can be recovered or detected by RT-PCR from nasal aspirates, nasal washes, nasal/throat swabs, and BAL specimens. It is not clear at this time what the optimal method of specimen collection from the upper respiratory tract is. Transport is generally performed using standard viral transport media, on ice. It is highly likely that optimal specimen collection and handling will be determined to be very similar to that for RSV, which is discussed in detail above. Specimens should be processed as soon as possible after collection and stored at 4°C until processing. For long-term storage of specimens or laboratory stocks, a temperature of –70°C is preferred, with specimens in O-ring-sealed cryovials.

Direct Detection

Microscopy

The virus is too small for detection by conventional microscopy but can be seen by electron microscopy (15, 135). This method, however, is not sufficiently sensitive or reproducible for clinical detection. Conventional bright-field microscopy of infected cell monolayer cultures does reveal some CPE, especially following multiple passages in culture (Fig. 3A and 3B). The characteristics of the CPE are not distinct enough that the virus could be identified on this basis, even by trained observers.

Antigen Detection

There are no direct antigen tests commercially available. Efforts have been spent in developing rapid antigen tests on nasopharyngeal aspirate samples using hMPV-specific monoclonal antibodies (37, 82, 116). Recently, a group of Italian scientists reported the development of monoclonal antibodies specific for hMPV and their use for D-IFA staining of nasopharyngeal samples or virus identification in shell vial cell cultures. A total of 40 nasopharyngeal swabs collected from infants and young children hospitalized because of acute respiratory infection during the winter-spring season

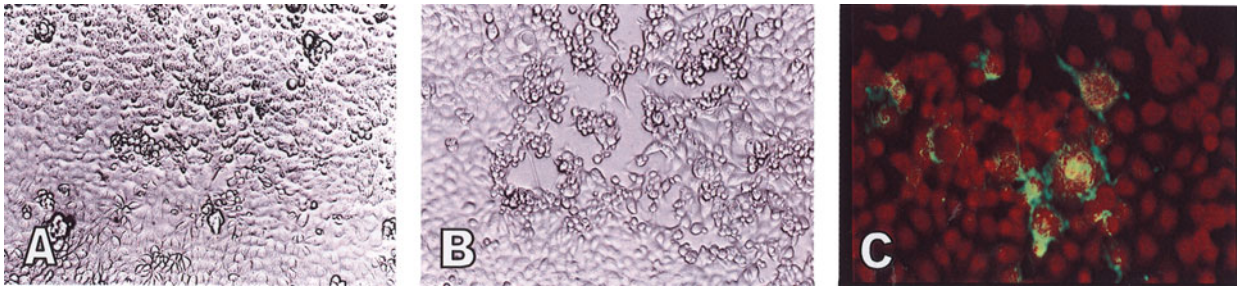

FIGURE 3 20× microscopic detection of hMPV in LLC-MK2 cell monolayer cultures. (A) Mock-infected cells form a confluent layer with only minor irregularities, as seen by light microscopy. (B) hMPV infection causes a focus of infection with rounding of cells and loss of monolayer integrity. (C) Indirect immunofluorescence of hMPV-infected LLC-MK2 centrifugation culture stained with monoclonal antibody MAb-8 (82). Images courtesy of John Williams (A and B) and David Ferguson (C).

were used to validate the D-IFA reagents. The sensitivity and specificity were 73.9 and 94.1%, respectively, in comparison to the results generated by an RT-PCR test (105).

Nucleic Acid

The most sensitive test for identification of hMPV in clinical samples to date is RT-PCR. Many of the early clinical reports used an RT-PCR test incorporating PCR primers hybridizing to the polymerase (L) gene, and the nucleotide sequence of the L gene PCR product was used to identify the virus (135, 147). Subsequently, real-time RT-PCR tests have been developed, especially targeting the N gene, which offer enhanced sensitivity and specificity, including an assay specifically designed to detect viruses from the four known genetic lineages, which are described below (29, 30, 86, 88, 118, 139, 145).

Isolation Procedures

hMPV replicates poorly in most conventional cell cultures used for respiratory virus diagnosis, such as HEK, HEp-2, and Madin-Darby canine kidney cells. Primary isolation is facilitated by the presence of a low concentration of trypsin, which is not used routinely in diagnostic virology cultures in many laboratories. The virus was first isolated in primary monkey kidney cells from a clean primate facility in The Netherlands that had been passed twice (designated tertiary monkey kidney [tMK] cells). Monkey kidney cells in the United States generally cannot be used for this purpose because many of these commercial cell cultures contain simian foamy viruses that cause CPE during the prolonged culture necessary to grow hMPV. hMPV can be isolated and grown in LLC-MK2 cell or Vero cell monolayer cultures. Growth is slow in these cell lines, and often several blind passages are required before CPE appears, especially following primary isolation. The CPE in tMK cells was reported to resemble that of RSV, although usually appearing later than with RSV. The CPE in cell lines is not particularly striking, often appearing only as focal areas of rounding of cells and minor patches of cell-cell fusion in LLC-MK2 or Vero cell cultures (Fig. 3). Virus can be isolated in about one-half of cases in which nasopharyngeal samples are positive for hMPV by RT-PCR. Shell vial centrifugation cultures may enhance recovery and shorten the time to recovery (82).

Identification

Currently, the virus is best identified when a specific RT-PCR test is found to be positive (optimally confirmed with sequence analysis of the cDNA copy of the RNA genome). The virus can be suspected when a virus isolated during the epidemic season in Vero or LLC-MK2 cells is not identified by specific immunofluorescence tests for related viruses. Recently, monoclonal antibodies specific for hMPV have been reported, and these can be used for identification of the virus by IFA, although they are not widely available currently (37, 82, 105).

Typing Systems

The nomenclature and classification of subgroups, subgroups, strains, variants, and isolates of hMPV are still being developed. Phylogenetic analyses of partial sequences of the viral genome have suggested in every case that there are at least two major genetic subgroups (designated A and B), and the phylogenetic groupings are consistent when analyses of any of five genes have been determined. Full-length sequences of hMPV genomes from viruses representing the two major subgroups have been performed by two groups using isolates from The Netherlands (strains NL/1/00 and NL/1/99) or from Canada (strains CAN97-83 and CAN98-75). These studies show that the diversity between hMPV subgroup A and B sequences is greatest for the SH and G proteins. The G glycoprotein genes exhibit nucleotide and amino acid sequence identities ranging from 52 to 58% and 31 to 35%, respectively, between the two subgroups, while the hMPV F protein is highly conserved in hMPV strains even across subgroups (with amino acid identity of 93 and 96%). hMPV phylogeny studies also suggest that the virus sequences within subgroups A and B can be further divided into two further clades per subgroup. Studies using experimental infection of animals and reciprocal cross-neutralization studies suggest, for the most part, that the viruses of varying subgroups all fall within one serotype.

Serologic Tests

Serology is not used for clinical diagnosis of acute infections, because diagnosis requires a comparison of acute- and convalescent-phase titers. Most of the serologic tests for evidence of previous infection have used relatively crude methods to date. Most reports used microtiter plate-based enzyme-linked immunosorbent assays coated with virus-infected cell lysates or fixed and permeabilized infected cell monolayers as the viral antigen, which are susceptible to high-background reading and false-positive tests. A recombinant viral protein-based assay was reported recently, which holds promise as a more reproducible assay (65). Serum neutralizing antibody assays have been used to demonstrate the induction of functional antibodies in both humans and experimentally infected animals. Most of these tests have used reduction of virus plaques or CPE as the readout; however, a more objective microneutralization test using a recombinant hMPV expressing green fluorescent protein has been reported recently (13).

Antiviral Susceptibilities

There are no licensed therapies or prophylactic treatments for hMPV infection at this time. Ribavirin and intravenous immunoglobulin, which have activity against RSV, were tested against hMPV in vitro and were found to have equivalent antiviral activity against hMPV and RSV (150). Heparin, and the sulfated sialyl lipid (NMSO3) also have been shown to have activity against hMPV (151), and a low-molecular-weight benzimidazole derivative that inhibits hMPV has been reported (6). None of these inhibitory treatments has been tested clinically.

Evaluation, Interpretation, and Reporting of Results

There are no FDA-approved tests for detection of hMPV, and diagnostic tests should be considered experimental at this time. Viral detection is available in a limited number of research and clinical laboratories, although the primers and probes for molecular testing are available in the literature and more are being developed all the time. Culture requires a very high level of technical experience, and even most research laboratories grow the virus with difficulty, especially from primary specimens. Diagnostic tests are of utility mostly in studies of epidemiology at this time. Because the average duration of shedding during infection is not defined and the role of coinfection in disease expression is not well understood, the clinical interpretation of a positive molecular test is difficult. In general, the diagnosis of hMPV infection is most likely when a positive NAA test for hMPV infection

with a replicon containing an hMPV nucleotide sequence is identified in a respiratory secretion during late winter or early spring in a patient with acute respiratory illness and negative tests for other respiratory viruses.

Measles and Rubella Viruses

WILLIAM J. BELLINI AND JOSEPH P. ICENOGLE

88

Clinical differentiation of fever and rash illnesses caused by measles and rubella viruses has become increasingly difficult. The paucity of measles and rubella cases in the United States and other developed countries has led to a decline in clinical diagnostic acumen among physicians and health care workers (52, 86). Milder forms of measles have been reported to occur in previously vaccinated individuals (34), further obscuring diagnosis based on the clinical case definition. As global programs to control and eliminate measles expand, the medical and public health communities have become more dependent on laboratory confirmation of clinical diagnosis. Moreover, many countries where measles has been controlled by routine vaccination, coupled with mass vaccination and follow-up campaign strategies, are now implementing rubella control measures through the incorporation of rubella and measles combined vaccines in their programs. Laboratory diagnostic tests and laboratory surveillance activities for measles and rubella are performed in parallel in many clinical and public health laboratories worldwide (20). Consequently, this chapter combines the current laboratory diagnostic methods for measles and rubella for convenient review and reference.

MEASLES VIRUS

Taxonomy

Measles is the prototypic member of the genus *Morbillivirus* in the family *Paramyxoviridae*, and it is the only member of the genus that causes human disease (91). With rare exception, the members of this genus have restricted host ranges, indicative of long-term association with, and adaptation to, their respective zoonotic hosts. Other genus members include rinderpest virus, canine distemper virus, peste des petits ruminants virus, and cetacean and phocine distemper viruses.

Description of the Agent

Measles virus is an enveloped, nonsegmented, single-stranded, negative-sense RNA virus with a diameter of 120 to 250 nm. The measles virus genome is 15,894 nucleotides in length and contains six structural genes organized on the single strand of RNA in a gene order consistent with most of the paramyxoviruses, i.e., 3′-N, P, M, F, H, L-5′. The genome encodes at least eight proteins; three gene products are coded for by the phosphoprotein (P) cistron. The nucleoprotein (N) gene encodes the N protein, which encapsidates both full-length minus-strand (genome) and full-length plus-strand (antigenome) RNAs. Only encapsidated full-length RNAs (nucleocapsids) serve as templates for replication and transcription. The protein products of the P and the polymerase (L) genes interact with the full-length viral RNA and form the ribonucleoprotein complex. Viral nucleocapsid structures are surrounded by a membrane, derived from the plasma membrane, which includes the gene products from the M, F, and H genes (matrix, fusion, and hemagglutinin proteins, respectively). The F and H envelope proteins are N-linked transmembrane glycoproteins. In contrast, the nonglycosylated M protein is associated with only the innermost regions of the lipid envelope and appears to be involved in enhancing and organizing regions of the plasma membrane for nucleocapsid binding and promoting viral assembly and budding processes. The F and H proteins are responsible for fusion of virus with host cell membranes, allowing viral penetration and release of the nucleocapsid complexes into the cytoplasm, where replication occurs (44, 91).

Two receptors have been identified on the surfaces of measles virus-susceptible cells. The CD46 molecule, a regulator of complement activity present on most cell types, appears to promote the entry of vaccine and certain wild-type viruses (66). A second receptor, signaling lymphocyte activation molecule (SLAM, CDw150), has been identified on the surfaces of human lymphocytes, dendritic macrophages, and activated monocytes (98). In contrast to CD46, both attenuated and wild-type measles viruses reportedly use the SLAM receptor for entry.

Epidemiology and Transmission

Measles virus infections are transmitted via aerosols, droplets, or contaminated fomites. Measles is a highly contagious disease, and susceptible individuals who come into close contact with measles patients have a 99% probability of acquiring the disease. In the prevaccine era, greater than 90% of individuals would acquire measles infections before 10 years of age.

In unvaccinated populations, measles causes periodic epidemics, with interepidemic periods of 2 to 5 years. These periods decrease as population size and density increase and are directly related to the availability of susceptible individuals for sustained disease transmission.

In vaccinated populations, the interval between measles outbreaks increases, and sufficiently high levels of vaccination can interrupt endemic transmission. With vaccination,

the age distribution of cases is determined by which groups are likely to lack vaccine- or measles-induced immunity. In the United States, an extensive effort to achieve high levels of first-dose measles vaccination at 12 to 15 months of age and the addition of a recommended second dose of vaccine in school-age children have resulted in a decrease in reported measles cases from 400,000 to 500,000 per year in the 1960s to record lows of approximately 100 cases per year from 1998 to the present (18). Endemic transmission of measles in the United States was interrupted in 1994, and subsequent cases have occurred through periodic introduction of measles from countries where measles is endemic, occasionally followed by only limited spread (7, 89). Given widespread international travel, measles will continue to occur even in highly vaccinated populations until global eradication is achieved.

Measles remains a formidable disease of children in many areas of the world. The World Health Organization (WHO) estimates that over 30 million cases occur annually, with approximately 500,000 deaths occurring in Africa alone and a total of 777,000 associated deaths occurring worldwide (110). In marked contrast, effective use of available live attenuated measles vaccines and a variety of multidose vaccination strategies (second opportunities) have combined to eliminate measles in many large geographic regions, including the Americas, many Scandinavian countries, and the United Kingdom.

Clinical Significance

Uncomplicated Clinical Course

Approximately 1 week to 10 days following exposure, the clinical presentation begins with cough, coryza, conjunctivitis, and fever. The prodromal stage then progresses over the next 3 to 4 days, with all symptoms intensifying and the associated fever reaching as high as 105°F.

Koplik's spots, pathognomonic for measles, appear on the buccal mucosa in 50 to 90% of cases 2 to 3 days before rash onset, and may persist for 1 to 2 days following rash onset. These lesions are small, irregular red spots with a bluish white speck in the center. The erythematous rash appears approximately 2 weeks following exposure and is first evident on the forehead or behind the ears. The rash presents as red macules 1 to 2 mm in diameter, becoming maculopapules over the next 3 days. The exanthem is usually most confluent on the face and upper body and initially blanches on pressure. By the end of the second day the trunk and upper extremities are covered with rash, and by the third day the lower extremities are affected. The rash resolves in the same sequence, first disappearing from the face and neck. The lesions turn brown and persist for 7 to 10 days and then are followed by a fine desquamation. In most cases, recovery is rapid and complete.

Death resulting from respiratory and neurological causes (see below) occurs in 1 of every 1,000 measles cases, but estimates during the 1989 to 1991 outbreaks were three to four times higher (4). The risk of death is greater for infants and adults than for children and adolescents. However, rates of acute measles virus infections of infants and children in developing countries, particularly malnourished populations, can approach 10%, with rates of morbidity being much higher.

Complications

The most common complications associated with measles virus infection are otitis media (7 to 9%), pneumonia (1 to 6%), and diarrhea (6%). Pneumonia may occur as a primary viral pneumonia (Hecht pneumonia) or as a bacterial superinfection. Measles commonly involves the central nervous system (CNS), with as many as 50% of cases reported to have electroencephalogram abnormalities during the acute or convalescent phase of the illness (42).

Notable CNS complications include acute disseminated encephalomyelitis (ADEM) and subacute sclerosing panencephalitis (SSPE). ADEM occurs approximately 1 week after rash onset in 1 per 1,000 cases and is manifested clinically by seizures, lethargy, irritability, and/or coma. It results in the death of 5 to 30% of patients and causes residual deficits in about 30% of survivors (15, 60). The disease is presently considered an autoimmune disease since an immune response to myelin basic protein has been reported and measles virus has not been isolated from these patients (55).

SSPE is a progressive, inevitably fatal, late neurological complication caused by persistent measles virus infection of the CNS that occurs in approximately 1 per 100,000 measles cases (63), although recent studies estimate the rate to be 1 per 11,000 cases (8). Only wild-type measles virus nucleic acid sequences have been found in association with this disease. The average time from natural measles virus infection to manifestations of SSPE is 7 years. The disease characteristically involves personality changes, decreased motor and intellectual capabilities, involuntary movements, and muscular rigidity and ultimately leads to death of the patient. The virus is difficult to recover from brain specimens, requiring cocultivation or brain explant techniques, yet measles virus proteins and RNA can readily be detected in brain tissue (58, 94). Patients with SSPE usually have high titers of measles virus-specific antibodies in their sera and cerebrospinal fluid.

Infection during pregnancy is associated with an increased risk of miscarriage and prematurity, although there is no convincing evidence that maternal infection with measles virus is associated with congenital malformations. Clinical illness in the newborn after intrauterine exposure follows a shortened incubation period and may vary from mild to severe.

Atypical measles syndrome occurred in children who had been vaccinated with multiple doses of formalin-killed measles vaccine and subsequently exposed to wild-type measles virus. The syndrome was believed to occur as a result of immunopathological responses due to a combination of the Arthus reaction and delayed hypersensitivity (12). The syndrome has little relevance today, but the experience serves to emphasize the safety concerns that should be addressed by those wishing to develop alternative measles vaccines or to explore alternate routes of vaccine delivery.

Recently the use of combined, live attenuated measles-mumps-rubella (MMR) vaccines has been the subject of controversy. Several reports have claimed an association between vaccination with MMR and inflammatory bowel disorder, Crohn's disease, and ileal lymphonodular hyperplasia associated with regressive autism (104, 106). Thus far, reviews conducted by expert panels assembled by the Institute of Medicine, as well as several carefully controlled epidemiological and laboratory studies, have failed to confirm those reports (99). Other described complications include thrombocytopenia, stomatitis, laryngotracheobronchitis, hepatitis, appendicitis and ileocolitis, pericarditis and myocarditis, glomerulonephritis, hypocalcemia, and Stevens-Johnson syndrome.

In immunocompromised patients, syndromes such as giant-cell pneumonia and measles inclusion body encephalitis (MIBE) have been observed (10, 65). Measles-induced giant-cell pneumonia is usually unrecognized due to the absence of rash. It usually occurs in patients with deficits in cell-mediated immunity, and several cases have been diagnosed following vaccination of children with severe combined immunodeficiency syndrome (64). MIBE is generally fatal and is best

described as the unchecked replication of measles virus in the CNS in the face of an impaired or absent cell-mediated immune response. There are anecdotal reports of more severe and even fatal measles in patients with AIDS (2). However, vaccination is considered safe unless patients are severely immunocompromised.

Collection, Transport, and Storage of Specimens

In general, specimens for successful virus isolation should be collected early in the acute phase of the infection, when the virus is present in high concentrations, and transported to a laboratory under conditions that maintain the infectivity of labile viruses. Suitable samples for isolation of measles virus or for detection of viral antigen can be whole blood, serum, throat and nasopharyngeal secretions, urine, and, in special circumstances, brain and skin biopsy samples. Specimens should be processed as soon as possible after collection and are best kept at 4°C rather than frozen, since freezing causes significant loss of recoverable virus. Specimens should be frozen and shipped with dry ice only if the time between specimen collection and delivery to the laboratory is expected to exceed 48 h.

Transport medium should be used to maintain measles virus until isolation of virus from clinical specimens can be performed. Samples requiring viral transport medium and commercial sources of viral transport medium are reviewed in chapter 80. Measles virus is lymphotropic, and macrophages are a known source of infectious virus during natural infection (38). Thus, peripheral blood mononuclear cells (PBMCs) are an excellent source for the isolation of measles virus. PBMCs are obtained from heparinized blood (diluted 1:3 in saline) by sedimentation through density gradients (reviewed in chapter 80).

Serum specimens from patients with suspected measles should be assayed in an immunoglobulin M (IgM) enzyme-linked immunoassay (EIA) within 7 to 10 days of rash onset, if possible. A single serum specimen is sufficient in most cases (102). To assess seroconversion following measles vaccination, serum specimens can be tested with IgG EIAs or plaque reduction neutralization (PRN) tests (see below). Ideally, paired specimens should be obtained: the first prior to vaccination and the second approximately 3 to 4 weeks later, so that a rise in measles virus-specific IgG can be measured. Serum samples should ideally be stored at −20°C, but antibody is stable for extended periods at 4°C. Samples for IgM determinations should not be frozen and thawed more than five times. Spinal fluid samples should also be obtained if neurological complications are present or suspected.

Respiratory specimens are appropriate for testing. Nasal aspirates or bronchial lavage samples yield virus more frequently than throat swabs, because of the greater likelihood of obtaining infected cells. For immunofluorescence assays (IFAs), slides of respiratory specimens should be fixed in cold acetone for 2 min and stored at 4°C.

For isolation of virus from urine, a large volume of midstream (clean-catch), preferably morning, urine should be collected into a sterile container. Measles virus is very cell associated; thus, the urine is centrifuged at 800 × *g* for 30 min. The pelleted cells and sediment are resuspended in 1 to 2 ml of Hanks' balanced salt solution in preparation for cell culture, PCR, or other diagnostic methods (88).

Two new approaches show promise in terms of alternatives to serum specimen collection for the diagnosis of measles: the use of oral fluid and the use of blood spots on filter paper. Oral fluid samples have been used both for detection of measles virus-specific IgM and IgG and for detection of hepatitis, rubella, mumps, and other infections (46, 72, 73, 75). This technique is already being used for routine measles surveillance in the United Kingdom (13). The use of oral fluid samples has appeal because the technique is noninvasive, it can be used for rubella testing, and it does not require processing of the sample in the field, and it may be possible to detect not only measles virus-specific IgM but also the measles virus genome for molecular characterization (54). Commercial assays performed on oral fluid samples have heightened background reactivity and decreased sensitivity. These disadvantages make oral fluids less useful in settings with low measles incidence.

Like oral fluid samples, blood spots collected onto filter paper do not require processing in the field, a cold chain does not appear necessary, they can be used to test for rubella as well as for measles (24, 25, 32, 47, 78, 90, 105), and they can be used for molecular characterization of the measles virus genome (33), although virus isolation would not be possible. In addition, the eluted serum from blood spots can likely be tested in commercially available measles EIAs without the loss of sensitivity and specificity (33, 47), making this technology very attractive for widespread use. Although still considered an invasive technique, fingerstick as a method for sample collection is often more acceptable to parents than phlebotomy (107).

Direct Examination

Cytologic Examination

Characteristic cytopathic effects (CPE) of measles virus infection include giant cells and cellular inclusions (intracytoplasmic and intranuclear). Cytologic examination of various tissue specimens and secretions for these Warthin-Finkeldey giant cells can be used as a diagnostic procedure. Slides can be stained with either Wright stain or hematoxylin and eosin (H+E). Tissue samples may be fixed in 10% formalin, embedded in paraffin, sectioned, and then stained with H+E (41). Staining of tissue specimens with monoclonal antibodies to the measles virus nucleoprotein has been used for the diagnosis of giant-cell pneumonia and MIBE (112).

Immunofluorescence

Detection of measles virus can be achieved using an IFA to examine clinical specimens as well as B95a cell cultures infected with clinical material. The standard assay uses a commercially available monoclonal antibody to the nucleoprotein of measles virus and fluorescein-conjugated goat anti-mouse antiserum. Nasal secretions should be centrifuged at 800 × *g* to pellet the cells. The cell pellets are then washed several times with sterile saline before being applied to a glass slide and fixed in cold 80% acetone for 10 min at −20°C (62, 96).

Nucleic Acid Detection Techniques

Reverse transcriptase PCR (RT-PCR) has been used in research settings to detect measles virus RNA in clinical specimens and infected cells (84, 88, 93). While serologic testing is best for routine diagnosis of measles virus infections, these assays do not provide any information about the genetic characteristics (genotype) of the virus required for molecular surveillance. Therefore, RT-PCR can be considered for diagnostic use in special cases where cell culture is not a practical alternative and/or when genotyping of the virus is required. In this regard, RT-PCR from tissue specimens has been particularly useful for the diagnosis of MIBE, SSPE, and giant-cell pneumonia. Sequence data obtained from the PCR products can sometimes identify the source of the virus and differentiate between vaccine and wild-type strains of measles virus (87). RT-PCR techniques have had the greatest impact on

molecular surveillance activities. Measles virus RNA is easily extracted and amplified from infected cell cultures, and measles virus RNA has been detected in oral fluid, nasal, urinary, and, sometimes, serum samples by RT-PCR, even when virus isolation has been unsuccessful (64, 84, 88).

Isolation of Measles Virus

Measles virus can be isolated from the conjunctiva, nasopharynx, and blood during the latter part of the prodromal period and during the early stages of rash development. Although virus has been isolated from the urine as late as 4 to 7 days after rash onset, viremia generally clears 2 to 3 days after rash onset in parallel with the appearance of antibody. Thus, virus can be most readily isolated from 2 to 4 days prior to rash onset, and then about 4 days after rash onset.

Though other cell lines have traditionally been used (44), an Epstein-Barr virus-transformed B lymphoblastoid cell line derived from marmoset lymphocytes is the preferred cell line for primary isolation of measles virus (59). These cells are up to 10,000 times more sensitive for isolation of measles virus from clinical specimens than other cell lines, such as Vero cells and primary monkey kidney cells. An adherent cell population was selected from the lymphoblastoid line B95–8. The adherent cell line was renamed B95a. B95a cells are relatively easy to maintain in the laboratory, and the measles virus CPE is readily observed. However, laboratorians should note that this cell line does produce Epstein-Barr virus and should be handled as infectious material at all times.

B95a cells should be at 85% confluency when inoculated with specimens. After inoculation with clinical material, the cells should be maintained in Dulbecco's modified Eagle's medium (DMEM) plus 2% fetal bovine serum and antibiotics. The medium should be changed every 3 to 5 days, and the cells should be passaged (proceeds divided equally into two flasks) every 5 to 7 days. The medium should be replenished until the CPE become extensive (Fig. 1). When CPE is visible over at least 75% of the monolayer, viral stocks can be prepared by freezing the cells at −70°C. It is advisable to perform three or four blind passages before discontinuing efforts at viral isolation. Recently, Vero cells that constitutively express the SLAM receptor have been constructed, and they appear to have the same sensitivity for wild-type measles virus infection as B95a cells (70). Vero-SLAM cells also express the simian CD46 molecule and have the advantage that they do not produce Epstein-Barr virus.

Serologic Diagnosis

The recommended laboratory method for the confirmation of clinically diagnosed measles is a serum-based IgM EIA. Several serum-based IgM EIAs are now commercially available and are used worldwide by public health, clinical, and commercial laboratories. These assays have been used as the primary confirmatory test by the laboratory network of the Pan American Health Organization-supported measles eradication effort throughout the Americas. The WHO Global Measles Laboratory Network has also recommended use of the IgM EIA for laboratory diagnosis of measles (20). The EIAs can be done using a single serum specimen, are relatively rapid (2 to 6 h), are simple to perform, and can be used to diagnose acute measles virus infection from the time of rash onset until at least 4 weeks after rash onset. Thus, the IgM EIAs fulfill all of the basic criteria for the accurate, effective, and efficient diagnosis of measles. Both indirect and IgM capture formats have been used (36, 51). Though the IgM capture assay format is often regarded as more sensitive than the indirect format, comparative studies of some commercial indirect formatted EIA kits have demonstrated that the two formats have equivalent sensitivities and specificities (3, 81).

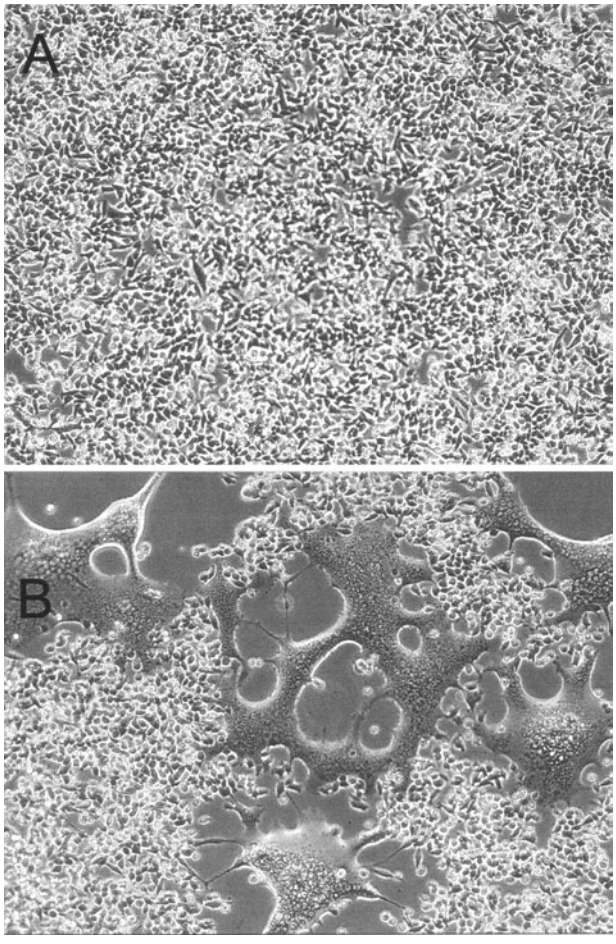

FIGURE 1 CPE of measles virus when propagated in B95a cells, a marmoset monkey lymphoblastoid cell line. (A) Uninfected monolayer of B95a cells. (B) Measles virus-infected monolayer of B95a cells with apparent syncytium formation. Reprinted from reference 7a.

Traditional antibody tests such as hemagglutination inhibition (HI), PRN, and EIA have been used extensively in the serologic diagnosis of measles. However, because of the availability of sensitive and specific commercial kits, EIA has become the most widely used test format. Commercial EIAs also have the ability to measure measles virus-specific IgM as well as IgG responses and therefore have particular importance in diagnosis as well as measles control programs. Some of the available kits were found to have sensitivities and specificities that compared favorably with PRN (30, 80). Most laboratories have trained personnel and are already equipped to run EIAs.

Standard EIAs

Many commercial assays now include measles virus antigens produced by recombinant DNA expression systems, such as baculovirus, rather than antigen produced by infected cell cultures. EIAs using baculovirus-expressed nucleoprotein in both capture and indirect formats have high sensitivity and specificity compared to those of other commercial EIAs (51). The advantages of the baculovirus expression system include extremely high yield and more consistent antigen quality.

Though the configurations of the commercial measles virus IgM kits vary, the tests are simple and straightforward to perform by following the manufacturers' protocols. Indirect EIA has been successful in the detection of IgG (51). For this indirect test, either whole virus antigen diluted in 0.05 M bicarbonate buffer (pH 9.5) or recombinant antigen diluted in phosphate-buffered saline (PBS) is distributed into polystyrene microtiter plates. Serum specimens are diluted in PBS containing 4% normal goat serum (plus 4% Sf9 cell lysate for recombinant antigen) and 0.05% EDTA and then added to the washed plates. Bound antibody can be detected with standard commercial reagents such as goat anti-human IgG conjugated to either alkaline phosphatase or biotin. Assays are developed with the appropriate substrate, and the plates can be read either by eye or with the aid of a spectrophotometer.

PRN

The PRN assay, which measures neutralizing antibodies that are directed against the surface glycoproteins of measles virus, is more sensitive and specific than HI or EIA (1). Since functional antibodies are detected, the PRN provides the best serologic correlate for the assessment of immune protection (22). However, the PRN test is not suitable for routine serologic diagnosis because it is very labor-intensive, requires paired serum samples, and takes 5 to 7 days to complete.

In the PRN assay, measles virus-specific antibody in serum combines with and neutralizes measles virus, preventing it from infecting a cell monolayer and forming a plaque under the overlay. The endpoint for the test is the highest dilution of serum which will reduce the number of plaques by 50%. Serum dilutions are made in 96-well microtiter trays, making either two- or fourfold dilutions (depending on the expected titer of the serum). Once the dilutions of serum samples are made, an equal volume (120 μl) of a dilution of virus containing 25 to 35 PFU is added to each well and incubated for 2.5 h at 36°C. After incubation, 100 μl of the serum-virus mixture is added to each of two 16-mm-diameter wells on a tissue culture plate(s) containing Vero cell monolayers. These plates are then incubated for 1 h at 36°C. Following incubation, the inoculum is removed by aspiration, and the monolayers are covered with overlay medium consisting of either 2% carboxymethyl cellulose in Leibovitz-15 medium or 1% agarose in Eagle's medium. The plates are then incubated for 4 days at 36°C, and the monolayers are stained with a solution of neutral red in cell culture medium. On day 5, the overlay is removed and the plaques are counted. The numbers of PFU in duplicate wells representing a given serum dilution are averaged.

New EIAs

A new and potentially promising development has been the use of EIAs to measure the avidity of IgG antibodies to measles virus (31, 103). As the immune response matures, low-avidity antibodies are replaced with high-avidity antibodies. These avidity differences can be detected by using protein denaturants, 6 to 8 M urea, in the washing step of the indirect EIA for measles virus IgG. An avidity index is then calculated by comparing the optical densities obtained with and without urea in the wash buffer. These tests have been able to successfully differentiate between primary and secondary responses to vaccination and to natural infection (74).

Evaluation, Interpretation, and Reporting of Results

EIA Interpretation

Although the EIAs are very good, they are nonetheless imperfect. These imperfections are manifested in both the positive and negative predictive values of the tests, and they are particularly apparent as the prevalence of measles disease decreases in the population. The vast majority of false-negative results stem from testing serum specimens taken too early with respect to rash onset. For example, the CDC capture IgM assay, which has a sensitivity and specificity equivalent to those of commercial EIAs, has been shown to detect IgM in only 77% of true measles cases within the first day of rash onset (45). In the case of indirect IgM assays, false-negative values can be the result of insufficient removal of high levels of measles virus-specific IgG from a test specimen. The residual IgG competes with IgM for viral antigen placed on the solid-phase support, thereby blocking IgM binding to the antigen and interfering with IgM detection. Current-day immune absorbent reagents are much improved over earlier reagents; thus, fewer problems of this nature occur.

False-positive tests due to the presence of rheumatoid factor (RF) appear to be more frequently encountered when using the indirect IgM assay. RF is an IgM class immunoglobulin that reacts with IgG and is produced as a result of some viral diseases and autoimmune diseases. Immune complexes may form that contain test antigen-specific IgG and RF IgM. By virtue of the IgG binding to the viral antigen, the IgM component of the RF immune complex is recognized by the detector system, thus rendering a falsely positive result. Similar false-positive results can occur in capture assays but appear to be enhanced by the presence of high levels of both antigen-specific antibody and RF (36).

The inherent sensitivities and specificities of the EIAs in times of low disease prevalence become a factor in interpretation. For instance, in a setting where measles has a prevalence of 50%, if the sensitivity of the EIA is 90% and the specificity is 99%, the positive predictive value is extremely high (99%). However, if the prevalence of measles drops to 1%, the positive predictive value falls to 48%. Moreover, a relatively small reduction in the specificity of the assay can have major effects on the positive predictive value of the assay. A reduction of specificity from 99 to 95%, when measles prevalence is 1%, decreases the positive predictive value from 48 to 15%. In other words, 85% of the positive test results would be "false-positive" results, even in the context of a highly specific assay. This situation occurs in countries that have eliminated endemic measles but remain vigilant in performing case-based surveillance of rash illnesses. In these geographic regions, both measles IgM and IgG EIAs are performed on serum specimens from suspected cases due to high vaccine-induced seroprevalence. In this setting, if the IgG test is positive and the IgM test is negative, the case is discarded (depending upon the timing of serum collection).

Unfortunately, EIA specificity is not 100%. Serum specimens from patients with parvovirus B19 and rubella have inherent rates of false-positive reactions (overall rate of about 4%) when tested in measles IgM EIAs and vice versa (53, 100). The reason(s) for these false-positive reactions is not understood, and attempts to remove immune complexes using anti-RF have proven unsuccessful.

There is also evidence that case contacts that have a resident IgG response, due either to a history of natural infection or to vaccination, may develop a secondary IgG or an IgM response to currently circulating virus (37, 48). The IgM is generally fleeting and weakly positive and, except for rare instances, should not pose as a source of confusion to the diagnostic laboratory.

Table 1 summarizes the possible interpretations of EIA results. Despite the vagaries associated with the EIAs, they are the best assays available for laboratory confirmation of

TABLE 1 Interpretation of measles EIA results[a]

IgM result	IgG result	Infection history	Current infection	Comment(s)
+	+ or −	Not previously vaccinated, no history of measles	Recent first MCV[b]	Seroconversion,[c] postvaccination
+	+ or −	Not vaccinated, no history of measles	Wild-type measles virus	Seroconversion,[c] classic measles
+	+ or −	Previously vaccinated, primary vaccine failure	Recent second MCV vaccination	Seroconversion,[c] postvaccination
−	+	Previously vaccinated, IgG positive	Recent second MCV vaccination	IgG level may stay the same or increase
+	+	Previously vaccinated, IgG positive	Wild-type measles virus	May have few or no symptoms[d]
+	+	Recently vaccinated	Exposed to wild-type measles virus	Cannot distinguish if vaccine or wild-type virus infection; evaluate on epidemiological grounds[e]
+ or −	+	Distant history of measles	Wild-type measles virus	May have few or no symptoms[d]; if clinically compatible may have been misdiagnosed initially

[a] Reprinted from reference 7a.
[b] MCV, measles virus-containing vaccine.
[c] IgG level depends on timing of specimen collection.
[d] Rare occurrence; do not consider contagious unless clinical presentation is consistent with measles.
[e] If result is IgM negative, it is helpful to rule out wild-type measles virus infection.

clinically diagnosed measles. It should be emphasized that the vast majority of serum specimens submitted for serology will yield a test result that will be easily interpretable. However, laboratorians should be provided with as much information as possible about the clinical disease and epidemiological investigation to aid in the final interpretation of the test result.

RUBELLA VIRUS

Taxonomy

A number of small, enveloped viruses having the same overall genetic organization and replication strategy as rubella virus exist, and they are grouped into the *Togaviridae* family. The *Togaviridae* family consists of the *Rubivirus* genus, containing only rubella virus, and the *Alphavirus* genus, containing about 25 other viruses, all of which are transmitted by arthropods (e.g., western equine encephalitis virus). Rubella virus has a restricted host range and appears to infect only humans.

Description of the Agent

Rubella virus virions are particles about 70 nm in diameter that are comprised of a core surrounded by a lipid envelope. The core consists of the positive-strand genome (~10,000 nucleotides) and the virus protein C. The viral envelope contains two viral glycoproteins, E1 and E2. The viral RNA replicates in the cytoplasm of infected cells, with nonstructural proteins being translated from the 5′ two-thirds of the genomic RNA and the structural proteins being translated from a subgenomic RNA that is a copy of the 3′ one-third of the genomic RNA. New virions are produced when genomic RNA, the E1 glycoprotein, the E2 glycoprotein, and the C protein assemble at cellular membranes (21, 85).

Compared to many RNA viruses, the rubella viral RNA is highly conserved. Nevertheless, rubella viruses currently circulating in the world contain RNAs that differ sufficiently that two clades of rubella viruses, differing by about 10% in the nucleotide sequence, have so far been identified (40, 56). Groups of related viruses within the clades have been classified as genotypes. At present, seven genotypes and three provisional genotypes of rubella viruses have been recognized (111). Only minor immunologic differences exist among circulating viruses. Immunity to one rubella virus is sufficient to protect against other known rubella viruses.

Clinical Significance

Rubella (German measles or 3-day measles) was first described in the 18th century and was accepted as a disease independent of measles and scarlet fever in 1881 (26). Postnatal rubella is characterized by an acute onset and generalized maculopapular rash with mild fever (greater than 99°F) and may include arthritis or arthralgia (mostly in postpubertal females), lymphadenopathy (specifically postauricular and suboccipital lymphadenopathy), and conjunctivitis. Because disease caused by rubella virus is mild, about 50% of postnatal rubella cases are not diagnosed. Although rubella had been largely ignored for 60 years, N. McAlister Gregg first recognized that cataracts in children followed maternal rubella during gestation (43). The association between congenital rubella and a spectrum of significant birth defects including sensorineural hearing loss, cardiovascular abnormalities, cataracts, congenital glaucoma, and meningoencephalitis is now accepted. Rubella virus is now recognized as the most potent infectious teratogenic agent yet identified (61, 92, 108).

When rubella occurs in a pregnant woman in the first 11 weeks of gestation, there is a high likelihood of defects in the infant (about 90%). After 18 weeks, the likelihood of birth defect is much lower, although the infant may still be infected with rubella. Congenital rubella infection (CRI) refers to infants born with rubella virus infection with or without birth defects. The pathogenesis of CRI leading to congenital rubella syndrome (CRS) is not well understood, but rubella virus infection early in gestation results in an altered immune response to the virus and altered organogenesis. The significant effect on the fetus of rubella virus infection during the first trimester is likely related to the facts that the fetus cannot synthesize IgM until about 20 weeks of gestation and cell-mediated immunity does not develop until about 27 weeks. Congenitally infected infants shed virus for long periods, have a slowly developing immune response to rubella virus, and

respond to particular rubella virus proteins differently than individuals with postnatal rubella. These three characteristics of congenital infection are all consistent with selective immune tolerance to rubella virus proteins in such infants (21). Infection during the first 11 weeks of gestation often results in multiple organ involvement and necrosis in many tissues (61). Organogenesis is affected by rubella virus infection, since specific organs are involved and small but normal organs in CRS infants have a reduced numbers of cells. Reinfection with rubella virus can occur, but viremia is rare, resulting in very low risk to the fetus in a reinfected pregnant woman (5).

CRI results in both shedding of virus and IgM antibodies in the neonate. Diagnosis is based on detection of rubella virus or rubella virus-specific IgM in such patients. If congenital defects characteristic of CRS are not present, the infant is diagnosed as having CRI only. The clinical definition of CRS is standardized, but laboratory confirmation of rubella virus infection in the newborn by either serologic or culture techniques is critical, especially when only a single defect presents, since the defects characteristic of CRS can occur for other reasons (16).

Epidemiology and Transmission

Rubella virus was not isolated until 1962, largely because infected cells are difficult to identify in tissue culture (71, 109). Introduction of rubella vaccine (licensed in 1969) in the United States, mostly through childhood immunization, immediately broke the 6- to 9-year epidemic cycle of rubella. The last major U.S. rubella epidemic was in 1964 to 1965, when 20,000 CRS cases occurred (50). The combined MMR vaccine was recommended for the United States in 1972. The current incidence of CRS in the United States is ~10 CRS cases per year. Most mothers of affected infants were born in countries without rubella immunization programs or with recently organized programs (83). Occasional outbreaks of rubella in some U.S. populations (e.g., foreign-born Hispanics) have not spread to the undervaccinated populations (e.g., those in inner cities), suggesting that herd immunity may be giving a protective effect (82). Indigenous rubella and CRS have been eliminated from the United States, and these diseases are targeted for elimination from the Americas and Europe by 2010 (14, 19) (http://www.euro.who.int/Document/E87772.pdf). Despite the possibility of worldwide rubella eradication, rubella remains endemic in many countries and about 100,000 to 200,000 CRS cases occur annually in the world (6, 28, 77). Postnatal transmission of rubella virus is usually by close contact with an infected individual, such as occurs in correctional institutions or day care centers.

The safety of live rubella virus vaccine strains is well documented (76). None of 293 infants born to susceptible mothers who were inadvertently vaccinated 1 to 2 weeks before to 4 to 6 weeks after conception were born with CRS. However, a small theoretical risk remains. Thus, the Advisory Committee on Immunization Practices recommends avoiding pregnancy after receipt of rubella-containing vaccine for 28 days (17).

Collection, Transport, and Storage of Specimens

Clinical specimens for culture of rubella virus are usually throat swabs or nasopharyngeal secretions diluted into transport medium (e.g., Culturette collection and transport devices). The virus can also be isolated from a number of other specimens, including cataract tissue and urine (provided that pH is controlled) (5). Urine is often a source of infectious virus from CRS patients. Specimens should be stored at 4°C for short periods (days) or at −70°C for longer periods (weeks); virions lose infectivity at higher temperatures (e.g., 37°C). Virions are rapidly inactivated by mild heat (56°C), detergents, or lipid solvents. Rubella virus-specific IgG can be detected in urine (97). Specimens for serology or culture can be transported by standard methods (e.g., overnight carrier) at 4°C since virions are relatively stable at 4°C. Oral fluid/saliva and blood spots dried onto filter paper may be used as alternatives to serum for rubella virus-specific antibody testing as discussed for measles (47, 54, 69, 79).

The timing of specimen collection is important. Rubella virus-specific IgM is the laboratory diagnostic criterion typically used for rubella, but about 50% of rubella cases are IgM negative on the day of rash (see Table 2 and related text below). Since postnatal rubella is a mild disease of short duration, special effort may be required to obtain a serum sample 5 to 7 days after rash, when most rubella patients are strongly IgM positive. Patients with CRS are IgM and virus positive for months; therefore, timing is less critical for these patients.

Direct Examination

Nucleic Acid Detection Techniques

Amplification of rubella virus RNA directly from a clinical specimen using RT-PCR can be used to determine if a patient

TABLE 2 Timing of biological markers of rubella virus infection[a]

Diagnostic criterion	Convenient time when many cases are positive (%)	An example of a time when >90% of cases are positive	Approximate time for 50% decline[b]
Postnatal rubella			
Virus in throat by culture	Day of rash (90%)	2 days **before** rash	4 days after rash
IgM in serum by ELISA	Day of rash (50%)	5 days after rash	6 wk after rash
IgG in serum by ELISA	3 days after rash (50%)	8 days after rash	Lifetime
Virus in blood by culture[c]	Day of rash (50%)	5 days **before** rash	1 day after rash
CRS[d]			
Virus in throat by culture	At birth (almost all)	2 wk after birth	3 mo of age
IgM in serum by ELISA	At birth (80%)	1 mo of age	6 mo of age
IgG in serum by ELISA[e]			

[a] Times and percentages given are approximate and are meant to guide typical specimen collection. Percentages will vary depending on the sensitivity of the assay used. Note that the times listed in the third column were chosen to help guide specimen collection and may not be the earliest time when >90% of cases are positive.
[b] After maximum number of cases are positive for a given criterion, the approximate time for 50% of cases to become negative.
[c] Data taken from reference 29.
[d] Information given is for fetal infection in the first trimester.
[e] Declining maternal IgG and developing IgG response in a CRS patient lead to high (steady) or increasing IgG levels in the CRS patient through the first year of life.

is infected with rubella virus. Not all RT-PCR protocols are sufficiently sensitive to be used directly with clinical specimens. Assays that can reliably detect 3 to 10 copies of rubella virus RNA are sufficiently sensitive. Nested RT-PCR protocols, although difficult to maintain, usually meet this criterion (11, 27). Direct detection of rubella virus RNA by RT-PCR requires the laboratory to evaluate the significance of results from such tests. Multiple negative controls and amplified product in more than one specimen from a given patient will increase confidence of a positive diagnosis based on direct RT-PCR. The significance of negative results is usually difficult to determine since false-negativity rates are usually not available. Nevertheless, when serum from a patient cannot be obtained, or when confirmation of serologic results is desired, direct detection of rubella virus RNA by RT-PCR may be necessary since it is more rapid than viral culture.

Isolation and Identification of the Virus

Growth of rubella virus from clinical specimens can be used to diagnose postnatal rubella, CRS, and CRI (Table 2). Throat swabs taken on the day of rash, typically a convenient time for sample collection, are usually positive for rubella virus, even though a slightly higher percentage of cases are positive 2 days before rash onset. Virus shedding in the throat declines rapidly, and by 4 days after rash onset, only about 50% of cases are positive. In addition, viral culture is used to monitor virus in CRS and CRI patients for the purpose of determining when isolation of these patients from susceptible contacts can be stopped. The virus will grow in a variety of cell types, including Vero, BHK21, AGMK, and RK-13 cells. The primary problem encountered with tissue culture is the lack of a cell type that produces CPE in a single passage of wild-type viruses. Historically, this problem was overcome by clever assays exploiting the fact that rubella virus growth interferes with the replication of lytic enteroviruses such as coxsackievirus A9. However, interference assays are quite difficult to maintain (23). Virus growth can now be identified in the absence of CPE using methods such as RT-PCR and IFA to detect viral RNA and proteins, respectively.

Bacterial and fungal contamination of tissue culture cells is prevented by treating specimens with high concentrations of antibiotics or by filtration through low-retention (pore size, 0.2 μm) filters prior to inoculation. Tissue culture cells (usually Vero) are inoculated with approximately 0.5 ml of the specimen. Virus is allowed to attach to cells for 1 h at 35°C, and then DMEM with about 5% fetal calf serum (FCS) is added. Virus is then allowed to grow for 1 week at 35°C. After 1 week, a portion of the medium from this initial culture is either stored or passaged immediately to another confluent monolayer of cells. The cells from the initial culture are processed for RT-PCR, IFA, or both. Two passages should be performed before a specimen is considered negative.

The sensitivity of the RT-PCR system used to detect viral RNA from infected tissue culture cells is not critical, since the amount of rubella viral RNA has been amplified by passage in tissue culture (about 10^6-fold) (40). Cell-associated RNA is extracted by standard means, cDNA is prepared by standard reverse transcription reaction [typically using oligo(dT) primers], and virus-specific primers are then used to amplify cDNA. Ethidium bromide staining of amplicons after agarose gel electrophoresis can be used for postamplification detection. Sequencing of the resulting amplified nucleic acid can provide useful information (e.g., vaccine or wild-type virus) (39). Detection of rubella virus-infected cell monolayers can also be accomplished by IFA. It is crucial that IFA reagents have low background, since rubella virus culture does not produce high levels of progeny virus (about 10^7 PFU/ml for laboratory strains such as f-Therien). Infected cells are easily identified when stained with high-quality reagents (Fig. 2). Dilution of specimens may be desirable since it is useful to have both infected and uninfected cells in the same field. Monoclonal antibodies to the E1, E2, and C proteins, which react with both reduced and nonreduced antigens on Western blots, often work well in the IFA.

Serologic Tests

ELISA

Detection of rubella virus-specific IgM by either IgM capture enzyme-linked immunosorbent assay (ELISA) or indirect IgM ELISA is the fastest and most cost-effective diagnostic test for recent postnatal infection. Unfortunately, only about 50% of postnatal rubella cases are IgM positive on the day of symptom onset (Table 2). Most postnatal rubella cases have virus-specific IgM detectable by capture ELISA from 5 until 20 days after symptom onset and IgG by indirect ELISA ≥8 days after symptom onset (Fig. 3) (35, 101). A negative IgM serologic result 4 to 5 days after onset should be followed with testing of a serum sample taken as soon as possible thereafter to avoid false-negative results (16). If acute- and convalescent-phase sera are available, a fourfold rise in rubella virus-specific IgG is diagnostic for postnatal rubella infection; such sera should be taken as early as possible after disease onset and about 2 to 3 weeks after disease onset. When IgG titers are used for diagnostic purposes, a dilution series of each serum sample should be made and ELISA results for each dilution series compared, since optical density values at a single dilution are unreliable.

The same ELISAs may be used to confirm CRS. Most congenitally infected infants have IgM detectable from birth to 1 month of age (Table 2). The percentage of infants who are IgM positive declines over the first year of life. At 1 year, most infants are negative. In CRS patients, the IgG response increases gradually over the first 9 months, while maternal IgG declines. Thus, high or increasing IgG levels in the first year of life are consistent with CRS. Precise recommendations for the best times for collection of samples from postnatal rubella and CRS cases have been published (16).

Latex Agglutination

Latex spheres coated with rubella virus antigen can be aggregated by either rubella virus-specific IgG or IgM, and they are the basis for commercially available rapid latex particle agglutination assays. These assays are often used when immunity determination is required (e.g., prenatal screening), since they are fast and easy to perform.

HI

The HI test was once the standard test for antibodies to rubella virus, and many current tests are calibrated using HI assays. However, indicator erythrocytes are not readily available and the assay is difficult to perform since removal of nonspecific inhibitors and internal standardization are required. If HI is used, it is usually desirable to verify results with another assay.

IFA

IFA is an option for detection of IgG and IgM antibodies to rubella virus. Commercial IFAs are available. Typically cells expressing rubella virus proteins and control cells are reacted with test serum and any rubella virus-specific antibodies are then detected with fluorescent dye-labeled goat anti-human IgG (or IgM) and fluorescence microscopy. Negative human

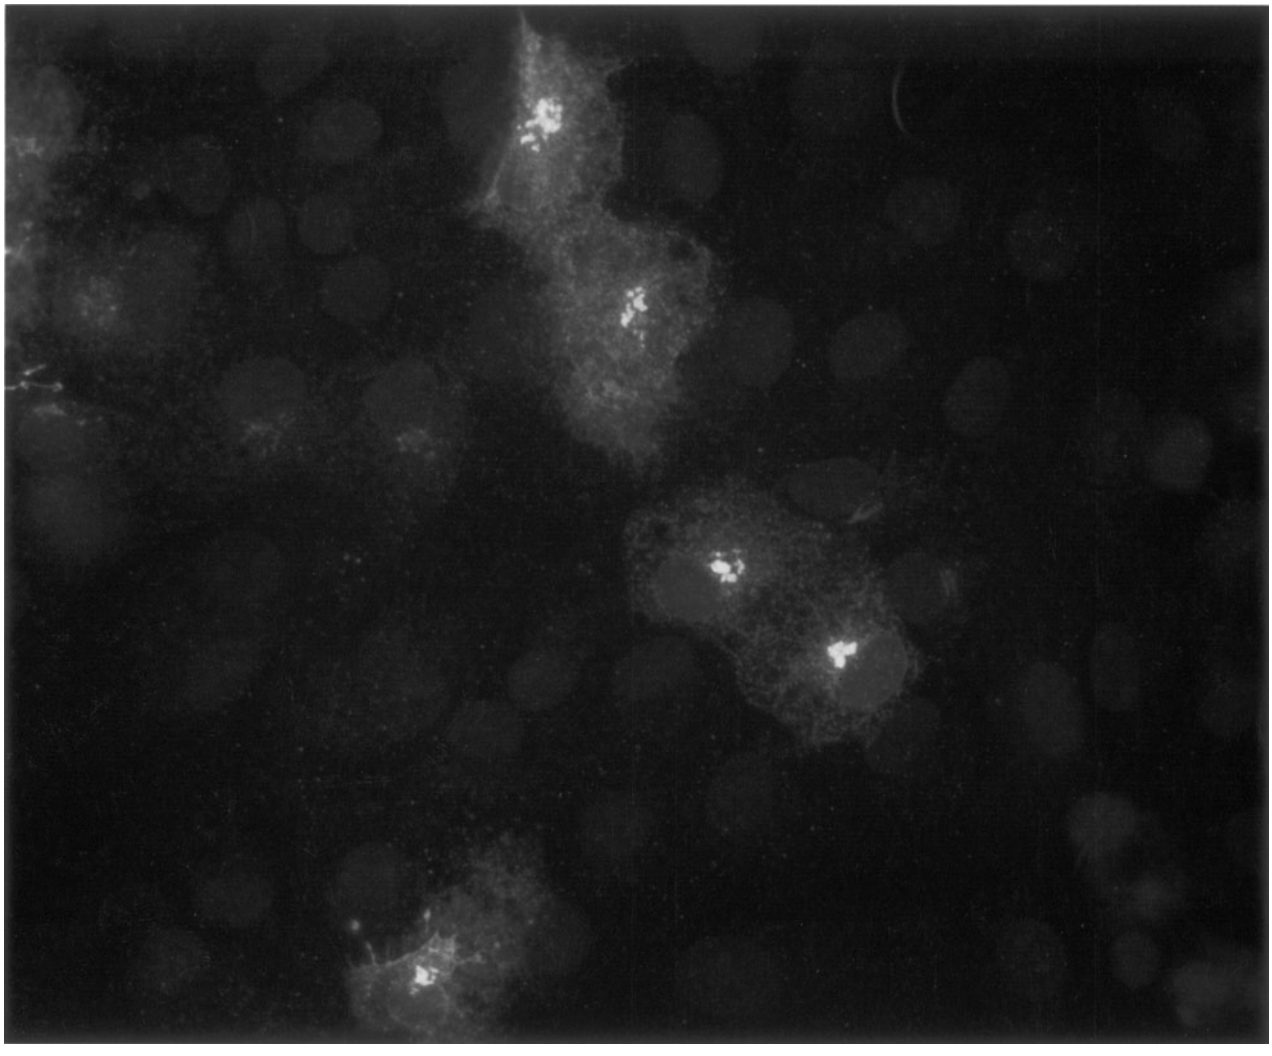

FIGURE 2 IFA for rubella virus-infected cells using monoclonal antibody to the E2 protein. Vero cells were infected with wild-type rubella virus and 3 days after infection were fixed with cold paraformaldehyde followed by permeabilization with –20°C methanol. Reaction of infected cells with monoclonal antibody to the E2 protein (monoclonal antibody 24–26; Viral Antigens, Memphis, Tenn.) was followed by detection of bound monoclonal antibody with Alexa Fluor 488-conjugated, highly cross-absorbed goat anti-mouse IgG (Molecular Probes Inc., Eugene, Oreg.) (green fluorescence in the original photograph). Cell nuclei were visualized by staining with propidium iodide (red fluorescence in the original photograph). About 25% of the cells which stained with propidium iodide were positive for E2 protein.

sera are useful for monitoring nonspecific signal. Fluorescence should be cell associated. Staining restricted to the periphery of the cell monolayer is not indicative of a true-positive result.

PRN

When a quantitative result on the neutralizing capacity of an antiserum is necessary, a PRN assay should be done. A laboratory strain (e.g., f-Therien) should be used since viruses from clinical specimens do not exhibit CPE. The assay follows a format common to many viruses. The initial step is incubation of 2- or 10-fold dilutions of antiserum and a standard amount of rubella virus (usually about 100 to 200 PFU) in medium or buffer containing protein to inhibit losses on surfaces (e.g., 0.1% bovine serum albumin) for 1 h at 35 to 37 °C followed by overnight in a refrigerator. A virus control must be carried through all steps, since some reduction in the number of plaques is observed at 35°C. Virus-antiserum specimens are then allowed to attach to confluent Vero cell monolayers for 1 h at 35°C and then overlaid with DEAE dextran (100 μg/ml)-containing medium with 0.5% agar (e.g., Oxoid). Medium in the agar overlay is typically DMEM; 1% FCS may also be included to maintain the monolayer. After 6 days, agar is removed and plates are stained with neutral red. Crystal violet can also be used; however, a wash step to remove dead cells should be used prior to crystal violet staining. The neutralizing capacity of the antiserum is the inverse of the antiserum dilution giving a standard reduction in plaques, typically 90% reduction.

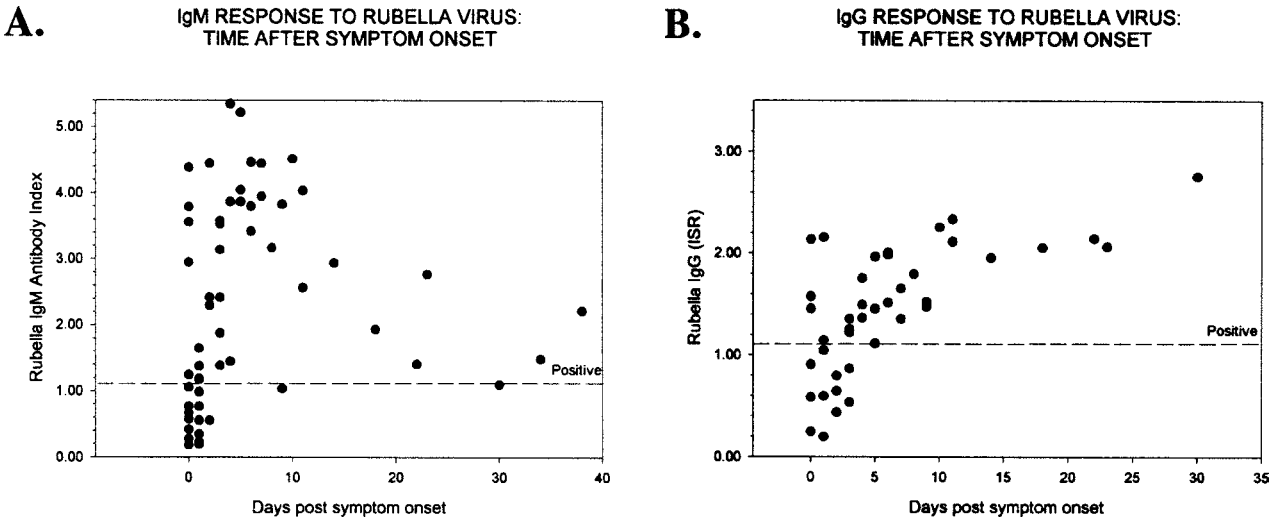

FIGURE 3 Time course of rubella virus-specific IgM and IgG detection by ELISA in sera of rubella patients. Commercial IgM capture ELISA (A) and IgG indirect ELISA (B) were used to detect rubella virus-specific antibodies at the indicated number of days after onset of symptoms (usually rash); antibody index and ISR are the commercial test designations for the ratio of the optical density obtained for the test serum to the optical density obtained for a standard (cutoff) serum. The minimum signal considered positive in each test is indicated by a dashed line. Only results from patients who tested positive for IgM to rubella virus at some time after the onset of symptoms are shown.

Other Serologic Tests

In cases where an IgM serologic diagnosis of recent infection is not reliable (e.g., first serum sample was collected months after clinical symptoms), low avidity of IgG to rubella virus proteins has been used to indicate recent infection (49, 67, 100). This test compares the ability of detergents or chaotropic agents to dissociate case IgG and mature IgG from rubella virus proteins.

Since the clinical symptoms of postnatal rubella and CRS are dramatically different, it is not surprising that there are significant differences in the immune responses of patients with these diseases. In Western blots, samples from CRS patients often have an altered distribution of antibodies to the viral glycoproteins compared to the distribution in samples from postnatal rubella patients (57).

Prenatal Screening

The present description of laboratory testing for rubella emphasizes identification of postnatal and congenital rubella cases. However, in the United States much of the testing is for immunity to rubella, since health care providers should test for immunity by a serum IgG test in all pregnant women at the earliest prenatal visit. There are slightly different criteria for rubella immunity that are recommended by various groups (range is about 10 to 15 IU/ml) (76). Commonly used tests, e.g., ELISA, are standardized to give positive results for 10 IU/ml, the breakpoint defining immunity to rubella in the United States (95). Much of the screening for immunity to rubella virus in the United States is done by automated random-access systems using microparticle immunoassays.

Evaluation, Interpretation, and Reporting of Results

Noncommercial tests must be standardized by the laboratory. Standard operating procedures should be written and followed. All necessary controls should be performed. Laboratories utilizing commercial assays are advised to adopt a quality assurance program that includes both testing with standard sera and data analysis to detect potential changes in assay performance due to defective reagents.

IgM and IgG testing should be done routinely with sera from individual patients, since results from both immunoglobulin classes often provide confirmatory data. For example, a serum sample taken on the day of rash may be negative for both rubella virus-specific IgM and IgG, while one taken 8 days postrash should be positive for both.

There is often a considerable burden on the laboratory in the diagnosis of rubella. For example, when primary rubella virus infection is suspected in a pregnant woman, false positives and false negatives may lead to incorrect clinical decisions (9). However, the laboratorian may be asked to go beyond just communicating false-positivity and false-negativity rates. Testing for recent infection with other viruses that cause clinically similar diseases (e.g., human parvovirus B19) is often prudent. Positive rubella results may be more believable if no other infection is found. Retesting of specimens and testing of multiple specimen types (e.g., serology and viral culture) from the same patient taken at the proper times (Table 2) often give a consistent set of results and reduce the likelihood of false-positive results. False positives can occur even with modern tests such as IgM capture ELISA. For example, in one report, 1 of 87 sera testing positive for rubella virus-specific IgM by IgM capture ELISA was from a patient whose final diagnosis was primary human parvovirus B19 (100). False negatives often can be identified by retesting of the same specimen or testing multiple specimens from a patient (e.g., sera taken 1 week apart). If only a single specimen is available, it may be tested by multiple assays. For example, IgG avidity may resolve the diagnosis from a single serum sample that is IgM positive for both rubella virus and human parvovirus B19 (100).

Postnatal rubella can be clinically similar to other diseases, or it can be asymptomatic. Additionally, birth defects characteristic of CRS occur for other reasons. Thus, correct

classification of suspected postnatal rubella and CRS is based on laboratory results rather than clinical presentation. Classification of a postnatal rubella case results in its categorization as suspected, probable, confirmed, or asymptomatic confirmed; for a case of congenital rubella, categories are suspected CRS, probable CRS, confirmed CRS, or infection only. Positive laboratory results are required to correctly classify asymptomatic confirmed or confirmed cases of postnatal rubella and CRS. Clinical, laboratory, and epidemiological information (e.g., international travel) all may enter into the final clinical decision(s). A full description of classification criteria and recommendations should be consulted (16). One specific diagnostic situation should be noted. A series of tests including a rubella virus IgM test should not be used to determine immunity in a pregnant woman because of the possibility of a falsely IgM-positive test; immunity should be determined by IgG testing alone. Since the TORCH (toxoplasmosis, other, rubella, cytomegalovirus, and herpes simplex virus) panel includes testing for rubella virus IgM, it should not be used to determine immunity.

Enteroviruses and Parechoviruses*

JOSÉ R. ROMERO

89

TAXONOMY

Members of the genus *Enterovirus* currently officially comprise 64 distinct serotypes (49) within the family *Picornaviridae* (with "pico" meaning small, "rna" indicating an RNA genome, and "viridae" signifying viruses). The traditional taxonomic criteria for the identification of enteroviruses (EVs) to the species level were based on the patterns of replication of the individual serotypes in cell cultures and on disease manifestations in animal systems (25, 26).

These original distinctions have been blurred significantly by the identification of new strains and the development of new cell lines, resulting in crossover EV growth patterns. Additionally, molecular methods for EV typing have replaced traditional serologic methods of serotype assignation (92, 96). EV taxonomy was effectively defined through phylogenetic analysis using the complete coding sequence of VP1, the major enteroviral capsid protein (48, 91, 93). This approach demonstrated that several EVs originally accepted as individual serotypes are likely strains of one another (93). Additionally, echoviruses 22 and 23 have been reclassified into a distinct genus, *Parechovirus* (49), since sequence analysis demonstrated that they are genetically distinct from other members of the genus (47), and they are now designated *Human parechovirus 1* (HPeV 1) and HPeV 2, respectively. The International Committee on Taxonomy of Viruses has issued revised species demarcation criteria for the genus *Enterovirus* (49). Based on these criteria, EVs are now classified into five species (poliovirus and human enteroviruses A through D) based on their molecular and biologic characteristics (Table 1).

The genus *Parechovirus* is comprised of three HPeV serotypes (8, 50, 124). HPeV 1 and 2 were originally identified in 1956. It is likely that, as with the EVs, molecular diagnostics will lead to the identification of additional members of the genus.

DESCRIPTION OF THE AGENTS

Similar to other members of the family *Picornaviridae,* the EVs are small (30-nm diameter in the hydrated state), nonenveloped viruses that possess a single-stranded positive (message)-sense RNA genome. Their buoyant density in cesium chloride is 1.30 to 1.34 g/cm^3 (49, 104). The EVs are stable in acid, ether, and chloroform and are insensitive to nonionic detergents. They are inactivated by heat (>56°C), UV light, chlorination, and formaldehyde. The EVs replicate optimally at 36 to 37°C.

The EVs are quite stable in liquid environments and can survive for many weeks in water, body fluids, and sewage. This is due to a number of virion properties, including thermostability in the presence of divalent cations, acid stability, and the absence of a lipid envelope.

The EV RNA genome is ~7.4 kb long (Fig. 1) and serves as a template for both viral protein translation and RNA replication (104). The genome is organized into a long (~740 nucleotides) noncoding region, designated the 5′ nontranslated region (5′NTR), which immediately precedes a single open reading frame (ORF). The ORF begins at approximately nucleotide 740 from the 5′ end and terminates at approximately nucleotide 7370. The ORF is subdivided into three regions, P1 to P3. The P1 region encodes the four structural proteins (VP1 through VP4) that comprise the viral capsid. These are organized 5′ to 3′ as VP4 (1A), VP2 (1B), VP3 (1C), and VP1 (1D). The P2 and P3 regions encode seven nonstructural proteins (organized 5′ to 3′ as 2A, 2B, 2C, 3A, 3B, 3C, and 3D) that are essential for the viral life cycle. The ORF is translated into a single polyprotein that is posttranslationally cleaved into several functional intermediates and the final 11 proteins by virus-encoded proteases. Immediately downstream of the ORF is a short noncoding region of approximately 70 to 100 bases (3′NTR) and a terminal polyadenylated tail.

The EV 5′and 3′ NTRs play critical roles in the EV life cycle (104). The 5′NTR contains multiple regions of predicted higher-order structure (i.e., stem-loops or domains). A domain located at the extreme 5′ terminus of the 5′NTR is essential for replication of viral RNA. Cap-independent translation of the EV genome is regulated by the internal ribosome entry site, which spans a discontinuous region within the 5′NTR. For polioviruses and several nonpolio enteroviruses (NPEVs), the 5′NTR has been documented to be a determinant of virulence phenotype and cell type specificity (9, 31, 77). Given the crucial nature of the functions controlled by the 5′NTR, it is not surprising that nucleotide sequences with absolute (or near absolute) conservation among the EVs exist within this region (110, 113). These regions of high nucleotide identity have been exploited for the design of

* This chapter contains information presented in chapter 93 by José R. Romero and Harley A. Rotbart in the eighth edition of this Manual.

TABLE 1 Human EVs and HPeVs

Human EVs[a]
Poliovirus (3 serotypes)
Human polioviruses 1–3
Human EV A (10 serotypes)
Human coxsackieviruses A2, A3, A5, A7, A8, A10, A12, A14, and A16
Human EV 71
Human EV B (36 serotypes)
Human coxsackieviruses A9 and B1 to B6
Human echoviruses 1–7, 9, 11–21, 24–27, and 29–33
Human EV 69
Human EV C (11 serotypes)
Human coxsackieviruses A1, A11, A13, A15, A17 to A22, and A24
Human EV D (2 serotypes)
Human EV 68 and EV 70
Serotypes not yet assigned to a species (2 serotypes)
Human coxsackieviruses A4 and A6
HPeVs
Human parechoviruses 1–3

[a] Coxsackievirus A23, echoviruses 8, 10, 22, 23, and 28, and EV 72 have been reclassified. New rules for species demarcation issued by the International Committee on Virus Taxonomy require that EV species members possess a genome base composition of guanine and cytosine that varies by no more than 1% and share the following characteristics: (i) >70% amino acid identity in the P1 coding region and 2C plus 3CD proteins, (ii) a limited range of natural hosts and host receptors, and (iii) proteolytic processing, replication, encapsidation, and genetic recombination schemes (83).

primers and probes used for the detection of EVs through nucleic acid amplification techniques (reverse transcription-PCR [RT-PCR] and nucleic acid sequence-based amplification [NASBA]). The 3′NTR has also been demonstrated to play a role in viral RNA replication.

The EV capsid is arranged in 60 repeating protomeric units that confer an icosahedral shape to the virion (104). VP1, VP2, and VP3 comprise the surface of the virion and possess an eight-stranded "beta-barrel" core structure. The external loops that connect the beta strands are responsible for the differences in surface topography and antigenic diversity among the EVs. Neutralization sites, typically three or four per protomer, are most densely clustered on VP1. VP4 is located internally within the capsid and has no surface-exposed regions.

The near-atomic structures of multiple human picornaviruses (104) have been resolved and reveal that the EVs (and rhinoviruses) share a number of conserved structural motifs. Surrounding a conserved protrusion at the fivefold axis of each pentameric unit (i.e., five protomers) is a narrow, deep cleft (25 Å) or canyon. It is into this site that the specific receptors for the EVs bind when the virus encounters a susceptible host cell.

The genomic organization of HPeVs is similar to that of EVs. However, unlike the EVs, HPeVs possess only three capsid proteins, VP0, VP3, and VP1 (124). No crystallographic structural information exists for the HPeVs. Sequence similarities between the HPeVs and other picornaviruses suggest that the major capsid proteins share the typical beta-barrel core structure. Relative to EVs, HPeVs are predicted to have a flatter surface topography (124), with antigenic variance determined by the external loops, as with EVs.

EPIDEMIOLOGY AND TRANSMISSION

The EVs and HPeVs are ubiquitous agents that are found worldwide (21, 124). In regions with temperate climates, the majority of EV infections occur in the summer and fall (21, 125), but it is important to note that EV infections continue to occur during the winter (13, 19). In tropical climes, EV infections occur year-round or with increased incidence during the rainy season (72). HPeV infections also occur in late summer to autumn as well as in winter to early spring (8). A recent report suggested that seasonal differences in incidence may occur among the serotypes (8).

The majority of the EVs were identified between 1948 and 1963 during the course of investigations of cases of paralytic poliomyelitis and other central nervous system (CNS) syndromes (25, 26, 99). Since the introduction of vaccines in the late 1950s and early 1960s, much of the world is now free or virtually free of poliovirus infections (56). The control of poliovirus infections in much of the world has focused attention on the NPEVs (Table 1).

It is estimated that the EVs infect a billion or more individuals worldwide each year (91). In the United States, NPEVs are estimated to cause 30 to 50 million infections each year (91, 93), which result in 10 to 15 million symptomatic NPEV infections annually (17). While several modes of transmission exist for the EVs and HPeVs (fecal-oral, respiratory, transplacental, perinatal, and self-inoculation routes), the major one is the fecal-oral route. For some EV serotypes (i.e., coxsackievirus A21 and EVs 68, 70, and 71), transmission via the respiratory and self-inoculation routes is important. The respiratory route may be an important mode of transmission for the HPeVs (124).

The highest incidence of EV infection is observed in young infants and in children of 5 to 10 years of age (117). Secondary infections are observed in >50% of susceptible household members (79). The incidence of HPeV infection is highest in children of <3 years of age, with the majority of infections occurring in infants of <12 months of age (8, 124).

The rank order of the dominant circulating EV serotypes varies annually (17, 18). The predominant NPEV isolates

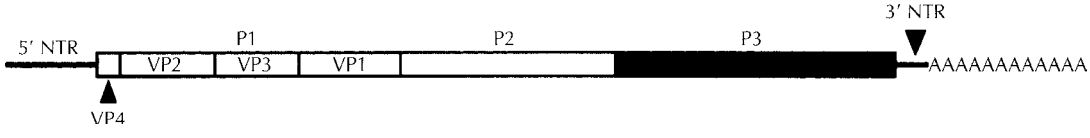

FIGURE 1 Organization of the EV RNA genome. (Reprinted with permission from reference 110.)

identified in the United States from 1997–2001 were echoviruses 30, 18, 13, 11, and 6, coxsackievirus B5, echovirus 9, coxsackievirus B2, coxsackievirus A9, and coxsackieviruses B3, 4, and 1 (listed in descending order). These 12 serotypes represent approximately 83% of all EVs identified during that period. Uncommon serotypes can cause periodic epidemics, such as the emergence of echovirus 13 as a major cause of EV disease (including meningitis) in the United States during the 2001 enteroviral season (83).

CLINICAL SIGNIFICANCE

The EVs are responsible for a wide array of clinical diseases affecting many organ systems. Despite the name "enterovirus," enteric disease is not a prominent manifestation, although diarrhea and vomiting may be significant manifestations of certain outbreaks of "summer flu" due to EVs. Mild hepatitis, almost always in association with other, more significant findings, is common during infection with many EV serotypes. In addition to the actual diseases that they cause, the EVs are of great concern because they mimic other pathogens. Distinguishing EV infections from those due to common bacteria and other viruses on clinical grounds alone is often difficult (36). Hence, unnecessary treatment for other infections is frequently instituted during EV infections.

No disease is uniquely associated with any specific EV serotype, and no serotype is uniquely associated with any one disease (21). This is true even of paralytic poliomyelitis, which has been associated with numerous NPEV serotypes. In most circumstances, it is therefore unnecessary to identify or diagnose the specific disease-producing EV serotype.

The majority of EV infections are asymptomatic (21). The most common symptomatic manifestation of EV infection is an acute nonspecific febrile illness, with or without an exanthem. This so-called viral syndrome is one of the most numerically important causes of fever among children. During the summer and fall, the EVs are responsible for 50 to 60% of hospital admissions for the evaluation of acute, nonfocal febrile illnesses in infants and children (8, 79). When accompanied by upper respiratory symptoms, the "summer cold" is indistinguishable from the same illness caused by rhinoviruses in the fall months.

The paralytic potential of the polioviruses, the prototypic EVs, is well recognized. In the Americas and regions of the world where the polioviruses have been eradicated, the NPEVs and circulating vaccine-derived polioviruses (VDPVs) are now the principal causes of EV-associated acute flaccid paralysis (AFP). Multiple NPEV serotypes are known to cause AFP (21). Recently, cases of AFP associated with VDPVs have been reported from Haiti, Dominican Republic, Madagascar, and China (56). These viruses are circulating strains derived from the vaccine (Sabin) strains of poliovirus.

By far the most vexing clinical EV syndrome that the physician encounters is aseptic meningitis. The EVs are the most common cause of meningitis in the United States and account for over 80% of all viral meningitides (125). The echoviruses and group B coxsackieviruses, particularly echoviruses 4, 6, 9, 11, 16, and 30 and coxsackieviruses B2 and B5, constitute the principal EVs associated with this syndrome (79). An estimated 30,000 to 50,000 hospitalizations for NPEV meningitis occur each year.

Approximately 10 to 20% of viral encephalitides are due to EVs (78). The group A coxsackieviruses are the predominant EV subgroup associated with this syndrome (79). A severe form of brain stem encephalitis, rhombencephalitis, has been associated with EV 71 infections (43). For patients with B-cell immunodeficiencies, a syndrome known as chronic EV meningoencephalitis in agammaglobulinemia has been described (70). The echoviruses, particularly echovirus 11, are the group of EVs most frequently associated with this syndrome.

The group B coxsackieviruses are responsible for one-third to one-half of all cases of acute myocarditis and pericarditis. Group B coxsackieviruses 2 to 5 are the predominant serotypes identified in clinical studies (21). The echoviruses and polioviruses have also been associated with myopericarditis, but significantly less so than group B coxsackieviruses.

Acquisition of EV infection in the perinatal period or within the first 2 weeks of life may result in a severe sepsis-like syndrome with multiorgan involvement in the neonate (1). The morbidity and mortality associated with this syndrome are significant. The echoviruses, particularly serotype 11, and the group B coxsackieviruses are frequently associated with this syndrome.

Although originally described for agammaglobulinemic patients (70), persistent, life-threatening EV infections can also occur in patients with combined variable immunodeficiency, severe combined immunodeficiency, hypogammaglobulinemia, or hyper-immunoglobulin M (hyper-IgM) syndrome and those undergoing bone marrow and solid organ transplantation. Manifestations almost always include meningoencephalitis.

Other acute clinical EV syndromes of significance include hemorrhagic conjunctivitis (predominantly caused by EV 70 and a variant of coxsackievirus A24), hand-foot-and-mouth syndrome (predominantly caused by coxsackievirus A16), herpangina, Bornholm disease, and pleurodynia (the major causes are coxsackieviruses B3 and B5) (21).

Symptomatic infections due to HPeVs are primarily respiratory (i.e., colds or pneumonia) and gastrointestinal (gastroenteritis) in nature (8, 124). However, as with the EVs, cases of neonatal sepsis, AFP, aseptic meningitis, encephalitis, and myocarditis have been reported as a result of HPeV infection.

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

The most commonly used and most clinically significant specimens for nucleic acid amplification-based diagnosis of EV infections are cerebrospinal fluid (CSF) and serum (Table 2). If obtained sterilely, CSF and serum require no additional processing prior to extraction of the EV genome. Residual samples found in clinical laboratory refrigerators may be suitable for nucleic acid amplification-based detection of EVs due to the inherent environmental stability of EVs. Specimens that have been handled on automated chemistry or hematology analyzers should be considered compromised due to the potential for cross-contamination with other specimens.

Specimen processing procedures for nucleic acid amplification methods should preserve viral capsid integrity so that the EV RNA genome is protected from ubiquitous nucleases in body fluids and the environment. Biopsy specimens should be snap frozen or transported to the laboratory in a small amount of sterile isotonic saline solution for immediate processing. A recently developed alternative to immediate freezing for transport of tissue samples may be the use of a high-salt RNA protection buffer (RNALater; QIAGEN, Valencia, Calif.) (127).

Specimen storage at room temperature has been documented to negatively impact RT-PCR detection of EVs (129). No appreciable loss in PCR signal may be seen in unextracted

TABLE 2 Clinical samples suitable for detection of EVs and parechoviruses by nucleic acid detection or viral isolation

Clinical sample	EV detection			Parechovirus detection		
	NAAT[a] only	Isolation only	NAAT and isolation	NAAT only	Isolation only	NAAT and isolation
CSF			X			X
Serum	X			X		
Respiratory tract secretions			X			X
Feces			X			X
Urine		X			X	
Myocardium	X			X		
Pericardial fluid	X			X		
Throat swab			X			X
Rectal swab			X			X

[a] NAAT, nucleic acid amplification test.

specimens kept at 4°C to −20°C for up to a month. However, longer storage at these temperatures can result in a gradual decline of viral nucleic acid copy number that could, in turn, potentially affect detection by RT-PCR or NASBA. Thus, specimens are best stored at −70°C. Freezing and thawing disrupt the viral capsid and should be avoided. Large-volume samples should be divided into aliquots prior to being frozen. Storage of samples in frost-free refrigerators should also be avoided. At no time should a specimen (i.e., CSF) be subjected to boiling.

Certain clinical specimens (Table 2) require processing prior to inoculation of cell cultures (71). Feces (1 ml if liquid and approximately pea-sized samples if solid) are added to viral transport medium (a 4-ml volume is sufficient), vortexed well, and centrifuged (1,000 × *g* 30 min, 4°C). One milliliter of supernatant is removed, added to 2 ml of viral transport medium, and vortexed. Monolayers are inoculated with 0.2 to 0.3 ml of diluted supernatant. Specimens (rectal, nasal, or throat) collected on swabs should be transported in viral transport medium. In the laboratory, the specimen is vortexed and the swab is removed. The specimen is then centrifuged, and cell cultures are inoculated as described for fecal samples. Nasopharyngeal aspirate and wash specimens are centrifuged (2,500 rpm, 15 min, 4°C), and cell cultures are inoculated with 0.2 to 0.3 ml of supernatant. Serum, CSF, and urine need no pretreatment and may be inoculated directly onto cell cultures. Serum and urine can be toxic to monolayers. Cell death can often be prevented by replacing the culture medium within 24 h of inoculation. Acid dissociation of antibody bound to virus may improve detection when attempting to isolate EVs from serum and CSF (71, 73).

NUCLEIC ACID DETECTION

Numerous compelling reasons exist for seeking rapid diagnostic assays, such as nucleic acid detection tests, for the EVs. The time required for isolation and identification of EVs by traditional cell culture is too prolonged to be of clinical utility. Some serotypes, particularly within the coxsackievirus A group (i.e., A1, A19, and A22), fail to grow in cell culture (42, 71, 123, 136), and 25 to 35% of specimens from patients with characteristic clinical findings of EV infections are negative by cell culture (22).

Detection of EV RNAs is best performed with nucleic acid amplification methods. The concentration of EVs in clinical specimens is too low (1 to 10 titratable virions per ml of CSF) for detection through direct hybridization (137). Options for nucleic acid amplification include different permutations of RT-PCR and NASBA. The limited available data suggest that the sensitivities of RT-PCR and NASBA assays may be comparable (14, 64). A growing number of laboratories have adopted the most rapid, least labor-intensive approaches, including one-step real-time RT-PCR using a DNA polymerase that performs RT and PCR.

Specimens must be extracted prior to being tested to dissociate the EV RNA genome from the protein capsid, to eliminate ubiquitous RNases, and to remove potential inhibitors of amplification reactions (38, 86). The most common method reported in the literature for RNA extraction from CSF prior to RT-PCR is the use of a nucleic acid-binding, silica gel-based membrane contained within a spin column (QIAamp Viral RNA mini kit; QIAGEN). The extracted RNA is subsequently eluted from the membrane and used directly for RT. Silica-based extraction has also been used for NASBA (20, 56, 99). Extraction reagents are provided with NASBA kits (NucliSens basic kit; Biomerieux, Durham, N.C.). Many laboratories are now replacing manual nucleic acid extraction with automated methods. EV RNA detection protocols that include robotic extraction (BioRobot M48 [QIAGEN] and MagNA Pure LC [Roche Diagnostic Systems, Indianapolis, Ind.]) of CSF, respiratory, and enteric specimens have been published (66, 103).

The design of nucleic acid amplification assays for EV detection in clinical specimens should optimally include internal controls to detect amplification inhibitors. Ideally, these controls are added to specimens prior to extraction to assess whether extraction has removed endogenous inhibitors. Internal control strategies have been reported for RT-PCR (5, 81) (Armored RNA; Asuragen Diagnostics, Austin, Tex.) and NASBA (14, 16, 33, 65, 66) methods.

EV RNA assay verification experiments and quality assurance protocols demand the use of standards. Unfortunately, no universal or nominal EV standard preparations exist. In place of such standards, most laboratories utilize propagated EV strains that have been quantified by plaque assay.

Conventional RT-PCR

The most significant development in rapid direct detection of the EVs and HPeVs has been the application of PCR (8, 27, 50, 52, 53, 67, 110, 113). The following three general

strategies have been employed: universal detection of all EV serotypes, species-specific detection of a limited number of serotypes, and serotype-specific or strain-specific detection within a single serotype. Universal and species-specific detection methods are clinically useful. Strain- or serotype-specific PCR is of use mainly for molecular epidemiology, phylogeny, and molecular virulence studies (10).

The development of PCR technology and its subsequent adaptation for detection of the RNA genomes of EVs via RT-PCR (20, 46, 114) have provided a sensitive, specific, rapid, versatile, and clinically useful (105, 109, 110) method for the detection of EVs. The wide array of reported conditions for EV PCR extraction, RT, amplification, and detection have been reviewed (110, 113). The assay requires only a small sample size, generally 100 to 200 μl of fluid or 1 mg of tissue.

RT-PCR for EV detection can detect as few as 1 to 100 molecules of EV genome, 0.001 to 1 PFU, or 0.003 to 0.1 50% tissue culture infective dose (110, 113). The robustness of RT-PCR assays in the clinical setting may be significantly lower. For CSF, the sensitivity and specificity of RT-PCR compared to those of the traditional "gold standard," cell culture, range from 86 to 100% and 92 to 100%, respectively (97, 110, 114, 122). Other studies have found RT-PCR with CSF to be more sensitive than cell culture (15, 36, 38, 63, 101, 110, 115, 118, 122, 132). For agammaglobulinemic patients with meningoencephalitis or encephalopathy, EVs have been detected in CSF by RT-PCR but not by cell culture (119, 135). A limited number of studies have evaluated the sensitivity and specificity of RT-PCR with other sample types. For serum, the sensitivity and specificity of RT-PCR range from 81 to 92% and 98 to 100%, respectively (2, 118). Urine appears to be the poorest sample source for RT-PCR (2, 87, 119). This may be due to the presence of an unidentified inhibitor(s) (86).

No cross-amplification has been found with 41 different nonrelated viruses, bacteria, fungi, and yeast species tested (110). However, certain primer pairings can result in the amplification of a limited number of rhinoviruses (14, 55, 63) due to shared 5′NTR sequences. Cross-amplification should be of minor importance in specimens where rhinoviruses should not be found, such as CSF, serum, or non-respiratory-tract tissues.

Reagents for EV RNA amplification by conventional PCR are available commercially (Enterovirus Consensus kit; Argene Biosoft, Varilhes, France) but are not approved by the U.S. Food and Drug Administration (FDA). Most laboratories develop and verify assays in-house, using published primers and probes. Conserved sequences within the 5′NTR and VP2 have been exploited to design primers and probes capable of nearly universal amplification of the EVs (20, 35, 46, 97, 115) (Fig. 2). Compared to homologous regions of the sequenced EVs, these primers and probes exhibit homologies to their target regions that ranged from 81 to 100% (110, 113). The two 5′NTR targets most frequently used are those reported by Rotbart et al. and Chapman et al. (20, 118, 120). Primers and probes targeting the highly conserved nucleotide regions 444 to 468, 542 to 560, and 577 to 596 of the EV 5′NTR (numeration relative to the poliovirus type 1 genome) (118, 120) are pan-reactive with the EVs (39, 55, 110, 141). While these primers do not detect the parechoviruses (discussed below), it is important that they do amplify the genomes of several rhinoviruses (14, 52, 63). The latter may be of importance only in the testing of throat and nasopharyngeal specimens because the rhinoviruses are not causes of CNS or systemic disease.

RT is accomplished by using oligonucleotide primers (either random hexamers or sequence-specific oligonucleotides) and one of several reverse transcriptases, such as that of avian myeloblastosis virus or Moloney murine leukemia virus (121). The former enzyme is available in its native form or as a genetically engineered version that exhibits greater thermostability (62). Theoretical and practical advantages exist in favor of the use of each reverse transcriptase (113). The cDNA is amplified by using a set of sequence-specific oligonucleotide primers and a thermostable DNA polymerase. The most commonly used thermostable DNA polymerase for PCR of the EVs is that of *Thermus aquaticus, Taq* polymerase. Other thermostable DNA polymerases, such as Vent polymerase (from *Thermococcus litoralis*) and *Tfl* polymerase (from *Thermus flavus*), have also been used (110).

RT and amplification can be performed with a single thermostable DNA polymerase, *Tth* polymerase (from *Thermus thermophilus*), with inherent reverse transcriptase activity that is enhanced in the presence of manganese (84, 120). The thermal stability of *Tth* polymerase permits the RT reaction to be carried out at higher temperatures. This single-tube RT-PCR approach offers a number of potential advantages, including decreased risk of cross-contamination, increased efficiency of RT due to greater destabilization of 5′NTR secondary structures at high temperatures (12, 62), and improved specificity of the primer-template interaction at high temperatures.

Amplicons can be detected by a number of methods (110). While agarose gel electrophoresis detection can be used, it does not verify amplicon authenticity. The use of seminested or nested primers to verify the authenticity of the amplicon has been reported. The internal PCR product can be detected by using agarose gel electrophoresis. Nucleic acid hybridization of the amplicon to a biotin-, digoxigenin-, or radioactively labeled probe targeted to conserved sequences internal to those of the amplification primers is a better approach since it is more sensitive and less prone to contamination than nested

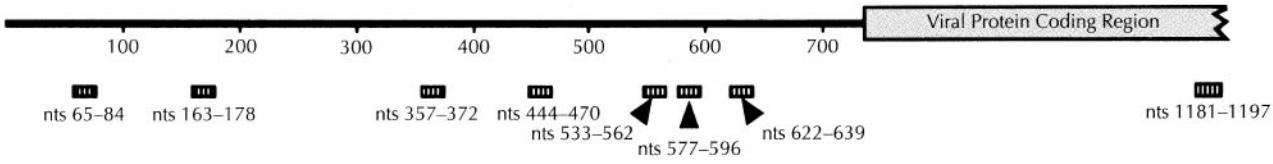

FIGURE 2 Relative locations of originally described primers and probes for detection of EVs. The diagram is a linear representation of the enterovirus 5′NTR and a portion of the viral protein coding region. Primers and probes are designated as hatched boxes below the genome. Numbering corresponds to the nucleotides in the poliovirus type 1 genome. (Reprinted with permission from reference 110.)

methods. Hybridization may be accomplished through slot- or dot-blot, Southern blot, or liquid-phase techniques. Colorimetric detection using biotinylated probes has been described previously (71). Two commercial tests have used this approach; one is no longer on the market (Amplicor EV; Roche Diagnostics, Branchburg, N.J.), but the other is still available (Enterovirus Consensus kit; Argene Biosoft) (64).

Multicenter proficiency testing programs for EV RT-PCR assays developed in-house indicated that properly designed tests can be equally effective in the detection of EV, regardless of the format used (68, 82). However, other studies have reported marked center-to-center variation in testing proficiencies. In one survey, one-third of participating laboratories were nonproficient in the detection of EV by RT-PCR (129). In another report, 6.8% of participating laboratories recorded false-positive results, pointing to the need for fastidious attention to methods for the prevention of cross-contamination (82). Overall, these findings underscore the importance of rigorous internal quality control standards and periodic proficiency reassessment to ensure uniformly high-quality testing.

Although only a small number of reports detailing the detection of HPeVs by RT-PCR have been published (8, 50, 52, 53, 67), these assays parallel EV RT-PCR assays in terms of sensitivity (52, 67). All reported assays have used primer pairs targeted to the HPeV 5′NTR in combination with amplification and detection methodologies similar to those for EV detection systems. In one report, a multiple RT-PCR assay was developed to detect EVs, HPeVs, and rhinoviruses from clinical specimens (52).

Real-Time RT-PCR

Sufficient information has accumulated to begin to assess the utility and pitfalls of real-time RT-PCR for EVs (3, 27, 52, 63, 80, 81, 87, 103, 130, 131, 134) and HPeVs (27). As with conventional PCR, careful optimization, including primer/probe design and amplification conditions, is required prior to assay implementation. However, well-designed assays appear to be at least as sensitive as traditional in-house assays (3, 27, 54, 63, 80, 87).

The major advantages of real-time RT-PCR compared to conventional PCR are decreased labor and a decreased time to result. These savings are due in part to simultaneous target amplification and amplicon detection. Additionally, the thermal conduction characteristics of real-time PCR vessels allow for rapid temperature transmission and permit ultrashort cycling times, further reducing the time to detection. Almost all reports of the clinical application of real-time RT-PCR for EV detection indicate that the assay can be completed in 4 h or less, including the time required for viral RNA extraction (3, 27, 54, 63, 80, 81, 87, 103, 130, 134).

Single-tube protocols, in which RT and subsequent cDNA amplification are carried out in a single reaction vessel, may be less sensitive and more variable (27, 54, 63, 134) than protocols where RT is initially performed in a separate tube prior to amplification. Several methods to increase the sensitivity of *rTth* polymerase- or Moloney murine leukemia virus polymerase-based assays have been employed, including incorporation of the T4 phage gene 32 protein (3, 27, 81). This phage-derived helicase may help to destabilize RNA secondary structures that are prevalent within the EV 5′NTR. Other approaches have included increasing the concentrations of the *rTth* polymerase and manganese (80) and using a second real-time amplification reaction to detect the product (103, 134) in a seminested manner.

Amplicons have been detected using either nonspecific DNA-binding fluorophores, such as SYBR green, or specific fluorophore-labeled oligonucleotide probes that exploit fluorescent resonance energy transfer (FRET) technology (69). SYBR green binds to the minor groove of DNA, and this association increases its fluorescence intensity. The intensity of the fluorescent signal increases further as amplicons are generated. Assays that employ melting-curve analysis of PCR products to verify amplicon authenticity (3) are preferable to tests that employ fluorescence intensity measurement alone (54).

FRET is the most commonly used detection method in real-time RT-PCR assays (3, 27, 54, 63, 80, 81, 87, 103, 130, 134). The biochemistry of FRET probes is reviewed in chapter 16. One major advantage of these dually labeled probes is the capability to simultaneously detect amplicons and confirm their identity. This approach has been used successfully to discriminate between amplicons generated from EVs and rhinoviruses (54) when using primers that target sequences common to both picornavirus genera (55) or from EVs and HPeVs in a duplex assay (27).

There are currently no FDA-approved real-time RT-PCR assays for EV detection. Components can be obtained commercially as analyte-specific reagents (Cepheid, Sunnyvale, Calif.; Chemicon Light Diagnostics, Temecula, Calif.; QIAGEN). Detection kits are also available in research-use-only formats (Nanogen, San Diego, Calif.).

NASBA

The biochemistry of NASBA assays is reviewed in chapter 16. NASBA assays are reported to detect 10 to 100 RNA copies/reaction (14, 32, 33, 40). Like RT-PCR, NASBA assays are significantly more sensitive than cell culture for the detection of EVs in clinical specimens (33, 65). A real-time NASBA assay utilizing molecular beacons (reviewed in chapter 16) as detection probes has been reported to have a similar clinical sensitivity to that of conventional NASBA (66). The advantages of this method are a decreased time to result and ease of use. Conventional and real-time NASBA reagents are commercially available as analyte-specific reagents (NucliSens Basic reagents and EasyQ Enterovirus reagents, respectively; Biomerieux), but primers and probes are supplied by the user. One advantage of commercial NASBA assays is the provision of internal controls. However, one problem with these assays has been the frequency of invalid results as a result of reaction inhibition (14, 33, 65). This appears to occur more frequently with the use of stool, rectal, throat, and nasopharyngeal samples than with CSF (14, 64, 65). In one report, CSF specimens that yielded indeterminate NASBA results were all significantly contaminated with blood (33).

ISOLATION PROCEDURES

Reported mean isolation times for EVs from CSF using traditional cell culture techniques range from 3.7 to 8.2 days (116); EVs from other sites, where viral titers are higher, often grow more rapidly (1 to 3 days) (41, 76, 137). Infections of susceptible cell monolayers with EVs and HPeVs result in a characteristic cytopathic effect (CPE) consisting of shrinkage and rounding of individual cells within the monolayer. The nuclei of infected cells exhibit pyknosis. As infection progresses, the cells degenerate and separate from the surface of the plate.

The general susceptibilities of commonly used cell lines for the EVs are summarized in Table 3. No single cell line is optimal for the replication of all EV serotypes. Monkey kidney cell lines have good sensitivities for the polioviruses, group B coxsackieviruses, and echoviruses, whereas human diploid fibroblasts, such as MRC-5 cells, WI-38 cells, and human embryonic lung fibroblasts (HELF), give higher yields

TABLE 3 Susceptibilities of cell lines commonly used for isolation of EVs[a]

Cell line	Susceptibility to virus			
	Polioviruses	Coxsackieviruses		Echoviruses
		Type A[b]	Type B	
Monkey kidney				
Rhesus	+++	+	+++	+++
Cynomolgus	++++	+	+++	+++
Buffalo green (BGM)	+++	+	++++	++
Human				
HeLa	+++	+	+++	+
Kidney (HK)	+++	+	++	+++
WI-38	++	++	+	+++
Embryonic lung (HELF)	+++	++	+	+++
MRC-5	+++	+	+	+++
Rhabdomyosarcoma (RD)	+++	+++	+	+++
HEp-2	+++	+	+++	+
A549	+++	+	+++	+++
NCI-H292	+++	+++	+++	+++

[a] Relative susceptibilities: +, minimally susceptible; ++++, maximally susceptible. Some EVs are difficult to isolate even on minimally susceptible cell lines.
[b] Some type A coxsackieviruses are not readily isolated (A1, A19, and A20).

for type A coxsackieviruses. Most laboratories that still perform culture for EV detection therefore use a combination of a primary monkey kidney cell line, such as cynomolgus monkey kidney cells, and a human diploid fibroblast line. The yield and speed of EV recovery can be improved with the addition of Buffalo green monkey kidney (BGMK) and rhabdomyosarcoma-derived RD cells (22, 23, 28). Recently, it was shown that in addition to BGMK cells, the cell line A549 is suitable for detection of the group B coxsackieviruses (98). RD cells are the most sensitive for detection of group A coxsackieviruses but fail with most type B coxsackieviruses, and successful isolation frequently requires blind passaging. Some type A coxsackieviruses (A1, A19, and A20) cannot be isolated in cell cultures. If enough cell lines are used, the pattern of growth in each by a single EV isolate may accurately predict the subclassification of the isolate (42, 51), although the clinical value of this information is limited.

A variety of nontraditional cell lines are also useful for EV isolation. Human colon adenocarcinoma-derived CaCo-2 cells can be used to isolate a range of EVs (106). BGMK cells genetically engineered to express the human group B coxsackievirus receptor (the complement regulatory protein decay accelerating factor) exhibit an expanded range of EV permissiveness (11, 45). The genetically engineered mouse cell line L20B, which carries the human poliovirus receptor, selectively supports the replication of polioviruses over that of NPEVs (85, 138).

Shell vial culture (SVC) combined with the use of monoclonal antibodies for virus detection in the absence of CPE reportedly reduces the time to detection to 2 to 3 days but appears to be less sensitive than traditional cell culture (60, 128). SVC using a mixture of cell lines in a single vial has shown promise. A mix of decay accelerating factor-expressing BGMK cells and A549 cells (Super E-Mix, Diagnostic Hybrids Incorporated, Athens, Ohio) was more sensitive than conventional culture but less sensitive than RT-PCR (11). The use of two shell vials containing mixtures of NCI-H292, BGMK, A549, and RD cells may achieve optimum sensitivity for EV detection (44). The greatest limitation of SVC may be the shortcomings of the monoclonal antibodies used in virus detection steps (discussed below).

Although no comparison studies have been carried out to determine the optimum cell line for isolation of HPeVs, they have been reported to grow on tertiary monkey kidney cells, embryonic lung cells, African green monkey kidney (Vero) cells, and A549 cells (9, 124).

SPECIFIC IDENTIFICATION OF EV ISOLATES

Determination of the specific serotypes of infecting EVs is often unnecessary because the diseases caused by the EVs are not serotype specific. In most circumstances, therefore, it is adequate and useful for the diagnostic laboratory to report the presence of an EV without further detail. Until recently (24), the most common exception to this principle was in pediatrics, where distinguishing between vaccine strain polioviruses and NPEVs is critical to the interpretation of viral culture results. Until 2000, children in the United States were repeatedly immunized with the trivalent oral polio vaccine (Sabin strains) during the first 2 years of life. This practice continues in many parts of the world. Like all EVs, the Sabin poliovirus strains may be shed from the throat for 1 to 2 weeks and in the feces for several weeks to months. Hence, isolates from those two sites must be identified as either nonpolio or polio serotypes. Vaccine poliovirus has only rarely been recovered from CSF or blood (37, 73); further characterization of EV isolates from these sites is thus less important.

Distinguishing between polioviruses and NPEVs can be accomplished by using traditional or molecular methodologies. The traditional method employs neutralization of the isolate with a pool of antisera directed against the three poliovirus serotypes (42). Successful inhibition of growth by the antisera confirms the poliovirus identity of the isolate, whereas failure to neutralize an isolate with typical CPE implies the presence of an NPEV.

Various molecular methods have been described for specific identification of the polioviruses, including PCR-restriction fragment length polymorphism analysis (4), probe hybridization

(29), and diagnostic PCR assays (57, 58, 59). Species-specific identification of the three poliovirus serotypes can be accomplished by testing a culture-passaged isolate with a set of degenerate pan-poliovirus oligonucleotide primers targeted to the VP1 coding region (59). These primers identify all poliovirus strains (wild-type and vaccine strains, i.e., Sabin strains) and accurately discriminate polioviruses from NPEVs. Serotype-specific identification of poliovirus isolates is possible by using degenerate oligonucleotide primers targeted to VP1 sequences that are conserved within but not across poliovirus serotypes (58). Most recently, the need to differentiate recombinant VDPV isolates from wild-type and vaccine poliovirus strains has been met by the use of a multiplex PCR assay that uses six Sabin strain-specific primer pairs targeted to the 2C and 3D viral coding regions (57).

Further identification of an NPEV's specific serotype is useful under certain circumstances. Epidemiologic studies of patterns of EV infections require knowledge of specific serotypes, as do descriptions of unusual or novel clinical manifestations, such as flaccid paralysis due to NPEVs (15, 16, 62) or, recently, echovirus 13 (83). While the criterion standard for EV serotype determination has traditionally been the use of the Lim and Benyesh-Melnick (LBM) pools of antisera (74, 75, 76), several limitations exist with this methodology. The pools identify only 40 of the 64 originally described EV serotypes and fail to identify newly identified EVs (88, 94, 95). Because the LBM pools were developed over 30 years ago, genetic drift of the EVs over time has given rise to antigenic variants of the prototypic strains, which may be difficult to conclusively serotype. The procedure is labor-intensive and time-consuming, and the supply of LBM pools available from the World Health Organization is limited (distribution is restricted to reference laboratories).

The confluence of nucleic acid amplification technology and bioinformatics has resulted in a novel and powerful method for "molecular serotyping" (93) of the NPEVs (96, 99) and HPeVs (8, 124). This approach is based on the use of sets of degenerate primers targeted to sequences within the VP3, VP1, and 2A coding regions of the NPEVs. The primers permit the amplification of approximately one-half of the upstream portion of the VP1 coding region. The amplicons generated are rapidly sequenced by using PCR and computationally compared to a VP1 sequence database for known EVs (93). The method greatly reduces the time required for identification of the EV from weeks to days (92). Furthermore, it has been extremely useful in typing isolates previously classified as "nontypeable" EVs because they failed to be neutralized by the traditional LBM pools (91). Lastly, this approach has led to the identification of multiple new EV serotypes (88, 89, 94, 95, 96) and a novel HPeV (50). Serotype-specific primers have been developed for other NPEVs (10).

Broadly reactive and serotype-specific EV monoclonal antibodies have been developed (71) and applied to cell culture confirmation by immunofluorescence. While preliminary studies suggested that these reagents, used singly and in blends (DAKO-Enterovirus 5-D8/1 [DAKO, Glostrup, Denmark] and Pan-Enterovirus blend [Chemicon International, Inc., Temecula, Calif.]), might find an important role in serotype identification, further studies have identified several limitations (60, 108, 128). Most notable is the lack of sensitivity and reported cross-reactivity with the rhinoviruses (60). The concordance of results for identification of clinical EV isolates to the species level by using monoclonal blends versus the neutralization assay has demonstrated the latter to be significantly superior for identification of EVs (108). Multiple studies have documented the lack of reactivity of monoclonal blends in detecting EV 71 (128). These studies appear to indicate that monoclonal antibodies for EV identification should best be used as a preliminary screen for species or serotype identification.

SEROLOGIC DIAGNOSIS

Homotypic enzyme-linked immunosorbent assays for the detection of EV serotype-specific immunoglobulin M (IgM) antibodies (i.e., coxsackievirus B-specific IgM and EV 71-specific IgM) as well as heterotypic assays for the detection of IgA, IgM, and IgG antibodies against EVs in general have been reported (6, 7, 28, 32, 101, 125, 132). Homotypic assays are generally impractical unless there is suspicion of a specific EV serotype. The IgM response to EVs may be nonspecific and may lead to a false-positive result and lack of sensitivity (102, 106, 133). Cross-reactivity with non-EV pathogens has not been studied thoroughly. In one report, sera from patients infected with acute hepatitis A virus (a member of the *Picornavirus* family) produced a significant number of false-positive results in an enzyme-linked immunosorbent assay for detection of enterovirus IgM antibodies (7). Because of the inherent difficulties associated with assays for the detection of EV serotype-specific IgM antibodies, these tend to remain in the realm of epidemiologic investigation.

ANTIVIRAL SUSCEPTIBILITY TESTING

There is no FDA-approved antiviral agent available for the treatment of EV or HPeV infections. A promising investigational drug, pleconaril, has undergone extensive in vitro susceptibility testing against EVs but is unavailable in the United States (111). A well-characterized 96-well cell culture protection assay to test the effectiveness of potential antiviral compounds has been reported (100). Briefly, cells in 96-well plates are infected with the EVs of interest, and a serially diluted test compound mixed with medium is added to each well and incubated for 3 days. The monolayers are then examined optically or manually. The 50% inhibitory concentration of the compound being studied is defined as the concentration that protects 50% of the cell monolayer from virus-induced CPE.

EVALUATION AND INTERPRETATION OF RESULTS

An understanding of the sites where asymptomatic shedding and disease-inducing replication occur is critical to the interpretation of EV assays. Detection of EV in the CNS, bloodstream, lower respiratory tract, and genitourinary tract implies a true invasive infection and a high likelihood of association with current illness. In contrast, EVs can be shed asymptomatically from the nasopharynx and the gastrointestinal tract for weeks to months. Detection of EVs by virus isolation or RT-PCR at these sites must be interpreted cautiously, because their presence alone does not establish a diagnosis. EV in the feces or nasopharynx of a patient with meningitis may represent residual shedding from an infection from weeks before and may have nothing to do with the current illness.

An additional factor potentially complicating the evaluation of results from these body sites in young children is the administration of live attenuated oral poliovirus in the first years of life. While this vaccine is no longer used in the United States (24), the majority of countries worldwide, including some in Europe, still employ oral poliovirus as part of their vaccination regimens. Reporting an EV isolate in a setting where oral poliovirus is used without specifying if it is

a poliovirus or NPEV can lead the physician to wrongly discontinue antibiotics or antiherpes therapy in the belief that an EV etiology has been established. The distinction between polioviruses and NPEVs from the CNS, bloodstream, lower respiratory tract, and genitourinary tract is less important, since vaccine strains of poliovirus have rarely been isolated from such specimens and, in those rare instances, may actually be causing the illness in question (37, 73).

A further cautionary note is warranted with regard to infections with dual agents. Rare reports of coinfections of the CSF by bacteria and EVs have appeared (139). In such cases, the bacterium-associated clinical sequelae dominated, i.e., the patients were clinically suspected of having bacterial meningitis and the virus was isolated incidentally. The patients were sick enough that identification of a virus before identification of the bacterium would have been unlikely to dissuade the clinician from continued use of antibiotics. In the much more common situation where the clinical presentation is typical of viral meningitis, coinfection with a clinically "silent" bacterium would be extraordinarily unlikely. Hence, identification of an EV from a nonpermissive site in a patient with a clinically compatible illness is sufficient evidence for establishing EV causality.

Rhinoviruses

MARIE LOUISE LANDRY

90

TAXONOMY

Human rhinoviruses (HRV) constitute a genus of the *Picornaviridae* family, which includes three additional genera that are pathogenic for humans: *Enterovirus, Parechovirus,* and *Hepatovirus*. The rhinovirus genus derives its name from the predominant site of its replication and symptomatology, the nose.

At present, more than 100 rhinovirus serotypes have been characterized on the basis of neutralization tests. While some cross-neutralization occurs, there is no group antigen (46, 49). Based on receptor binding, rhinoviruses can be divided into two groups (76, 78). Intercellular adhesion molecule 1 (ICAM-1) is the cell receptor for the major group, comprising approximately 90% of known HRV serotypes. ICAM-1 is a member of the immunoglobulin supergene family and may be expressed on the surface of many different cells, including those that are active in respiratory immune responses (64, 82). The natural ligand for ICAM-1 is lymphocyte function-associated antigen (LFA-1), and since the binding sites for LFA-1 and rhinovirus overlap, rhinovirus may block ICAM-1/ LFA-1 binding on leukocytes and disrupt local airway immune responses. It has been postulated that this may be a factor in the pathogenesis of secondary viral or bacterial respiratory tract infections (24). The minor group of serotypes binds to members of the low-density lipoprotein receptor family (36). Originally comprised of 10 serotypes, the minor group now includes two additional serotypes previously classified in the major group (78). Rhinovirus type 87 (HRV 87) does not fit either receptor group and is now considered to be an acid-sensitive strain of enterovirus type 68 (8, 76).

Based on antiviral susceptibility, rhinoviruses have been divided into two groups, A and B, which do not coincide with receptor groups. Serotypes within each group share sequence homologies for VP1 and antiviral binding site (2). Phylogenetic analysis, based on sequencing of capsid protein genes VP4/VP2 and VP1, also supports dividing the genus into two major species, A and B (49). Again, HRV 87 does not fit this subdivision but belongs instead to human enterovirus species D (8). As more is learned about the molecular genetics of HRV, further revisions in classification and taxonomy are anticipated in the future (65).

DESCRIPTION OF THE AGENT

The rhinovirus virion consists of a nonenveloped icosahedral nucleocapsid, 20 to 27 nm in diameter, with 60 protomeric units consisting of four protein subunits: VP1, VP2, VP3, and VP4. These structural polypeptides are obtained by posttranslational cleavage of a large polypeptide precursor (14). The 3C protease that participates in cleavage of this polypeptide is a target for antiviral drugs (52). VP1, VP2, and VP3 reside on the exterior of the virus and make up its protein coat. Located within VP1 is a hydrophobic pocket into which antiviral compounds such as pleconaril bind (85). VP4 resides inside the protein shell. X-ray crystallography and cryoelectron microscopy studies have identified large depressions or "canyons" on each of the 60 protomeric units, which appear to be sites for cell receptor binding and also play a critical role in conformation changes that follow attachment (84). Conformational changes in the canyon floor can also be induced by certain antiviral agents, thus inhibiting virus attachment to cells or virus uncoating.

The HRV genome is single-stranded, plus-strand RNA, approximately 7,200 nucleotides in length, with a single open reading frame, and coupled at the 5′-noncoding region (5′-NCR) with a short peptide (VPg). Rhinovirus replicates in the cytoplasm of infected cells, producing infectious virions that sediment at a buoyant density of 1.40 g/l in cesium chloride. Empty capsids and particles lacking one or more structural polypeptides are also produced.

As they have no lipid envelope, rhinoviruses are fairly resistant to inactivation by organic solvents such as ether, chloroform, ethanol, and 5% phenol. Although rhinoviruses are relatively thermostable, heating at 50 to 56°C progressively decreases infectivity. Rhinoviruses are traditionally differentiated from enteroviruses by their loss of infectivity upon exposure to pH 3 for 3 h at room temperature, although this may not be the case with all serotypes and strains (65).

EPIDEMIOLOGY AND TRANSMISSION

In temperate zones, rhinovirus infections occur year-round, with a peak in September and a second peak in late spring. Seasonal fluctuations relate in part to improved survival of rhinoviruses under conditions of high relative indoor

humidity and herding of children together when school opens in the fall (53). Prevalent serotypes can change from year to year, with multiple types circulating in a given area at any time, and epidemic strains can also persist over consecutive seasons. Although the molecular epidemiology of HRV strains is still in its infancy, it appears that genetic variability is common, due to error-prone replication (65).

Studies with volunteers have shown that inoculation of virus into the nose or conjunctivae is the most efficient way to initiate infection (19). Rhinovirus is present in highest titers in the nose of infected persons and commonly contaminates their hands. Consequently, investigators have found that rhinovirus can be transmitted via hand-to-hand contact (27) or by contaminated fomites, followed by self-inoculation of virus into the nose or conjunctivae (3, 28). Furthermore, transmission can be interrupted by using tissues impregnated with virucidal agents for nose blowing, by treating surfaces with disinfectant, or by applying iodine to the fingers (35). Studies with volunteers have also shown that, with very prolonged exposure times, rhinovirus transmission can occur by the aerosol route (18).

Rhinoviruses replicate primarily in the ciliated epithelial cells in the nose, and the incubation period after inoculation is 2 to 3 days. The peak of virus shedding coincides with acute rhinitis. Virus may become undetectable by culture at 4 or 5 days or may be present in low titers for up to 2 to 3 weeks. Symptoms persist for 7 days on average and include profuse watery discharge, nasal congestion, sneezing, headache, mild sore throat, cough, and little or no fever. Rhinovirus causes minimal pathology in the nasal epithelium, and the symptoms of rhinovirus infection parallel the rise and fall of chemical mediators of inflammation (28, 34, 43, 57). Psychological stress appears to increase susceptibility and the development of clinical symptoms (13), whereas exposure to a cold environment does not (21). Immunity is type specific and correlates best with local production of immunoglobulin A (IgA) (5, 10).

CLINICAL SIGNIFICANCE

The rhinoviruses cause approximately two-thirds of the cases of the common cold and thus are responsible for more episodes of human illness than any other infectious agent (34). Although a trivial illness, the common cold is acutely disabling, and its cost in days lost from work, cold remedies, and analgesics is in the billions of dollars. In recent years, HRV has been increasingly implicated as the major viral cause of asthma exacerbations and decompensation of chronic lung disease (25, 81). Severe asthma exacerbations have been linked to prolonged shedding of rhinovirus RNA (42). Consequently, the pathogenesis of rhinovirus infection is currently the subject of intense study (38, 43, 57, 61, 69, 80, 86). In addition, rhinovirus infection appears to have a more important role in sinusitis and otitis media than has been previously thought (56, 62, 73).

Since rhinovirus has long been considered an upper respiratory pathogen of minor clinical consequence, most diagnostic laboratories do not use optimal conditions for its recovery. With use of more-sensitive molecular diagnostic methods, rhinovirus has been increasingly recognized as an important etiology of lower respiratory tract infections (22, 33, 59, 60), especially in the very young (40, 44, 57), school-age children (40, 72), the elderly (51, 55, 71), and in those with chronic illnesses (22), cancer, immunosuppressive illnesses, or transplants (11, 45, 63, 77), or underlying pulmonary disease (47, 81). In fact, the clinical manifestations of rhinovirus infection in hospitalized infants are similar to those caused by respiratory syncytial virus (RSV). However, the mean age of infants affected by HRV tends to be slightly older (44). Although rhinovirus viremia has rarely been found by culture, rhinovirus RNA was recently detected, using sensitive molecular methods, in the blood of 11.4% of HRV-infected young children, including 25% of those with HRV-associated asthma exacerbations (83).

While many antivirals show activity against rhinoviruses in the laboratory, inadequate drug delivery to the site of infection has reduced clinical benefit for patients and treatment remains experimental. Studies have included intranasal administration of soluble ICAM-1 to rhinovirus-infected volunteers, use of intranasal ipratropium bromide, an anticholinergic agent, intranasal imiquimod, or administration of antivirals and anti-mediators in combination (12, 28, 30, 74, 75, 85). A picornavirus capsid binding agent, pleconaril, has shown some benefit against natural colds in clinical trials (31). Recently, inhibitors of rhinovirus 3C protease have shown potent antiviral activity and are undergoing clinical trials (32, 52). The usefulness of these approaches requires further study and validation. Due to numerous HRV types, prospects for a vaccine in the near future are negligible.

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

In natural infections, rhinovirus can generally be isolated from 1 day before to 6 days after onset of cold symptoms, but it is shed in highest concentration on day 1 or 2 of illness. Of note, with sensitive molecular methods, rhinovirus can be detected for several weeks after infection. Since rhinovirus is excreted in highest titers from the nose, nasal rather than throat specimens should be obtained for virus isolation. Likewise, sputum is a low-yield specimen for the isolation of rhinovirus. Comparisons of nasal wash, nose swab, throat gargle, and throat swab specimens for the isolation of rhinovirus from clinical specimens revealed nasal wash to be the best (1, 4, 10). Nasal wash specimens are obtained as follows. Tilt the patient's head backwards and instill 1 ml of sterile phosphate-buffered saline into one of the nostrils. Then, ask the patient to lean forward and allow the washing to drip into a sterile petri dish or other collection container. Repeat with the other nostril until each nostril has been washed with 5 ml of phosphate-buffered saline. The washings are then transferred into a sterile container with an equal volume of viral transport media (VTM) containing antibiotics. The inclusion of phenol red in the VTM allows the detection of acid pH, which would adversely affect the isolation of rhinovirus.

If a nasal wash cannot be performed, a nasopharyngeal aspirate is preferred, or a deep nasal or nasopharyngeal swab and a throat swab should be collected and combined (10, 34). Of note, a nasal swab or throat swab yields only half the number of positives detected by a nasal wash or aspirate method (10). The swabs are then immersed in a vial containing 2 ml of VTM. An endotracheal aspirate, bronchoalveolar lavage, or bronchial wash specimen should be collected to diagnose lower respiratory tract disease.

Specimens should be transported promptly to the laboratory. Best results are obtained with rapid inoculation of cell cultures; however, specimens can be held up to 24 h at 4°C in VTM with neutral pH. If longer delays are necessary, specimens should be frozen at −70°C and thawed just prior to inoculation. Freezing does not appear to be detrimental to virus recovery (4). In general, a similar

sample handling is acceptable for molecular analysis; however, the compatibility of various VTM with different extraction reagents must be confirmed in each laboratory.

DIRECT DETECTION

Antigen

Due to the large number of serotypes and the lack of a common group antigen, it has been difficult to develop direct antigen tests for rhinovirus in clinical specimens. The enzyme immunoassays that have been developed have suffered from narrow reactivity and low sensitivity and are no longer used (16, 48).

Nucleic Acid

Fortunately, picornavirus genomes have a high degree of nucleic acid sequence homology in the 5′-NCR. By using primers or probes based on sequences in the 5′-NCR, all rhinovirus serotypes can theoretically be detected in a single assay. However, enteroviruses as well as rhinoviruses can be detected. Reverse transcriptase PCR (RT-PCR) and nucleic acid sequence-based amplification (NASBA) have been much more sensitive than culture methods, doubling or even tripling the number of HRV infections detected (7, 29, 37, 39, 50, 67, 77, 79). Nevertheless, culture can occasionally detect some rhinoviruses missed by RT-PCR because of variability in techniques and primer or probe mismatches (7, 37, 79). Although in these comparative studies suboptimal culture conditions are often used (34), amplification methods are clearly superior and continue to improve in sensitivity and in time to result.

At present there is no standardization of molecular methods, and blinded comparative studies have not been reported. The published techniques have differed in types of samples tested, RNA extraction methods, primer selection, and amplification and detection protocols. Since primer pairs from the 5′-NCR region will commonly detect both enteroviruses and rhinoviruses, a universal problem is differentiating these two picornavirus groups from each other. Unfortunately, primers that are best able to distinguish rhinovirus from enterovirus may not be the most sensitive for detection of rhinovirus in clinical specimens (39). Thus, more broadly reactive primers are often used. Sequencing of amplicons to differentiate rhinovirus from enterovirus in all positive clinical samples may be feasible in the near future; however, the necessary equipment and expertise are not widely available at present in the routine clinical lab (17). Alternative strategies to distinguish rhinovirus from enterovirus have included primer pair design to generate amplicons of different sizes for rhinovirus and enterovirus (29), restriction enzyme digestion of a common-sized amplicon (58), differential internal probe hybridization (7, 17, 29), and nested PCR with annealing and extension times optimized for rhinovirus detection (67). In general, methods relying on simple gel electrophoresis for detection are cost- and time-saving but tend to be 10-fold less sensitive than either nested PCR or detection by hybridization. Unfortunately, Southern blot hybridization can extend time to result by a day, and nested PCR increases the risk of cross-contamination. Furthermore, most methods reported have failed to detect or accurately differentiate a few of the viruses tested, and to date no study has evaluated all rhinovirus and enterovirus serotypes.

Important recent advances have been the use of real-time amplification using SYBR green, TaqMan hybridization probes, or molecular beacons (15, 17, 41, 50, 77), and multiplex PCR to detect multiple respiratory viruses (6, 26, 66). Real-time amplification methods have the advantages of simplicity, reduced risk of contamination by use of closed tubes, the potential for quantitation, and a shortened time to result since detection occurs concurrently with amplification.

Since some antivirals, such as pleconaril, may be effective against both enterovirus and rhinovirus infections (31), a single assay that detects both virus groups could ultimately turn out to be an advantage.

ISOLATION PROCEDURES

Cell Culture

Rhinoviruses grow only in cells of human or monkey origin. Although the original isolation of rhinoviruses was in primary monkey kidney cells, these cells have not been consistent in yielding a broad range of isolates. The use of sensitive human embryonic lung fibroblast (HELF) strains has provided superior results. Rhinoviruses were originally separated into M and H strains based on their ability to replicate in monkey and human cells (M strains replicate in both monkey and human cells, whereas H strains replicate only in human cells). However, this distinction is no longer used since H strains can be adapted to grow in monkey cells.

The most commonly used cells in clinical laboratories are the HELF strains WI-38 and MRC-5. WI-38 cells are significantly more sensitive than MRC-5 (4), but MRC-5 cells are more commonly available in clinical laboratories. Human embryonic kidney (HEK) can also support rhinovirus replication. Unfortunately, different lots of normally sensitive cell lines have been found to vary over 100-fold in sensitivity to rhinovirus (9); the reasons for this variation are not known. Therefore, for optimal results, simultaneous use of at least two sensitive systems is recommended.

In the research setting, several HeLa cell clones, such as HeLa M or Ohio HeLa cells, HeLa H, HeLa R-19, and HeLa I cells have been shown to support the replication of rhinoviruses to high titers (1, 4). A human fetal tonsil cell line was initially reported to be more sensitive than MRC-5 and HeLa cells for rhinovirus isolation (23). However, HeLa I cells were recently found to be more sensitive than WI38, MRC-5, fetal tonsil, or HeLa H or M cells for recovery of rhinovirus from clinical specimens (4). These specialized cell lines can be obtained only from research laboratories.

After inoculation, cultures are incubated in standard cell culture medium such as Eagle's minimum essential medium with 2% fetal calf serum and antibiotics at a neutral pH. It is important that culture conditions mimic those of the nose; cultures should be incubated at 33 to 35°C with continuous rotation in a roller drum to provide aeration of the monolayer (68). Of note, these incubation conditions also promote the replication of other respiratory viruses that may be present in clinical specimens. Rhinovirus cytopathic effects (CPE) can be observed as early as 24 to 48 h after inoculation and are often detected by day 4. Passage of infected HeLa cell cultures may be necessary for some isolates before CPE are apparent. In fibroblasts, cellular changes are easier to read and are often detected earlier than in epithelial cell lines. Both large and small rounded, refractile cells with pyknotic nuclei are observed in foci that also contain cellular debris (Fig. 1). Rhinovirus CPE are similar to enterovirus CPE but may sometimes be confused with nonspecific changes. The CPE progress over a 2- to 3-day period with the degree of cellular

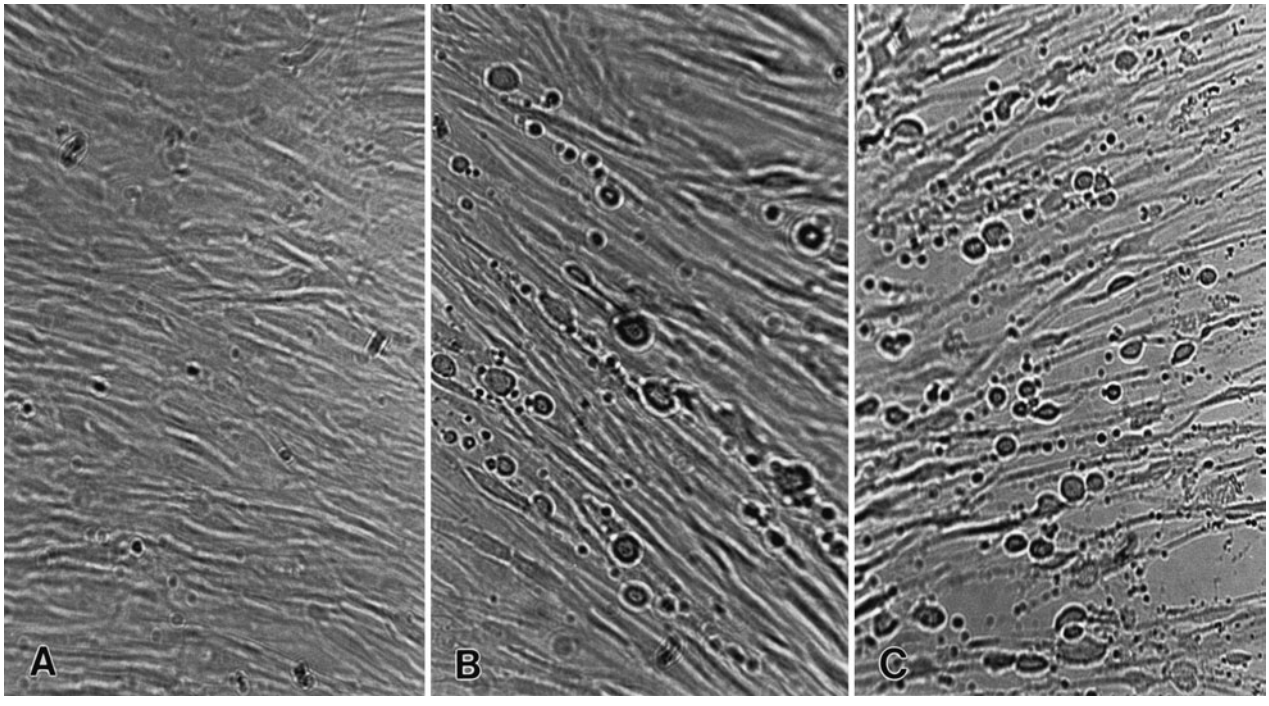

FIGURE 1 Rhinovirus cytopathic effects in human embryonic lung fibroblasts. (A) Uninfected cells. (B) Early focus of rhinovirus CPE. (C) More advanced rhinovirus CPE. Magnification, ×100.

change depending on the serotype and the inoculum dose. It should be noted that rhinovirus CPE can regress or virus may inactivate if left too long. Therefore, cultures should be promptly passaged. Passage is also necessary to increase viral titers prior to the performance of identification tests.

HELF cell cultures should be observed for 14 days, with refeeding at 7 days to increase recovery of virus. HeLa cell cultures can be observed for only up to 7 to 8 days, when passage becomes necessary due to nonspecific cell degeneration and rounding.

Organ Culture

Organ cultures of human fetal nasal epithelium or trachea were used in the past to isolate rhinoviruses not grown in standard cell cultures but are no longer used for this purpose. Details of the procedure have been reviewed elsewhere (1). Recently, however, cultures of nasal and tracheal mucosa obtained from biopsy material have been used for research studies of rhinovirus pathogenesis (38).

IDENTIFICATION OF VIRUS

A presumptive diagnosis of a rhinovirus isolate is made by the appearance and progression of characteristic CPE in the appropriate clinical setting. Further identification of a presumed rhinovirus isolate is usually limited to differentiating it from enterovirus by determining sensitivity to acid pH (Fig. 2). First, passage of the isolate is necessary to obtain a minimum titer of 10^3 50% tissue culture infective doses ($TCID_{50}$)/ml. Testing for other properties of rhinovirus, such as sensitivity to temperature and resistance to lipid solvents, is rarely done in a routine viral diagnostic laboratory. With over 100 rhinovirus serotypes, neutralization testing is time-consuming, costly, and not routinely available. Further identification of presumptive rhinovirus isolates can be obtained by genotypic analysis in research laboratories.

Acid pH Stability

Rhinoviruses are sensitive to low pH, whereas enteroviruses are stable. Thus, a reduction in virus titer by 2 to 3 $\log_{10}$ $TCID_{50}$ can be expected upon exposure of rhinovirus to low pH. First, prepare two solutions of a buffer, such as HEPES, one at pH 3.0 and one at pH 7.0. Add 0.2 ml of unknown virus suspension to 1.8 ml of pH 3.0 HEPES and 0.2 ml of virus to 1.8 ml of pH 7.0 HEPES. Keep the mixtures at room temperature for 3 h, adjust the pH to 7.0, make serial dilutions of the mixtures, and inoculate them into the cell culture. If the unknown virus is a rhinovirus, a minimum 2 $\log_{10}$ reduction in viral titer should be evident in the acid-treated sample. A known rhinovirus and a known enterovirus should be treated in a similar fashion as controls.

Resistance to Lipid Solvents

Since rhinoviruses lack a lipid envelope, they are resistant to treatment with lipid solvents such as chloroform or ether, and infectivity titers should not be affected. Add 0.1 ml of chloroform to 1 ml of isolate, shake vigorously for 10 min, and then centrifuge at 1,000 × *g* for 5 to 10 min. Remove the top or aqueous phase, prepare serial dilutions, and inoculate them into the cell culture. Alternatively, add 0.2 ml of diethyl ether to 0.8 ml of isolate in a stoppered tube and shake vigorously. Allow the mixture to react at room temperature for 1 to 2 h; shake the tube intermittently. Then, transfer the mixture into an open glass petri dish in a fume hood and allow the ether to evaporate. Prepare serial dilutions and inoculate them into the cell cultures.

An equal volume of unknown virus should be handled in a similar manner but not treated with chloroform or ether. A known picornavirus and a chloroform-sensitive virus, such as herpes simplex virus (HSV), should also be included as controls. The picornavirus should be unaffected, and the HSV should be completely inactivated.

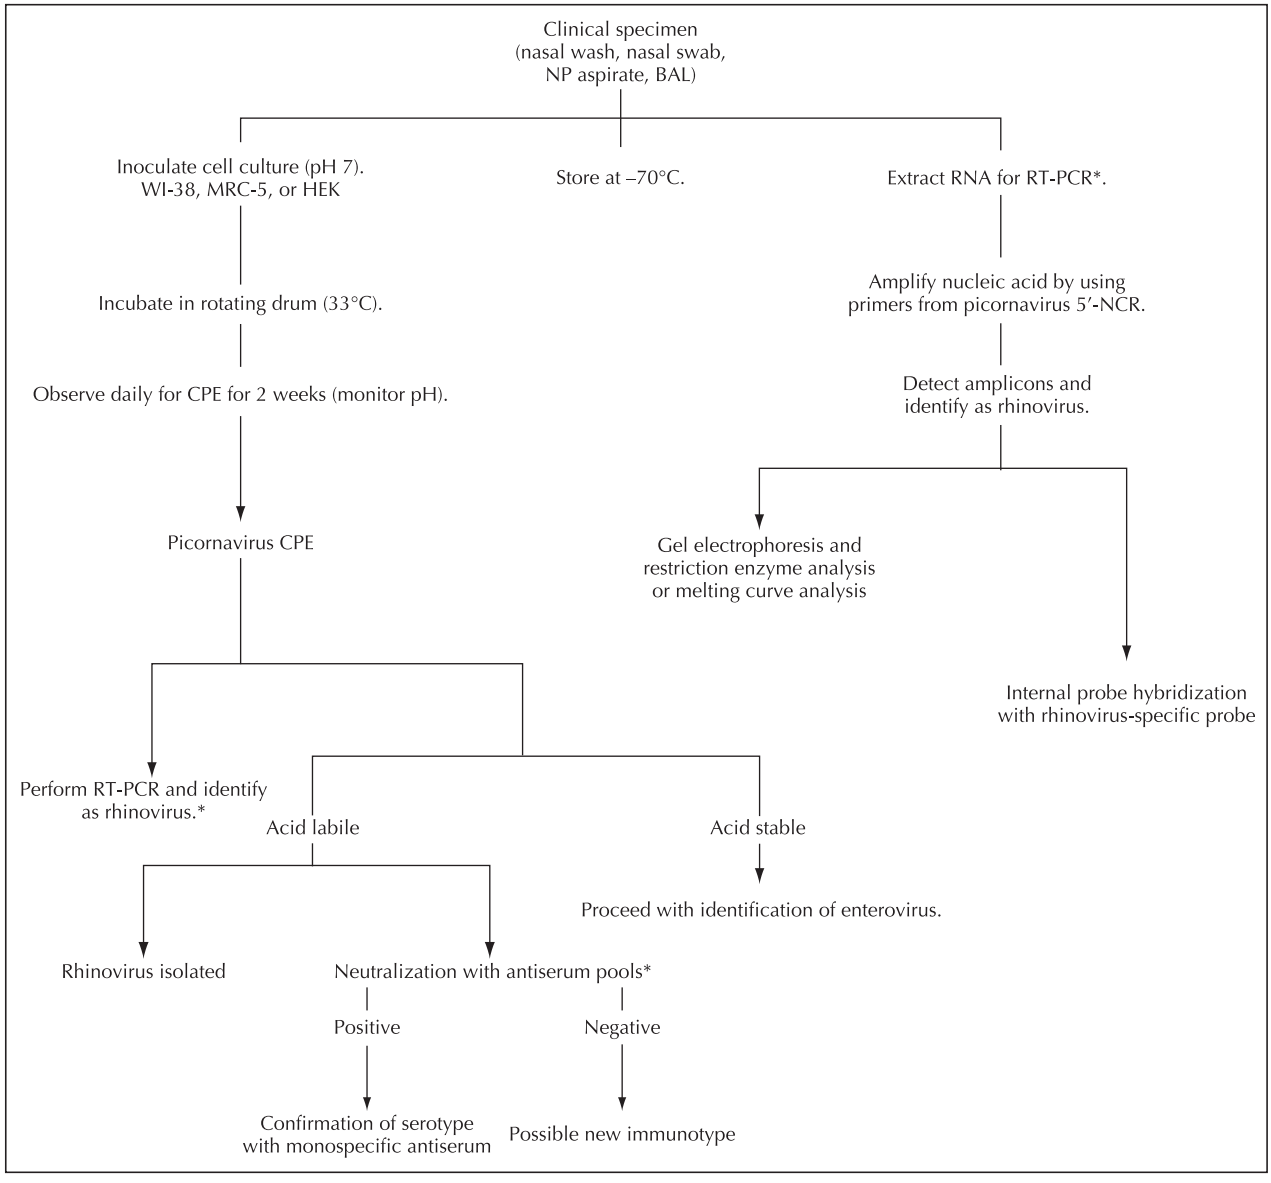

FIGURE 2 Flow scheme for the isolation or detection and identification of rhinovirus. Techniques usually reserved for the research laboratory are marked by an asterisk. HEK, human embryonic kidney cells; BAL, bronchoalveolar lavage.

Temperature Sensitivity

Since rhinoviruses often grow best at 33°C, they may be distinguished from enteroviruses by inoculation of serial dilutions of the unknown virus and incubation of one set of cultures at 33°C and a replicate set of cultures at 37°C. The onset of CPE should be more rapid and the titer of virus obtained should be higher at the lower temperature. It is important to note that some rhinovirus isolates may not show this temperature sensitivity (59).

Virus Identification by RT-PCR

Nucleic acid amplification techniques can also be used for identification of rhinovirus isolates in cell culture. However, cross-reactions with enteroviruses can occur more often with high-titered culture isolates than with clinical samples, especially when 5′-NCR regions are targeted (70).

TYPING SYSTEMS

Neutralization Tests

Specific identification of rhinoviruses by serotyping is an expensive and labor-intensive procedure that is rarely performed. Hyperimmune antisera for types 1A to 100 are available through the American Type Culture Collection. Intersecting serum pools similar to those used for enterovirus identification have been prepared, and isolates are usually tested in a microneutralization procedure to conserve reagents. Confirmation of serotype is then performed using monospecific antiserum. Neutralization generally involves the neutralization of 30 to 100 $TCID_{50}$ of virus-induced CPE by 20 U of antiserum. Nontypeable isolates are occasionally found. Detailed procedures are described elsewhere (1).

Virus Typing by RT-PCR

PCR of variable regions of 5′-NCR has also been used successfully to type a limited number of serotypes (54). In addition, HRV serotypes can be differentiated by sequencing of capsid protein genes (46, 49).

SEROLOGIC TESTS

The number of HRV serotypes makes blind serologic testing impractical in the clinical setting. In research studies, the standard serologic assay to measure antibody in serum or nasal wash specimens is the neutralization test (20). For maximum sensitivity, a low challenge dose (3 to 30 $TCID_{50}$) should be used. Plaque reduction neutralization has also been described. Hemagglutination inhibition has also been used but is not as sensitive as neutralization, and not all rhinoviruses react with red blood cells. EIAs using HRV-EL and HRV-2 antigens have been used to detect serum and nasal IgG and IgA in volunteers inoculated with these two rhinovirus types (5); EIA was 100 to 10,000 times more sensitive than neutralization. The problem of detecting antibodies to multiple serotypes in natural infection has not been addressed.

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

A comparison of HRV diagnostic methods is shown in Table 1. The diagnosis of rhinovirus infection in the clinical laboratory is currently based upon isolation of virus with characteristic CPE in commonly available cell systems, such as WI-38, MRC-5, or HEK. Incubation at 33 to 35°C and rotation of cultures provide optimal conditions for virus replication. Differentiation of rhinoviruses from enteroviruses, with which their CPE can be confused, is based primarily on acid stability testing of isolates. Rhinovirus infectivity is reduced 2 to 3 $\log_{10}$ after incubation at pH 3 to 5, whereas enterovirus infectivity is unaffected. Of note, exceptions to both acid sensitivity and low incubation temperatures have been recognized (65). Specific identification of rhinovirus serotypes by neutralization test or molecular methods is reserved for epidemiologic research studies. Serologic testing is impractical and not commercially available.

Nucleic acid amplification assays have revolutionized rhinovirus detection. Yet application of this methodology to rhinovirus diagnosis has not yet made the transition into the routine clinical laboratory, due to the expense and expertise required for in-house test development and the

TABLE 1 Comparison of diagnostic methods for rhinoviruses

Method	Advantages	Disadvantages and limitations	Clinical applicability	References
Virus isolation	Rhinoviruses replicate in cell cultures commonly used in clinical laboratories (e.g., WI-38, MRC-5, HEK) These cultures may detect other viruses as well as rhinovirus (e.g., CMV, VZV, HSV, adenovirus, enterovirus, RSV)[a]	Optimal recovery of multiple rhinovirus serotypes requires use of additional sensitive cell cultures not routinely used in diagnostic laboratories (e.g., Ohio HeLa cells, HeLa I cells, or fetal tonsil) Normally sensitive cells can vary over 100-fold in sensitivity Differentiation of rhinovirus from enterovirus isolates is time-consuming (e.g., quantitative acid sensitivity test)	Most common test in clinical laboratories	1, 4, 9, 23, 68
RT-PCR or NASBA	More sensitive and more rapid than culture methods Broadly reactive primers that are most sensitive for the detection of rhinoviruses in clinical specimens usually also detect enteroviruses Amplicons can be detected in real-time assays by rhinovirus-specific probes Multiplex assays can detect multiple respiratory viruses	Molecular assays must be established and validated in-house, which is time-consuming and expensive Differentiation of rhinovirus from enterovirus can be difficult Rhinovirus-specific diagnosis is rarely requested Since the same clinical syndrome may be caused by other viruses, samples must be tested for additional viruses	Expected to increase with advent of real-time assays	6, 7, 15, 17, 26, 29, 37, 39, 41, 50, 58, 66, 67, 77, 79
Organ culture	May detect some infections not detected by virus isolation in cell culture Useful in studies of pathogenesis Biopsy specimens or surgically removed tissues can be used	Fetal nasal or tracheal tissues are not readily available Largely supplanted by molecular assays for detection of rhinovirus in clinical specimens	Occasionally used in pathogenesis research	1, 38
Serology	May detect some infections not detected by virus isolation Research tool used after infection of volunteers with a known serotype or in epidemiologic studies	The number of serotypes in natural infections makes blind serologic testing impractical Serologic tests are not commercially available	Used only in research settings	5, 18

[a] CMV, cytomegalovirus; VZV, varicella-zoster virus.

lack of clinical demand. At present in the clinical laboratory, rhinoviruses are rarely if ever specifically requested. Rather, rhinoviruses are isolated when the suspected virus is influenza or RSV. Although molecular techniques applied in the research setting will continue to elucidate the important role of rhinoviruses as lower respiratory tract pathogens and as significant causes of asthma and chronic obstructive pulmonary disease exacerbations, the standard diagnostic approach may not change substantially until either effective therapy becomes available or the impact of rapid and sensitive rhinovirus diagnosis on the management of hospitalized patients can be demonstrated.

Coronaviruses

JAMES B. MAHONY

91

TAXONOMY

All coronaviruses (CoV) belong to the genus *Coronavirus* within the family *Coronaviridae* and are enveloped viruses possessing a positive-strand RNA genome of 27 to 32 kb. CoV contain the largest known genome among all RNA viruses. There are five CoV known to infect humans, including strains OC43 and 229E, severe acute respiratory syndrome-associated CoV (SARS-CoV), and strains NL63 and HKU1. Based on genotypic and serologic characterization, CoV have been divided into three distinct groups: 229E and NL63 are group 1 CoV, and OC43, SARS-CoV, and HKU1 are group 2 CoV. No human pathogens have been reported for group 3 CoV, which include avian infectious bronchitis virus. The genomic RNA is capped and polyadenylated and comprises several genes encoding both structural and nonstructural proteins. The genome organization of CoV has the characteristic order 5′-replicase gene, spike (S) gene, envelope (E) gene, membrane (M) gene, and nucleocapsid (N) gene-3′ (22). The G+C content ranges from a low of 32% for CoV HKU1 to a high of 41% for SARS-CoV. In addition to the S, E, M, and N structural proteins, the genome also encodes a chymotrypsin-like protease, replicase (polymerase), helicase, and hemagglutinin-esterase. In the replicase gene, a frameshift interrupts the protein coding regions and separates open reading frames 1a and 1b. Both the 5′ and 3′ ends contain short untranslated regions. The RNA genome is translated as a polyprotein which is subsequently cleaved by the chymotrypsin-like protease activity. The S gene encodes the S glycoprotein which binds to the host cell receptor (ACE-2 for SARS-CoV and aminopeptidase N [CD13] for CoV 229E) and leads to membrane fusion and viral entry.

DESCRIPTION OF THE AGENTS

CoV have been associated with a very high mutation rate that has led to altered properties, host ranges, and disease manifestations in animals. Recombination rates are very high, which is unusual for a nonsegmented RNA virus, due to discontinuous transcription and polymerase jumping. Group 2 CoV have apparently acquired the hemagglutinin/esterase (HE) gene from influenza C virus in this manner. CoV have been identified in a wide range of animals including mice, rats, chickens, turkeys, swine, dogs, cats, bats, rabbits, horses, cattle, and humans and cause a variety of severe diseases including gastroenteritis and respiratory tract diseases. CoV-like particles have been identified in human feces since the early 1980s, but the link with gastroenteritis has not been firmly established. Prior to 2002, there were only two CoV known to infect humans, namely, CoV OC43 and CoV 229E. Since 2002, three additional human CoV have been discovered, bringing the total number of CoV infecting humans to five. Severe acute respiratory syndrome (SARS) emerged from China in the fall of 2002, and SARS-CoV was identified as the causative agent (34). On the basis of genome analysis, SARS-CoV was originally assigned to a fourth CoV group but more recently has been recognized as a distant relative to the group 2 CoV and is now considered a group 2 subgroup (12, 22). In 2004, a novel group 1 CoV associated with respiratory tract infections, CoV NL63, was discovered in The Netherlands and its genome was sequenced (45). In 2005, a fifth human CoV, a group 2 CoV, was discovered in patients with pneumonia in Hong Kong (47). All CoV are pleomorphic, are 80 to 160 nm in size, and contain a corona consisting of club-shaped peplomers (Fig. 1). CoV replicate in the cytoplasm and bud off the cytoplasmic membrane. Virion release occurs via membrane fusion and exocytosis, with eventual cell death.

EPIDEMIOLOGY AND TRANSMISSION

Many CoV have been identified in a variety of different animals, and for the most part, these viruses do not cross over into other species. SARS-CoV is believed to be zoonotic in origin, having crossed into humans most likely from animal hosts in the wild-game markets in Guangdong, China. Many of the first infected individuals in November and December 2002 had contact with the live-game trade. The disease was first called "infectious atypical pneumonia" because it caused clusters of disease in families and health care workers. The etiologic agent of SARS was identified as a new CoV by Peiris and coworkers at the University of Hong Kong (34), and the viral genome was fully sequenced in a record time of 3 weeks, first by workers at the University of British Columbia, Vancouver, Canada (32). Genomic analysis revealed that SARS-CoV was a new CoV not previously found in humans. The absence of antibody in healthy humans suggested that SARS-CoV had recently emerged in the human population and that animal-to-human interspecies transmission was the most probable explanation for its emergence. Specimens collected from apparently healthy animals in the wild-game animal markets in China indicated that a number of animals

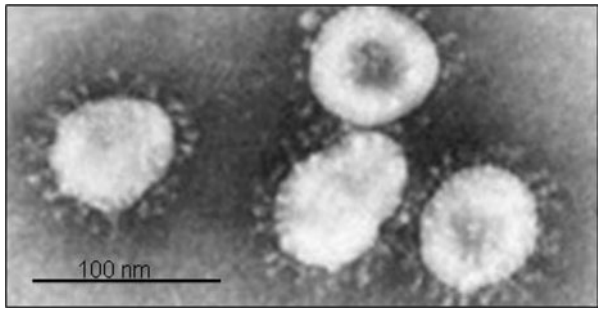

FIGURE 1 Electron micrograph of CoV OC43 showing pleomorphic shape and characteristic coronas made up of surface peplomers.

including the Himalayan palm civet cat and raccoon dogs yielded a SARS-CoV-like virus with more than 99% nucleotide homology to human SARS-CoV (15). Many animal handlers with no previous history of a SARS-like illness had serum antibodies to SARS-CoV. Taken together with the fact that a number of SARS cases had an epidemiologic link to wild-game animals, it is very likely that these markets in Guangdong provided the interface for transmission to humans. The early transmissions to humans were probably inefficient, causing little disease or human-to-human transmission. The animal SARS-like virus probably adapted in humans for efficient human-to-human transmission, and SARS-CoV emerged. There is evidence that SARS-CoV evolved toward greater fitness during the SARS outbreak as human viruses isolated late in the outbreak contain a 29-nucleotide deletion in open reading frame 8 that is absent both from human viruses isolated early in the outbreak and from animal viruses (15). Similarly, the gene encoding the S protein that mediates viral entry shows high rates of nonsynonymous mutation in early isolates that are absent in later isolates, probably reflecting the ongoing adaptations to the new host. Recent reports on the detection of SARS-like CoV from the blood and feces of Chinese horseshoe bats in the wild and Chinese markets raise the possibility of a bat origin of SARS-CoV (25).

The major routes of CoV transmission in humans are droplet infection, aerosolization, and fomites. Deposition of droplets onto the respiratory epithelium probably initiates infection. Whether infection can occur through the oral or conjunctival epithelium remains unknown, but SARS-CoV has been detected in tears. As mentioned above, SARS first appeared as a potentially fatal cause of pneumonia in the Guangdong province of China in 2002. The first human case was identified on 16 November, and within 6 months SARS had spread to 29 countries, infecting 8,098 and killing 774 individuals (50). The last known case in this outbreak occurred 15 July 2003 in Taiwan. This outbreak had a profound effect on public health and economies worldwide, with an estimated $100 billion lost from global economies. SARS has arguably been the most significant event in medical virology since the emergence of human immunodeficiency virus and AIDS in the early 1980s.

At the beginning of the SARS outbreak, nosocomial infections played an important role in the outbreak. The first major outbreak in Hong Kong occurred in the Prince of Wales Hospital around 10 March 2003, resulting in 138 SARS cases, 69% of which were in hospital workers. By the end of the outbreak, there were 1,755 SARS cases in Hong Kong, 339 of which were in workers in 16 hospitals. In Canada, the first large outbreak also occurred in a community hospital, affecting 128 patients, of which 37% were members of the hospital staff (37). Asymptomatic infection of humans appears to be a rare event. Despite the rapid spread of SARS worldwide, the average number of secondary infections caused by any one case is low (2.2 to 3.7) compared with that in influenza (5 to 25) and household transmission of SARS is relatively inefficient (13). Superspreading events in which a few infected individuals disproportionately contribute to transmission (e.g., a difficult intubation in the intensive care unit's resulting in infection of a number of house staff) were characteristic of the outbreak. Factors associated with superspreading events are not well understood but may include coinfection with other viruses, host factors such as immunosuppression, and/or environmental factors. The number of infected staff members in hospitals was strongly correlated with the number of admitted SARS patients, the length and type of exposure, and the use of personal protective equipment (PPE) such as gloves and masks. Late in the outbreak, it was shown that PPE significantly decreased the occurrence of nosocomial infections and played a significant role in outbreak management (29). These and other studies clearly indicate that exposure to infected individuals is the driving force behind the horizontal transmission of SARS.

CLINICAL SIGNIFICANCE

Human CoV OC43 and 229E were among the first human CoV to be discovered in the mid-1960s. These viruses were isolated from adults with respiratory illness and grew only in embryonic tracheal organ cultures. They usually cause a mild, self-limited upper respiratory tract infection with common cold-like symptoms in adults. Overall, OC43 and 229E account for between 5 and 30% of respiratory tract infections, with outbreaks occurring at 3- to 4-year intervals (44). Like those with other respiratory viruses, infections with human CoV can present with a wide range of signs and symptoms, from a common cold with a cough, runny nose, and fever to a lower respiratory tract infection with bronchiolitis or pneumonia. Human CoV OC43 and 229E have been associated with respiratory tract infections in a variety of settings and have been linked to nosocomial infections in high-risk immunocompromised children, in hospitalized elderly patients with noninfluenza severe respiratory tract infection and pneumonia, and in newborns, children, and hospital staff (10, 35, 43). In one recent prospective study of 501 patients in France, OC43 was found in 6% of patients compared with 6.1% for respiratory syncytical virus, 7.8% for influenza virus, 6.4% for rhinovirus, 1% for parainfluenza 2 virus, 2% for adenovirus, and 1% for enterovirus (43). Symptoms included fever (59%), rhinitis (37%), pharyngitis (30%), laryngitis (3%), otitis (13%), bronchitis (17%), bronchiolitis (10%), and pneumonia (7%). Like other respiratory viruses, human CoV OC43 and 229E are spread by large-droplet infection. Of concern to infection control practitioners is a recent finding that 229E can survive for up to 3 h when dried on solid surfaces and for up to 6 days in saline solution at room temperature.

The first reported SARS death was that of a restaurant chef who first presented with pneumonia. The natural history of SARS-CoV has now been documented in several studies. The initial symptoms are unremarkable and typical of an upper respiratory tract viral infection. After a few days, coughing and low-grade fever progress rapidly into full-blown pneumonia requiring hospitalization and often mechanical ventilation. Fever, malaise, lymphopenia, and

elevated liver enzymes, together with infiltrates and consolidation visible upon chest X ray, are usually present. Quantitative PCR studies have shown that the viral load is high in the lower respiratory tract but low in the upper respiratory tract. Viral loads in the upper respiratory tract and feces are low during the first 4 days and peak at around day 10 of illness (37). This is in marked contrast to viral loads in other respiratory viral infections such as influenza, in which the loads peak soon after the onset of symptoms. This unusual feature of SARS-CoV infection explains its low transmissibility early in the illness and perhaps explains why outbreaks in some countries were limited to only a few cases. More importantly, it explains the poor sensitivity of early reverse transcriptase (RT)-PCR tests on nasopharyngeal (NP) specimens collected early in the illness.

Although the main signs and symptoms of SARS are associated with the respiratory tract, the virus also infects other organs. About a quarter of SARS patients had watery diarrhea, and virus can be cultured from the feces and urine as well as the respiratory tract. Virus also can be detected by RT-PCR in serum, plasma, and peripheral blood leukocytes; however, the viremia may be short lived. Patients have pronounced peripheral T-cell lymphocytopenia with reduced CD4 and CD8 cell counts, with a third of individuals having a CD4 count of less than 200 cells/mm^3. Infected individuals with high serum viral loads have a poor prognosis. Between days 10 and 15 of illness, high viral loads in NP aspirates (NPA), feces, and serum are independent predictors of adverse clinical outcome. SARS-CoV is invariably found in the lungs of individuals dying of SARS, but viral loads are usually higher in those dying earlier in the course of illness (<21 days after the onset of symptoms). About one-quarter of patients with SARS require management in intensive care units, and the overall case fatality rate was 10%. Disease severity and mortality are correlated with age, with the highest mortality rates (52%) occurring in those >65 years of age and the lowest rate in the 0- to 24-year-old group. Children acquiring SARS seldom require intensive care or mechanical ventilation (18). Although SARS-CoV can be found for months in the feces of an infected individual, there is no evidence that the virus persists following resolution of the illness.

The fourth human CoV, NL63, was first discovered in The Netherlands in a 7-month-old boy who presented with coryza, conjunctivitis, and fever and who had chest X-ray findings consistent with bronchiolitis (45). The virus grew in tertiary monkey kidney cells, which distinguished it from human CoV OC43 and 229E. Sequencing of the genome indicated that it was not a recombinant virus and was genetically distinct from all other human CoV. Following the first case of infection, NL63 was detected in five additional children and three adults, two of which were immunocompromised. NL63 has also been detected in 2% of prospectively studied patients with respiratory tract infections in Brisbane, Australia. Fouchier et al. independently reported a novel group 1 CoV with a 27,555-nucleotide genome with a 34% G+C content (11). This virus was first isolated in 1988, from an 8-month-old with pneumonia by using monkey kidney cells and is most likely the same virus as NL63. Use of an RT-PCR assay and primers based on the first isolate permitted detection of this virus in 4 of 139 specimens collected from pediatric patients with upper respiratory tract infections between 2000 and 2002, indicating that this virus has been circulating in The Netherlands for a number of years.

The fifth human CoV, HKU1, was discovered in January 2004 in Hong Kong in a 71-year-old man returning from Shenzhen, China. He presented with fever and a productive cough with purulent sputum and had a chest radiograph showing patchy infiltrates. All attempts to grow a virus from NP specimens failed, but CoV RNA was detected in the NPA by RT-PCR using *pol* gene consensus primers (47). Quantitative PCR indicated high titers of virus (10^6 genome equivalents) present in the NPA during the first week of illness, with decreasing titers in the second week and undetectable levels of virus in the third and fourth weeks. The virus was absent from urine or stool specimens. A recombinant-N-protein-based enzyme-linked immunosorbent assay (ELISA) indicated seroconversion in the first week of infection, with both immunoglobulin M (IgM) and IgG antibody detectable. A second case was subsequently identified, that in a 35-year-old woman with pneumonia with unknown etiology. The recent discovery over the past 2 years of two new human CoV isolated from the upper respiratory tracts of symptomatic patients suggests that additional, as yet unidentified human CoV may await discovery.

COLLECTION, TRANSPORT, AND HANDLING OF SPECIMENS

Specimens for the detection of the non-SARS-CoV may include either upper or lower respiratory tract specimens. NP, oropharyngeal, endotrachial, bronchoalveolar lavage (BAL), and postmortem lung specimens are all useful for detecting CoV. With respect to SARS-CoV, NP specimens, which are often negative during the first week of infection, have the highest positivity rates in the second week of illness, with rates peaking at about day 10. Quantitative PCR revealed that viral loads were highest in lower tract specimens (BAL and sputum specimens and endotracheal aspirates), and BAL specimens have been positive more frequently than NP specimens (4, 8, 40). The collection of BAL specimens, however, has been associated with an increased risk of nosocomial transmission and risk to health care workers and was halted in many institutions. The low virus detection rate for NP specimens early in the course of infection underscores the importance of optimal timing and specimen type for diagnosis. The Centers for Disease Control and Prevention, Atlanta, Ga., has recommended that multiple specimen sources be tested, namely, NP plus oropharyngeal and serum or plasma specimens during the first week of illness and NP plus oropharyngeal and stool specimens after the first week of illness. For the interpretation of a positive diagnosis based on PCR testing, it is generally recommended that a patient have either two positive clinical specimens from different anatomical sites or positive specimens from the same site collected on two separate occasions (http://www.cdc.gov/ncidod/sars/guidance/f/pdf/app4.pdf).

Natural history studies of SARS patients indicate that SARS-CoV is also present in nonrespiratory specimens including blood, cerebrospinal fluid, urine, tears, and feces. Serum, plasma, and buffy coat specimens are prepared from coagulated or noncoagulated blood specimens, the latter including EDTA, heparin, or mononuclear cell tubes (Becton Dickinson), for use in SARS-CoV detection. Rectal swabs or fecal specimens are good diagnostic specimens, especially late in the course of infection. Replication of SARS-CoV in the gastrointestinal tract has been confirmed by electron microscopy, in situ hybridization, and RT-PCR testing of biopsy and postmortem specimens (42). The discovery of SARS-CoV in feces indicates that the virus rapidly disseminates from the NP to other tissues and suggests that the virus could be transmitted by the fecal route. In the case of stool specimens, SARS-CoV RNA can be detected at high levels for several weeks or even months whereas virus culture

is positive only during the first 2 to 3 weeks of illness (33). Fecal specimens have a high viral load at the end of the first week of illness and are the specimen of choice for diagnosis during the second week of disease. It is possible that virus replication continues for weeks in the gastrointestinal tract but that virus is complexed with antibody and is no longer infective or transmissible. This possibility is consistent with epidemiologic findings. Of the nonrespiratory specimens, stool specimens have shown the highest positivity rates and highest viral loads. Testing of serum or plasma specimens for viral RNA was disappointing at first, but a subsequent study has shown 50 and 78% positivity rates for serum and plasma samples during the first week of illness (46). A second study confirmed these results for plasma with a 79% positivity rate during the first 3 days of illness (14).

Given the severity of SARS and recent reports of laboratory-acquired infections (27), appropriate precautions should be followed for handling specimens submitted for SARS investigation. Testing of respiratory or stool specimens must be done using biosafety level 2 precautions in a class II biological safety cabinet with laboratory workers wearing PPE including long-sleeved gowns, gloves, eye protection, and N95 masks. Virus isolation should not be attempted by routine clinical laboratories since SARS-CoV is a level III agent and propagation of virus requires a biosafety level 3 facility.

DIRECT DETECTION

Microscopy

Histopathologic changes due to CoV infections vary greatly depending on the virus, the host species, and the cell type infected, and ergo, there are no tissue changes indicative of a CoV infection. CoV-infected cells can be detected by indirect immunofluorescence (IF) staining using antibody specific to the desired CoV and a fluorescein isothiocyanate-conjugated anti-species antibody. IF staining can be used in combination with the shell vial technique employing centrifugation-assisted inoculation and staining at 24 h postinfection to detect early antigens. Electron microsocopy can be used to identify CoV directly in clinical specimens or in infected cell cultures. Negative staining of tissue culture media or aqueous specimens with phosphotungstic acid reveals the pleomorphic virions with diameters of 80 to 160 nm and characteristic coronas consisting of club-shaped peplomers (Fig. 1).

Antigen Detection

Human CoV antigens can be detected in cells from NP or throat wash specimens by standard methods and stained with CoV-specific monoclonal antibodies and a fluorescence-labeled anti-mouse IgG conjugate (28, 38). Specific CoV antigens can also be detected by ELISA using immobilized antibody to capture antigens from clinical specimens and a second species of CoV antibody and anti-species IgG conjugate. This approach has recently been used for detection of SARS-CoV N antigen in serum or NP specimens (7, 17, 26, 28). In one study involving serially collected specimens, detection of N protein in serum was more sensitive than IgG ELISA or RNA PCR tests for diagnosing SARS in the first 10 days after onset (26). To date, no commercial assays are available for CoV antigen detection.

Nucleic Acid Analysis

A variety of nucleic acid amplification tests (NAAT) including RT-PCR, nucleic acid sequence-based amplification (NASBA), and loop-mediated isothermal amplification (LAMP) have been used to detect CoV RNA. The first RT-PCR assays described for SARS-CoV RNA targeted the polymerase *(pol)* 1B region of the 5′-replicase gene. The *pol* 1B primers have been used for the development of both nested and nonnested, 1- and 2-step (involving combined and separate RT reactions, respectively) conventional heat block RT-PCRs as well as real-time PCR assays (Table 1). Drosten et al. (2003) used two sets of primers in a nested PCR format to amplify a 109-bp fragment and the same primers in a real-time assay and showed that the real-time assay had sensitivity equivalent to that of the nested assay for detecting SARS-CoV RNA in 18 clinical specimens (9). Ksiazek et al. (2003) used different *pol* 1B primers and described a 2-step assay with a sensitivity of 100 genome equivalents (GE) that was more sensitive than culture (21). Poutanen et al. (2003) also described a 2-step *pol* 1B assay for detecting SARS-CoV RNA in clinical specimens obtained from 10 patients in the Toronto, Canada, SARS outbreak (37). These first three assays were used to test only a small number of clinical specimens and were not compared to any other NAAT, precluding an assessment of their performance.

Lau et al. (2003) described an enhanced RT-PCR involving target preamplification by using two separate amplifications within the *pol* 1B gene (23). The first PCR was a conventional heat block assay followed by real-time amplification using the product from the first reaction. The product of the enhanced RT-PCR was a 68-bp amplicon. The assay was used to test 120 specimens from 80 patients in Hong Kong and China and detected 28 of 120 positive specimens versus 21 of 120 positive specimens detected by the real-time assay (23). Additional testing of the discordant specimens was not performed to allow a comparative assessment of assay performances.

Following the introduction of these original assays, additional tests were developed that amplify alternative gene targets. Mahony et al. (2004) introduced 1- and 2-step real-time assays that amplify a 149-bp fragment of the N *(nuc)* gene (31). The 1-step real-time assay was evaluated by testing 68 specimens and has an analytical sensitivity similar to that of the *pol* 1B assay (10 GE). Bressler and Nolte (2004) described a 2-step real-time Taqman assay amplifying a 66-bp fragment of the *nuc* gene with an analytical sensitivity of 90 GE (2). They showed that the *nuc* gene assay has a sensitivity similar to that of their *pol* 1B assay using armored-RNA-spiked specimens. Drosten et al. (2004) also showed that a 1-step real-time assay targeting the *nuc* gene detected numbers of positive specimens similar to those detected by two other *pol* 1B assays when 66 specimens were evaluated (8).

Real-time assays offer faster turnaround time and the ability to quantitate viral load. Wang et al. (2004) tested 116 SARS specimens by using a 2-step assay amplifying a 123-bp fragment of the *pol* 1B gene (46). Houng et al. (2004) introduced a 2-step real-time assay that amplifies a region of the 3′ noncoding region of the genome (19). This assay has an excellent analytical sensitivity of 6 to 8 GE but has not been evaluated with SARS specimens. Poon et al. (2004) introduced a real-time multiplex assay that targets both the *pol* 1B gene and 18S rRNA as an internal control (36). This 1-step Taqman assay has an analytical sensitivity of 10 GE and was evaluated by using 86 NP specimens from SARS cases. An internal control was used to identify specimens that contained amplification inhibitors or that lacked specimen RNA because of a failed extraction. In their study, 0 of 86 NP specimens failed to amplify the internal control, indicating successful RNA isolation and the absence of amplification inhibitors.

TABLE 1 Description of 14 nucleic acid amplification assays for detection of human CoV RNA[a]

Target	Primer name	Primer sequence	Amplicon size (bp)	Format[b]	Analytical sensitivity[c]	No. of clinical specimens	Comments	Reference
pol 1B	BNIoutS2 BNIoutAS BNIinS BNIAs	5′-ATGAATTACCAAGTCAATGGT TAC-3′ 5′-CATAACCAGTCGGTACAGCTAC-3′ 5′-GAAGCTATTCGTCACGTTCG-3′ 5′-CTGTAGAAAATCCTAGCTGGAG-3′	190 109	2 step nested, 1 step Taqman, real time	10 GE	49	Sensitivities of nested and real-time assays were equivalent for detecting SARS-CoV in 18 specimens.	8
pol 1B	Cor-p-F2 Cor-p-R1	5′-CTAACATGCTTAGGATAATGG-3′ 5′-CAGGTAAGCGTAAAACTCATC-3′	368	2 step	100 GE	19	PCR more sensitive than culture for detecting SARS-CoV	21

LAMP *pol* 1B		6 primers used included 2 outer, 2 inner, and 2 loop primers that recognize 8 distinct regions on the target zone.	196	1 step	0.01 PFU	59	LAMP detected 7 additional SARS-CoV positives.	41

[a] ND, no data available; 3′NCR, 3′ noncoding region.
[b] Format refers to whether the RT step is combined with (1 step) or separate from (2 step) the PCR.
[c] Sensitivity refers to the number of SARS-CoV RNA GE per reaction.

Two recent reports have described consensus *pol* 1B gene primers for the detection of CoV RNA including that of SARS-CoV. Adachi et al. (2004) used consensus primers to amplify a 220-bp fragment of *pol* 1B in a 1-step assay with an analytical sensitivity of 10 GE (1). They tested 44 SARS specimens as well as cultured CoV 229E and OC43 and turkey infectious bronchitis virus and showed that these consensus primers could detect all four CoV. Woo et al. (2005) described a 2-step conventional heat block (non-real-time) assay that uses consensus *pol* 1B primers to amplify a 440-bp fragment of the *pol* 1B gene (47). This assay was used to detect a novel human respiratory CoV, HKU1, in a 71-year-old with non-SARS pneumonia during the SARS outbreak in Hong Kong. This assay, which uses consensus primers, should be able to detect SARS-CoV, although the authors did not show that the assay was able to do so.

Isothermal amplification formats including NASBA and LAMP have also been used to detect SARS-CoV RNA. Thai et al. (2004) developed a LAMP assay using six primers, including two outer, two inner, and two loop primers, that recognize eight distinct regions of the *pol* 1B gene (41). The 1-step LAMP assay amplifies a 196-bp fragment and has an analytical sensitivity of 0.01 PFU. They evaluated the assay by testing 59 specimens from Vietnamese patients by both LAMP and conventional RT-PCR. LAMP detected 13 positive specimens compared to 6 detected by RT-PCR. Analysis of the discordant results was not performed to determine whether the additional positive specimens were true positives or false positives. A NASBA test for SARS-CoV RNA has been described, but this test has not yet been evaluated with clinical specimens (5). Juang et al. recently described a multiplex RT-PCR that amplifies two SARS-CoV genes and uses a gene chip detection platform (20).

Commercially available tests have recently appeared and include the RealArt HPA CoV RT-PCR assay from Artus GmbH (Hamburg, Germany), the GeneCode SARS-CoV NP and POL MultiCode-RTx kits from EraGen Biosciences (Madison, Wis.), and the LightCycler SARS-CoV kit from Roche Diagnostics (Branchburg, N.J.). Limited evaluations of these assays have been performed, and their true performance has yet to be determined. These first-generation assays appear to have suboptimal performance with low clinical sensitivities (36.4 to 94.4%) and low specificities (87 to 100%) when a combined reference standard of positivity is used (30). The introduction of second-generation tests with improved sensitivities and specificities is eagerly anticipated. Diagnostic companies are presently working on chip- and bead-based assays for the detection of human CoV and other respiratory viruses.

ISOLATION PROCEDURES

Cell culture has proven to be unreliable for primary isolation of CoV, and some strains grow in cell culture only after adaptation. Human CoV OC43 and 229E can be isolated in human embryonic lung cells (L132) or MRC-5 cells but require incubation at 32 to 34°C (6). Human CoV NL63 and HKU1 can be isolated in tertiary monkey kidney (cynomolgus monkey) or LLC-MK2 cells. Cytopathic effects may take 7 to 10 days to appear and vary from a ground-glass refractive appearance to cell rounding and detachment depending on the host cell (Fig. 2). SARS-CoV can be isolated in Vero-E6 cells, although this must be attempted only in a biosafety level 3 laboratory.

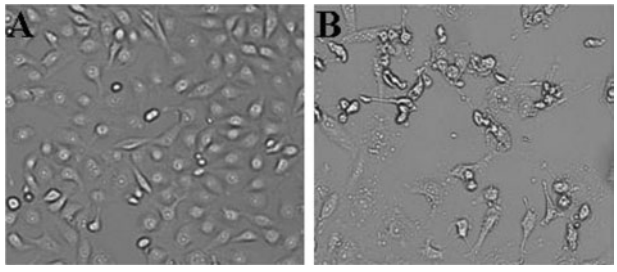

FIGURE 2 Cytopathic effect at 5 days postinfection for NL63-infected LLC-MK2 cells (B). Panel A shows uninfected LLC-MK2 cells.

TYPING SYSTEMS

Although human CoV can be isolated by using cell culture, there are no type-specific antibodies for typing of isolates. Nucleic acid sequence analysis must therefore be used for viral typing. CoV typing can be performed by PCR using consensus primers followed by amplicon sequencing or PCR using type-specific primers.

SEROLOGIC TESTS

Due to the benign nature of the non-SARS-CoV infections, CoV antibody tests have not been widely used for diagnosis but have been used primarily by research laboratories for seroepidemiologic studies. Early in the SARS outbreak, detection of SARS-CoV antibody was considered the "gold standard" for diagnosis. The first antibody tests were IF assays using virus-infected cells spotted onto microscope slides or ELISAs using crude virus-infected cell lysates to coat microtiter plates. Both methods proved useful in diagnosing SARS, but it soon became clear that serology had a major limitation for diagnosis. Seroconversion following infection with SARS-CoV usually occurred in weeks 2 and 3 of illness, and some patients seroconverted as late as 28 days postinfection. Given the delayed seroconversion, serology has limited utility for the diagnosis of infection during the acute phase of illness. SARS-CoV IgM and IgG class antibodies appear at the same time following infection, and therefore IgM testing does not assist in the serodiagnosis. IgA antibody appears about the same time as IgG and persists in serum for 1 to 2 months. IgM antibody persists for about 11 weeks and is then undetectable, whereas IgG persists for months and probably years. The SARS whole-cell immunofluorescence (IF) test detects mostly antibody to the N protein, and about 4% of sera from healthy individuals give a positive result, due to the presence of antibodies cross-reacting with N proteins of other CoV. ELISAs using crude antigens showed sensitivities and specificities similar to those of the IFA test. Western blot (WB) assays using whole virus cell lysates show the presence of a predominant N protein band (often a doublet or triplet of around 36 to 48 kDa), an S antibody band at 150 kDa, and less predominant antibody bands at 80, 60, 32, and 24 kDa (24). Recombinant S and N proteins have quickly replaced viral lysates in ELISAs and WB and immunodot assays and provide a safe, low-cost alternative for serodiagnosis. The N protein has been shown to be the immunodominant protein of SARS-CoV and an excellent antigen for use in the ELISA. The recombinant-N-protein-ELISA has improved sensitivity and specificity compared with the whole-lysate assay and can be used to measure IgG, IgA, and IgM class antibody by using specific conjugates. Several laboratories have compared the use of the recombinant N protein in a WB assay and an immunodot assay or ELISA and found sensitivities and specificities in the range of 94 to 96 and 96 to 98%, respectively (48). Although the S protein is an important viral protein and elicits neutralizing antibody, the recombinant-S ELISA is less sensitive than a recombinant-N ELISA (49) and it has not been widely used in serologic tests. The development of commercial tests for the measurement of SARS-CoV antibody has been slow; the Euroimmun IFA test from Germany has been the only test to be introduced into North America. Further evaluations using large numbers of sera will be required to determine the true performances of individual antibody tests compared with that of the neutralization test (NT).

The gold standard test for detecting SARS-CoV antibody is the NT. The performances of all new serologic tests should be evaluated by comparing them with that of the NT. Because this test measures neutralizing antibody by reacting serum with live virus, the test can be performed only in a biosafety level 3 facility and is limited to only a few laboratories. For this reason, the kinetics for the appearance of NT antibody and the role of IgM and IgA class antibody in virus neutralization are poorly understood. The recent development of SARS-CoV pseudotype virions and their use in neutralization and virus entry assays provide a novel method for assessing neutralizing antibody in SARS patients' sera that is safe (does not require biosafety level 3 containment) and cost-effective (16). This assay can easily be automated for high-throughput capacity for the large-scale screening of neutralizing antibody for vaccine trials. Recent comparisons of different SARS antibody tests indicate that the NT has the highest specificity and that the ELISA using recombinant N or S proteins has higher sensitivity (49; M. Smieja, J. Mahony, M. Petric, T. Mazzulli, M. Fearon, G. Hawes, D. Dick, T. Booth, L. deKoning, R. Spafford, L. Haynes, and S. Richardson, *20th Annu. Clin. Virol. Symp.,* abstr. B40, 2004). A WB assay can be used to confirm N protein ELISA positive results (48).

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

In the event that SARS returns, laboratories will be faced with significant challenges to diagnose SARS when other common respiratory viral infections and possibly new, unconventional agents such as avian influenza virus are cocirculating in the population. Of the nearly 20 different NAAT that have been described for the detection of SARS-CoV RNA, most of the assays have been evaluated only with small numbers of clinical specimens from infected patients, and their true performance characteristics are poorly defined. This is particularly the case for the first generation of commercially available assays. The unique natural history of SARS-CoV infection, together with its clinical importance, dictates the testing of both respiratory and nonrespiratory specimens, the testing of multiple specimens from the same patient, and confirmatory testing performed by a reference laboratory before a positive diagnosis is reported.

Laboratory policy for reporting positive test results should be based on recommendations from the Centers for Disease Control and Prevention and the World Health Organization as follows: for a positive RT-PCR result, (i) repeat the test using a second aliquot of the original specimen and, if positive, confirm the result by sending the specimen to a reference laboratory, or (ii) test the positive specimen by using

a second RT-PCR test targeting a different part of the genome and, if positive, confirm by sending the specimen to a reference laboratory (http://www.cdc.gov/ncidod/sars/guidance/f/pdf/app2.pdf). A negative RT-PCR test result for an NP specimen from a suspected SARS patient does not rule out SARS since SARS-CoV is present in low levels in the upper respiratory tract in the first week of infection (3, 40). A negative result from an infected patient may be due to the presence of PCR inhibitors that copurify with RNA, a poor-quality specimen, or a specimen lacking virus. Specimens containing a small amount of virus may test negative if an insufficient volume of the specimen is used for nucleic acid extraction or if a low number of target molecules are partitioned into a large aqueous volume and only a portion of the sample is tested (39). Since the levels of viral RNA in NP and stool specimens rise in the second week of illness, a follow-up NP and/or fecal specimen should be collected and tested by PCR. Detection of SARS-CoV in plasma or peripheral leukocytes should be considered since this approach provides sensitivities of around 80% during the first week of illness. The use of multiple and serial respiratory tract and fecal specimens will improve the sensitivity of PCR diagnostic testing especially when a large volume of the sample is extracted and a large proportion of the sample RNA is used for amplification (4, 36). Recognizing that the first human infections were caused by a zoonotic virus that adapted to its new human host and that humankind faces the continuing possibility of the introduction of new variants of animal SARS-associated viruses, greater vigilance will be required to make a diagnosis of infection if new animal CoV are introduced into the human population. The use of RT-PCR assays employing consensus primers and sequencing that can detect all known CoV would be recommended in this scenario.

Hepatitis A and E Viruses*

DAVID A. ANDERSON

92

Viral hepatitis is the general term for inflammatory disease of the liver caused by at least five different viruses, with hepatitis A, B, C, D, and E viruses having a definite association with acute viral hepatitis. Of these, only hepatitis A virus (HAV) and hepatitis E virus (HEV) are enterically transmitted, and both cause acute and generally self-limiting infections without any long-term carrier status. While there are no serious long-term sequelae in patients who recover from hepatitis A or hepatitis E, both viruses are associated with significant risks of acute, fulminant hepatitis and liver failure. These severe outcomes are most commonly seen in patients with acute hepatitis A on a background of chronic hepatitis C or hepatitis B virus infection, and for patients with hepatitis E during pregnancy, especially during the third trimester. In the absence of these cofactors, the diseases show a general trend toward greater severity with increasing age, with the majority of infections being subclinical in children; however, severe and fulminant HAV and HEV infections can occur at any age.

TAXONOMY

HAV

HAV is the type species of the *Hepatovirus* genus within the family *Picornaviridae*. No other members of this genus have been identified. HAV is distinguished from other picornaviruses (such as poliovirus) by its tropism for the liver, its high thermal stability, the small size of the VP4 protein, and the assembly of a unique capsid intermediate (PX) during virus assembly (Fig. 1). Although there is significant genetic diversity among HAV strains, with two major genotype groups found in humans and a third genotype considered to be a true simian strain (AGM-27) (34, 100), all strains of HAV represent a single serotype, and this diversity does not affect the performance of serological assays. Genotyping of HAV is based on sequence analysis around the VP1-2A region and is useful as a research tool for outbreak investigations (81, 82).

HEV

HEV is the type species of the *Hepevirus* genus within the family *Hepeviridae* (38). Recent descriptions of an HEV-related virus from chickens which causes big liver and spleen disease (77) and hepatitis-splenomegaly (45, 50) demonstrate that this viral family is more extensive than previously suspected. The avian HEV-like virus has been fully sequenced (50), but due to its rather low sequence homology with human and swine strains (around 50% at the nucleotide level, compared to a minimum of 75% between mammalian strains), it is uncertain whether this should be considered a strain of HEV (avian HEV) or, rather, the type species of a second genus within the *Hepeviridae* family. This would be analogous to the taxonomy for mammalian and avian hepatitis B viruses (*Orthohepadnavirus* genus and *Avihepadnavirus* genus, respectively, within the family *Hepadnaviridae*).

Four genotypes of HEV have been described to occur in humans, at least two of which appear to represent zoonotic infections originating from viruses endemic in swine and other animals (see below) (36, 49, 86, 87, 109).

DESCRIPTION OF THE AGENTS

HAV

HAV is a small virus with a nonenveloped, icosahedral capsid approximately 27 nm in diameter enclosing a single-stranded, positive-strand RNA genome of around 7,500 nucleotides (nt) (Fig. 1A). Viral particles have a sedimentation coefficient of around 156S and a buoyant density of 1.325 g/cm^3 in cesium chloride (60). HAV is resistant to low pH (3.0) and shows remarkable thermal stability, especially in the presence of magnesium salts (3). Thorough cooking is necessary to inactivate HAV in contaminated foods.

An outline of the viral replication mechanism is shown in Fig. 1A. The positive-strand RNA genome contains a single open reading frame (ORF) which is translated to yield a giant polyprotein, and the virus-encoded 3C protease cleaves the polyprotein at a number of sites, liberating eight proteins in the first instance, including the RNA-dependent RNA polymerase (RDRP or 3D^{pol}) and protease, 3C^{pro}. The small VPg protein (part of 3AB) then serves as a primer for the synthesis by RDRP of a complementary, negative-strand RNA, and subsequently for further copies of positive-strand RNA. These identical "daughter" positive-strand RNAs serve as templates for further transcription to amplify the RNA pool, as mRNA for synthesis of viral proteins, and finally as new genomes for encapsidation within the viral particle (see reference 83 for a

* This chapter contains information presented in chapter 95 by Edwin A. Brown and Jack T. Stapleton and chapter 98 by George G. Schlauder and George J. Dawson in the eighth edition of this Manual.

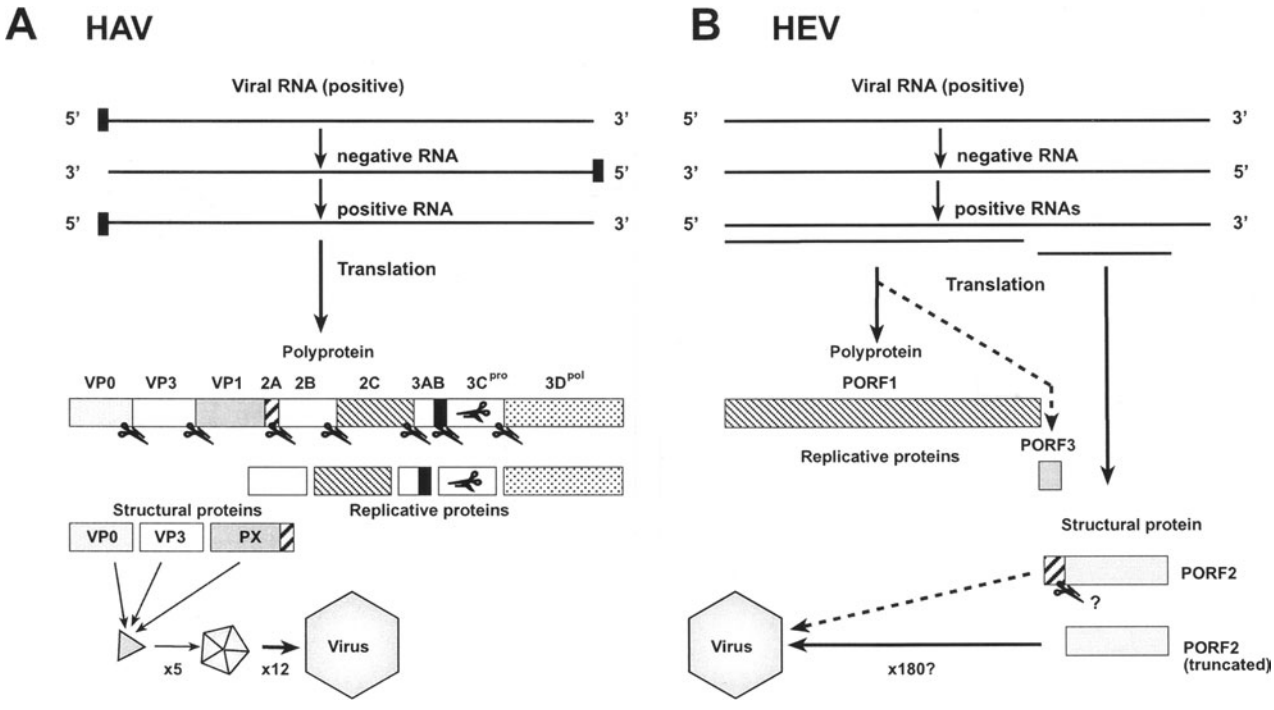

FIGURE 1 Genome replication and proteins of HAV and HEV. Both viruses have positive-strand RNA genomes of around 7,200 to 7,500 nt. (A) HAV replication proceeds via transcription from the genome to give full-length negative-strand and then positive-strand RNA, which can be either assembled into the virus particle or used to translate further copies of a single, giant polyprotein which is processed by viral protease to yield the replicative proteins and capsid proteins. Assembly of five copies of each of the three capsid proteins (VP0, VP3, and PX) into pentamers and then 12 pentamers into capsids is required to form the antigenic sites of the virus. (B) Details of HEV replication are unknown, but it most likely produces a full-length negative-strand RNA and then full-length positive-strand RNA (new viral genomes) as well as subgenomic mRNAs which are used to translate the ORF2 (capsid) and ORF3 proteins, as well as the ORF1 polyprotein, which is cleaved at unknown sites to yield the replicative proteins. Cleavage of full-length PORF2 results in assembly of virus-like particles from the truncated product, but the size of the authentic viral capsid protein is unknown. Modified from reference 4.

comprehensive review of picornaviral replication). The HAV particle is initially composed of three proteins, VP0, VP1–2A (also known as PX), and VP3 (6), that are liberated from the polyprotein by 3C protease (Fig. 1A). Five copies of each of the three proteins associate to form pentamers, and 12 copies of the pentamer form virions (with viral RNA) or empty capsids with the same antigenicity. Following assembly, 2A is removed from VP1 by cellular enzymes and/or 3C protease, and VP0 is cleaved to yield VP2 and VP4. The mechanism by which virus is released from the liver is unknown; liver damage is most likely a result of cellular immune responses to the virus rather than direct lysis of hepatocytes by the virus.

Diagnosis and immunization for hepatitis A are not complicated by strain differences, despite significant levels of amino acid variation in the capsid proteins, because HAV exists as a single serotype worldwide. This is especially notable in the case of the highly divergent AGM-27, which is considered a true simian strain of HAV and causes disease in African green monkeys and other lower primates (34, 100). The antigenic sites of HAV are formed through the complex interactions of the proteins within and between pentamers (95), which has hampered the production of HAV antigenic material through recombinant DNA techniques. As a result, cell culture remains the only reliable source of HAV antigens for serological diagnostic tests and for vaccines. The replication of HAV in cell culture is rather inefficient compared to that of most picornaviruses, which necessitates very-large-scale cell culture production, but the virus is highly immunogenic. A number of highly effective licensed vaccines are available against HAV: Havrix (GlaxoSmithKline) and Vaqta (Merck) within the United States, together with Avaxim (Sanofi Pasteur) and Epaxal (Berna Biotech) worldwide. A combination hepatitis A and hepatitis B vaccine, Twinrix (GlaxoSmithKline), is also widely available.

HEV

Virions of HEV are nonenveloped, icosahedral particles approximately 32 to 34 nm in diameter, most likely comprising a single viral protein which encapsidates the single-stranded, positive-sense RNA genome of approximately 7,200 nt. Virions of HEV are much less stable than those of HAV, being sensitive to conditions such as CsCl and freeze-thawing that have no effect on HAV, and showing much greater sensitivity to heat than does HAV (32). This lower stability is likely to be a major factor in the low secondary attack rate for HEV. Virions have a sedimentation coefficient of 183S and a buoyant density of 1.29 g/cm^3 (measured in potassium tartrate-glycerol) (17). The single capsid protein is

encoded by ORF2, expected to yield a protein of 660 amino acids; however, the capsid protein of authentic viral particles has not been characterized.

Extensive progress has been made in the development of HEV diagnostics and experimental vaccines based on heterologous expression systems for viral proteins, but HEV has proven refractory to propagation in conventional cell cultures. Studies using infectious cDNA clones of HEV (35) are now revealing many aspects of HEV replication.

A schematic of the HEV genome and encoded proteins is shown in Fig. 1B. The 7,204-nt infectious cDNA clone of the SAR-55 strain of HEV described by Emerson and colleagues (35) can be assumed to be full length. Most isolates of HEV are close to this length, with the larger swine (69), US-2 (85), and T1 strains (110) having insertions of around 54 nt within ORF1, while the recently described avian HEV is substantially smaller, at 6,654 nt, due to deletions in both ORF1 and ORF2 (50).

The 5′ end of the genome has a 7-methylguanosine cap, while both the 5′ and 3′ ends of the viral RNA have short, highly conserved untranslated regions which are likely to function in viral replication. Three ORFs, organized as 5′-ORF1-ORF3-ORF2–3′, with ORF3 and ORF2 largely overlapping, encode the viral proteins (described here as PORFs) PORF1 (replicative polyprotein), PORF3 (unknown function), and PORF2 (capsid protein), respectively (Fig. 1B).

HEV shows a much greater degree of genetic diversity than HAV (see references 50 and 87 for detailed reviews of HEV genotypes). HEV can be classified into four putative "genotypes" (as defined by Wang and colleagues) (109); the Burmese and related strains (including most Chinese strains) are classified as genotype 1, the Mexican strain is classified as genotype 2, the swine HEV strain discovered in the United States (67) and closely related strains isolated from patients infected in the United States (85) are classified as genotype 3, and distinct isolates from patients in China (T1 strain) (109) and both patients and swine in Taiwan (48, 49) are classified as genotype 4. Until recently, the original Mexican strain was the only known representative of genotype 2; however, strains isolated in Nigeria also appear to be genotype 2 (18), whereas other African strains have been genotype 1 (105).

In contrast to HAV, the genotypic differences between HEV strains are associated with significant antigenic differences, with corresponding effects on the sensitivities of many serological assays (see below). However, these antigenic differences appear to lie outside the principal neutralizing antibody domains, since HEV appears to exist as a single serotype, with experimental vaccines providing strong cross-genotype protection (102, 118). Similarly, the identification of conserved, immunodominant epitopes has resulted in greatly improved diagnostic tests that appear to detect all HEV strains (5, 20, 39, 42, 47, 66, 72, 113, 115). A candidate HEV vaccine, based on a truncated HEV ORF2 protein (amino acids 112 to 607) expressed in insect cells, has been the subject of extensive preclinical studies (33, 78, 102, 117, 120), and a phase III trial was concluded in Nepal during 2003, with analysis ongoing.

EPIDEMIOLOGY AND TRANSMISSION

Despite sharing the primary mode of transmission via human feces, HAV and HEV have very different distributions of both disease and infection worldwide. These differences appear to be linked at least partly to the efficiency of virus transmission, with HAV being excreted in very high titers allowing both waterborne and person-to-person spread, whereas HEV is more commonly seen in waterborne outbreaks. However, unresolved questions remain regarding the prevalence of HEV infection in areas in which HEV is highly endemic, such as Nepal, where infection with HAV is almost universal and yet less than 50% of the population shows evidence of exposure to HEV (5, 23).

HAV

Transmission

The generalized course of infection and serological responses for both HAV and HEV are shown in Fig. 2. Due to its enteric route of transmission, HAV has been widely assumed to infect cells lining the alimentary tract. However, studies in Caco-2 cells suggest that progeny HAV from intestinal epithelial cells is released back into the lumen of the gut rather than into the circulation (16), and the virus is around 10,000-fold more infectious when administered by the intravenous route rather than the oral route (79), consistent with early studies that suggested the liver as the primary site of replication, with amplification in the alimentary tract making little or no contribution (56). During the incubation period of 4 to 6 weeks after first exposure to the virus, HAV spreads throughout the liver without causing any cytolytic effects, but liver damage eventually results and is most likely mediated by the cellular immune response to the virus, with infections in young children generally following a benign course. Virus is excreted through bile to the gut, and very high titers of infectious HAV will be present in most patients at the onset of illness. Virus is generally cleared within several weeks, although prolonged excretion of HAV has been reported in a significant proportion of cases. In general, titers of excreted virus will be highest before the onset of obvious symptoms.

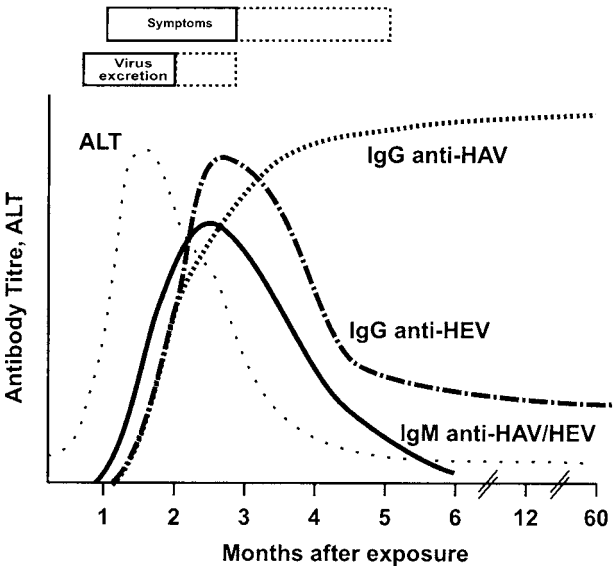

FIGURE 2 Serological and virological courses of infection with HAV or HEV. For HAV, the serological responses shown are typical of those detected with numerous commercially available assays. For HEV, the serological responses shown are those that probably occur in most patients, but the detection of these responses will vary widely depending on the assays used. High levels of HAV-specific IgG provide lifelong protection from reinfection, but HEV-specific IgG declines rapidly during the first 6 months and might not persist at protective levels for life. Modified from reference 4.

Although the vast majority of progeny virus is excreted in the feces, HAV patients display a viremia that may last for some weeks around the time of clinical presentation. Transmission of HAV via blood products has been demonstrated (71), and inactivation procedures to eliminate HAV are clearly required in the manufacture of blood products (58). Fortunately, such processes have now been validated for HAV, and further transmission is unlikely (1, 53, 59).

Epidemiology—High, Low, and Intermediate Rates of Infection

HAV is found worldwide, but with widely varying epidemiological patterns that largely reflect sanitation standards (14). In countries or areas with poor sanitation, high levels of HAV exposure result in most individuals becoming infected at an early age, but in these circumstances HAV is not a major public health problem because the symptoms tend to be mild or absent in children and very few members of the adult population are susceptible. However, HAV can certainly cause clinical disease in children, most obviously in foodborne outbreaks in schools of developed countries (51, 80) but also in endemic populations in countries such as Nepal (I. L. Shrestha, personal communication) and Turkey, where HAV was the most commonly identified cause of fulminant hepatic failure in children from 1 month to 17 years of age (12).

Conversely, in countries or populations with high standards of personal and public sanitation, relatively few individuals are exposed at an early age. In many countries of Western Europe, uniformly high standards of sanitation result in very low rates of HAV disease even though the vast majority of the population is susceptible. In the United States, Australia, and other countries with generally high sanitation levels but a wide diversity of socioeconomic circumstances, sporadic HAV infection continues at a low level, especially in the very young and even more so in disadvantaged communities where standards of personal hygiene are low. Combined with high transmissibility, this focal circulation of virus in some populations and geographic areas provides an ongoing source of virus for sustained transmission throughout the broader community.

Household or sexual contact with a person known to have hepatitis A was the most commonly identified risk factor for disease during the period from 1990 to 2000 in the United States (14%), but 46% of cases had no identified risk factor (15). Children in day care centers were identified as a risk factor in 8% of cases, but children are likely to be a factor in a large proportion of the cases where no risk factor was identified (94). An important aspect in the epidemiology and transmission of HAV is the high titer of virus produced, combined with the very great physical stability of the viral particle, which is relatively insensitive to extremes of heat: infectious virus is readily recovered after heating for 10 min at 60°C, and as much as 78°C when in the presence of 1 M $MgCl_2$ (3).

HAV disease burden in the United States was estimated at more than 140,000 cases and 80 deaths annually in 1990 (43), but it declined rapidly over the next 10 years (see reference 15 for a comprehensive review). This decline was most pronounced in children, from a peak incidence of 39 cases/100,000 in 1990 to around 2 cases/100,000 in 2002, coincident with the introduction of targeted immunization of children from high-risk ethnic and racial groups and geographic areas, but the rate in adults (>18 years) also fell, from around 17 cases/100,000 to 2 cases/100,000, during the same period (15).

The public health problem of HAV in the United States and other countries with low-level HAV endemicity is compounded by the potential for large outbreaks of HAV spread by contaminated foods. Food- and waterborne infection with HAV was identified as a factor in 4% of cases from 1990 to 2000 (15), but this proportion is likely to increase because such cases will not be prevented by targeted immunization strategies.

In the past, such outbreaks were largely confined to shellfish, which concentrate viruses such as HAV from large volumes of water and which are generally eaten raw or only lightly cooked. Examples are provided by outbreaks seen in Shanghai, China, in 1988 (44), the United States in 1991 (31), and Australia in 1997 (24). However, the increased trade in foodstuffs between countries now creates additional sources of infection, such as a number of outbreaks within the United States which have been traced to fresh and frozen foods imported from Mexico (29, 51, 80, 111), where they had presumably been exposed to contaminated water during production or processing.

Intravenous and other illicit drug use is also positively associated with a higher risk of HAV infection, and may play a major role in the epidemiology of HAV in some societies (90). Men who have sex with men are at increased risk, and outbreaks in this population in different countries have been described in recent years (15).

Residents from developed countries who travel to regions of endemicity, especially those visiting friends and relatives in regions of endemicity, are at greatly increased risk of HAV infection (8). The relative contribution of travel to the HAV disease burden may be underestimated, because travel history is often overlooked in diagnosis.

The greatest disease burden for HAV worldwide falls on countries that have previously had high rates of HAV infection but are now undergoing rapid economic growth and improvements in public sanitation and infrastructure, resulting in intermediate rates of HAV infection. Improved sanitation has the effect of sparing many young children from infection, but this results in a much larger pool of susceptible older children and young adults in whom disease is more pronounced. HAV may continue to circulate widely through household and close contact, resulting in high rates of clinical disease. Universal immunization programs may be required to reduce disease burden in these populations, but this is unlikely to be feasible for most countries in the near future.

HEV

Transmission

Hepatitis E is primarily transmitted via the fecal-oral route. HEV RNA is detectable in the feces of 50% of patients 2 weeks after onset (22), and in one case has been detected at 52 days after onset (73). Consumption of contaminated water is by far the most common route of transmission for clinical cases of HEV in countries where HEV is endemic, with household contact being much less important than for HAV.

Travel to HEV-endemic areas is the most common source of HEV infections in areas of nonendemicity such as the United States and Western Europe, but locally acquired HEV infections also occur, representing zoonotic infections from pigs or other unidentified hosts (45, 48, 69, 85). Genotyping has demonstrated close relationships between viruses from human cases of HEV and local swine HEV strains in many developed countries (for an example, see reference 48), and cross-species infection has been experimentally established for swine and human HEV (68), although other strains are unable to cross species (67). The route of transmission for these HEV cases is unknown, as patients with clinical cases generally have no

evidence of contact with swine. In Japan, a number of reports have demonstrated HEV infection following the consumption of raw or partially cooked liver or meat from swine or deer harboring corresponding strains of HEV (70, 75, 76, 93, 96, 114), but this is unlikely to be a significant source of infection in other countries.

HEV leads to a significant viremia, with the majority of patients being positive by reverse transcriptase PCR (RT-PCR) at the time of disease onset, and there have been several reported cases of hepatitis E associated with transfusion both in countries where HEV is endemic and in countries where it is not (10, 65).

Epidemiology—HEV-Endemic and Non-HEV-Endemic Countries

In countries where HEV is endemic, sporadic HEV infection is often the most common form of viral hepatitis on an annual basis, accounting for around 70% of cases in Kathmandu, Nepal (7), but above this background major epidemics also occur with a period of around 7 to 10 years. For example, HEV was shown retrospectively to be responsible for 16 of 17 epidemics of enterically transmitted hepatitis in India (9), but HEV is also responsible for at least 25% of cases of sporadic hepatitis between epidemics (54). Epidemics are most often associated with the wet season; however, one study has shown an increased rate of infection associated with a period of unusually low rainfall, presumably by concentrating human wastes in a riverine ecology (25).

Clinical HEV infection in HEV-endemic countries is most common in adolescents and young adults, but occurs to a lesser extent from childhood (52) to late ages. There appear to be considerable differences in exposure rates among countries where HEV is considered endemic: in Egypt around 60% of children were exposed to HEV by the age of 10, and this rate did not increase further with age (26), whereas in Nepal only 16% of 12-year-olds had evidence of exposure to HEV, peaking at 31% later in life (23).

It is likely that the risk of clinical disease increases with age, as for hepatitis A, but while clinical HAV infection is uncommon in many developing countries because of high exposure rates in children, HEV exposure rates are never as high as for HAV and a large proportion of the population remains susceptible to adulthood.

In developing countries, exposure to water contaminated with human waste is a clear risk factor for disease, and close contact with domestic animals may also be a risk. Importantly, boiling of drinking water appears to be protective (46), but while this will not be practical for all residents in many developing countries, it is advisable for pregnant women because of the high risk of fulminant hepatitis E in this population (see below). The low rate of person-to-person spread of HEV is likely to be due to a combination of lower particle stability (32) and lower virus titers in excreta than for HAV.

Reported seroprevalence rates for immunoglobulin G (IgG) anti-HEV in presumed non-HEV-endemic countries vary widely, at least partly due to the different assays used, which show very poor concordance (64). Observed rates of antibody between 1 and 5% are most common, at least some of which can be considered to represent true anti-HEV reactivity on the basis of neutralization tests (119). Experimental infections of macaques have demonstrated a strong dose response for the development of clinical HEV disease (104), and the unexpectedly high rate of HEV seroprevalence in countries where clinical HEV is very rare may represent subclinical infection with low doses of zoonotic strains of HEV. There is some evidence for increased exposure to HEV in groups with occupational exposure to swine (55). Travel to countries where HEV is endemic remains the greatest risk factor for clinical HEV infection in residents of non-HEV-endemic (developed) countries (88). This risk can be assumed to be especially great for travelers visiting friends and relatives, as for HAV (8).

CLINICAL SIGNIFICANCE

Clinical Presentation and Course

Acute infections with any of the hepatitis viruses cannot be distinguished on clinical characteristics or pathological examinations, and the diseases caused by HAV and HEV are considered together here. However, HEV is unique among the hepatitis viruses in being associated with a high mortality during pregnancy due to fulminant hepatitis with a very rapid onset, approaching 30% in the third trimester, and the rate of fulminant hepatitis for HEV outside of pregnancy is probably around 10-fold higher than for HAV (1 versus 0.1%) (13). The reasons for such severe outcomes of HEV infection are not known, but it is clear that women should take all possible precautions to avoid exposure to HEV during pregnancy. A major risk factor in this regard is travel from non-HEV-endemic countries to HEV-endemic areas such as India and Pakistan.

Infection with HAV or HEV can result in a broad range of clinical outcomes, from subclinical infections (especially in children, or with low doses of HEV) to fulminant hepatitis. Disease severity shows a general increase with age; however, clinical and even fulminant hepatitis A and E do occur in children, and there is no reason to exclude the enterically transmitted hepatitis viruses from diagnostic consideration on the basis of patient age. A retrospective study in Turkey has shown HAV to be the most common identifiable cause of fulminant hepatitis in children (12).

Clinical presentation of acute viral hepatitis commonly begins with nonspecific, "flu-like" symptoms such as fever, headache, anorexia, nausea, and abdominal discomfort. Physical examination will usually reveal an enlarged, tender liver. The first distinctive sign of hepatitis is usually dark urine (excretion of conjugated bilirubin), followed by pale feces and jaundice (yellow discoloration of the skin and sclera), but many patients will not show visible signs of jaundice despite severe symptoms, even when raised levels of serum bilirubin are present. However, it must be stressed that these nonspecific symptoms alone are not sufficient to infer acute viral hepatitis in a patient without jaundice, and liver function tests are an important adjunct to diagnosis (19), with raised levels of aspartate aminotransferase (AST) and alanine aminotransferase (ALT) detectable at the time of onset. Unless there are strong epidemiological grounds for suspicion, hepatitis A or E should not be considered in the absence of one of these biochemical markers or jaundice.

In most developed countries, hepatitis A is much more likely than hepatitis E unless there are specific indications to suggest HEV, such as past HAV infection or recent travel to HEV-endemic areas combined with a history of receiving inactivated HAV vaccine. Patients with proven evidence of past HAV infection will not have HAV, other than those cases that represent relapses after recent HAV infection (92). In most developing countries HEV is more likely than HAV, although HEV appears to be relatively infrequent in many parts of South America.

Serum aminotransferase levels usually resolve after a period of 3 to 4 weeks. Normalization of liver enzymes usually marks complete recovery; however, many patients will report an intolerance to fatty foods which may last for years. Relapses are rare for hepatitis A, occurring in around 7 to 12% of

patients beyond 1 month (92, 98). Protracted hepatitis A has been associated with a particular HLA allele (37). Prolonged disease with hepatitis E has also been observed in some areas of endemicity and is frequently characterized by cholestasis with jaundice and itching. Cholestasis can occur with both hepatitis A and hepatitis E.

While both HAV and HEV (outside pregnancy) have low overall rates of fulminant hepatitis, the onset of encephalopathy can be quite rapid (around 7 days from onset of dark urine for hepatitis A). HEV has been found to be responsible for around 62% of cases of fulminant hepatitis in studies from India (74) and Bangladesh (91), where the virus is highly endemic. Acute HAV infection on a background of chronic hepatitis C or hepatitis B is associated with more severe outcomes (107).

Dose Response to Infection

HAV and HEV differ markedly in the relationship between infecting dose and the course of infection and disease. For HAV, studies in tamarins have shown a very clear correlation between higher infectious doses and reduced incubation period to develop disease, but no correlation with disease severity (79). This is consistent with the high secondary clinical attack rates seen for HAV. Low-dose infections of cynomolgus macaques with HEV have also demonstrated an increased time to seroconversion, but HEV disease severity showed a positive correlation with high infectious doses (2, 104). This attenuation of low-dose infections may help to explain the low secondary attack rates of HEV, and the rarity of clinical HEV disease in non-HEV-endemic countries despite a seroprevalence of around 2%.

Vaccines and Antiviral Agents

Passive immunization with human gamma globulin has been used for many years to provide short-term protection against hepatitis A, and it is still used for postexposure prophylaxis (<2 weeks postexposure) and for infants less than 2 years of age. As noted above, there are now a number of highly efficacious inactivated vaccines available against hepatitis A (Havrix and Vaqta in the United States, plus Avaxim and Epaxal worldwide) or hepatitis A and B (Twinrix), and these have replaced the use of gamma globulin for protection of individuals with future risk of HAV infection. Active immunization against hepatitis A is recommended for children (>2 years) in communities with elevated rates of hepatitis A, travelers to countries where standards of hygiene and sanitation are low, men who have sex with men, recipients of clotting factors, injecting drug users, and patients with chronic hepatitis (in whom disease severity is exacerbated) (19). Targeted HAV immunization has contributed to the rapid decline in HAV disease rates from 1990 to 2002.

No vaccines are yet available for protection against hepatitis E, but the prospects for these are very good. Studies by Purcell, Emerson, and colleagues at the NIH have demonstrated that antibody to PORF2 is sufficient to protect against hepatitis E (101) and that active immunization of macaques with 56-kDa subunit antigen (amino acids 112 to 607) expressed in the baculovirus system has conferred protection against viral challenge with both homologous and heterologous HEV strains (33, 66, 78, 101–103, 117, 120). A phase III clinical trial was completed for this candidate vaccine in Nepal in 2003, and results should be available in the near future. It is likely that this vaccine would be most useful for travelers (including the military, Peace Corps volunteers, etc.) and for residents of countries where HEV is endemic.

No antivirals are available for treatment of hepatitis A or E, and it is unlikely that antivirals would be useful because the acute disease is largely immunopathogenic. Experimental inhibitors have been developed that are active against the 3C protease of HAV, but clinical development of these is unlikely.

No specific symptomatic or anti-inflammatory treatments can be advised for hepatitis A or E. Bed rest and attention to diet (avoiding fatty foods) are commonly recommended to minimize symptoms and speed recovery; alcohol intake should be minimized. Pruritus is a feature of cholestatic hepatitis that may justify the cautious use of corticosteroids.

Intensive supportive medical care, as for acute liver failure due to other causes, is required in cases of fulminant hepatitis A or E. Fulminant hepatitis A has a better prognosis for spontaneous recovery than hepatitis B (69 versus 19% [84]). Liver transplantation is less frequently performed, and there is some risk of graft reinfection (41).

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

Standard methods for collection, transport, and storage of sera or plasma are adequate for the detection of both IgG and IgM antibodies to HAV and HEV, which are the only standard diagnostic tests performed. Sera or plasma can be stored at 4°C for weeks but should be frozen under other circumstances (−20 or −70°C for storage and dry ice for shipping). Shipping is most often an issue with HEV testing, which is not available in many routine diagnostic laboratories. IgM is more sensitive to freezing and thawing than is IgG, and repetitive cycles should be avoided. Feces may be collected for epidemiological studies of HAV (genotyping of strains) and are stable as a solid mass or slurries in phosphate-buffered saline or water for months or years at −70°C. Serum is generally preferable for this purpose. HEV is difficult to detect in feces, and serum is preferred for RT-PCR and genotyping. Because HEV is more labile than HAV, sera for HEV RT-PCR studies must be tested within 24 h or frozen and shipped at −70°C.

Rapid, point-of-care (RPOC) tests for HEV-specific IgM are now available outside the United States (20, 72), which can overcome the need for collection and shipping of venous blood. These tests can be used either for fresh whole blood or for serum and plasma as for laboratory assays.

DIRECT DETECTION

Electron Microscopy

Electron microscopy and especially immunoelectron microscopy are of historical importance for their roles in identifying HAV (40) and HEV (17) particles before the characterization and molecular cloning of the viruses and development of specific diagnostic tests, but they are insensitive and technically difficult and have no diagnostic value.

Antigens

HAV

HAV antigen (HAAg) is very stable and is readily detected in acute-phase fecal samples collected from many patients. Viral antigen is detected by enzyme-linked immunosorbent assay (ELISA) using monoclonal antibodies, and may be present in very high titers in some patients, but patients almost invariably have IgM anti-HAV present by the time of clinical presentation and antigen detection provides no diagnostic advantage over serology. There are no commercially available tests for HAAg.

HEV

HEV antigen is less stable than HAAg, and no reliable tests are available (either commercially or on a research-only basis) for the detection of antigen in clinical samples. It is unlikely that antigen detection would have any clinical value relative to serology or RT-PCR performed on sera.

Nucleic Acids

HAV

HAV patients are viremic in the prodromal phase, and one recent study from Brazil has reported around 12% of children during a common-source outbreak to have been RT-PCR positive but IgM negative ("window period") at the time of testing, together with 26% of patients initially classified as acute, sporadic non-A-C hepatitis (30). The high proportion of window period cases found in this study may be related to high-dose infections with short incubation periods, as all patients available to follow-up seroconverted. Serum is the preferred specimen for nucleic acid detection, but plasma is acceptable provided that anticoagulants do not interfere in the reactions; feces are least suitable, with variable levels of virus and high levels of inhibitors. RT-PCR is not currently recommended for routine diagnostic testing of possible acute hepatitis A, but further studies may be warranted. The blood supply is not currently tested for HAV RNA by RT-PCR; conversely, many manufacturers now routinely conduct HAV RT-PCR screens on pools of source plasma for blood products. HAV RNA can also be used for genotyping of virus for research purposes using RT-PCR primers in the region of VP1-2A (Fig. 1) (11, 21).

HEV

RT-PCR remains the "gold standard" for specificity in the diagnosis of acute HEV infection. However, levels of HEV RNA are generally low and the sensitivity of RT-PCR for diagnosis is very dependent on (i) patient presentation early in disease, (ii) rapid and careful processing of serum or plasma samples and appropriate transport at –70°C, and (iii) reference laboratories for testing and quality control. Serological tests will be preferable for routine diagnosis, and improved tests are now becoming available (see below). RT-PCR has provided the vast majority of information on zoonotic infections with HEV around the world (49, 57, 65, 86, 109, 114, 116), and will remain useful for confirmatory testing in countries of low endemicity such as the United States.

VIRAL ISOLATION

Many isolates of HAV have been adapted to cell culture, but virus isolation is insensitive and generally requires multiple passages over a period of many months, and it is not useful in diagnosis or epidemiological studies. HEV replication has been demonstrated in primary macaque hepatocytes (97), but the virus has proven refractory to propagation in standard cell cultures and virus isolation is not useful.

VIRAL IDENTIFICATION AND TYPING SYSTEMS

As described above, the direct detection of HAV and HEV RNA by RT-PCR and sequence-based genotyping has been used for the identification of potential sources of sporadic cases of HEV in non-HEV-endemic countries, and for the investigation of common-source outbreaks of HAV. HEV genotyping is usually based on the ORF1 region and to a lesser extent on the ORF2 region (49, 57, 86, 109), while HAV strains and genotypes are determined by sequencing in the VP1-2A region of the genome (11, 21).

SEROLOGICAL TESTS

Despite the very good specificity of most serological tests for HAV and HEV, their appropriate use and interpretation are dependent on patients meeting the clinical criteria for acute hepatitis, particularly in areas where the viruses have low incidence, such as the United States and other developed countries. The clinical criteria for the HAV surveillance case definition in the United States consist of "an acute illness with discrete onset of symptoms (e.g., fatigue, abdominal pain, loss of appetite, intermittent nausea, and vomiting) and jaundice or elevated serum aminotransferase levels" (19). Serological testing should be limited to persons who meet the clinical criteria or to persons likely to have been exposed to HAV (19), and in light of the nonspecific nature of the symptoms, the importance of jaundice or elevated ALT or AST in meeting the case definition must be stressed. In the absence of these clinical criteria for patients in regions of nonendemicity, the positive predictive value of the tests will be severely compromised.

HAV

Tests for HAV-specific IgM are commercially available from numerous sources in a variety of formats (ELISA, enzyme immunoassay, and IMx). The technology for detection of HAV-specific IgM is sufficiently well established that there are no significant differences between the diagnostic performances (sensitivities and specificities) of the laboratory-based testing platforms. Choices of diagnostic assays for HAV may reasonably be made on the basis of convenience for the testing laboratory, with a range from single-strip ELISAs for small numbers of specimens to completely automated systems for high-volume laboratories.

Test principles are either IgM class capture or indirect ELISA. In the IgM class capture assays, plates coated with anti-human IgM are used to capture IgM from patient samples, with HAV-specific IgM being detected by binding of labeled HAAg (inactivated HAV derived from cell culture). Indirect ELISAs use plates coated with HAAg, to which HAV-specific IgM will bind, and bound IgM is then detected using anti-human IgM conjugates. In both cases, assay reactivity and cutoffs are determined from internal controls supplied with the kits. Because HAAg binding to plates is generally inefficient, monoclonal antibodies are sometimes used to facilitate the binding of antigen to plates. All commercially available HAV serological assays use inactivated, whole HAV derived from cell culture and thus detect the same antibody specificities.

Total or IgG anti-HAV does not have diagnostic value because antibody persists for life, although a rising titer of IgG (greater than fourfold in specimens taken 2 weeks apart) is indicative of acute HAV. Total HAV-specific antibody is a marker of immunity and can be used for prevaccination screening to identify those who require immunization, but the cost-effectiveness of screening depends on many factors (106). Postvaccination tests are not required due to the very high efficacy of available HAV vaccines. Tests for the measurement of total anti-HAV use a competitive ELISA format, where HAAg is used to coat plates and specific antibody in patient serum binds to the antigen, resulting in a proportionately reduced assay signal from the binding of labeled monoclonal antibodies to HAAg.

In addition to serum or plasma, saliva can be used for detection of anti-HAV IgM or total antibody (99, 108), but

the use of saliva or other samples, such as urine, falls outside the manufacturers' recommendations for current tests. These samples can be useful for research and investigational purposes but require internal validation.

RPOC tests for HAV-specific IgM have been developed (4) but are not yet commercially available. In common with the RPOC test for HEV-specific IgM (20, 72) (see below), these tests may prove especially useful in outbreak investigations.

HEV

A number of research and commercial immunoassays for HEV-specific IgG and IgM are available in various countries, but with major differences in sensitivity and specificity (see below). Only IgG ELISAs are currently available in the United States. The appropriate use and interpretation of current serological assays for HEV infection must take into account differences in assay sensitivity and specificity, the pattern of serological responses (IgG and IgM) to various antigens, and the widely varying rates of prevalence of clinical HEV infection worldwide.

Laboratory-Based HEV Serological Tests

Many recombinant and synthetic peptide antigens have been used in diagnostics for HEV. Antigens included in early HEV diagnostic tests were notable for the transient IgG response observed in most patients (27, 28), which provided some specificity for acute infection but at the cost of sensitivity (7). This variability in IgG responses also contributes to the uncertainty regarding seroprevalence rates around the world, as studies using different antigens cannot be compared. Using more advanced antigens (such as the truncated forms of PORF2 expressed in insect cells, and ORF2.1 expressed in *Escherichia coli*), IgG levels appear to persist for many years (Fig. 2). High titers of IgG in patients are suggestive of acute infection, but this correlation is imperfect (5, 42) and the detection of IgG antibody is thus of little use for diagnosis of acute infection, especially in developing countries where HEV is endemic and large numbers of patients will have antibody from past infections.

HEV-specific IgM is therefore preferable for diagnosis. As in the case of IgG, antigens vary significantly in their rates of reactivity with HEV-specific IgM. Second-generation commercial tests use a cocktail of three antigens (113), each of which has IgM reactivity with a proportion of HEV patient sera; however, positive sera show widely variable reactivities, presumably related to the number of individual antigens recognized by each patient, and the total reactivity rate is still around 60% (112). An artificial recombinant mosaic protein, incorporating numerous linear peptide epitopes, has also been used in research settings (39) but suffers from a similar variability in patient reactivity which decreases assay performance.

Improved IgM ELISAs have now been developed, based on highly conserved and immunodominant antigens derived from the capsid protein, PORF2. The ORF2.1 antigen, representing amino acids 394 to 660 of PORF2 expressed in *E. coli*, was originally shown to be highly conserved and immunodominant in the IgG response to HEV infection (61–63) and has subsequently been developed into an ELISA for HEV-specific IgM (20). This test has an overall sensitivity of 98.7% (149 positive of 151 confirmed HEV patients) and a specificity of 97.6% (203 negative of 208 patients with other forms of viral hepatitis or other diseases) (20), and it is commercially available outside the United States.

Sensitive and specific tests for HEV-specific IgM have also been developed using the truncated r55k antigen, representing amino acids 112 to 607 of PORF2 expressed in insect cells, in both indirect ELISA and IgM class capture ELISA formats (89, 115), but these are not commercially available.

RPOC HEV Serological Tests

The major disease burden of HEV falls in developing countries and is especially severe among displaced populations such as refugees, with major epidemics observed from 2004 to 2005 in the Greater Darfur region of Sudan. Timely access to sophisticated laboratory facilities is not available in these situations, highlighting the need for rapid diagnostic assays that can provide reliable diagnosis at the point of care, with minimal training or infrastructure. RPOC tests for HEV-specific IgM have now been developed using the ORF2.1 antigen and corresponding monoclonal antibodies in a novel format of immunochromatographic test (Fig. 3) (20, 72), and they will be commercially available in many countries (outside the United States) in the near future.

The HEV IgM RPOC test has been evaluated in two separate studies. In the first study (20), the RPOC test showed a sensitivity of 96.7% (146 of 151) and an overall specificity of between 98.6% (205 of 208) and 96.9% (220 of 227) depending on exclusion or inclusion of sera having high levels of rheumatoid factor (RF), a common source of false-positive reactivity in rapid assays. In the second study (72), the RPOC test showed a slightly lower sensitivity, of 93% (186 of 200), but a specificity of 99.7% (320 of 321) against a panel including RF-positive sera and sera from patients with acute Epstein-Barr virus infection, a further source of problems in many RPOC tests. The positive and negative predictive values of the test were estimated at 98.0 to 99.5% and 97.6 to 95.0%, respectively (20, 72). These results suggest that RPOC tests will certainly prove useful for the diagnosis of HEV in field situations in regions of endemicity and may also be considered as an alternative to ELISAs for laboratory use in both non-HEV-endemic and HEV-endemic regions.

These RPOC tests offer the further benefit of reduced collection of venous blood, which is difficult in small children and not well tolerated in some cultural settings.

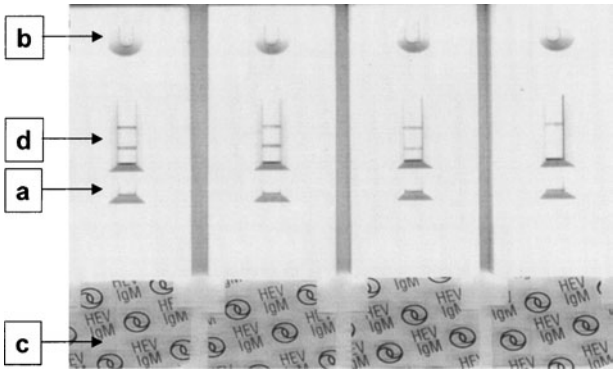

FIGURE 3 RPOC tests for HEV-specific IgM. Undiluted serum (25 μl) was added to the specimen window (a) and allowed to migrate through part of the membrane. Approximately 30 s later, 3 drops of buffer were added to the buffer window (b), the separator was removed by pulling the protruding end (c), and 1 drop of wash buffer was added to the specimen window. Results were visible through the viewing window (d) after 8 min. Samples are considered positive for IgM anti-HEV if two colored lines appear in the viewing window and negative for IgM anti-HEV if a colored line appears only at the control line. Test kits were as described in references 20 and 72 and were kindly provided by Genelabs Diagnostics. Data are from my laboratory.

Serological Diagnosis of HEV Infection in Areas of Low Prevalence

In areas with a low incidence of clinical HEV infection, such as the United States and Western Europe, assay specificity will have a very large impact on the predictive value of HEV serological tests. In order to be useful, HEV diagnostic assays will need to demonstrate very high specificity, high sensitivity, and the ability to detect infections caused by the diverse range of HEV strains (including potentially zoonotic strains) that are present worldwide. Diagnostic assays for the detection of HEV-specific IgG have considerable value for the diagnosis of acute hepatitis in travelers returned from areas of endemicity, among whom the incidence may be much higher than the approximate 2% prevalence in the healthy population. However, with the recognition that HEV should be considered in the diagnosis of sporadic acute hepatitis *without* a travel history, the need for more specific tests becomes evident. For example, if the incidence of HEV infection among acute hepatitis patients in the United States was 0.2%, then only 1 in 10 patients with samples reactive in a test for HEV-specific IgG would be a true positive, leading to an unacceptable positive predictive value.

The detection of HEV-specific IgM should therefore become the method of choice for diagnosis of acute HEV infection in areas of low prevalence. Early assays for HEV-specific IgM showed false-positive reactivity in 3% of U.S. blood donors (technical bulletin; Genelabs Diagnostics, Singapore, Singapore, 1998), roughly equivalent to the rate of IgG reactivity, which limited their usefulness in areas of nonendemicity. A prototype IgM ELISA based on the ORF2.1 antigen was positive for only 1 of 500 Australian blood donors (specificity of 99.8%; D. Anderson, M. Riddell, F. Li, I. Shrestha, T. Howard, G. Perry, and G. Mearns, *Abstr. 10th Int. Symp. Viral Hepatitis Liver Dis.,* abstr. E001, 2000). A modified version of this test demonstrated a higher level of false-positive reactivity (2.4%) in studies to evaluate the RPOC test (20), but the commercial version of the ELISA has not been fully evaluated to date. The quantitative indirect IgM ELISA (89) and the IgM class capture assay (115) using r55k antigen have reported specificities of around 100%. Notably, the RPOC assay is also IgM class capture and has a specificity between 98.6 and 99.7% in different studies (20, 72). Many of these new tests should be suitable for use in regions of nonendemicity.

Serological Diagnosis of HEV Infection in Areas of High Prevalence

Although the titer of HEV-specific IgG tends to decline markedly in the first year after infection (Fig. 2), this relationship is not reliable enough to form the basis of differential diagnosis (5, 42). The detection of HEV-specific IgG is therefore of little use for diagnosis of acute infection in developing countries where HEV is endemic and large numbers of patients will have antibody from past infections. Detection of HEV-specific IgM must therefore be the method of choice in areas of endemicity.

As HEV accounts for as much as 70% of the cases of acute sporadic hepatitis in countries where HEV is endemic, the specificity of assays is less critical in these settings, and assay sensitivity is of primary concern. The HEV IgM assays based on recombinant antigens expressed using the baculovirus system (89, 115), or the ORF2.1 antigen expressed in *E. coli* (5, 20) all appear to have sufficient sensitivity to allow their use in settings of endemicity. The robustness of assays should also be considered. For example, assays will sometimes be processed and interpreted manually where equipment such as ELISA washers and readers is not available. The ORF2.1 IgM ELISA has been evaluated in routine clinical laboratories based in regions of endemicity, allowing the identification of acute sporadic hepatitis E in a large proportion of patients in Nepal (7).

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

In many developed countries, including the United States, the rarity of HEV infection and declining rates of HAV infection, coupled with increasing rates and recognition of hepatitis C and hepatitis B virus infections, provide a challenge in the correct diagnostic test selection for individual patients. In particular, testing for HAV IgM in the absence of clinical or epidemiological features consistent with acute hepatitis A is likely to result in false-positive results (19), and the same is true of HEV. Close attention should be paid to the clinical characteristics and patient history, including overseas travel, in interpretation of test results.

Hepatitis A is a reportable disease in the United States, Australia, and many other developed countries, where patient contacts are generally managed by active or passive immunoprophylaxis. In routine laboratories, interpretation of HAV and HEV IgM serological tests is based on reference to internal test controls according to manufacturers' specifications. Many laboratories test for total HAV Ig and if positive retest for HAV IgM, which may be more convenient for sample throughput in areas of low endemicity. There are no standard confirmatory tests for HAV and HEV, again highlighting the need for test requests to be justified on clinical and/or epidemiological grounds in order to reduce false-positive results. False-negative results are uncommon for HAV and should be uncommon with the more recently developed HEV tests, because patients almost always have IgM present by the time of clinical presentation and the window period for seroconversion is very narrow. When false negatives are strongly suspected, for example, a negative HAV IgM test for a patient with raised ALTs and contact with a person with a confirmed case of HAV, it may be appropriate to request a second specimen for retesting.

Hepatitis C and G Viruses*

JOHN D. SCOTT AND DAVID R. GRETCH

93

HEPATITIS C VIRUS

Taxonomy

Hepatitis C virus (HCV) is classified in the *Flaviviridae* family, in the genus *Hepacivirus*. It is distantly related to arthropod-borne flaviviruses such as yellow fever virus, West Nile virus, and dengue virus but is more closely related to GB virus (GBV) type C (also known as hepatitis G virus) and pestiviruses.

Description of the Agent

HCV is an enveloped, single-stranded, positive-sense RNA virus which is 30 to 60 nm in diameter (121). Figure 1 displays the organization of the HCV genome, approximately 9,600 nucleotides in length. It consists of highly conserved 5′ and 3′ noncoding regions with a single open reading frame region producing a 3,011-amino-acid polyprotein. After posttranslational processing, the polyprotein is cleaved into structural and nonstructural proteins. The four structural proteins consist of the core (C), envelope 1 (E1), envelope 2 (E2), and transmembrane (p7) proteins. The six nonstructural proteins (NS2 to NS5B) are essential to viral replication and growth and therefore are attractive targets for antiviral therapy. The highly conserved NS5B protein produces the RNA-dependent RNA polymerase. Viral kinetic studies with patients receiving antiviral treatment suggest that HCV replicates at a prolific rate, producing 10^{12} virions/day, with a half-life of 2 to 3 h (83).

Hepatitis C virus infects primarily humans, and the vast majority of human infections are transmitted by other humans, usually through some blood exposure. Although persistent infection occurs in the chimpanzee, *Pan troglodytes*, the animal is not a significant reservoir for HCV.

One of the major hurdles in hepatitis C research has been the inability to grow the virus in cell culture. In recent years, the replicon system was developed to allow limited in vitro study of the virus. This system was developed by inserting part of the HCV genome containing the 5′ untranslated region (5′ UTR), along with the neomycin resistance gene and heterologous viral regulatory sequences into hepatoma cells (69). The replicon produced abundant proteins and viral RNAs de novo in hepatoma cell lines, as well as B cell and epithelial cell lines (118, 142), but did not produce infectious virus. Production of infectious HCV particles was recently facilitated by the discovery of a wild-type strain taken from a patient with fulminant hepatitis, JFH1, which was genetically altered to create an infectious chimeric HCV. By using the nonstructural region of the JFH1 strain in combination with RNA from a different HCV strain, infectious virus was grown and passaged in an optimized cell culture milieu, representing a major breakthrough in the study of hepatitis C virus (67, 132, 141).

HCV has been classified into six major genotypes, which differ in nucleotide sequence by as much as 30%, and more than 80 subtypes (32). These genotypes, numbered 1 through 6, have unique geographical niches and important clinical implications. Genotype 1 is most common in the United States and Europe, while genotypes 4, 5, and 6 are common in Egypt, South Africa, and Southeast Asia, respectively. In the United States, genotype 1 accounts for approximately 71.5%, genotype 2 for 13.5%, genotype 3 for 5.5%, and genotype 4 for 1.1% of the total HCV infections (57). While there is little difference in the transmission and natural history among the various genotypes, the genotype is the strongest predictor of response to peginterferon and ribavirin therapy and thus is routinely determined during the evaluation of patients. Previously, researchers believed that patients were infected with only one genotype (129); however, with new serotyping methods, it appears that sequential infections with different HCV isolates may occur more frequently than previously recognized, although simultaneous viremia with more than one HCV isolate is rarely observed (41, 101, 126). Finally, genotype 3 infections seem to be more commonly associated with hepatic steatosis, although the exact mechanism is undetermined (1).

Within an infected host, there are closely related, but genetically distinct, HCV variants known as quasispecies. Because hepatitis C is an RNA virus which lacks a proofreading RNA polymerase, it is able to generate a large population of different viral variants. HCV quasispecies diversity is thought to be a result of host immune pressure and is maximally observed in the hypervariable region 1 (HVR-1) of the second envelope gene (E2) (135). Conversely, in chronically infected patients, a higher pretreatment genetic diversity correlates with treatment failure (89).

Epidemiology and Transmission

HCV infection is a growing major health problem in the United States and worldwide, afflicting an estimated 3.8 million people

* This chapter contains information presented in chapter 97 by Margaret C. Shuhart and David R. Gretch in the eighth edition of this Manual.

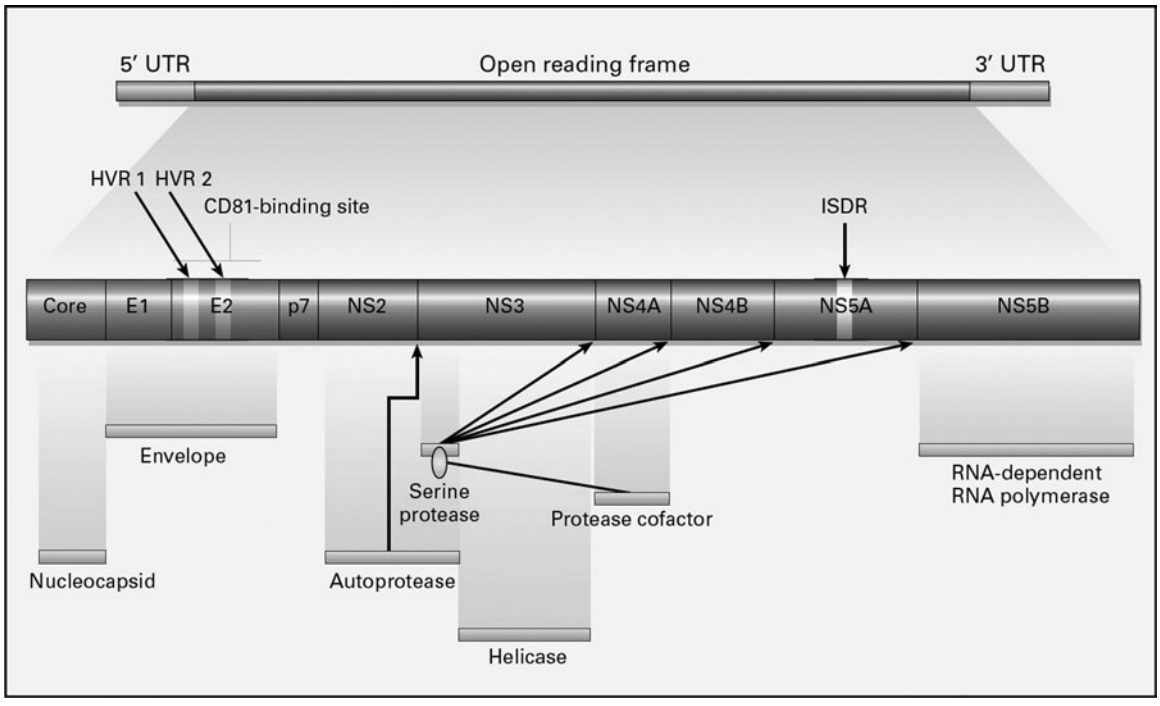

FIGURE 1 The HCV genome and expressed polyprotein. HCV, a single-stranded RNA virus of 9.5 kb, consists of a single open reading frame and two untranslated regions (UTRs). It encodes a polyprotein of approximately 3,000 amino acids, which is cleaved into single proteins by a host signal peptidase in the structural region and the HCV-encoded proteases in the nonstructural (NS) region. The structural region contains the core protein and two envelope proteins (E1 and E2). Two regions in E2, called hypervariable regions 1 and 2 (HVR 1 and HVR 2), show extreme sequence variability, which is thought to be the result of selective pressure by virus-specific antibodies. E2 also contains the binding site for CD81, the putative HCV receptor or coreceptor. The nonstructural proteins have been assigned functions as proteases (in the case of NS2, NS3, and NS4A), helicase (in the case of NS3), and RNA-dependent RNA polymerase (NS5B). Although the crystal structure of NS3 and NS5 is known, the function and properties of the other proteins (such as p7) are less well characterized. A region in NS5A has been linked to the response to alpha interferon therapy and is therefore called the interferon sensitivity-determining region (ISDR). However, the relevance and importance of this region are still unclear. (Reprinted with permission of B. Walker and the *N. Engl. J. Med.* **345:**42, copyright 2001 Massachusetts Medical Society, all rights reserved.)

in the United States (1.6%) and 170 million persons worldwide (4, 8). Over 10,000 persons die each year in the United States from HCV-related disease, and it ranks as the leading cause of liver failure requiring transplantation (4, 60). Death from chronic liver disease is the tenth leading cause of death in Americans; hepatitis C-related deaths from chronic liver disease increased by 220% from 1990 to 1998 (130). The incidence of HCV climbed steadily until the late 1980s, peaking at 230,000 cases per year (20). Since the institution of HCV screening and a greater awareness of the transmission routes, this rate has declined to 36,000 per year. In the United States, HCV infection is more common in men, blacks, and middle-aged persons (8).

HCV is spread predominantly through contaminated blood via percutaneous exposures. Injection drug use (IDU) is the most common route of transmission, accounting for 55 to 65% of all infections (35). Receipt of infected blood products or organs represented an important cause of HCV infection prior to 1992; however, since initiation of screening for HCV, this is an uncommon source of infection. With later-generation antibody screening, the risk of acquiring HCV through a blood transfusion was reduced to 1 in 103,000 (100) and has been further reduced to 1 in 2 million by minipool testing of blood donations by nucleic acid tests (114). In contrast to human immunodeficiency virus (HIV) and hepatitis B virus, HCV is not efficiently transmitted through sexual intercourse; the estimated annual risk of transmission in long-term monogamous partnerships is 0 to 0.6% (120). Intranasal cocaine use, exposure to contaminated medical equipment, needlestick exposures, and vertical transmission all contribute to the spread of HCV infection. HCV can be detected in saliva, but casual contact is thought to be a very uncommon route of transmission. For occupational exposures, the risk of HCV transmission from a hollow-bore needlestick injury is 1.8% (20). Finally, a small proportion (10%) of cases does not have an identifiable transmission source.

Clinical Significance

Although HCV infection is the most common bloodborne infection in the United States, the natural history tends to be mild for the vast majority of patients (50, 104). Between 15 and 40% of patients exposed to HCV clear the infection in the acute setting (4, 47). The remaining 60 to 85% are

chronically infected, although spontaneous clearance infrequently occurs (134). Approximately 20% of HCV-infected patients develop cirrhosis, a process which takes over 2 decades on average. Progression to cirrhosis is accelerated by concurrent heavy alcohol use, HIV infection, male gender, and acquisition after age 40 (90, 98). Patients with cirrhosis are then susceptible to end-stage liver disease (30% over 10 years) and hepatocellular carcinoma (1 to 4% per year) (33).

The clinical presentation of HCV infection is indolent and often asymptomatic. Fatigue is the most common complaint. A small percentage (10 to 30%) of patients with acute HCV infection develop the classical symptoms of viral hepatitis: jaundice, nausea, vomiting, abdominal pain, lethargy, and myalgias (84). Hepatitis C is frequently diagnosed after routine laboratory testing results for hepatic transaminases are abnormal. If there is HCV-related cirrhosis, patients may complain of abdominal distention, edema, jaundice, easy bruising, or clay-colored stools. In addition, HCV is associated with extrahepatic manifestations, mainly through immune-mediated mechanisms, including type II cryoglobulinemia, membranoproliferative glomerulonephritis, porphyria cutanea tarda, lichen planus, and non-Hodgkin's lymphoma (30).

The results of several large clinical trials have established the benefit of pegylated alpha interferon (peginterferon-α) and ribavirin for treatment of chronic HCV infection (37, 72), with sustained virologic response (SVR) rates of 56% (peginterferon-α2a[Pegasys]) and 54% (peginterferon-α 2b [PEG-Intron]). Infection with genotypes 2 or 3 had the greatest influence on the likelihood of achieving SVR; patients with genotype 2 or 3 had response rates of 76 to 82% compared to 42 to 46% for genotype 1 (37, 72). Furthermore, the SVR rates in genotype 2 or 3 infection are equivalent for 24 and 48 weeks of therapy (44), allowing for a shorter course of therapy without compromising efficacy. While high-dose ribavirin (1,000 to 1,200 mg/day) is equivalent to low-dose ribavirin (800 mg/day) in genotype 2 or 3 infection, the higher dose is necessary for genotype 1 infection (113). Thus, the current treatment recommendations are (i) 48 weeks of peginterferon plus high-dose ribavirin for genotype 1 infection or (ii) 24 weeks of peginterferon plus low-dose ribavirin for genotype 2 or 3 infection. Because of the significant cost and side effects associated with treatment, treatment is usually recommended for patients with significant fibrosis on liver biopsy specimens, compensated liver disease, normal hematologic and biochemical indices, no or stable depression, and no autoimmune disease (113).

Although hampered by the lack of a cell culture system, development of new treatments for HCV is brisk and many therapies are in initial clinical trials. These therapies are categorized into life cycle inhibitors, virus attachment and cell entry blockers, immunotherapies, therapeutic vaccination, and antifibrotics (74). Various methods to improve the efficacy of interferon are under way, including conjugation to albumin, different types of interferon, and oral interferon inducers. Minimizing side effects of current therapy, such as hemolysis with ribavirin, is the impetus behind expanded-spectrum nucleoside analogs (like Viramidine) and inosine 5′-monophosphate dehydrogenase (IMPDH) inhibitors (like VX-497).

Currently, there is no FDA–licensed vaccine available for prevention of HCV infection. Vaccines in development include protein subunit, DNA, and viral vector vaccines. An effective vaccine must elicit a durable, high-titer, and cross-reactive anti-E2 response as well as a multispecific cell-mediated immune response (49).

Collection, Transport, and Storage of Specimens

Serologic testing can be performed on serum or plasma after routine processing. For viral RNA quantification, serum is preferred, but plasma is acceptable if collected in tubes containing EDTA or citrate. Collection tubes with heparin should be avoided because it binds *Taq* polymerase, a necessary enzyme for PCRs (133). After collection, blood specimens should be promptly transported to the laboratory; transportation of specimens at room temperature is acceptable. For serum samples, the blood should be allowed to clot and then centrifuged within 4 h (Bayer bDNA 3.0) or 6 h (Amplicor/Amplicor Monitor 2.0). After centrifugation, the serum should be removed aseptically. Plasma samples are handled in a similar fashion, with removal of the plasma after centrifugation. For PCR-based detection, transportation and processing within 2 h is preferred; there is a slight but insignificant decrease in viral RNA levels if the specimens are stored at 25°C for 72 h (42). Storage of processed specimens at −70°C is optimal; however, one study found no decay in HCV RNA levels for specimens stored at −20°C for over 2 years and tested by reverse transcription-PCR (RT-PCR) and bDNA (48). Manufacturer instructions state that specimens may be stored at 2 to 8°C (Amplicor) or −20°C (bDNA) up to 72 h. Repeated freeze-thaw cycles should be avoided because they may lead to loss of HCV RNA; specimens tested by the Amplicor and bDNA assays may be frozen and thawed up to three and four times, respectively. For similar reasons, thawed specimens should be kept cold.

Specimen processing should be performed in an approved biosafety level two laboratory because the virus is potentially infectious, especially with blood-blood exposures, such as a needlestick injury.

Direct Detection

Microscopy

Traditional electron microscopy is rarely used as a diagnostic tool because it is expensive and unable to detect the low levels of viral particles in serum. Employed in research situations, electron microscopy studies describe HCV as spherical, approximately 40 nm in size, and of a relatively smooth contour (88).

Antigen Detection

An assay for antigen detection of the core protein has been developed (Total HCV Core AG assay; Ortho-Clinical Diagnostics, Raritan, N.J.) using an enzyme-linked immunosorbent assay (ELISA) method for detection. It appears to be accurate and specific, but lacking in sensitivity (lower limit of detection, 20,000 IU/ml) (15), and is not currently licensed by the FDA.

Nucleic Acid Tests

Nucleic acid tests (NAT) differ from serologic assays in several ways. They directly detect the presence of HCV RNA, and thus a positive NAT nearly always means that a patient is HCV infected. HCV RNA can be detected in serum 1 to 3 weeks after exposure, several weeks earlier than by detection of antibodies (113). NAT can be classified into qualitative methods (RT-PCR and transcription-mediated amplification [TMA]) and quantitative methods (bDNA and quantitative RT-PCR). An expert panel recommends testing with a sensitive NAT for patients who are (i) serologically positive, or (ii) serologically negative but have unexplained liver disease, or (iii) serologically negative and immunocompromised, or (iv) suspected of having acute HCV infection (113).

Qualitative Tests

The FDA has approved three qualitative RT-PCR diagnostic kits: AMPLICOR 2.0 (Roche Diagnostics, Indianapolis, Ind.); Ampliscreen 2.0 (Roche Diagnostics); and UltraQual (National Genetics Institute, Los Angeles, Calif.) (Table 1). Adaptation of the complete bioanalytical system (COBAS) for AMPLICOR test has allowed for semiautomation, simplified extraction, and a single-tube reaction for reverse transcription and amplification. With the COBAS instrument, sensitivity and specificity remained excellent (96 and 100%, respectively, using antibody status and elevated alanine aminotransferase [ALT] tests as the "gold standard") while reducing technician "hands-on" time (2). It has a very low limit of detection, 50 IU/ml (82), although recent refinements in the extraction method and concentration of specimens suggest that detection of viremia <12 IU/ml may be possible (36).

Qualitative NATs are useful, then, in cases where one is trying to confirm viremia or where low-level viremia is possible. Although the qualitative assay is quite sensitive, it is possible that viremia below the limit of detection and/or intermittent viremia occurs (19, 36). Therefore, follow-up HCV RNA testing is indicated 1 year after exposure with documented seroconversion even if initial RNA tests were negative, and in high-risk populations whenever ALT elevation occurs even if RNA tests were previously negative. As with any PCR-based test, contamination may lead to false-positive results. One source of contamination is amplicon carryover, although this is less common than in the past and can be reduced by the addition of uracil-*N*-glycosylase (UNG) to the PCR mixture. However, in the 1996 EUROHEP study of 86 laboratories, there were 5 laboratories that generated false-positive results in six HCV RNA-negative samples, despite the use of UNG (23). Contamination from positive clinical samples can occur, and this source of contamination is not affected by the addition of UNG. This finding emphasizes the need for careful controls in all assays and ongoing proficiency testing by all laboratories using PCR-based assays for molecular diagnosis.

TMA tests are also available. VERSANT HCV RNA Qualitative Assay (Bayer Diagnostics, Emeryville, Calif.) has a lower detectable limit of 5 IU/ml and sensitivity of >98% compared to serially diluted specimens quantified by bDNA (96). Approved by the FDA for screening blood and organ donations, the VERSANT and the Procleix HIV-1/HCV nucleic acid (TMA) tests, (Gen-Probe, San Diego, Calif.) can detect early or immunologically silent infections, thus improving the safety of blood transfusions. Additionally, TMA may be useful in predicting which patients are at risk for virologic relapse upon cessation of interferon and ribavirin therapy, defining treatment response and determining acute infection (25, 99).

Quantitative Tests

HCV quantitative viral tests have several important clinical applications (Table 1). For example, they are important tools in predicting response to antiviral treatment. In one study using the SuperQuant quantitative PCR assay (National Genetics Institute) to quantify HCV RNA, patients with a baseline HCV RNA count of >2 million copies/ml had a 9% lower sustained virologic response rate than those with <2 million copies/ml (37). (Subsequent to this report, HCV RNA quantification was standardized using a WHO standard in international units, and it was determined that 800,000 IU/ml corresponds to 2 million copies/ml in the SuperQuant assay [85]). For patients with genotype 1 infections who have a <2-log drop in HCV RNA levels after 12 weeks of therapy, it is unlikely that they will have an SVR and treatment is usually stopped in these situations (37, 72, 124). This early cessation spares patients from the high cost and toxicity associated with year-long therapy. Similarly, recent data suggest that patients with genotype 2 or 3 who have an undetectable HCV RNA level after 4 weeks of treatment may receive a shortened course (12 weeks total) of therapy without any compromise in efficacy compared to the standard 24-week course (71), although more studies are needed before these findings can be translated into clinical recommendations.

Two competing methods were introduced for HCV quantification: the quantitative RT-PCR (MONITOR 2.0; Roche Diagnostics) and the branched-chain DNA assay (VERSANT HCV RNA assay 3.0; Bayer Diagnostics). In the clinical diagnostic setting, we reported that 97.6 and 95.2% of all viremic specimens (defined as positive for HCV RNA by qualitative RT-PCR) were positive using these quantitative HCV RNA tests (MONITOR 2.0 and VERSANT 3.0, respectively) (77), which suggests that these assays may be useful for initial screening of specimens with a high likelihood of being positive for HCV RNA.

Analytical studies have also found the MONITOR 2.0 assay to be only slightly more sensitive than the VERSANT bDNA 3.0 test (62, 77), with a 95% detection rate at 732 IU/ml for the MONITOR 2.0 test versus 817 IU/ml for the bDNA 3.0 test in our study (77). Importantly, the former test suffered from increased variability and a limited dynamic range above 500,000 IU/ml, while the bDNA test was linear to 7.7 million IU/ml (62, 77). Furthermore, a subset of specimens gave nonlinear results between 200,000 and 500,000 IU/ml in the MONITOR 2.0 test, leading to the recommendation that all specimens be diluted 1:50 or 1:100 in healthy human serum prior to testing in the MONITOR assay if diagnosis is likely (77); negative specimens should then be retested undiluted to achieve the best assay linearity (55, 77). Neither the MONITOR 2.0 nor the in-house proprietary SuperQuant quantitative PCR assay (National Genetics Institute) is FDA approved for HCV quantification. The latter test is mentioned here because it has been used in several key interferon clinical trials (73, 91) and levels are tightly correlated to those of the MONITOR 2.0 (55).

In studies comparing the bDNA 3.0 to the MONITOR 2.0, the overall concordance was high (R^2 range, 0.86 to 0.95) (11, 77). For patients coinfected with HIV and HCV, there was significant variability between the assays in the classification of high (≥800,000 IU/ml) or low (<800,000 IU/ml) viral level (107). Because of this variability and difficulties in comparing the two assays for patients with high viral levels, it is recommended that clinicians use the same assay to follow patients' response to treatment (107).

The bDNA 3.0 method is more precise and reproducible than that of the MONITOR 2.0 and has achieved similar sensitivity (29). The bDNA assay has undergone three iterations, with improved sensitivity and linearity and equivalent quantification of all genotypes (75). The third-generation assay (Versant bDNA 3.0; Bayer Corporation, Tarrytown, N.Y.) has a lower limit of detection of 615 IU/ml and a reduced upper range of 7.7 million IU/ml (29), improvements that better reflect the HCV viral loads seen clinically. Although not as sensitive as the qualitative NAT, it does provide quantitative results, which can be helpful in predicting and monitoring treatment response. The specificity is good, ranging from 96 to 98.8%, in specimens from seronegative blood donors (11). The assay is highly reproducible (127); infected patients not on treatment should not vary more than 2.6-fold (29). High levels of unconjugated bilirubin (>20 mg/dl) and total protein (>9 g/dl) interfered with

TABLE 1 Diagnostic assays for HCV RNA detection and quantification

Assay	Method	Manufacturer[a]	Stated sensitivity (IU/ml)	Upper range (IU/ml)	Use	Comments
Qualitative						
Ultra-Qual	RT-PCR	National Genetics Institute	40–50	NA[b]	Blood donation screening	
AMPLICOR (v2.0)	RT-PCR	Roche	50	NA	Evidence of active infection, defining treatment response	
Ampliscreen (v2.0)	RT-PCR	Roche	50	NA	Blood donation screening	
Procleix HIV-1/ HCV assay	TMA	Gen-Probe	5–10	NA	Blood and organ donation screening	
Versant	TMA	Bayer	5–10	NA	Evidence of active infection, defining treatment response	
Quantitative						
Monitor (v2.0)	RT-PCR	Roche	600	500,000	Pretreatment quantification, determination of response to treatment	Sensitive, but unreliable at higher viral loads
Quantiplex bDNA (v3.0)	Branched chain amplification	Bayer	615	7.7 million	Pretreatment quantification, determination of response to treatment	No extraction or clean room required, broader linear range than MONITOR
TaqMan real-time PCR	RT-PCR	Roche	10–71	100 million	Pretreatment quantification, determination of response to treatment	Very sensitive, wide dynamic range, automated
TaqMan real-time PCR	RT-PCR	Abbott	10	At least 10 million	Pretreatment quantification, determination of response to treatment	Very sensitive, wide dynamic range, automated

[a] Roche, Roche Diagnostics; Bayer, Bayer Diagnostics; Gen-Probe, Gen-Probe Inc. (marketed by Chiron), Abbott, Abbott Molecular.
[b] NA, not applicable.

HCV RNA quantification (29), but these are relatively uncommon clinical situations. Additionally, it is important that the specimen be homogeneous and well mixed prior to addition to the microwell. Otherwise, the protein matrix is not formed and there is no blocking agent for the hybridization step, leading to a high background and false positives (29).

Two real-time PCR methods use TaqMan technology (Roche Diagnostics and Abbott Molecular, Des Plaines, Ill.) yielding quantitative results with comparable sensitivity to the qualitative test and a broad linear range (>6 $\log_{10}$) (9, 56). Real-time methods are faster, more automated, reliable, and cost-effective and thus represent real progress in HCV RNA quantification. Both Roche and Abbott make TaqMan HCV RNA analyte-specific reagents (ASR); the Abbott assay is run on the ABI 7000 series sequence detector, and the Roche assay employs the TaqMan 48 instrument. Both assays use internal controls. The Roche ASR has a limit of detection between 10 and 71 IU/ml with a linear range between 1.5 and 6.5 $\log_{10}$ (36, 56), while the Abbott ASR has a limit of detection of 10 IU/ml and is linear to at least 10 million IU/ml (18a).

The LightCycler is a real-time instrument which uses glass capillaries to allow for more rapid heating and cooling, thus shortening the assay time after RNA isolation to 70 minutes (54). An alternative real-time method, which has been used for HCV quantification on the LightCycler instrument, employs SYBR green I dye to bind the intermediate, double-stranded HCV RNA (93) and obviates the use of a probe, thus reducing the variation in quantification between different genotypes (53). Specificity is determined by amplicon melting temperature.

Many of the initial quantitative HCV RNA tests used different units, making direct comparisons difficult. To correct this problem, the National Institute for Biological Standards and Controls established in 1997 the first WHO international standard, taken from a high-titer genotype 1a sample and diluted with pooled serum to achieve a concentration of 10^5 IU/ml (97). The second international standard was created from the same lot as the original and will have the same unitage. These standards allow for conversion of the various quantitative tests into a common unit. With the SuperQuant PCR (National Genetics Institute), 1 IU/ml is equal to 2.5 copies/ml (85). For the MONITOR 2.0, 1 IU/ml equals 2.7 copies/ml. The bDNA v2.0 reported output in equivalents; 1 IU/ml equals 6.3 equivalents/ml. By contrast, the bDNA v3.0 gave results in copies/ml; 1 IU/ml equals 5.2 copies/ml (11).

It is important to emphasize that the stated sensitivities of the various assays are not always reproducible in the clinical setting. In College of America Pathologists (CAP) proficiency testing, it is not uncommon to see "less sensitive" tests detecting HCV RNA whereas "more sensitive" tests report as negative. In addition, given the extensive genetic diversity of HCV, precise determination and quantification of different HCV genotypes have been problematic for quantitative tests in the past. This issue will persist until there is accurate proficiency testing specific for different HCV genotypes.

Isolation Procedures and Identification

No routine culture method is available for HCV.

Genotyping

As mentioned previously, knowledge of a patient's genotype is important because it directs the duration and dosage of therapy and is the most powerful predictor of response. The gold standard for genotyping is sequencing, whereby the viral nucleic acid is amplified and then a specific region is compared by computer analysis to the established genotypes. Sequencing of the core, E1, NS3, and NS5 genes can each determine genotype and produce equivalent results (70). While sequencing of these HCV genetic regions represents the most definitive test for defining HCV genotypes, the approach is presently too expensive and time-consuming for large-scale diagnostic use although with increasing automation the costs may decline (6).

At present, most commercially available genotyping tests target the highly conserved 5′noncoding region (5′NCR) of HCV. All tests which target the 5′NCR do not accurately subtype. Since this region is also used for most qualitative and quantitative HCV RNA tests, it is the most convenient and least costly region to assay. However, mixtures of 5′NCR mutations within the same clinical isolate lead to erroneous results interpreted as mixed genotype infections in approximately 5% of specimens, results that have not been confirmed using more sensitive and definitive molecular approaches capable of detecting a second HCV genotype at levels below 1:100 relative to a primary genotype (D. Gretch, unpublished data). Despite this limitation, rapid tests for 5′NCR-based genotyping of HCV clinical isolates have been developed and implemented in many laboratories. A commercially available sequencing kit (Trugene 5′ NC, Bayer) targets this region and is accurate in detecting all six genotypes, yet is still susceptible to misclassification based on spurious mutations occurring in vivo. The technique requires a processing time (5 h) and incurs costs similar to those of another popular technique, the line probe assay (45). Like the line probe assay, the Trugene assay is less accurate in detecting subtypes because of the minor nucleotide changes between subtypes in the 5′NCR.

Recently, the real-time PCR method was adapted to detect genotypes (18, 102). This method uses melting curve analysis with fluorescent resonant energy transfer (FRET) probes targeted to the 5′NCR. Similar to other methods which use a 5′NCR target, subtyping is not reliable. However, when compared to the reference standard of NS5B sequencing, the method detected 99% of genotype 1, 94% of genotype 2, 91% of genotype 3, and 100% of genotype 4 isolates (95). The method has excellent concordance with the line probe assay but takes 60% less time, and the reagents cost less. Other tests using real-time PCR to genotype HCV are also under development.

The Invader assay (Third Wave, Madison, Wis.) is a commercially available ASR which can be performed directly on amplified products without purification. It uses a microplate format and takes 2 h to perform; however, it is unable to subtype (40).

Restriction fragment length polymorphism (RFLP) analysis on the amplified 5′NCR and NS5 detects point mutations associated with specific genotypes. Using endonucleases to cleave at genotype-specific sites, RFLP produces unique banding patterns on ethidium bromide gels. The technique has a sensitivity of 96% but is hampered by partial digestions and indeterminate results.

The line probe assay mentioned above (INNO-LiPA HCV II; Bayer) is a DNA hybridization test which uses the biotinylated PCR products of the 5′NCR to hybridize to type-specific probes on a nitrocellulose strip (115). It is as accurate as any test using the 5′NCR and able to detect the six major genotypes (116). The LiPA II has a near 100% concordance to the Trugene sequencing test but an 83 to 84% concordance with "home-brew" sequencing techniques and may be less accurate for RNA levels less than 20,000 IU/ml (6, 76). Mistyping is possible due to spurious mutations; these novel line probe

patterns have been described (76). In a comparison of 5′NCR sequencing to the LiPA II tests, 4/50 (8%) isolates had a genotype 1a isolate by sequencing but a genotype 2a isolate on LiPA, a difference which has significant implications for treatment decisions and outcomes (6). Furthermore, the line probe and RFLP methods detected mixed genotype infections in 5 to 10% of specimens. As mentioned above, definitive confirmatory testing has not supported conclusions drawn from these screening assays about mixed genotype HCV infections in humans.

Two serologic methods, recombinant immunoblotting (Chiron RIBA and in-house NS4 IBA) and ELISA (Abbott Murex), have also been used to detect genotype-specific antibodies to the NS4 or core regions (27, 39, 86, 103). Because they detect antibodies, rather than HCV RNA, they are simpler, cheaper, and more rapid and can provide a serotype in the absence of detectable RNA. Furthermore, they can detect exposure to multiple genotypes (101). However, antibody response is diminished in HIV-infected persons (10). Fewer serotypes (three or four instead of six) are detected by the immunoblot assays (10, 27, 101, 103). The current ELISA assay (HC03; Abbott Murex) detects all six serotypes and has improved sensitivity and specificity over earlier versions (39, 58, 86). Concordance between serotyping, line probe, and sequencing methods has been good in various studies (58, 86, 103).

Serologic Tests

Screening for hepatitis C is most often performed with an enzyme immunoassay (EIA) because it is inexpensive, easy to use, reproducible, automated, and now quite accurate. The first-generation EIAs (EIA 1.0) were licensed by the FDA in 1990 and detected antibodies to the c100-3 epitope of NS4. Screening of the blood donations significantly reduced transfusion transmission of HCV (28); however, this test suffered from low sensitivity (80% in high-risk populations) and low specificity (30% in the blood-donor setting) (43). The second-generation EIAs (EIA 2.0) were introduced in 1992 and improved both the sensitivity and the specificity (to 92 to 95% and 88 to 95%, respectively) by incorporating additional antigens from the core and nonstructural regions (43, 94). Furthermore, the mean window period of seroconversion was reduced from 16 weeks to 10 weeks (43). In 1996, the third-generation test (Ortho ELISA 3.0; Ortho-Clinical Diagnostics, Inc.) was licensed and incorporated a fourth antigen (NS5), as well as reconfigured core and NS3 antigens (Fig. 2).

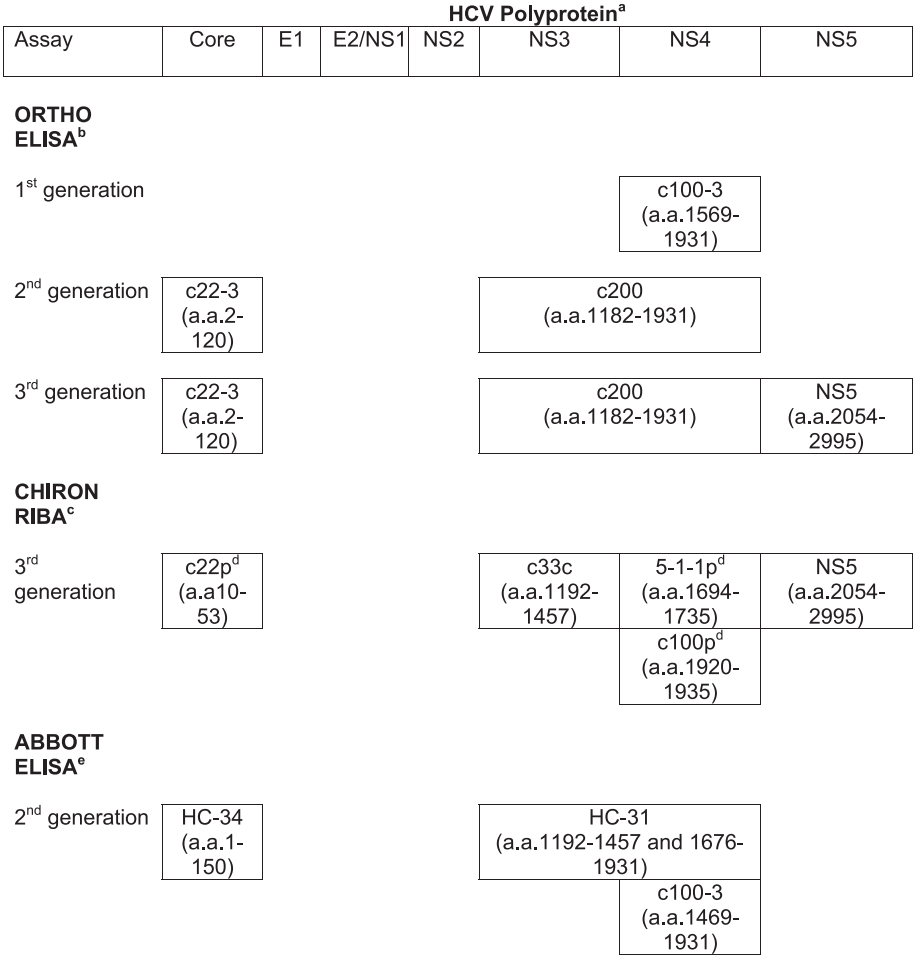

FIGURE 2 HCV antigens used for serologic assays. It is a highly sensitive (97 to 99%) and specific (≥99%) assay (21, 131), although false negatives can occur in the immunosuppressed (i.e., HIV-positive persons and transplant recipients) and hemodialysis populations (5, 43, 82). This false-negative rate can be significant; in one study, 19/100 (19%) of HIV-infected patients were serologically negative but HCV RNA positive. If the test is used in low-prevalence populations (<10%) such as volunteer blood donors or active military personnel, the false-positive rate is estimated to be 35% (95% confidence interval, 16 to 60%), illustrating the need for confirmatory testing (5). Additionally, children born to HCV-infected women may test positive for anti-HCV antibodies for the first year of life (94).

The current FDA-approved HCV antibody assays are the Ortho ELISA 3.0 and the Abbott EIA 2.0 (Abbott Laboratories, Abbott Park, Ill.). The ELISA 3.0, when compared to EIA 2.0, is better able to detect acute infection and remote nonviremic HCV infections (38, 123). Nevertheless, antibodies still require 4 to 10 weeks (average, 8 weeks) to develop so this assay is of limited use in detecting acute HCV infection (113).

The recombinant immunoblot assay (RIBA) (RIBA v 3.0 Strip Immunoblot Assay; Chiron Corporation, Emeryville, Calif.) is another serologic test which detects recombinant HCV antigens derived from different regions of the HCV genome and identifies responses to individual HCV proteins. Human superoxide dismutase (hSOD) is included as a control to detect nonspecific antibodies. Results are reported as positive (detection of two or more antigens at 1+ or greater reactivity, no reactivity to hSOD), indeterminate (one antigen detected or a reaction to hSOD and one or more HCV antigens), or negative (no antigens detected). The test can be helpful in discerning false-positive EIA results from resolved infections (the latter will be RIBA+) and therefore may be used as confirmation in low-risk patients (healthy blood donors) and if a high-risk patient is HCV RNA negative (94).

In an attempt to predict which supplemental tests will be positive in patients screening positive by EIA, the Centers for Disease Control and Prevention (CDC) conducted a study of the signal to cutoff ratio (S/Co). In the EIA test, samples are compared against a standard and an optical density reading is generated for laboratory use. The S/Co is the sample absorbance compared to the predetermined cutoff absorbance and serves to distinguish positive from negative readings. An S/Co of ≥1 is reported as positive, while a ratio of less than 1 is reported as negative. Samples which are just over 1 are more likely to be false positives (seen in patients with autoimmune diseases). The CDC study found that an S/Co greater than 3.8 provides positive confirmatory RIBA tests 95% of the time (5); thus, routine RIBA testing of specimens with S/Co greater than 3.8 is not needed routinely. The S/Co is incorporated into the recommended laboratory algorithm for anti-HCV testing and result reporting (Fig. 3).

A similar S/Co study of the enhanced chemiluminescence assays (VITROS; Ortho-Clinical Diagnostics) found that an S/Co of ≥8 predicted RIBA positivity in 95 to 98% of chemiluminescence assay-positive samples (5). This microparticle-based test detects HCV core antigen and may detect antibodies more quickly in acute infection but more frequently has indeterminate results and false positives, thus limiting its use as a screening test (51, 78).

Antiviral Susceptibility

Although HCV is commonly refractory to interferon and ribavirin, testing for antiviral susceptibility is not available

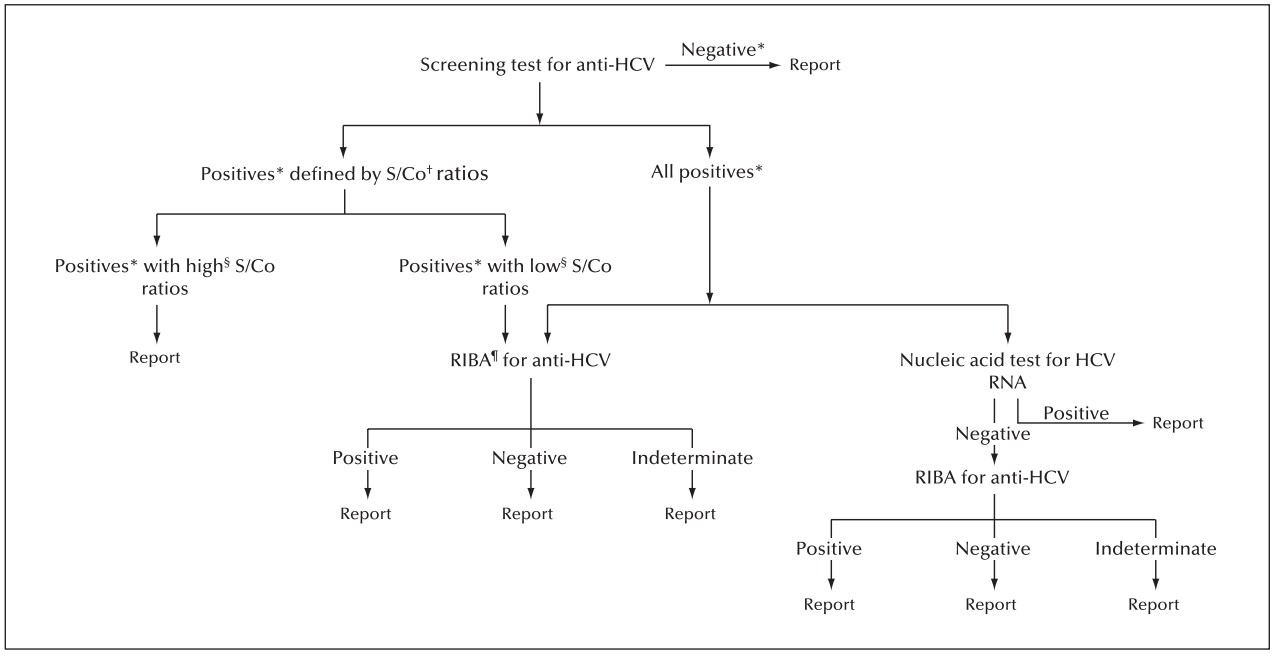

FIGURE 3 Laboratory algorithm for antibody to HCV (anti-HCV) testing and result reporting. Symbols: *, interpretation of screening immunoassay test results based on criteria provided by the manufacturer; †, signal to cutoff; §, screening-test-positive results are classified as having high S/Co ratios if their ratios are at or above a predetermined value that predicts a supplemental test-positive result ≥95% of the time among all populations tested; screening-test-positive results are classified as having low S/Co ratios if their ratios are below this value; ¶, recombinant immunoblot assay. (Used with permission from M. Alter, *Morb. Mortal. Wkly. Rep.* **50:**1–15, 2003.)

currently because clinical isolates cannot be cultured for antiviral susceptibility. An early study suggested that a large number of mutations in the NS5A region (the interferon sensitivity determining region) correlated with the poorer treatment response in genotype 1-infected patients (31), but the significance of this association has not been confirmed in either clinical or molecular studies in Western countries (46). More recently, researchers have overcome the hurdles necessary to developing in vitro replicon cell lines that are resistant to interferon and have highlighted the importance of cellular factors and interferon signaling pathways in the response to interferon (81).

Evaluation, Interpretation, and Reporting of Results

Patients at risk for HCV should be screened according to CDC guidelines (Table 2). An anti-HCV high positive result in a patient with hepatitis is highly suggestive for HCV infection. However, confirmatory testing, usually with a sensitive nucleic amplification test (i.e., Amplicor, TMA, or real-time PCR), is required because 15 to 40% of patients resolve their HCV infection acutely and there may be other explanations for the liver enzyme abnormalities (i.e., alcohol abuse, hepatitis B, or medications). A single negative confirmatory NAT is usually indicative of resolved infection, but it is possible that a patient may have low-level or intermittent viremia. For this reason, a second NAT is usually performed within 6 to 12 months. A high positive EIA test indicates past or current infection in over 95% of cases. A negative EIA test for a low-risk, immunocompetent patient who has not had any recent potential exposures to HCV can be interpreted as no evidence of infection. A negative HCV EIA is not as reliable for acute infections (within 3 months) and for immunosuppressed persons (HIV positive or with chronic renal disease). Therefore, for suspected acute infections, as in occupational exposures, one should assess HCV by EIA at the time of exposure, 4 to 6 weeks later, and then 4 to 6 months after exposure (117). HCV RNA testing should be performed at 4 to 6 weeks and 4 to 6 months and to confirm any positive HCV EIA. Also, immunosuppressed patients with risk factors for HCV acquisition and/or elevated ALT should be tested for HCV RNA. Other situations and the associated interpretations are listed in Table 3. Guidelines for the reporting of results are detailed in Fig. 3.

The rarely used RIBA test is reserved for confirming infections in low-risk EIA-positive patients and in patients who are high risk but NAT negative. Low-risk patients testing EIA positive but RIBA negative are likely not infected, but instead have a false-positive EIA. In contrast, RIBA-positive, NAT-negative patients with risk factors for HCV may have intermittent viremia and follow-up NAT is recommended in the subsequent 6 to 12 months.

In general, HCV genotype and quantitative tests should be performed only for patients for whom HCV treatment is being considered. Although quantitative HCV RNA assays are standardized into international units per milliliter, there is substantial variability between the quantitative tests, so the same assay should be used prior to and during treatment (107).

HEPATITIS G VIRUS/GB VIRUS TYPE C

Taxonomy

Although hepatitis G virus (HGV) is the most closely related virus to hepatitis C in the *Flaviviridae* family, it shares only 27% genetic homology (68, 108) and therefore is not classified in the *Hepacivirus* genus, but rather in an unassigned genus, group GB. It was discovered concurrently by two independent groups: one group isolated the virus from a patient with cryptogenic hepatitis (non-A to non-E) and gave the virus the name of hepatitis G (68). The second group employed subtractive cloning to isolate the virus from patients at high risk for hepatitis (IDUs and persons of West African origin) and volunteer blood donors (108). The second group had previously isolated two viral strains from a 34-year-old surgeon (whose initials were GB) who had post-transfusion non-A, non-B hepatitis (24), and thus the group named the virus GB virus, type C (GBV-C), based on genetic similarities. These viruses were later shown to have 96% homology and are essentially the same virus (61). Neither name is accurate, however, because studies over the ensuing decade demonstrated that the virus is not associated with hepatitis, and the virus was not isolated from the patient with the initials GB. For the sake of simplicity, GBV-C is used here to designate this virus, as others have done (111).

Description of the Agent

GBV-C is a single-stranded, positive-sense, enveloped RNA virus with a genome of 9,392 nucleotides (68). Organized similarly to other flaviviruses, GBV-C has a single, long open reading frame encoding a single large polyprotein with structural proteins at the 5′ end and nonstructural proteins at the 3′ end. The structural proteins include two enveloped proteins,

TABLE 2 Persons for whom HCV testing is recommended[a]

Persons who have injected illicit drugs in the recent and remote past, including those who injected only once and do not consider themselves to be drug users
Persons with conditions with a high prevalence of HCV infection, including:
Persons with HIV infection
Persons with hemophilia who received clotting factor concentrates before 1987
Persons who were ever on hemodialysis
Persons with unexplained abnormal aminotransferase levels
Prior recipients of transfusions or organ transplants, including:
Persons who were notified that they had received blood from a donor who later tested positive for HCV infection
Persons who received a transfusion of blood or blood products before July 1992
Persons who received an organ transplant before July 1992
Children born to HCV-infected mothers
Health care, emergency medical, and public safety workers after a needlestick injury or mucosal exposure to HCV-positive blood
Current sexual partners of HCV-infected persons

[a] Table adapted from M. Alter, *MMWR Recomm. Rep.* **47**(RR-19)**:**1–39, 1998.

TABLE 3 Recommendations for reporting results of testing for antibody to HCV (anti-HCV) by type of reflex supplemental testing performed[a]

Anti-HCV screening test results	Supplemental test results	Interpretation	Comments
Screening-test negative	Not applicable	Anti-HCV negative	Not infected with HCV, unless recent infection is suspected or other evidence exists to indicate HCV infection; false negatives can occur in immunocompromised persons
Screening-test positive with high S/Co ratio	Not done	Anti-HCV positive	Probably indicates past or present HCV infection; supplemental serologic testing not performed. Samples with high S/Co ratios usually (≥95%) confirm positive; however, if patient is asymptomatic and lacks risk factors, a false-positive test is possible and supplemental testing is recommended.
Screening-test positive with low S/Co ratio	Not done	Anti-HCV positive or negative	More likely to be a false positive; confirmatory testing with RIBA or NAT recommended
Screening-test positive	RIBA positive	Anti-HCV positive	Indicates past or present HCV infection
	RIBA negative	Anti-HCV negative	Not infected with HCV, unless recent infection is suspected or other evidence exists to indicate HCV infection
	RIBA indeterminate	Anti-HCV indeterminate	HCV antibody and infection status cannot be determined; another sample should be collected for repeat anti-HCV testing (>1 month) or for HCV RNA testing.
	NAT positive	Anti-HCV positive, HCV RNA positive	Indicates active infection
	NAT negative, RIBA positive	Anti-HCV positive, HCV RNA negative	The presence of anti-HCV indicates past or present infection; a single negative HCV RNA result does not rule out active infection.
	NAT negative, RIBA negative	Anti-HCV negative, HCV RNA negative	Not infected with HCV
	NAT negative, RIBA indeterminate	Anti-HCV indeterminate, HCV RNA negative	Screening test with anti-HCV result probably a false positive, which indicates no HCV infection. Alternatively, it may represent a resolved infection with waning antibody titers.

[a] Table adapted from M. Alter, *Morb. Mortal. Wkly. Rep.* **52:**1–15, 2003.

E1 and E2, which are less heavily glycosylated than in hepatitis C, perhaps explaining the greater frequency of viral escape and viral persistence seen in HCV infections (61). Although the core protein was difficult to identify, electron microscopic images showed the existence of a nucleocapsid and it is now believed to exist in a truncated form proximal to E1 (140). The nonstructural proteins are similar to those in HCV: a thiol protease in NS2 region, a serine protease and helicase in NS3 region, a protease cofactor in NS4, an interferon sensitivity determining region (ISDR) in NS5a region, and an RNA-dependent, RNA-polymerase in NS5b region (111). In addition, a portion of the 5′ NCR serves as an internal ribosomal entry site (IRES), but its activity is very weak compared to the IRES in HCV. There are four different genotypes, which are strongly linked to particular geographic locations but do not have any important clinical implications (109).

GBV-C has a density between 1.07 and 1.18 g/ml (140). The virus is found primarily in humans, although monkeys can also harbor the virus. Both in vivo and in vitro studies suggested that the virus is hepatotropic (105, 106). However, other studies contradicted this finding, instead suggesting that the virus is primarily lymphotropic and may replicate in $CD4^+$ T cells (92, 140). These differences may be due to poorly specific strand-specific RNA detection (i.e., self-annealing primers) or serum contamination of hepatocytes. A further study found a low liver:serum ratio of GBV-C virus, but a high liver:serum ratio of HCV (87), weakening the evidence for hepatotropism. Thus, it remains controversial whether the agent replicates in hepatocytes.

Epidemiology and Transmission

Exposure to, and infection with, GBV-C is very common worldwide. Using GBV-C viremia as a marker of infection, the prevalence of GBV-C in healthy blood donors is especially high in South and West Africa (10 to 14%), moderately high in Southeast Asia (4 to 6%), and low in Japan, the United States, and China (0.6 to 2%) (52). In persons living in the United States who had no exposure to blood products, the prevalence of viremia ranged between 0.8 and 4.2% (34, 68, 111). This prevalence rate was even greater, 13 to 38%, in patients with frequent exposure to blood products, such as IDUs and patients receiving frequent blood transfusions. Serological studies showed that *exposure* to GBV-C was still more common, with rates three to six times greater than in

viremia studies. Using an assay to detect antibodies to E2, researchers found that 9 to 16% of blood donors and 41 to 65% of IDUs were seroreactive. Not surprisingly, coinfection with HIV and HCV also occurs frequently: 29 to 46% of HIV-positive and 37% of HCV-positive patients were seroreactive to GBV-C (34, 136). Between 10 and 20% of patients with HCV also have detectable GBV-C RNA (16, 68).

GBV-C is transmitted predominantly through exposure to contaminated blood (3) but may also be spread sexually and vertically during childbirth. Therefore, GBV-C resembles more closely the transmission routes of HIV, rather than HCV, which is primarily bloodborne (111). For example, the rates of GBV-C viremia are similar in HIV-positive patients who acquired HIV parenterally and in those who acquired it sexually (139). Of infants born to HIV-negative, HCV-negative women with GBV-C viremia, 89% have detectable viremia at 3 to 9 months of age (66).

Clinical Significance

Despite being a very common infection, GBV-C does not have any direct association with disease in humans and is believed to be nonpathogenic. The initial identification of the agent came from isolated cases of cryptogenic hepatitis (68, 108); however, subsequent studies using reliable controls determined that there was no causal relationship with hepatitis (3). Furthermore, there is a poor correlation between viremia and ALT elevation (3, 68), in contrast to HCV and HBV viremia. Studies of patients coinfected with HCV and GBV-C found no difference in the rate and severity of their liver disease compared to those of patients with isolated HCV infection (3).

The majority of infections are subclinical, persist for years at a constant high level, and then clear without a preceding decline in viral load (63). Clearance seems to occur when patients develop E2 antibodies, suggesting that these antibodies have neutralizing activity (111, 119). In contrast to HCV, clearance of GBV-C occurs in the majority of cases (70 to 80% of the time) and immunity is lifelong (34, 111, 121).

Perhaps the most important clinical aspect of GBV-C is its apparent beneficial effect on HIV infection in patients infected with both viruses. Several studies have found that patients with GBV-C viremia have lower HIV viral levels, greater CD4 counts, and increased survival (65, 125). In one study, GBV-C RNA-negative patients were 3.7 times more likely to die than patients with detectable GBV-C RNA (112). The apparent protection of GBV-C viremia persists even in the era of highly active antiretroviral therapy; GBV-C levels were inversely proportional to HIV RNA levels (122). Two studies, however, did not find an association between GBV-C infection and better HIV outcomes, but they studied patients with greater CD4 counts and classified GBV-C on the basis of a single time point, possibly introducing misclassification of viremia (14, 17). Several authors have speculated that GBV-C has a direct inhibitory effect on HIV replication (137), perhaps by induction of HIV-inhibitory cytokines and down-regulated expression of HIV-coreceptor CCR5 (138). More recently, other researchers have found that *loss* of GBV-C RNA is more predictive of HIV progression, perhaps by an associated decline in CD4 count (128, 136).

GBV-C appears to be sensitive to interferon and, to a lesser extent, ribavirin, but viremia recrudesces after cessation of treatment (59). Coinfection with HCV and GBV-C does not impact the efficacy of interferon/ribavirin therapy for HCV infection (16). Finally, GBV-C-infected patients receiving liver transplants do not have poorer posttransplant outcomes than do GBV-C-uninfected patients (16, 22).

Collection, Transport, and Storage of Specimens

No studies have examined the stability of GBV-C; however, because of its similarity to HCV, the methods used for handling and storage of HCV samples should be sufficient. Although GBV-C appears to be nonpathogenic, it is prudent to use a biosafety level two cabinet when working directly with the virus.

Direct Detection

A variety of nucleic acid amplification techniques have been used to directly detect GBV-C, including real-time PCR and bDNA (87, 111). Initial PCR assays used the NS3 region as an amplification target, but the 5′ untranslated region (5′ UTR) is more highly conserved than either the NS3 or NS5 regions and thus provides better sensitivity. Combining the 5′ UTR and NS5a amplification targets, PCR has demonstrated a sensitivity of >90% (7, 13). In comparison to laboratory-developed PCR assays, a commercial assay from Abbott (LCx) showed better sensitivity, probably because it targeted the 5′UTR region (12). However, there was a great amount of heterogeneity in the detection of GBV-C RNA from 18 specialty laboratories, even those which used a commercial assay (64). Interestingly, GBV-C exhibits a much a wider range of viremia than does HCV, from 25,000 to 250,000,000 genome equivalents/ml (111).

Isolation Procedures and Identification

Infectious GBV-C clones have been generated in vitro, but routine culture methods are not available for clinical use (140).

Genotyping

There are at least five different genotypes of GBV-C as detected using RFLP, type-specific PCR, and phylogenetic analysis (79, 80). Genotype 1 predominates in West Africa, genotype 2 in the United States and Europe, genotype 3 in Asia and South America, genotype 4 in Southeast Asia, and genotype 5 in southern Africa (80, 110).

Serologic Tests

By cloning the E2 protein and expressing in Chinese hamster ovary cells or *Escherichia coli*, an ELISA using anti-E2 antibodies has been developed (26, 119). As mentioned previously, the development of antibodies to E2 is associated with resolution of GBV-C viremia (119). A strip immunoblot assay detecting core, NS3, and NS4 proteins is also available (34).

Evaluation, Interpretation, and Reporting of Results

GBV-C does not appear to cause disease in humans. Therefore, testing for GBV-C antibodies or GBV-C RNA in patients with cryptogenic cirrhosis or abnormal liver function tests is not warranted. There are no FDA-approved tests for GBV-C, but a PCR assay from Abbott (LCx) is available. An antibody response to E2 is indicative of exposure to GBV-C and clearance, whereas a positive GBV-C RNA test is indicative of acute or chronic infection.

Rotaviruses, Caliciviruses, Astroviruses, Enteric Adenoviruses, and Other Diarrheic Viruses*

TIBOR FARKAS AND XI JIANG

94

Common causes of infectious gastroenteritis include bacterial, parasitic, and viral pathogens. In comparison, the study of viral gastroenteritis, which started with the discovery of many prototype viruses in the early 1970s, in general has been limited by the inability to grow most of these pathogens in cell culture, the lack of efficient animal models, and the high genetic and antigenic variation of these viruses. The disease burden of viral gastroenteritis, however, has been increasingly recognized, particularly in the developed countries, where improved sanitation has led to a significant decrease in bacterial and parasitic gastroenteritis but has had little effect on viral gastroenteritis. Viruses associated with gastroenteritis diseases in humans include rotavirus, calicivirus (norovirus and sapovirus), astrovirus, and enteric adenovirus. Rotaviruses are the most important cause of severe acute gastroenteritis in young children. Noroviruses have been recognized as the most important cause of nonbacterial epidemics of gastroenteritis. Sapoviruses, astroviruses, and enteric adenoviruses are important causes of pediatric gastroenteritis. Other viruses, such as coronavirus, torovirus, Aichi virus, and picobirnavirus, have been implicated in human gastroenteritis, but their etiologic role is not well established.

TAXONOMY

Rotaviruses

Rotaviruses are classified as members of the *Rotavirus* genus within the family *Reoviridae,* which contains 10 other distinct genera. Based on group-specific antigens of the major viral structural protein VP6, rotaviruses are serologically classified into seven groups (A to G) (32). Group-specific epitopes are also found on other structural proteins as well as on some nonstructural proteins. Groups A to C rotaviruses infect both humans and animals, with the group A rotaviruses infecting humans most frequently and causing disease mainly in young children. Groups D to G rotaviruses are mainly animal pathogens. Within each group, rotaviruses are further classified into serotypes based on neutralization assays using antibodies against two major outer capsid proteins, VP4 and VP7. VP4 is a spike protein on the capsid surface which is sensitive to protease cleavage; therefore, the types based on the VP4 protein are also called P types (protease sensitive). VP7 is a glycoprotein, and the types based on this protein are also called G types. There are 14 VP7 (G) serotypes of rotaviruses, and strains of animal and human origin may fall within the same serotypes. A correlation between genotype and serotype has been observed for VP7 (G) types, but this correlation is less clear for VP4 (P) types. Recently a new G genotype (G genotype 15) has been described from a cattle farm in India; however, serotype determination of this strain has not been reported yet. Due to a lack of readily available typing serum or monoclonal antibodies for VP4 (P) serotypes, the classification of VP4 (P) types has relied mostly on sequencing of the VP4 gene (P genotype). Numbers assigned for P serotypes and genotypes are different, and 14 P serotypes and 23 P genotypes of VP4 have been described.

Caliciviruses

The *Caliciviridae* family includes four genera from which *Norovirus* and *Sapovirus,* also called human caliciviruses (HuCVs), mainly cause gastroenteritis in humans (47, 101). These two genera were previously called "Norwalk-like viruses" and "Sapporo-like viruses," named after their prototype strains, the Norwalk and the Sapporo viruses, respectively. Classification of HuCVs is based on genetic analysis of the viral genomes. Within each genus, strains are further grouped into genogroups (GG) and genetic types or clusters. Noroviruses can be classified into five genogroups with GG I, II, and IV containing the human isolates, GG III containing the bovine strains, and GG V containing the recently discovered murine norovirus (7, 80, 149). Noroviruses from pigs closely related to GG II human isolates also have been described. There are over 20 established norovirus genetic clusters within the five genogroups; with the continuous discovery of new strains, the number is growing. According to the most recent classification scheme, sapoviruses are classified into nine genetic clusters within five genogroups. GG I, II, IV, and V contain human isolates, and GG III contains the porcine sapoviruses (38).

The antigenic relationships among different HuCVs have been studied mainly based on recombinant virus-like particles (VLPs) and antibodies raised against them in laboratory animals. Since HuCVs are genetically and antigenically diverse and the currently available assays do not cover all types, these results remain preliminary. Overall the antigenic types correlate with the genetic types: noroviruses and sapoviruses are

* This chapter contains information presented in chapter 94 by Martin Petric and Raymond Tellier in the eighth edition of this Manual.

antigenically distinct; limited cross-antigenic reactivity can be detected within genera and between genogroups, and the cross-reactivity increases among strains within the same genogroup. The relationship of the antigenic types with the serotypes of HuCVs remains unknown because a virus neutralization assay remains unavailable for HuCVs.

Astroviruses

The family *Astroviridae* contains human and animal viruses with a characteristic star-like (*astron* means star in Greek) surface structure. Astroviruses were discovered in stools of infants with vomiting and diarrhea in 1975 (97) and later isolated from numerous wild and domestic animal species. Recently astroviruses have been grouped into two genera, *Mamastrovirus* and *Avastrovirus*, for their major host species (152).

Eight serotypes of human astrovirus have been distinguished by immunofluorescence, neutralization, immune electron microscopy (IEM), or genotyping (11, 62, 88). Complete or partial sequences of the viral genome of the prototype strains have been reported, and the reagents for typing and the reference strains of each type are available from the Oxford Group in the United Kingdom. The genetic sequence of the major human astrovirus serotypes allowed molecular classification of the viral family, and available data indicated a good correlation between the serotyping and genotyping (11, 116). Astroviruses seem to cause disease in a species-specific manner, and viruses isolated from different species are serologically unrelated.

Enteric Adenoviruses

The *Adenoviridae* family contains two genera, *Mastadenovirus* and *Aviadenovirus*. There are 51 different human adenovirus serotypes, which are grouped into six subgroups (A to F) based on their ability to agglutinate red blood cells and the size, composition, homology, and organization of their genome. Many adenoviruses are readily isolated from human stools, but their role in acute gastroenteritis is unclear. There are two serotypes, however, Ad40 and Ad41, in subgroup F, that have been clearly associated with infantile diarrhea (25, 40, 143, 160) and are referred as "enteric adenoviruses." These enteric adenoviruses are also called "fastidious" adenoviruses, due to their difficulty to grow in cell culture.

Coronaviruses and Toroviruses

Coronavirus and *Torovirus* represent two genera of the *Coronaviridae* family, which, with two other families, *Arteriviridae* and *Roniviridae*, forms the *Nidovirales* order, a group of enveloped, positive-sense RNA viruses that all synthesize a 3′ coterminal set of subgenomic mRNAs in infected cells (56).

Aichi Virus

According to genetic analysis, Aichi virus has been classified as a new genus, *Kobuvirus*, in the *Picornaviridae* family (144). Recently a new species, the bovine kobuvirus, has been isolated from HeLa cell cultures that possibly had been contaminated with this virus from the calf serum used to maintain the cells.

Picobirnaviruses

The name *Picobirnavirus* was proposed for a new genus of viruses that are different from the existing members of the *Birnaviridae* family. The name picobirna reflects their small size (pico-) and bisegmented double-stranded RNA (dsRNA) genome.

DESCRIPTION OF THE AGENTS

Rotaviruses

Viruses described as ~70-nm particles with a wheel-like appearance were described from a number of animal species during the 1960s. Similar viruses of humans were first identified in 1973 by thin-section electron microscopy (EM) of the duodenal mucosa of children with acute gastroenteritis. Later these viruses were designated rotaviruses (*rota* means wheel in Latin). Mature rotavirus particles are about 70 nm in diameter and nonenveloped (Fig. 1) and possess a triple-layered icosahedral protein capsid composed of an outer layer, an intermediate layer, and an inner core. The rotavirus genome contains 11 segments of dsRNA, ranging in size from ~660 bp (segment 11) to ~3,300 bp (segment 1). The gene coding assignment of the 11 genome segments has been determined and includes six major structural proteins (VP1, VP2, VP3, VP4, VP6, and VP7) that appear on the matured viral particles and six nonstructural proteins (NSP1 to NSP6) that are expressed in infected cells and play important roles in the viral genome replication, protein synthesis, and viral capsid assembly and maturation. One of the nonstructural proteins, NSP4, has been found to be a viral enterotoxin (9, 33).

Caliciviruses

Caliciviruses are small (30 to 38 nm), round, and nonenveloped (Fig. 1). Sapoviruses have the typical calicivirus morphology with the "Star of David" appearance (Fig. 1). Noroviruses reveal a smoother surface structure and therefore were also called "small round structured viruses" (SRSV). Cryoelectron microscopy and X-ray crystallography analysis of recombinant VLPs revealed that noroviruses possess a T = 3 icosahedral capsid, composed of 180 capsid proteins that form 90 dimeric capsomers. Each capsid protein possesses two major domains, the shell (S) and the protrusion (P) domains. The P domain consists of two subdomains (P1 and P2). The P2 subdomain is the most variable region of the capsid protein and is responsible for the receptor binding and possibly for the antigenic properties of noroviruses.

Noroviruses contain a single-stranded, positive-sense, poly(A)-tailed RNA genome of ~7.5 kb (67, 70, 87). It is organized into three open reading frames (ORFs), with ORF1 encoding the nonstructural proteins, ORF2 encoding the capsid protein, and ORF3 encoding a minor structural protein. The sapovirus genome is slightly different in that the nonstructural and capsid protein encoding sequences are fused into one large ORF.

Astroviruses

Astroviruses are small (28 to 30 nm in diameter), round, nonenveloped viruses (Fig. 1). They reveal a star-like appearance, but the typical star-like morphology may be visible on only 10 to 15% of the virions in negatively stained EM preparations. Cryoelectron microscopy images of human astrovirus serotype 1 revealed a rippled solid capsid shell with 30 dimeric spikes and an icosahedral symmetry (100).

Astroviruses contain a single-stranded, positive-sense RNA genome of about 6.8 kb excluding the poly(A) tail. The viral genome contains three ORFs. ORF-1a and ORF-1b encode the nonstructural proteins; ORF-1a contains a protease motif, transmembrane helices and nuclear localization signals, and a ribosomal frame shifting signal, while ORF-1b contains an RNA polymerase motif. ORF 2 encodes the capsid precursor protein (~87 kDa) that is intracellularly cleaved to a 70-kDa protein that forms the capsid and later cleaved by

trypsin to smaller peptides of 25 to 34 kDa, resulting in infectious virions.

Enteric Adenoviruses

The name adenovirus originates from the Greek word *aden,* which means gland, because the first human adenoviruses were isolated from adenoid tissue in 1953. Since then, human adenoviruses have been linked with a number of diseases including respiratory illness, conjunctivitis, and diarrhea (57). Adenoviruses are nonenveloped, icosahedral particles 70 to 100 nm in diameter (Fig. 1). Mature virions consist of a DNA-containing core surrounded by a protein shell. The genome is a linear double-stranded DNA of 30 to 38 kb (the size varies from group to group). The protein shell (capsid) is composed of 252 capsomeres, of which 240 are hexons and 12 are pentons. There are a total of 11 viral structural proteins from which three coat proteins (hexon, penton base, and fiber) are of important clinical significance. These proteins are involved in viral entry (fiber) and intracellular transportation, and the hexon and fiber contain the major neutralization epitopes.

Coronaviruses and Toroviruses

Coronaviruses and toroviruses are pleomorphic, enveloped positive-stranded RNA viruses. The genomic RNA is 25 to 31 kb, making them the largest RNA viruses. The RNA is surrounded by nucleoprotein (N); the nucleocapsid is enclosed in an envelope composed of membrane protein (M) and a host cell-derived lipid bilayer containing inserted S (spike), HE (hemagglutinin-esterase), and other surface proteins (56).

Aichi Virus

The Aichi viruses are ~30 nm in diameter, a size which is indistinguishable from that of other picornaviruses (Fig. 1). They encapsidate a genome of ~8.2-kb, positive-sensed RNA with a poly(A) tail. The genome contains a single large ORF that encodes a polyprotein which is processed by protease cleavage to individual functional proteins. The virion is composed of three structural proteins (VP0, VP1, and VP3) from which VP0 strongly reacts with convalescence phase patient sera (157).

Picobirnaviruses

The picobirnaviruses are nonenveloped, 35- to 41-nm-diameter, round particles with a smooth surface (Fig. 1) and an icosahedral T = 3 symmetry. The sizes of the two genomic segments vary, ranging from 2.3 to 2.6 kb for genomic segment 1 and 1.5 to 1.9 kb for genomic segment 2 (19). The full-length genomic segment 2 sequences of two human isolates (3-GA-91 and 1-CHN-97) have been determined, and both sequences contained a single ORF with RNA-dependent RNA polymerase motifs that are common among many RNA viruses.

EPIDEMIOLOGY AND TRANSMISSION

Gastroenteritis viruses are transmitted by the fecal-oral pathway and through person-to-person and environmental surface contact (Table 1). These viruses also can be transmitted by contaminated water and food, which usually results in large outbreaks. Most viral gastroenteritis remains endemic and represents a significant disease burden in both developing and developed countries. In temperate countries, viral gastroenteritis does not have the typical summer peak of most bacterial and parasite-caused gastroenteritis; instead, viral gastroenteritis is more common in colder seasons, with rotavirus diarrhea having a typical winter-spring peak.

Rotaviruses

Rotaviruses usually cause severe dehydration in infants and children under 2 years of age, which makes rotaviruses a major cause of childhood deaths in the developing countries. Rotavirus mortality is much lower, but the disease burden remains high, in the developed countries, representing approximately 2.7 million diarrheal episodes each year in the United States with significant numbers of physician visits and hospitalizations and high medical and societal costs.

The source of infection for young infants is likely acquired from older siblings or parents with subclinical infection. Shedding of rotavirus from the intestinal tract prior to onset of diarrhea or following cessation of diarrhea has been well documented. Rotaviruses are able to survive on the environmental surfaces at ambient temperature and are resistant to physical inactivation, which may contribute to their efficient transmission (1, 131). Cross-species transmission of rotaviruses has been demonstrated, and comparison of genetic sequences of human and animal rotaviruses often reveals close identity, indicating a zoonotic potential of rotavirus disease. In temperate countries rotavirus diarrhea usually exhibits a typical winter/spring peak, during which over one-third of the diarrhea cases seen in the emergency room and regular clinics are caused by rotaviruses. This seasonal pattern of rotavirus infection observed in temperate climates does not occur uniformly in tropical countries.

Caliciviruses

HuCVs are highly contagious and environmentally stable, characteristics which are particularly important for transmission through contaminated surfaces, food, and water (30). Noroviruses have been recognized as the most important causes of nonbacterial acute gastroenteritis in all ages in both developing and developed countries (34). Sapoviruses cause disease mainly in children; however, outbreaks among adults also have been reported (20, 73, 117). Because of their ability to cause large outbreaks, incapacitating the affected individuals and causing public panic, noroviruses are listed as category B agents by the National Institute of Allergy and Infectious Diseases (NIAID) Biodefense Research Agenda. Such outbreaks are often described as occurring in hospitals, educational institutions, nursing homes for the elderly, military settings, and cruise ships. Seroprevalence studies showed

TABLE 1 Epidemiology, transmission, and clinical significance of gastroenteritis viruses

Virus	Mode of transmission	Target population	Clinical significance	Disease control and prevention
Rotavirus	Fecal-oral	Children <5 yrs	Acute severe gastroenteritis, mostly sporadic, nosocomial infection can occur	Rehydration in severe cases, vaccines have been developed
Norovirus	Fecal-oral, close contact, water and food	All age groups	Moderate-severe gastroenteritis, commonly causes outbreaks in variety of settings	Personal hygiene, hand washing, avoid crowds, control food handlers
Sapovirus	Fecal-oral, close contact	Mainly children	Mild-moderate gastroenteritis, subclinical infection occurs, sporadic but outbreaks occur	Personal hygiene, hand washing
Astrovirus	Fecal-oral	Mainly children	Mild-moderate gastroenteritis, subclinical infection occurs, sporadic but outbreaks occur	Personal hygiene, hand washing
Adenovirus	Fecal-oral	Mainly children <5 yrs	Moderate-severe gastroenteritis, sporadic, nosocomial infection, persists in immunocompromised patients	Personal hygiene, hand washing
Picobirnavirus	Unknown, possibly fecal-oral	Children and adults	Possibly sporadic mild-moderate gastroenteritis	Personal hygiene, hand washing
Aichi virus	Unknown, possibly fecal-oral	Children and adults	Possibly sporadic mild-moderate gastroenteritis	Personal hygiene, hand washing
Coronavirus	Unknown, possibly fecal-oral	Possibly all age groups	Possibly sporadic mild-moderate gastroenteritis	Personal hygiene, hand washing
Torovirus	Unknown, possibly fecal-oral	Possibly all age groups	Possibly sporadic mild-moderate gastroenteritis	Personal hygiene, hand washing

that both noroviruses and sapoviruses have a worldwide distribution with 70 to 100% of individuals >5 years of age possessing antibodies against them (71, 72, 112, 113). Recently human histo-blood group antigens including the ABO, Lewis, and secretor/nonsecretor types were identified as the receptors for noroviruses (63, 92, 98, 137). Different norovirus strains recognize different histo-blood group antigens, resulting in a variation of natural resistance/susceptibility between the human host and the different norovirus types (60, 61, 137). The discovery of enteric caliciviruses from animals that are genetically closely related to human strains raised the question about calicivirus gastroenteritis as a zoonotic disease and animals as possible reservoirs for human illness (54, 80, 94, 135). Direct evidence for interspecies transmission of enteric caliciviruses is still missing.

Astroviruses

Mammalian astroviruses are generally associated with gastroenteritis, whereas avian astroviruses can cause both intestinal and extraintestinal diseases such as nephritis, hepatitis, or immunodeficiency. Human astroviruses are associated mainly with pediatric gastroenteritis, although cases among caretakers of sick children or immunocompromised adults (50) and outbreaks among military troops (12) or in nursing homes (90, 103) have been described. Astrovirus infection was linked to 2 to 10% of pediatric gastroenteritis cases worldwide depending on the settings and diagnostic tests used. Asymptomatic infections are common in all ages. Among school-age children there is a 70 to 90% seroprevalence to astroviruses, indicating frequent infections during childhood.

Enteric Adenoviruses

Although the role of enteric adenoviruses in acute gastroenteritis has been definitively established, the incidence of adenovirus-related gastroenteritis differs considerably among various studies and locations. Outbreaks of enteric adenovirus diarrhea have been reported in hospitals and more often in day care centers. Enteric adenoviruses are associated with 5 to 20% of cases of pediatric diarrhea (142). It occurs most often in children younger than 4 years of age, and symptoms last for 5 to 12 days, which is longer than the duration of other viral diarrhea. Like other enteric pathogens, enteric adenoviruses are frequently detected in stool specimens of children with asymptomatic infection. Prolonged or chronic diarrhea of immunocompromised patients linked to enteric adenoviruses also has been reported (132, 141).

Coronaviruses, Toroviruses, Aichi Virus, and Picobirnaviruses

The role and significance of these viruses in human diarrhea are not yet firmly established. Coronaviruses infect the respiratory and gastrointestinal tracts, and they are a recognized cause of common cold in humans. Although coronaviruses, such as transmissible gastroenteritis virus of pigs and canine coronavirus, are major gastrointestinal pathogens of animals, agents resembling these viruses have been only sporadically reported in cases of human gastrointestinal illness, particularly in newborns. The evidence for human enterotropic coronaviruses depends on visualization by EM of coronavirus-like particles in stools of infants with diarrhea, serologic studies of outbreaks of infant diarrhea, and infrequent isolation of coronaviruses from stools of infants and children with diarrhea.

Toroviruses seem to be associated with asymptomatic enteric infections in swine and with severe diarrheal disease in horses (Berne virus) and cattle (Breda virus) and were also implicated in human gastroenteritis (10, 65, 85, 86). The detection of human torovirus-like particles in gastroenteritis was first reported in 1984, and these agents were shown to be associated with acute and persistent diarrhea in children and to be potentially important nosocomial pathogens. Seroconversion following infection has been demonstrated by IEM and hemagglutination inhibition assays with virus purified from stool specimens (29).

Aichi virus was first isolated from stool samples of patients during an investigation of oyster-associated gastroenteritis outbreaks that occurred in 1989 in Japan. The antibody prevalence to Aichi virus was 7.2% in children less than 4 years of age, and it increased with age to around 85% by 35 years of age, indicating the circulation of these viruses in the human population (158).

Picobirnaviruses were first identified by analysis of stool samples of humans and rats by polyacrylamide gel electrophoresis (PAGE) in 1988. Since their original description, they have been detected in fecal samples of a wide range of domestic and wild animals. The frequency of picobirnaviruses in human stool samples (normal or with diarrhea) has been investigated in several countries mainly by PAGE detection of viral dsRNA. The detection rate was ~20% in outbreaks of human gastroenteritis and 9 to 13% in inpatients with or without diarrhea in various age groups. A much lower detection rate (~0.5%) also has been reported in children. Picobirnaviruses are more frequently detected in immunocompromised patients (42, 50).

CLINICAL SIGNIFICANCE

Clinical symptoms of viral gastroenteritis include watery diarrhea, vomiting, anorexia, abdominal pain, and fever, with rotavirus gastroenteritis being the most severe. The disease in most cases lasts for 2 to 3 days; however, viral shedding can continue for several weeks. Due to the lack of effective antiviral drugs against gastroenteritis viruses, treatment of patients with viral gastroenteritis has been focusing mainly on the relief of the clinical symptoms. Rehydration therapy is the most important treatment for severe cases and for reducing mortality in the developing countries. A prompt diagnosis of viral gastroenteritis is important; although it may not help to cure the disease, it can help avoid unnecessary use of antibiotics.

Rotaviruses

Although, as previously described, rotaviruses cause mainly severe gastroenteritis in infants, rotavirus infection also has been implicated in biliary atresia and central nervous system disease. The lack of antiviral drugs against rotaviruses and the significant disease burden necessitate a vaccine for rotaviruses. The first licensed rotavirus vaccine (Rotashield; Wyeth) was a tetravalent vaccine that contained reassortants of four major serotypes in a simian rhesus rotavirus background. Rotashield went on the market in 1998 in the United States, but it was withdrawn in 1999 due to concern that it caused intussusception. A second rotavirus vaccine (LLR; Lanzhou Institute of Biological Products), based on an attenuated strain of a lamb rotavirus, was licensed in China in 2000, and a third rotavirus vaccine (Rotarix; GlaxoSmithKline), based on an attenuated single human strain, was licensed in Mexico in 2004. The newest rotavirus vaccine, a live, oral, pentavalent human-bovine (WC3) reassortant vaccine (Rotateq; Merck & Co., Inc.), was licensed by the Food and Drug Administration (FDA) in early 2006.

Caliciviruses

Since noroviruses can be linked to the great majority of viral gastroenteritis epidemics, the need for vaccines or antivirals is apparent. At present, preventive strategies for calicivirus infection target the elimination of the source of infection by increased personal hygiene, cleaning and disinfecting of environmental surfaces, and identification of sick food-handlers and contaminated food or water. Several approaches to norovirus vaccine development have been investigated, such as transgenic plants expressing norovirus proteins as an edible vaccine and VLPs produced in baculovirus as a subviral vaccine. The major challenges of vaccine development for HuCV gastroenteritis are the tremendous genetic and antigenic diversity of these viruses and the lack of a suitable animal model for efficacy studies.

Astroviruses and Enteric Adenoviruses

Acquired immunity might be protective against astrovirus and adenovirus gastroenteritis, since symptomatic infections occur mainly in young children. In both cases the severity of gastroenteritis is usually mild and self-limiting and rarely requires rehydration therapy. Interruption of transmission should be the main focus of prevention by increased personal hygienic measures and disinfection of contaminated environment. At present there are no vaccines or antivirals available.

Coronaviruses, Toroviruses, Aichi Virus, and Picobirnaviruses

As mentioned previously, the real significance of these viruses in human gastroenteritis is not yet well established.

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

Gastroenteritis viruses replicate and cause disease mainly in the intestine. Therefore, stool specimens are the major source of specimens for laboratory diagnosis, although vomitus can also be used. Specimens are preferably collected within the first 48 h of illness. Specimens collected in later stages have a lower detection rate, although prolonged shedding of some gastroenteritis viruses up to several weeks after onset of illness has been reported. Stool specimens of a few grams are sufficient for detection by EM or antigen or nucleic acid detection methods. The samples can be collected by bedpan and then transferred into smaller containers or test tubes. Specimens can be recovered from a diaper with a wooden tongue depressor. Alternatively, a portion of the diaper can either be lined with plastic wrap to capture watery stool or cut out and soaked with sterile water or phosphate-buffered saline (PBS) to extract diagnostic material. Rectal swabs may be easy to obtain, but they are poor specimens for viral diagnosis and should be discouraged.

In general, the best results are obtained by testing the samples fresh, particularly for good viral morphology by EM. Stool samples can be stored at 4°C for weeks if they are not tested immediately after collection or need to be transported to the diagnostic laboratory. For prolonged storage, specimens should be kept frozen, preferably at −70°C. If multiple tests are planned for multiple pathogens or for confirmation of the results, aliquots of the samples are usually prepared to avoid repeated freezing and thawing of the bulk samples, which usually destroys the viral structures and results in decreased detection rates. Stool samples can be shipped on ice or dry ice depending on their storage conditions (e.g., short- or long-term storage), with care being taken to avoid unnecessary freezing and thawing between shipment and storage.

Serum samples are used for detection of antibodies against gastroenteritis viruses. Documenting seroconversion between acute- and convalescent-phase serum samples has been particularly useful for diagnosis of viral infection in outbreak investigations, but it is used mainly in research laboratories. An acute-phase serum is usually collected within a few days of the onset of illness, and a convalescent-phase serum is obtained 2 to 3 weeks later. Blood and serum samples should be handled with precautions for transmission of bloodborne pathogens. For long-term storage, the samples are preferred to be kept at −20 or −70°C in aliquots.

Drinking water, food, or other environmental specimens are used in research on viral (mainly norovirus) gastroenteritis outbreaks. If a food or water item is suspected as the source of an outbreak, a sample should be obtained as early as possible and stored at 4°C. Since testing of these items for the presence of viruses is not routinely done in most of the diagnostic laboratories and often requires special methodology (e.g., filter concentration of 5 to 100 liters of water and processing of food to remove food debris), a laboratory with the capacity to test these specimens should be contacted (e.g., local health departments or CDC).

LABORATORY DIAGNOSIS OF VIRAL GASTROENTERITIS

Diagnostic assays commonly used for viral gastroenteritis include direct visualization of viruses in clinical samples (EM, IEM, or solid phase-IEM [SPIEM]), detection of viral antigens (enzyme-linked immunosorbent assay [ELISA] or enzyme immunoassay [EIA], latex agglutination), detection of viral nucleic acids (RNA-PAGE, DNA-agarose gel, dot blot hybridization assay, PCR, reverse transcription-PCR (RT-PCR), real-time PCR, and nucleic acid sequence-based amplification [NASBA]), and virus isolation in cell culture. Due to the lack of reagents for some viral families described above, many diagnostic methods are not commercially available yet or are under development. The principles of these methods have been described in chapter 18. In this chapter, special emphasis has been placed on the detection of viruses or viral components in stool specimens, which is difficult because of the low viral load of many gastroenteritis viruses and the presence of unknown factors in stools that can interfere with the assays.

Direct Detection

Direct EM

Direct EM is used to visualize the negatively stained viral particles on a grid without the additional steps of grid preparation (121). It is fast, does not require specific reagents, and can be used for any viruses, but it is relatively less sensitive (minimum of $\sim 10^6$ viral particles per ml) than other techniques and requires expensive equipment. Liquid stool samples can be applied to the grid following a low-speed centrifugation (4,000 × *g* for 10 min) to remove large debris. For solid stool samples, a 10 to 20% stool suspension in either distilled water or a 1% ammonium acetate solution is made. One drop (5 to 10 μl) of the sample is then applied to a copper EM grid (300- to 400-mesh size) which is coated with formar (polyvinyl formol) reinforced by carbon shadowing (commercially available). The sample drop also can be placed on a piece of Parafilm, and then the grid is floated on the top of the drop. After incubation for approximately 1 min, excess

specimen is removed from the grid with a filter paper. Longer incubation may be used but without letting the samples dry out. If the resulting grid is too thick, the sample may be diluted or the grid may be washed with a drop of distilled water. The grid is then stained with a drop of 2% phosphotungstic acid (pH 7) for 10 to 30 s and then blotted with a filter paper. The dried grid is ready for EM examination.

For specimens containing a low concentration of viruses, a step of concentration by ultracentrifugation may be used. The Beckman Airfuge with an EM-90 rotor is useful to deposit the specimens on the EM grid for small volume samples. A centrifugation at 100,000 × *g* for 1 h is used to pellet most of the viral particles. Following the centrifugation, the pellet is resuspended in distilled water and processed for making the grids as outlined above. The samples may be further diluted if the sample layer on the grid is too thick. A step of low-speed centrifugation to remove large aggregates also may help to avoid overloading.

The stool suspension can also be subjected to agar diffusion to concentrate the virus particles. Briefly, the stool specimen is placed on a small block of 1% agar made up in distilled water, and the grid is floated on the surface of the drop. After incubation at room temperature until the drop is absorbed into the agar, the grid is removed and processed for EM as described above. This procedure not only concentrates the viruses but also removes excessive quantities of salts which may precipitate on the grid, obscuring the viruses.

Under EM, negatively stained virus particles appear as lighter structures surrounded by a dark background (Fig. 1) (121). The most definitive of the spherical structures are the adenoviruses and rotaviruses, whose icosahedral capsids are readily discerned (Fig. 1). Each of the smaller round viruses, including the norovirus, sapovirus, astrovirus, and Aichi virus, although with similar shape (round) and size (30 to 40 nm in diameter), has its unique surface appearance: sapovirus reveals a rigid surface structure with cup-like depressions of a typical "Star of David" appearance; norovirus has a less rigid surface appearance and does not have the Star of David structure; astrovirus reveals a distinct five-point star appearance; and Aichi virus reveals a smooth surface indistinguishable from that of other picornaviruses (Fig. 1). However, viral particles lacking well-defined features are commonly seen, which can pose diagnostic dilemmas, particularly when they are seen as individual particles. Thus, a confident diagnosis relies on a repeated observation of identical particles in more than one EM field with some particles revealing typical morphology.

Among the nonspherical particles, the coronavirus forms pleomorphic structures with well-delineated dumbbell-shaped peplomers or spikes. Generally, the peplomers form a dark halo around the enveloped capsid. Torovirus-like particles have a less well defined peplomer fringe. A proportion of them are kidney shaped, while others have well-established darker-staining regions in the center of the particle (Fig. 1).

In addition to the above well-recognized virus particles, there are a number of other structures visualized in stool specimens. These include the obvious flagella, pili, and bacteria, as well as cell wall components, cell membrane blebs, and bacteriophages. The bacteriophage may pose problems since they may be confused with small gastroenteritis viruses, especially if their tails are absent. Membrane blebs can be confused with toroviruses.

IEM

IEM technique has played an important role in the discovery of a number of viral pathogens including the prototype Norwalk virus (79, 121). The principle of the technique is to form virus-antibody aggregates by incubation of the samples with specific antibodies, and these aggregates are much easier to identify under EM, which may improve the sensitivity up to 100-fold. This technique also is used to measure antibody against a virus, by comparison of the numbers and sizes of the viral aggregates at different concentrations of serum samples used. For detection of viruses in stool samples, antibodies from different sources (serum samples of patients, hyperimmune antibodies from animals, or monoclonal antibodies) can be used. The dilution of antibodies used should be determined empirically in each case. For convalescent-phase sera from patients, a ratio of 1:1 of the sera and stool suspensions may be used. Hyperimmune antisera from animals may be used in a much higher dilution. Using too much antibody may result in overcoating of the viral particles, making it difficult to recognize fine surface structures.

After incubation for 1 h at 37°C, the samples are centrifuged for 30 min at 15,000 × *g*. The resulting pellet that contains the virus-antibody complexes is then processed for making the grid directly or by the agar block technique described above. The antibodies used in the IEM technique can also be labeled with colloidal gold, which may help the detection of viruses on the grids. A further modified method is the solid-phase IEM, which is designed to capture the viruses by specific antibodies with which the EM grid is precoated (89). This method may not result in typical virus clumps but leaves less debris on the grid.

Antigen Detection Assays

Antigen detection assays can be highly sensitive and specific if hyperimmune or high-titered monoclonal antibodies are used. Common formats include ELISA or EIA and latex agglutination and rapid membrane-based assays which are simple, fast, and suitable for clinical diagnosis. Because of the lack of reagents due to the difficulty to propagate many gastroenteritis viruses, reliable antigen detection assays remain unavailable for many viral families. In addition, due to the high degrees of genetic and antigenic variations, some existing assays need to be improved for better sensitivity and specificity.

Commercial ELISA or EIA and latex- and rapid membrane-based assays are available for rotaviruses and enteric adenoviruses (Tables 2 and 3) but are limited or not yet available for other gastroenteritis viruses. Several companies have developed and commercialized antigen detection tests for astroviruses and noroviruses (e.g., R-Biopharm AG and Dako), but at present these tests are available only for research and not used in clinical diagnostic laboratories in the United States. Some commercially available antigen detection tests are listed in Table 2 and recommended mainly for rotavirus and enteric adenovirus diagnosis.

ELISAs

Several antigen detection ELISAs for the diagnosis of astroviruses and human caliciviruses utilizing monoclonal antibodies or hyperimmune polyclonal antibodies have been described (55, 69, 71, 82, 106, 119), and commercial kits based on these reagents are under development. Finally, ELISAs have been developed and used in research for the detection of human toroviruses and Aichi virus.

In commercial ELISA kits, 96-well plates with breakaway strips are commonly used, especially for diagnosis of rotaviruses in clinical laboratories. Stool suspensions (10 to 20%) are prepared in PBS, pH 7.4, or sodium carbonate buffer, pH 9.5. The whole assay can be completed within 2 h and has a sensitivity equal to or greater than that of EM.

TABLE 2 Commercial antigen detection tests available for diagnosis of viral gastroenteritis[a]

Company (website)	Organism(s) detected (product trademark name)
Inverness Medical Professional Diagnostics (http://www.invernessmedicalpd.com)	Rotavirus (Virogen Rotatest)
Bio-Rad Laboratories (http://www.bio-rad.com)	Rotavirus (Pastorex Rotavirus, Pathfinder Rotavirus)

[a] This list is based on a search of the Internet and the literature with the best knowledge of the authors. Many of the assays listed in the previous editions of this chapter cannot be found, possibly due to name or brand change, product withdrawal, or reorganization or merge of manufacturers. Some of the kits are available only for research use in the United States or other countries. Requesting information of FDA approval of a test kit from the vendor is necessary before it is used in clinical diagnostic laboratories in the United States.

ELISAs also have been used for typing viruses such as the G typing of the group A rotaviruses based on type-specific monoclonal antibodies (124). ELISA also can be used to detect antibodies by coating the plate with specific viral antigens. Such assays have been used in the serosurveillance or outbreak investigations for rotaviruses and caliciviruses (37, 134). With the cloning and expression of viral genomes, similar assays are expected to be developed for other viral families.

Rapid membrane-based ELISA or EIAs are valuable for small laboratories with sporadic demand for diagnosis of viral gastroenteritis (28). Kits for these tests include all reagents and require minimal equipment, as the test results can be read visually. The tests generally include built-in positive and negative controls to ensure that it has been performed appropriately. These tests can be completed within 30 min. Because of their speed and simplicity, these kits are amenable to point-of-care testing.

Latex Agglutination Assays

The latex agglutination tests are based on the agglutination of latex beads coated with virus-specific immunoglobulins by the virus particles or viral antigens present in the specimens. Since some fecal specimens can cause nonspecific agglutination, negative-control latex beads coated with nonspecific immunoglobulins are also included in the test. Usually a 10% stool suspension is prepared in PBS, large particles are removed by low-speed centrifugation, and the supernatant is mixed with the latex reagent. A positive result is indicated by visible clumping (agglutination) of the latex particles, which usually occurs within minutes. The assays are generally less sensitive than ELISA but are useful in small diagnostic laboratories.

Nucleic Acid Detection Assays

Diagnosis based on detection of viral genome includes detection of viral DNA or RNA by electrophoresis, by hybridization, or following amplification of the viral DNA or RNA by PCR or RT-PCR. The general principle of each technique has been described in chapter 16. The selection of methods depends on the nature of the viral genomes, e.g., DNA or RNA, single or double strands, single or segmented genome, and sizes of the genomes (Table 4). The selection of methods also depends on the purpose of the study: rapid diagnosis (direct detection methods and PCR or RT-PCR), typing (PCR or RT-PCR by type-specific primers), or research (PCR or RT-PCR followed by sequencing).

Direct Staining following Electrophoresis

Direct staining of viral RNA or DNA by ethidium bromide is not widely used for diagnosis of viral gastroenteritis because of the insensitivity of the methods.

Detection of Enteric Adenoviral DNA following Restriction Enzyme Digestion

Direct detection of enteric adenoviral DNA by electrophoresis requires a step of restriction enzyme digestion because of the large size of adenoviral genomic DNA. In addition, the resulting DNA fragments reveal unique patterns by specially selected restriction enzymes, which are useful for genetic identification of the strains. Among the restriction endonucleases, SmaI proved effective in identifying adenoviruses 40 and 41 (17).

Electropherotyping of Double-Stranded, Fragmented RNA Genome of Rotaviruses

The segmented, dsRNA genome of the rotaviruses has traditionally been the target for detection and typing (109). The viral RNA is extracted directly from stool specimens and then subjected to electrophoresis followed by detection with silver staining. This method is as sensitive as EM. It is also used in the classification of rotaviruses, in which the appearance of an unusual electropherotype could denote a novel strain or group of rotavirus. Schematic diagrams of electropherotypes of group A to G rotaviruses have been compiled and serve as a reference. Similar methods of electrophoresis,

	EM	Antigen detection	Nucleic acid detection	Virus isolation	
Rotavirus	Readily detected but not commonly used	Commercial kits available	Good for genotyping	Difficult but adaptable	22, 26, 27, 28, 31, 41, 93, 139
Norovirus	Low sensitivity, IEM used in research	Recombinant-antigen-based assays used in research laboratories[a]	For detection and molecular epidemiology in research laboratories	NA[b]	18, 126
Sapovirus	Low sensitivity, typical calicivirus morphology	Recombinant-antigen-based assays under development	For detection and molecular epidemiology in research laboratories	One porcine strain was adapted, not for human strains	NA
Astrovirus	Low sensitivity, difficult to see typical star-like morphology	Monoclonal antibody-based assays, good for typing	For detection and molecular epidemiology in research laboratories	Adapted in cell culture	23, 102, 122
Adenovirus	Readily detected, but not specific for Ad 40 and 41	Commercial assays available	For typing and detection	Difficult to grow in cell culture	108, 140, 151
Picobirnavirus	Difficult to detect	NA	For detection	NA	NA
Aichi virus	Cannot differentiate from other picornaviruses	Limited tests available in research laboratory	For detection	Readily grows in cell culture	NA
Coronavirus	Atypical morphology	Limited tests available in research laboratory	For detection	NA	NA
Torovirus	Atypical morphology	Limited tests available in research laboratory	For detection	NA	NA

[a] Commercial kits are available for research purposes, not for clinical diagnostic laboratories in the United States.
[b] NA, not available.

using silver staining instead of ethidium, have been used for the detection of picobirnaviruses.

Dot Blot Hybridization

In general, dot blot hybridization is more sensitive than direct staining methods and is comparable to most antigenic detection methods. Dot blot hybridization has been used for the detection of rotaviruses, caliciviruses, astroviruses, and enteric adenoviruses but has been less frequently used since the introduction of PCR or RT-PCR because of the higher sensitivity of the last two methods. In addition, dot blot hybridization requires long prehybridization and hybridization incubations, which are time-consuming. However, hybridization has been used in combination with PCR or RT-PCR to improve the sensitivity and specificity of the methods. Dot blot hybridization has been used particularly for detection of toroviruses in stool specimens because detection of these viruses by EM is difficult. In general, dot blot hybridization is used mainly in research laboratories.

PCR and RT-PCR

PCR and RT-PCR are the most sensitive methods used for the diagnosis of gastroenteritis viruses. They are particularly useful in combination with sequencing for molecular epidemiology studies of these viruses (34, 38, 104, 148). For example, RT-PCR assays have been used for the G and P typing of the group A rotaviruses, in which type-specific primers targeting the unique regions of the VP7 and VP4 genes have been used to differentiate the G and P types, respectively, by DNA electrophoresis analysis following the RT-PCR amplification of the viral RNA (43, 111). RT-PCR is also used for studying the genetic variation and genotyping of caliciviruses and astroviruses. In these studies, primers targeting the highly conserved regions of the viral genome, usually in the viral nonstructural protein regions, such as the RNA polymerase region, are used for broad detection followed by sequencing of the RT-PCR products. Primers targeting the less conserved viral capsid gene also have been used, which is believed to be biologically more relevant. Simultaneous analysis of both the RNA polymerase and capsid regions led to the description of several recombinant calicivirus strains.

Advanced technologies such as real-time PCR (53, 75, 127) using automated processes have been developed for rapid diagnosis of gastroenteritis. The particular importance of these techniques is the quantitative measurement of the

TABLE 4 Taxonomy and virologic properties of gastroenteritis viruses

Virus	Family	Size (nm)	Appearance under EM	Viral genome	Genetic or antigenic types
Rotavirus	*Reoviridae*	70	Wheel-shaped, triple-layered capsid	dsRNA	7 antigenic groups (A–F) and 14 G and 23 P types
Norovirus	*Caliciviridae*	30–38	SRSV[a]	ss(+)RNA[b]	5 genogroups and >20 genetic types (clusters)
Sapovirus	*Caliciviridae*	30–38	SRSV, with Star of David appearance	ss(+)RNA	5 genogroups and >9 genetic types (clusters)
Astrovirus	*Astroviridae*	28–30	SRSV, star shaped	ss(+)RNA	8 serotypes
Adenovirus	*Adenoviridae*	70–100	Icosahedral capsid	dsDNA	Ad40 and Ad41 linked to gastroenteritis
Picobirnavirus	*Birnaviridae*	35	Small round virus	dsRNA	Unknown, genetic variation found
Aichi virus	*Picornaviridae*	30	Small round virus	ss(+)RNA	Unknown
Coronavirus	*Coronaviridae*	60–200	Pleomorphic with club-shaped projections	ss(+)RNA	Unknown
Torovirus	*Coronaviridae*	100–150	Pleomorphic with torus-shaped core	ss(+)RNA	Unknown

[a] SRSV, small round structured virus.
[b] ss, single stranded.

PCR products in a timely fashion, which makes possible measuring viral load for viruses that do not grow in tissue culture. Multiplex PCR and RT-PCR assays with pooled primers have been used for broad detection of viruses from different families (15, 110, 128). Finally, microarray and gene chip technology has been explored for diagnosis of viral gastroenteritis (21, 96) but is not widely used yet.

One of the big challenges of virus detection in stool specimens by PCR or RT-PCR is the potential presence of inhibitors to the assays. Inhibitory effects can be monitored by including internal nucleic acid controls to the assays. Approaches to reduce such inhibitors include dilution of the extracted RNA or addition of detergents or denaturing chemicals during RNA extraction (125). Among many reagents, guanidinium thiocyanate is the most frequently used agent for a number of commercial methods for extraction of nucleic acid from different clinical specimens including stools (e.g., RNAzol and TRIzol). The extracted viral DNA or RNA is recovered by phenol choloroform extraction followed by ethanol precipitation or by adsorption onto silicon particles or membranes. Stool specimens often contain different microorganisms as well as host cells, which could release a large amount of nucleic acids that could be nonspecifically amplified by the virus-specific primers. Sometimes these nonspecific PCR products cannot be avoided even under high-stringency conditions of the assays. In this case, hybridization with virus-specific probes usually is required to confirm the results of the assay (133).

Most viral families causing gastroenteritis are genetically diverse, which imposes a further challenge in the application of PCR and RT-PCR for clinical diagnosis. In the example of human noroviruses, there are over 20 genetic clusters within two or three genogroups (46, 47, 81). By using primers targeting highly conserved regions of the genomes, mainly in the RNA-dependent RNA polymerase (RdRp) region, the majority of known human noroviruses are detected (5, 16, 68). However, due to the high diversity of the norovirus genus, there is probably no single primer pair that can detect all strains. A similar situation also is true for the sapoviruses and astroviruses. For better diagnosis, multiple primer sets targeting different regions of the genome have been used to increase the chance of detection of genetically distantly related strains (147, 150). In addition, degenerate primers based on sequence variation of known family members also have been used (34, 35, 38, 76). It should be pointed out that even with the improved primers these assays may still miss some strains and continued efforts for the design and evaluation of new broadly reactive primers are necessary. Some of the commonly used primers for the detection of astroviruses, noroviruses, and sapoviruses are listed in Table 5.

Because there are readily available antigenic diagnostic methods, RT-PCR has not been as widely used for diagnosis of rotavirus-associated gastroenteritis, although it has been specially used for genotyping of rotaviruses. On the other hand, due to the lack of readily available and reliable antigenic assays for many other enteric viruses, RT-PCR plays an important role in their diagnosis, including noroviruses, sapoviruses, and astroviruses (36, 38, 153), and a commercial RT-PCR kit for the detection of astroviruses and noroviruses has been recently developed (Calici/Astrovirus Consensus kit; Argene). PCR and RT-PCR also have been developed and increasingly used in the clinical and basic research of enteric adenoviruses, coronaviruses, toroviruses, picobirnaviruses, and Aichi virus (3, 8, 29, 129, 156, 158). Further improvement by standardization and automation of these methods may help their wider application in the diagnosis of viral gastroenteritis in general clinical laboratories.

NASBA

Nucleic acid sequence-based amplification (NASBA) of RNA targets utilizes a multienzyme reaction modeled after retroviral replication. It is based on the simultaneous activities of reverse transcriptase, RNase H, and T7 RNA polymerase. The NASBA reagents are commercially available in an easy-to-use format (NucliSens Basic kit; bioMerieux Inc., Durham, N.C.), and only the target-specific primers and the capture probe need to be provided by the investigator. It is an isothermal reaction conducted at 41°C, which does not require expensive thermocyclers and generates the same number of copies as RT-PCR in a shorter time. Detection methods utilizing NASBA have been described for rotavirus (66), astrovirus (136), and norovirus (49, 107).

Isolation in Cell Culture

While growth in cell culture has a major impact on the investigation of a virus, it is generally time-consuming and is not considered sufficiently rapid to contribute to the meaningful management of disease. Most of the enteric viruses causing human gastroenteritis are fastidious in cell culture.

TABLE 5 Commonly used RT-PCR primers for astro-, noro- and sapovirus detection

Virus	Primers	Genomic regions	Length (bp)	Reference

[a] Norovirus regions A and B are in the RNA-dependent RNA polymerase (RdRp) region, and regions C and D are in the capsid gene (Cap).
[b] UTR, untranslated region.

Even for rotaviruses, although many strains have been successfully adapted to cell culture, the primary isolation of these strains usually requires multiple passages. Cell lines for isolation of rotaviruses include MDBK, PK-15, BSC-1, LLC-MK2, MA104, CaCo-2, and HRT-29. To grow them in cell culture, the medium must be supplemented with proteases such as trypsin or pancreatin. This approach can be adapted for titration of viruses by plaque assay and serotyping by virus neutralization.

The enteric adenovirus types 40 and 41 grow best in a Graham 293 human embryonic kidney cell line that has been transformed by adenovirus type 5 DNA. Isolation of astroviruses from clinical samples is also difficult, although most of the astrovirus serotypes have been adapted in HEK or LLC-MK2 cell culture (138). Cell culture propagation of astroviruses requires the presence of trypsin in the culture medium.

Propagation of human caliciviruses, human coronaviruses, toroviruses, and picobirnaviruses in cell culture has not been achieved yet. The porcine enteric calicivirus, a sapovirus, has been successfully adapted to grow in porcine kidney cell lines but only in the presence of intestinal contents of pigs as a supplement in the culture medium. The murine norovirus has been reported to replicate in primary dendritic cells and macrophages (155). The only gastroenteritis virus to be readily cultivated in cell culture is the Aichi virus, which grows well in monkey kidney cell lines (BSC-1 or Vero).

IDENTIFICATION

Typing Systems

The typing of gastroenteritis viruses includes antigenic (serotype) and genetic typing. Antigenic typing methods require type-specific antibodies, usually monoclonal antibodies against specific antigenic epitopes of the viruses. If the antibodies are known to be specific for a neutralization epitope, they may be used for typing by a regular solid-phase format of ELISAs. However, for serotyping, tissue culture-based neutralization tests using type-specific antibodies are commonly used. Due to the lack of a cell culture for many

gastroenteritis viruses, such assays remain unavailable for most gastroenteritis viral families. The genotyping methods are usually based on the genomic sequence variation determined by typing PCR or RT-PCR using specific primers, or by regular PCR or RT-PCR followed by sequencing or probe hybridization.

Both antigenic typing and genetic typing of gastroenteritis viruses are important in understanding the classification and epidemiology of these pathogens and for developing preventive strategies against viral gastroenteritis. Typing does not affect clinical treatment. Therefore, typing of gastroenteritis viruses is used mainly in research laboratories.

Rotaviruses

Monoclonal antibody-based typing assays have been developed for typing the G and P types of rotaviruses. However, due to the limited supply of monoclonal antibodies representing all serotypes, genotyping methods have been used more frequently. Genotyping of group A rotaviruses is performed by RT-PCR using type-specific primers targeting the gene segment coding for VP7 (G-genotype) or VP4 (P-genotype). Two common primer sets are currently used in rotavirus G-typing surveillance programs (24, 43); however, it was shown that point mutations in genotype-specific primer regions can lead to mistyping or failure to genotype, indicating that primer usage requires close monitoring and updating (64, 123).

Caliciviruses

Because of the lack of a cell cuture system, serotyping of HuCVs has not yet been achieved. Genetic typing of HuCVs is based on probe hybridization or sequencing of RT-PCR products targeting the RdRp or capsid encoding regions (6, 39, 149).

Astroviruses

For typing of astroviruses, immunologic assays such as IEM and typing ELISA have been described but are not commercially available (88, 114, 116). The most commonly used RT-PCR-based typing methods for astroviruses are summarized in a recent review by Guix et al. (51).

Adenoviruses

Typing of adenovirus types 40 and 41 can be established by a variety of methods. Adenovirus genomic DNA restriction enzyme analysis has been used in the past for the differentiation of enteric adenoviruses. Recently, PCR by itself or in combination with restriction enzyme analysis has become a convenient tool for type-specific identification of adenoviruses (2, 156) and a quantitative real-time PCR assay also has been described (74). With the development of monoclonal antibodies that are able to detect and distinguish the enteric adenoviruses from each other and from the nonenteric adenoviruses, commercially available EIAs have become more widely used (13, 91, 108).

Serologic Tests

Neutralization tests based on plaque reduction or based on epitope-blocking assays using type-specific monoclonal antibodies have been described for rotaviruses. Other methods have also been developed for seroepidemiology study of rotavirus; more information about these methods can be found in several review articles (58, 59, 77, 78). There are no neutralization-based serologic tests available for the diagnosis of other viral gastroenteritis. However, antibody detection ELISAs based on specific viral proteins as the capture antigens have been used in epidemiology studies of gastroenteritis viruses. Recombinant viral capsid proteins of caliciviruses and astroviruses generated in the baculovirus and other systems have been an excellent source of viral antigens for these studies (44, 48, 71). Application of these assays in serosurveillance against gastroenteritis viruses has played an important role in an understanding of the importance of these viruses in different populations. Monitoring seroconversion based on the collection of paired acute- and convalescent-phase sera has been used in outbreak investigations.

ANTIVIRAL SUSCEPTIBILITIES

There are no effective antiviral agents available for the prevention or treatment of viral gastroenteritis. Specific antivirials have been tested in animal models or in vitro but are not used for human treatment.

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

Diagnosis of viral gastroenteritis remains difficult because of the lack of readily available commercial kits for many viral families causing acute gastroenteritis (Table 3). The fact that a variety of microbial pathogens, including bacterial and parasitic agents in addition to viruses, as well as noninfectious causes, cause acute gastroenteritis in humans further complicates the situation. Furthermore, many viral pathogens are known to cause subclinical infection, and in some cases, more than one pathogen is detected in the same clinical sample or same episode of clinical illness, which may further complicate the diagnosis for true etiology. Thus, diagnosis of viral gastroenteritis largely relies on the clinical information and sometimes on exclusion of other causes with available tests.

Generally, the EM technique remains the most simple and rapid method for those clinical laboratories that have access to the equipment. Although it is relatively less sensitive, EM still serves as the "gold standard" for other methods in clinical diagnosis of many gastroenteritis viruses. The method requires experienced individuals who are familiar with the morphologies of different gastroenteritis viruses, including differentiation of atypical viral particles from many unrelated cellular and microbial debris and structures commonly seen in the stool specimens. The use of reference grids (121) with typical viral morphology of gastroenteritis viruses is helpful for a person who is new to the field to gain such experience.

The antigenic methods are highly sensitive and specific, and, if available, are the best choice for clinical diagnosis. They are also simple and relatively free of problems and are suitable to be commercialized. Good examples include the assays for rotaviruses and enteric adenoviruses (Table 2).

The nucleic acid-based assays, particularly the PCR and RT-PCR assays, are most sensitive and specific, and therefore of great potential for clinical diagnosis. The combination of these assays with hybridization and other technology, such as real-time PCR, further increases specificity, sensitivity, and speed. A further application of great potential for PCR and RT-PCR is the detection of viruses in environmental samples to assess the burden of viral gastroenteritis originating from food and water sources and to better understand the epidemiology of these viruses (83, 95, 120). However, due to the expertise required and the lack of commercial kits, PCR and RT-PCR for gastroenteritis viruses remain largely confined to research or public health laboratories. The genetic diversity of individual virus families poses further challenges for the use of these assays in clinical laboratories. Despite these challenges, commercial RT-PCR kits for the detection of these viruses will hopefully be available in the near future.

Rabies Virus*

LILLIAN A. ORCIARI AND CHARLES E. RUPPRECHT

95

TAXONOMY

The etiologic agents responsible for the acute, progressive viral encephalomyelitis known as rabies belong to the order *Mononegavirales*. These single-stranded, bullet-shaped RNA viruses are in the family *Rhabdoviridae* and the genus *Lyssavirus* and contain nonsegmented genomes of approximately 12 kb (13). Included in the genus are the prototype species, *Rabies virus;* the less commonly known species of nonrabies lyssaviruses, *Mokola virus, Lagos bat virus, Duvenhage virus, European bat virus 1, European bat virus 2,* and *Australian bat virus;* and four proposed new lyssavirus species, *Aravan virus, Khujand virus, Irkut virus,* and *West Caucasian bat virus* (1, 22, 24). Although rabies viruses are endemic to five of seven continents, the geographic distributions of the other lyssaviruses are more localized (2, 11, 27, 30, 47). Differences among lyssaviruses were first noticed by serologic cross-neutralization studies and were used to divide them into serogroups according to these phenotypic differences from *Rabies virus* serogroup 1 (51). Later, differences among these species were based on nucleotide sequence analysis, and viruses were grouped as different species or by genotypes (1 through 7). Current commercial human and animal vaccines are based upon rabies virus and provide adequate cross-protection against most other lyssaviruses, with the exception of *Mokola virus, Lagos bat virus,* and *West Caucasian bat virus*.

DESCRIPTION OF THE AGENT

The virions are rod shaped, approximately 180 by 75 nm, consisting of five structural proteins: the glycoprotein (G), matrix protein (M), nucleoprotein (N), phosphoprotein (P), and large polymerase protein (L). The outer surface of the virus is contained in an envelope bilayer derived from the host cell cytoplasmic membrane during budding (Fig. 1). Peplomers, viral G protein trimeric spikes of approximately 10 nm, are inserted within the surface of the envelope. The rabies virus G protein binds with host cell surface receptors (adsorption), thus initiating a cascade in the infectious cycle and replication. The inner surface lining of the envelope is formed by the M protein, which binds with the G protein and envelope and the ribonucleoprotein (RNP) core.

The RNP is composed of tightly wound RNA, encapsidated by the phosphorylated N protein, and associated with the P and L polymerase proteins. The RNA-nucleoprotein complex is responsible for viral replication. The virus-encoded polymerase (L gene) transcribes the genomic strand of rabies virus RNA into leader RNA and five capped and polyadenylated mRNAs, which are translated into proteins. Translation, which involves the synthesis of the N, P, M, G, and L proteins, occurs on free ribosomes in the cytoplasm. Although G protein synthesis is initiated on free ribosomes, completion of synthesis and glycosylation (processing of the G protein) occurs in the endoplasmic reticulum and Golgi apparatus. In part, the intracellular ratio of leader RNA to N protein regulates the switch from transcription to replication, and when this switch is activated, replication of the viral genome begins. The first step in viral replication is synthesis of full-length copies (positive strands) of the viral genome. When the switch to replication occurs, RNA transcription becomes "nonstop" and stop codons are ignored. The viral polymerase enters a single site on the 3′ end of the genome and proceeds to synthesize full-length copies of the genome. These positive strands of rabies virus RNA serve as templates for synthesis of full-length negative strands of the viral genome. During the assembly process, the N-P-L complex encapsidates negative-stranded genomic RNA to form the RNP core, and the M protein forms a capsule, or matrix, around the RNP. The RNP-M complex migrates to an area of the plasma membrane containing G protein inserts, and the M protein initiates coiling. During assembly, the M-RNP complex binds with the G protein, and the completed virus buds from the plasma membrane (44, 54, 55).

From a diagnostic viewpoint, the N and G proteins have been the focus of most laboratory research evaluations. Rabies diagnosis is based on the ability to detect intracellular viral inclusions, which are collections of RNP. Since the rabies virus G protein and host cell receptor interactions initiate the infection cycle, the G protein is directly involved in pathogenesis and virulence, induction of immune response, and binding of neutralizing antibodies (10, 12). Vaccines prepared from whole virions, purified rabies virus G proteins, or recombinant viral vaccines encoding rabies virus G proteins have been used to successfully immunize and protect animals from rabies virus infections (34, 52). Additionally, antibodies to the G protein have been used as a method to evaluate vaccine potency.

Detailed reviews of rabies virus replication and virus pathogenesis have been published recently (12, 14).

* This chapter contains information presented in chapter 102 by Jean S. Smith in the eighth edition of this Manual.

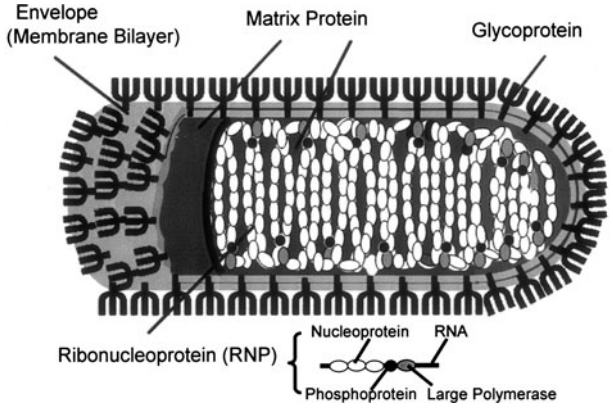

FIGURE 1 Rabies virus structure.

As an enveloped RNA virus, the rabies virus is sensitive to lipid solvents (detergent solutions, ethers, and chloroform), alcohols (70% ethanol or isopropanol), iodine preparations, and quaternary ammonium compounds. Despite susceptibility to lipid solvents, acetone does not inactivate virus completely after routine fixation times of 1 h. However, the rabies virus is sensitive to drying and is inactivated by pasteurization and UV light (7, 20).

EPIDEMIOLOGY AND TRANSMISSION

Nearly 7,000 rabies cases were reported in animals from the United States during 2004. The majority of these cases were reported in wildlife, accounting for 92% of all reported rabies cases. Among these, raccoons were the predominant host species, with more than 2,500 cases. There are seven predominant patterns among mesocarnivores in defined geographic regions of the United States (Fig. 2). Among these are raccoons in the eastern United States, skunks in the north central, south central, and California regions, Arctic and red foxes in Alaska, gray foxes in Texas and Arizona, and mongoose in Puerto Rico. Although dogs represent a major reservoir species in most developing nations, enzootic canine rabies has been eliminated in the United States and other developed countries. Due to canine vaccination programs, rabies cases in dogs in the United States have declined over the last 60 years from >6,000 cases annually to only 94 in 2004 (all due to spillover infections from rabid wildlife). Domestic animal rabies represented only 8% of the total reports. Rabid bats (19.9%) were reported from all parts of the mainland United States. Of the human rabies cases detected in the United States during 2000–2004, 15 of 21 were associated with rabies virus variants of bat origin (four due to transplanted organs or tissues from a donor exposed to a bat). The remaining six human cases were related to terrestrial variants, four from dogs acquired outside the United States (Africa, Philippines, Haiti, and El Salvador), one case related to a raccoon variant, and one case from Puerto Rico, associated with a virus found in mongooses and dogs (21).

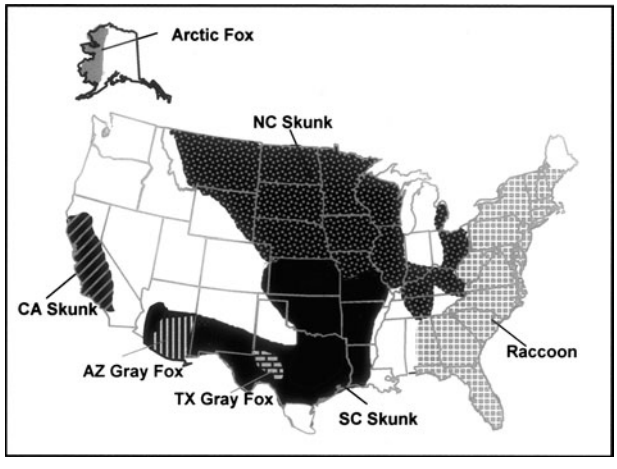

FIGURE 2 Distribution of major terrestrial rabies reservoirs in the United States.

Rabies viruses are usually transmitted in infected saliva via the bite of a rabid animal. Human rabies cases due to nonbite exposures are extremely rare. Nonbite exposures include scratches, open wounds, and mucous membranes contaminated with a source of rabies virus, such as infected saliva or central nervous system (CNS) tissues from a rabid animal. Inhalation of aerosols is another source of nonbite exposure. Two human rabies cases were related to exposures with aerosolized high-titered rabies viruses, and two cases occurred in bat cave researchers without clearly defined exposure histories (5, 53). Immediate wound cleansing with soap and water should be performed if an exposure is suspected, and medical care should be obtained. The local health department should be consulted if there are questions regarding prophylaxis, based on the recommendations of the Advisory Committee on Immunization Practices (ACIP) for Rabies Prevention in Humans. Persons who have been bitten by an animal suspected or proven to be rabid by laboratory diagnosis should receive prompt postexposure prophylaxis. Unvaccinated individuals exposed to a rabid animal should receive human rabies immunoglobulin (RIG) at a dosage of 20 IU/kg of body weight. The RIG should be infiltrated around the wound, and any remaining amount should be given at a site distant from where the vaccine was administered. In addition, five doses of a human rabies vaccine licensed for use in the United States should be administered on days 0, 3, 7, 14, and 28 postexposure. Individuals who have received preexposure vaccinations require only two doses of vaccine on days 0 and 3, regardless of the preexposure antibody titer (6).

CLINICAL SIGNIFICANCE

Rabies may be misdiagnosed because of the nonspecific symptoms associated with the prodromal period, which appear as flu-like symptoms. The usual incubation period is approximately 20 to 90 days after exposure. Following the prodromal period, an acute neurological phase occurs. The majority of rabies cases manifest as an encephalitic form, and fewer than 20% of cases are observed as a paralytic presentation. Among patients exhibiting classical encephalitic symptoms, generalized arousal or hyperexcitability with intermittent lucid periods may appear, including periods of confusion, hallucinations, agitation or aggressive behavior, autonomic dysfunction, difficulty swallowing, hypersalivation, lacrimation, sweating, and dilated pupils. Cranial nerve deficits include anisocoria and facial or tongue weakness. Hydrophobic and aerophobic spasms can be dramatic. Finally, disease presentation includes cardiopulmonary problems and instability leading to coma, cardiac arrest, and death.

The paralytic form of presentation includes flaccid muscle weakness, frequently spreading in an ascending pattern to the

other extremities. In some cases there is laryngeal and facial muscle weakness or bilateral deafness. These cases may resemble Guillain-Barré syndrome. Other symptoms include urinary incontinence. Hydrophobia is less common. Mild inspiratory spasms may be present. Cardiopulmonary complications and instability result in cardiac arrest and death (16, 17, 19).

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

All samples collected for rabies virus testing may contain infectious virus. Appropriate handling and shipping precautions should be maintained. Acetone-fixed brain impressions and infected cell culture slides should be manipulated with forceps or gloves, because acetone fixation for 1 h does not fully inactivate rabies virus. Minimum personal protective equipment for routine work should include a gown or lab coat with sleeve protectors, double gloves, safety glasses, and a biological safety cabinet. The addition of heavy rubber gloves and a face shield is required when removing brains from animals. Although rabies virus is a biological safety level 2 agent in diagnostic laboratories, if large quantities of the virus are handled in a high-volume research laboratory or if nonrabies lyssaviruses are evaluated, biological safety level 3 precautions are recommended. The virus is susceptible to a number of disinfectants (e.g., 1:256 quaternary ammonium compound, 0.5% sodium hypochlorite, 70% isopropanol, and 10% iodinophor). All laboratory surfaces need to be decontaminated after use with one of the above disinfectants. All contaminated waste and instruments should be decontaminated by autoclaving for a minimum of 60 min at 15 lb of pressure (7, 20).

Preexposure rabies vaccination is recommended for persons at risk of exposure, including veterinarians, animal control workers, field biologists, and rabies laboratorians. For all individuals working in a routine rabies diagnostic laboratory, periodic determination of rabies virus neutralizing antibody (VNA) titer is recommended every 2 years. Individuals working in high-volume rabies research facilities with continuous exposures should check VNA levels every 6 months. Preexposure vaccination does not equate with protection. All potential rabies virus exposures need to be evaluated on a case-by-case basis, and true exposures should be treated regardless of prior vaccination, as recommended in current ACIP guidelines (immediate wound cleansing and booster vaccinations on day 0 and day 3) (6).

The latest information on the collection, transport, and storage of specimens for rabies diagnosis may be obtained from the CDC rabies website resources. For information on collection of (unfixed) postmortem brain tissues for rabies diagnosis, refer to http://www.cdc.gov/ncidod/dvrd/rabies/Professional/publications/DFA_diagnosis/DFA_protocol-b.htm#IV; for information regarding diagnosis of rabies from formalin-fixed brain tissues from animals or humans, refer to http://www.cdc.gov/ncidod/dvrd/rabies/Professional/Prof.forms/formalin.htm; and for antemortem diagnosis of human rabies cases, refer to http://www.cdc.gov/ncidod/dvrd/rabies/Professional/Prof.forms/antem.htm. Submission forms must accompany each sample and may be obtained at http://www.cdc.gov/ncidod/dvrd/rabies/Professional/Prof.forms/patienth.htm. The CDC should be consulted before samples are submitted for primary rabies diagnosis or confirmation (404-639-1050). A summary of the routine laboratory tests for rabies is given in Table 1. Samples for antemortem and postmortem diagnosis of rabies in humans should be transported to the laboratory on dry ice within 24 h. Samples should be shipped in approved leak-proof containers inside an outer container according to the current International Air Transport Association and interstate or local shipping regulations for diagnostic samples.

DIRECT DETECTION METHODS

Microscopic Methods

Laboratory methods may be used to detect histopathological changes and viral antigen and to observe virion morphology. Direct examination methods may utilize routine stains (e.g., hemotoxylin and eosin) to examine abnormal histopathology consistent with rabies encephalomyelitis and specialized stains (e.g., Seller's) to observe typical viral inclusions, such as classical Negri bodies (26, 43). Although of historical importance, these methods lack both the specificity and sensitivity of modern methods to detect specific rabies virus antigen. Properly performed, the Seller's staining technique may identify Negri bodies in 50 to 80% of rabid animals (33). Observation of virions by electron microscopy provides supportive evidence of a rhabdovirus infection, but this method is less sensitive and too costly for routine diagnosis (18).

ANTIGEN DETECTION

DFA Test

The standard test for rabies virus antigen detection in CNS tissues is the direct fluorescent-antibody (DFA) test. This test is easy to perform and highly specific, approximates 100% sensitivity, and can be completed within 3 to 4 h. A copy of the standard DFA may be obtained online at http://www.cdc.gov/ncidod/dvrd/rabies/Professional/publications/DFA_diagnosis/DFA_protocol-b.htm. The rabies virus diagnostic conjugates consist of antibodies to the whole virion or to the RNP, labeled with fluorescein isothiocyanate. The conjugates may be hyperimmune polyclonal or monoclonal antibodies directed against highly conserved rabies virus epitopes. The rabies virus infects neurons and replicates in the cytoplasm. Within infected cells there are abundant collections of rabies virus proteins (inclusions), especially RNP. When these diagnostic conjugates are added to rabies virus-infected, acetone-fixed brain impressions, the antibodies bind with the rabies virus proteins (antigens) in the cytoplasm of cells and the antigen-antibody complexes fluoresce an intense apple green color. Morphologically, rabies virus antigen may be fluorescent large or small inclusions, dust-like particles, or strands (Fig. 3). The standard protocol for rabies diagnosis includes guidelines for thorough sampling of tissues (complete cross-section of brain stem and cerebellum), optimizing antigen detection with the use of two antirabies conjugates, avoidance of cross contamination, the reduction of nonspecific staining, preservation of fluorescence with 20% glycerol Tris-buffered coverslip mounting medium (pH 9.0), interpretation of results, and repeat or confirmatory testing (35).

DRIT

The direct rapid immunohistochemical test (DRIT) uses a cocktail of purified biotinylated anti-rabies virus nucleocapsid monoclonal antibodies. The test has demonstrated preliminary sensitivity and specificity equal to that of the DFA test in detecting rabies virus antigen. Suggested uses include application to confirmatory DFA testing and enhanced field surveillance in suspect animal cases without human exposure. The advantages of this procedure include rapidity of test

TABLE 1 Routine tests for rabies diagnosis[a]

Analysis	Test method	Detection	Sample	Source	Requirements	Provider	Results
Microscopic examination	Specialized stains, e.g., H&E and Seller's	Eosinophilic intracytoplasmic inclusions	Postmortem CNS	Human or animal	Brain stem, cerebellum, hippocampus	Pathology laboratories (hospital, veterinary)	Detects eosinophilic intracytoplasmic inclusions, low sensitivity (60–80%)
Antigen detection by immunofluorescence	DFA	Rabies virus antigen	Postmortem CNS	Human or animal	Full cross-section of brain stem and cerebellum	State P.H., veterinary laboratories, CDC	Detects rabies virus-specific antigen, very high sensitivity (100%)
	DFA (cryostat)	Rabies virus antigen	Antemortem nuchal biopsy specimen	Human	Full thickness of skin (5–6-μm cryosections)	CDC (some regional or national labs)	Detects rabies virus-specific antigen
	FF DFA	Rabies virus antigen	FF postmortem CNS	Human or animal	Full cross-section of brain stem and cerebellum	CDC (some regional or national labs)	Detects rabies virus-specific antigen, very high sensitivity (~100%)
Antigen detection by IHC	IHC	Rabies virus antigen	FF postmortem CNS	Human or animal	Full cross-section of brain stem and cerebellum	CDC (some regional or national labs)	Detects rabies virus-specific antigen, very high sensitivity (~100%)
	DRIT	Rabies virus antigen	Postmortem CNS	Human or animal	Full cross-section of brain stem and cerebellum	CDC, USDA (some regional or national labs)	Detects rabies virus-specific antigen, very high sensitivity (~100%)
Nucleic acid	RT-PCR	Rabies virus RNA	Postmortem CNS	Human or animal	50 mg of brain stem and cerebellum	CDC (some regional or national labs)	Produces specific RT-PCR amplicons. Very sensitive, detects ~1 infectious unit, but related to primer specificity.
	Nested RT-PCR	Rabies virus RNA	Antemortem saliva, throat, skin, other	Human	100 μl of fluid samples or ≤50 mg of tissue	CDC (some regional or national labs)	Produces specific RT-PCR amplicons. Very high sensitivity, detects less than 1 infectious unit, but related to primer specificity.
Virus isolation	Cell culture (e.g., MNA) and animal inoculation (e.g., MI)	Infectious rabies virus	Postmortem CNS	Human or animal	20% brain homogenate (brain stem and cerebellum)	State P.H., veterinary laboratories, CDC	Detects infectious rabies virus
Serology—virus neutralization	RFFIT, FAVN, MNT	Rabies virus neutralizing antibodies	Antemortem or postmortem serum or CSF	Human or animal	Serum or CSF	CDC (some commercial, regional, or national labs)	Detects neutralizing antibodies. NT are useful in determining immunization status.
Serology—IFA	IFA	Rabies virus IgG or IgM antibodies	Antemortem or postmortem serum or CSF	Human or animal	Serum or CSF	CDC (some regional or national labs)	Detects specific rabies virus IgM and IgG antibodies from serum or CSF. Very sensitive as a diagnostic technique.

[a]Abbreviations: H&E, hematoxylin and eosin; MNA, mouse neuroblastoma; MI, mouse inoculation; MNT, mouse neutralization test; FF, formalin fixed; P.H., Public Health.

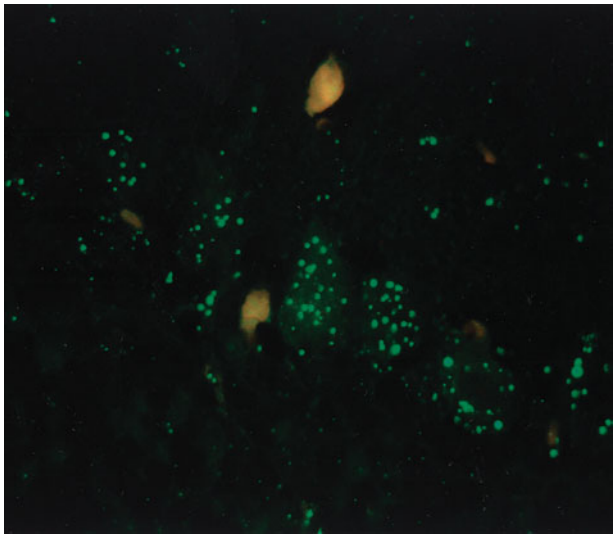

FIGURE 3 Rabies virus antigen detected by FF DFA test. Typical fluorescent (apple green) rabies virus antigen is detected in the cerebellum of a rabid brain by the FF DFA test. Large and small inclusions are seen within the cytoplasm of rabies virus-infected Purkenji cells by using a fluorescence microscope with ×200 magnification.

protocol; fixation of brain touch impression slides in formalin, which inactivates rabies virus; and use of a light microscope to observe test slides (25).

Formalin-Fixed Tissues

Routine formalin-fixed CNS tissue samples cannot be tested by the standard DFA test. The fixation process causes chemical cross-linking of proteins. Formalin-fixed tissue samples which have been processed, embedded in paraffin, and sectioned may be tested by a formalin-fixed DFA (FF DFA). The FF DFA includes modifications of the standard DFA, such as proteinase K digestion to disassociate chemical bonds and to expose rabies virus epitopes (50). An immunohistochemical test (IHC) for rabies virus antigen detection is an alternative protocol (15). All tests for rabies virus antigen require the same thorough tissue sampling (complete cross-section of brain stem and cerebellum) as the standard DFA test.

DFA Test of Nuchal (Neck) Biopsy Specimens

Antemortem DFA tests for rabies virus antigen are performed on serial 5- to 6-μm-thick tissue cryo-sections of neck skin biopsies and provide a rapid method for viral antigen detection in nerves at the base of hair follicles. The sample may be obtained by cosmetically removing a 5- to 6-mm-diameter biopsy specimen from a shaved area just within the hairline. The biopsy sample should contain a minimum of 10 hair follicles and be of sufficient depth (i.e., full skin thickness) to contain the nerves at the end of the follicles. This is an alternate method to brain biopsies for diagnosis of rabies in antemortem samples and is less invasive.

NUCLEIC ACID DETECTION

Reverse transcription (RT)-PCR methods are the most sensitive tests for rabies diagnosis. However, the reliability of RT-PCR depends in part on the sample (type and condition), the particular method of RNA extraction and RT-PCR, the primers selected for amplification, the quality of reagents, individual technical expertise, interpretation of the results, and confirmatory methods. The usefulness of RT-PCR as a routine diagnostic test on postmortem (fresh and fixed) CNS tissues is limited. Highly sensitive, broadly reactive, less expensive, and less time-consuming procedures for antigen detection by DFA are more efficient routine tests for rabies diagnosis. RT-PCR may be a useful tool for molecular typing and in some cases to confirm a positive diagnosis in CNS tissues, but the maximum utility is the detection of nucleic acid in non-CNS samples (e.g., antemortem saliva, skin, cornea impressions, tears, eye swabs, and throat swabs or postmortem vitreous fluid) when fresh CNS tissues are unavailable (31). When all conditions are optimal, RT-PCR can detect RNA in one infectious unit of rabies virus and nested RT-PCR increases the sensitivity (10- to 100-fold) to below one infectious unit of virus (32). RNA may be limited or degraded when examining non-CNS samples, and nested RT-PCR is usually required. The diversity among rabies virus variants and lack of specific nondegenerate universal primers (Table 2) make real-time PCR less useful for detection of rabies virus RNA in non-CNS samples when the rabies virus variant is unknown.

The use of N-gene primers 21g (RT) and 21g/304 (PCR) takes advantage of the conserved sequence at the initial methionine of the N and P proteins to produce an amplicon of 1,459 bp, which includes the entire N gene and hypervariable nontranslated region between N and P (Table 2). From experience, it can be stated that primers at this location usually amplify the variants of rabies virus found in the United States. However, no single rabies virus N primer set amplifies all lyssaviruses equally well. In some cases RNA may be degraded, and amplification of the 1,459-bp amplicon may be unsuccessful. In these cases, primers which amplify shorter regions, 398 bp (1066 deg/304) and 369 bp (1087 deg/304),

TABLE 2 Examples of synthetic oligonucleotides used in sample analysis[a]

Primer ID	Sense	Primer sequence	Gene target	SAD NT position
21g	Forward	5′ ATGTAACACCTCTACAATG	N	55–73
10g	Forward	5′ CTACAATGGATGCCGAC 3′	N	66–82
1066 deg	Forward	5′ GA(AG)AGAAGATTCTTCAG(AG)GA3′	N	1136–1155
1087i deg*	Forward	5′ GAGAA(AG)GAACTTCA(AG)GAiTA3′	N	1157–1176
1087s deg	Forward	5′ GAGAA(AG)GAACTTCA(AG)GA3′	N	1157–1173
504s	Forward	5′ TCATGATGAATGGAGGT 3′	N	1296–1312
304	Reverse	5′ TTGACGAAGATCTTGCTCAT 3′	N	1514–1533

[a] The N gene primers listed are used to amplify RNAs from the rabies viruses found in the United States. Multiple primer sets or degenerate primers are necessary when RT-PCR is used as a diagnostic tool. For example, the published primer 1087i deg* is a degenerate primer which will amplify all of the lyssaviruses with the exception of RNAs of skunk rabies viruses found in California. These RNAs possess two base changes at the 3′ end primer. An alternate primer (e.g., 1087s deg or 1066 deg) is necessary to amplify this region of the rabies virus N gene.

should be used. Degenerate primers are needed to amplify less conserved regions.

Measures to avoid cross contamination include preparation of sterile tips, tubes, and reagents in a clean area which has not been used for rabies testing; careful opening and closing of tubes; centrifugation of microcentrifuge sample tubes before uncapping; the frequent changing of gloves (immediately if contaminated); and use of separate laboratory areas where RNA is extracted and RT reactions occur from cDNA (PCR products). When selecting tissue for RT-PCR, try to cut small internal pieces of tissue, as these are less likely to be contaminated on the surface.

All positive diagnostic tests need to be confirmed by sequence analysis or restriction digest analysis to avoid misinterpretation of non-rabies virus amplicons, and negative diagnostic tests need to be confirmed with additional primer sets if there is a high suspicion of rabies.

ISOLATION OF RABIES VIRUS

Isolation methods are useful in detecting infectious virus in samples and may be applied as an alternate confirmatory test to the standard DFA. The classical methods include in vivo isolation in animals (usually intracerebral inoculation of young mice) and in vitro virus isolation in cell cultures. For most routine diagnostic needs, the inoculation of cell cultures, such as mouse neuroblastoma (obtained from Biowhittaker, Walkersville, Md.) or an alternative similar cell culture line, CCL 131 (ATCC, Rockville, Md.), provides the same sensitivity as animal inoculation, but with quicker results and without the maintenance required for the use of laboratory animals. Ideally, in vivo use should be reserved for purposes of efficacy and safety studies for biologics or virulence and pathogenesis studies. Cell cultures may be useful in the propagation, amplification, and quantification of virus and antibodies, to produce vaccines, determine the safety of vaccine lots, and study the pathogenesis of rabies virus in particular cells (45, 48, 49).

TYPING SYSTEMS

Rabies viruses are separated into terrestrial carnivore and bat variants by use of antigenic and molecular methods. In the United States, there are at least five major reservoirs detectable among wild terrestrial mammals, as identified by antigenic typing (Fig. 2). Genetic typing adds resolution and identifies seven distinct virus lineages among the current terrestrial variants. Antigenic typing is less useful in certain cases involving rabid bats. Nucleotide sequence analysis adds resolution when studying these samples. Typing methods are useful in a variety of circumstances, such as determining the rabies virus variants in human cases with unclear or unknown virus exposure histories; discovering the emergence of new viruses; monitoring the epidemiologic spread or reemergence of virus in defined geographical areas; detecting host switching or spillover of variants from the predominant host species to another species; and monitoring the success of rabies vaccination programs through typing of surveillance samples.

Antigenic Typing

Antigenic typing with monoclonal antibodies (MAbs) can be performed on acetone-fixed direct brain impression slides and rabies virus-infected cell culture slides. The best results are obtained from brain impressions if 75 to 100% of the microscope fields contain viral antigen. If there is insufficient antigen present, it is best to amplify virus by inoculating cell cultures or mice. The antigenic typing test is an indirect fluorescent-antibody (IFA) test. Murine anti-rabies-N MAbs (a panel of seven is commercially available) are used to distinguish rabies virus variants by the different reaction patterns. Antigenic typing is inexpensive, rapid, and easily performed, as a relevant method to determine rabies virus variants. Limitations include the necessity for amplification when antigen amounts are inadequate and a lack of resolution for certain terrestrial and bat rabies virus variants. Additional testing of these samples can be performed at reference laboratories, such as the CDC, which have additional MAbs and resources for sequence analysis (36–38).

Nucleotide Sequence Analysis

The use of genetic typing as a method for molecular epidemiologic studies has increased because more laboratories have the ability to extract RNA, perform RT-PCR tests, and sequence viruses. Methods of sequencing cDNA products have now become routine. Of the rabies virus genes of interest, the N protein gene has been one of the most frequently utilized in molecular epidemiology, and earlier studies usually analyzed short sequences, less than 400 nucleotides (40, 41, 46). Current analyses have included complete N gene sequences (23, 28). At present, there are thousands of N gene sequences (complete and partial) in GenBank. Lyssavirus researchers are now focusing on the G, P, and L genes (3, 22, 29). These data may assist in a better understanding of specific gene functions in viral pathogenesis and replication and virion formation.

SEROLOGIC TESTS

The serologic tests for rabies antibody include neutralization and IFA tests. Each varies in sensitivity, specificity, type of antibody detected, and the viral antigen (protein) recognized (8, 9, 39, 42).

Neutralization Tests

The neutralization test is the standard test for antibodies to the rabies G protein. The rapid fluorescent focus inhibition test (RFFIT), fluorescent-antibody virus neutralization test (FAVN), and mouse neutralization are highly specific tests which measure the ability of rabies virus antibodies in serum or cerebrospinal fluid (CSF) samples to neutralize a known standard challenge virus dose. The RFFIT and FAVN tests are comparable and are most frequently used today to determine the immunization status of vaccinated humans and animals, respectively. The FAVN, a modification of the RFFIT microneutralization test, is performed in microtiter plates instead of chamber slides. The results of RFFIT and FAVN are equivalent when converted to international units per milliliter, and the two tests exhibit the same sensitivity and specificity in determining rabies virus neutralizing antibodies (4, 8, 42).

IFA Test

IFA tests are sensitive methods for detection of specific rabies virus immunoglobulin M (IgM) and IgG antibodies in human serum and CSF for antemortem diagnosis. Unlike the NTs, the IFA detects antibodies to rabies proteins other than G, and predominately to the RNP. Serum or CSF samples are titrated and added to acetone-fixed cell culture slides infected with rabies virus (CVS-11). The endpoint antibody titer is the last dilution demonstrating specific fluorescence. The IFA titers cannot be interpreted as neutralizing antibody levels since the test is not G protein specific.

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

Since the development of the first rabies vaccine, accurate and timely diagnosis of rabies infections in animals has been essential for decisions regarding postexposure prophylaxis of humans. Of all the tests for rabies diagnosis, the DFA test performed on postmortem brain tissues is the standard by which all other rabies diagnostic procedures are evaluated. Misinterpretation of laboratory results may have a fatal outcome or cause unneeded and costly postexposure prophylaxis. Establishment of a standard DFA protocol addresses the common problems related to diagnosis by establishing requirements for sample tissues, sample integrity, evaluation of reagents, control samples, use of at least two rabies conjugates, equipment standards, evaluation of tests by two individuals, reporting results, confirmatory testing, specificity control reagents, and reference laboratory submissions. All rabies laboratory diagnosticians should provide reliable testing, be familiar with methods to avoid problem tests, and be aware of the resources available, such as the assistance of reference laboratories. Specific details for the interpretation and reporting of DFA test results, the availability of alternative tests, and related diagnostic methods are described in the standard protocol.

We thank Pamela Yager for her assistance in the preparation of this chapter and acknowledge the contributions of the CDC, DVRD, Rabies Team members.

Hendra and Nipah Viruses

PIERRE E. ROLLIN, PAUL ROTA, SHERIF ZAKI, AND THOMAS G. KSIAZEK

96

In September 1994, a respiratory disease was responsible for the sickness and death of several thoroughbred horses in Hendra, near Brisbane (Queensland, Australia) (30, 31). Two persons involved in the care and training of the horses developed a severe flu-like sickness within days after exposure. Both were hospitalized and one died. The causal virus, previously undescribed, was initially named equine morbillivirus but was subsequently renamed Hendra virus. In October 1995, a second outbreak near Mackay (Central Queensland, Australia) was retrospectively recognized when a horse owner died of a relapsing encephalitic disease. His probable infection occurred in August 1994 when two horses died after exhibiting severe respiratory distress and neurological symptoms. Since no known link could be traced between the two outbreaks, extensive surveys in domestic and wildlife animals were initiated around the two foci. In April 1996, anti-Hendra antibodies were detected in flying foxes (frugivorous bats, genus *Pteropus*) in Queensland. In September 1996, a virus identical to that found in the infected horses and humans was isolated from the reproductive tract of a gray-headed flying fox (*Pteropus poliocephalus*). Extensive serologic surveillance among flying foxes in Queensland as well as other areas within the geographic range of these bats demonstrated a very high prevalence of antibodies against Hendra virus. In January 1999, a fatal case of Hendra virus infection was reported in a horse near Cairns in northern Queensland. No secondary cases occurred in companion horses or in humans.

In September 1998, a highly contagious respiratory disease in pigs, with a low mortality, emerged in the northern part of Peninsular Malaysia. In the early months of 1999, an outbreak of severe febrile encephalitis in humans with a high mortality rate was recognized and Nipah virus, a previously unrecognized virus, was identified as the causal agent (7). The majority of affected humans had a history of contact with pigs, most of them being pig farmers. The outbreak subsequently spread to various states of the country and Singapore due to the movement of infected pigs. A total of 265 people were infected, of whom 105 died. The associated outbreak among pig abattoir workers in Singapore during March 1999 led to 22 cases, with one death. These workers had been handling pigs that had been imported from the outbreak areas in Malaysia. Antibodies were found in flying foxes in Malaysia (25). Nipah and Hendra viruses share ultrastructural, antigenic, and molecular characteristics.

Bangladesh was the site of successive outbreaks of Nipah encephalitis in 2001, 2003, and 2004 (1, 23, 50). Human encephalitis cases in Siliguri, India, in 2001 were retrospectively diagnosed as Nipah virus infections (4). No studies were conducted to identify potential reservoirs of infection in India; however, *Pteropus* fruit bats were found with Nipah virus antibodies in the outbreak areas of Bangladesh in 2004.

TAXONOMY AND DESCRIPTION OF THE AGENTS

Members of the family *Paramyxoviridae* are nonsegmented, negative-stranded RNA viruses composed of helical nucleocapsids enclosed within an envelope to form roughly spherical, pleomorphic virus particles (28). Within the family *Paramyxoviridae*, there are two subfamilies, the *Paramyxovirinae* and the *Pneumovirinae*. The subfamily *Paramyxovirinae* has been divided into five genera: *Rubulavirus* (prototype, mumps virus), *Respirovirus* (prototype, human parainfluenza virus 1), *Avulavirus* (prototype, Newcastle Disease Virus), *Morbillivirus* (prototype, measles virus), and the fifth genus, *Henipavirus*, which has been added recently, with Hendra virus as the prototype virus and Nipah virus as the second member. The complete sequences of Hendra and Nipah viruses are available from GenBank. The structure of the genome is consistent with those of the other members of the subfamily. The six transcription units encode six structural proteins: nucleocapsid protein (N), phosphoprotein (P), matrix protein (M), fusion protein (F), glycoprotein (G), and large protein (L) or RNA polymerase, in the order 3′-N-P-M-F-G-L-5′ (31). The Nipah virus genome is 18,246 nucleotides in length, whereas that of Hendra virus is 18,234 nucleotides.

EPIDEMIOLOGY AND TRANSMISSION

The geographic distribution of Hendra and Nipah viruses should overlap with the distribution of the bat reservoirs, the flying foxes (genus *Pteropus*). About 60 species of bats are described in that genus, which inhabit an area extending from Madagascar and Mauritius to Australia. Many species are restricted to islands, but others are widespread in Australia and Southeast Asia. At this time, antibodies have been found in only a few species. Hendra antibodies were identified in black flying foxes (*P. alecto*), gray-headed flying foxes (*P. poliocephalus*), little red flying foxes (*P. scapulatus*), and spectacled

flying foxes *(P. conspicillatus)*. Hendra virus has been isolated from gray-headed flying foxes *(P. poliocephalus)* and from one black flying fox *(P. alecto)* (20). Nipah serological evidence has been found in *P. hypomelanus* and *P. vampyrus* in Malaysia (25); *P. lylei* in Cambodia (32); *P. hypomelanus, P. lylei, P. vampyrus*, and *Hipposideros larvatus* in Thailand (43); and *P. giganteus* in Bangladesh. Nipah virus has been isolated from a *P. lylei* urine specimen in Cambodia (37).

Several aspects of the epidemiological features of both viruses are not fully understood. The densities of bat populations and the prevalence of Hendra antibody positives among them can be very high in certain areas, but the frequency of transmission to human or susceptible intermediate animal hosts (horse or other mammals) seems to be rare. The virus has been circulating among bats since at least 1982 (14). Only a few bat isolates of Hendra virus are available despite numerous attempts at isolation. In bats, urine is the most likely route of excretion, and it is the source of infection of susceptible animals such as pigs or horses. Under laboratory conditions, the transmissibility of Hendra virus was very low. There was no transmission from bats to horses, horses to horses, or horses to cats, and only one case of transmission from infected cats to one horse was observed (46). Transmission and maintenance of Nipah virus among pigs, mostly via the respiratory route, were very efficient in Malaysia, as demonstrated by the epidemic spread within farms; farmers were mostly responsible for the transmission between farms by moving infected animals within states in Malaysia and to Singapore. Only a very severe culling strategy was effective in stopping the epidemic (15, 27). No nosocomial cases were described during the large Nipah outbreak in Malaysia. As for the Hendra virus, it was present earlier in Malaysia (retrospective diagnosis on pig disease in 1996). For both viruses, the amplification through a secondary host (horse or pig) was necessary for the infection of humans. Ecological and economical factors are certainly important in this sequential process.

CLINICAL SIGNIFICANCE

Only three persons are known to have been infected by Hendra virus, and two of them died (34, 35, 38). In all three cases, the disease started with a nonspecific flu-like syndrome including fever, myalgia, headache, lethargy, sore throat, nausea, and vomiting. Despite supportive treatment, the first patient developed respiratory and renal failure and died. The second patient recovered without sequela. The third patient recovered fully from this initial stage but a year later developed neurological signs with seizure and loss of consciousness and died 25 days after admission. The pathogenesis of this last patient's illness could be similar to that of a persistent measles virus infection, subacute sclerosing panencephalitis.

During the Malaysian epidemic, Nipah virus was identified as the cause of the encephalitis outbreak among pig farmers in Malaysia (5, 7, 16, 39). The incubation period ranged from 2 days to 1 month, but in most of the cases it lasted between 1 and 2 weeks. Prodromal signs and symptoms are nonspecific, with fever, headache, myalgia, and sore throat followed by drowsiness, confusion, and reduced level of consciousness after a few days (Table 1). Neurological symptoms usually appeared within a week after onset. The most common neurological signs were coma, hyporeflexia or areflexia, segmental myoclonus, gaze palsy, and limb weakness. Notable laboratory findings include thrombocytopenia, elevated alanine aminotransferase and aspartate aminotransferase, and abnormal cerebrospinal fluid (elevated protein and white-cell count). Systolic hypertension, tachycardia, high fever, and severe brain stem involvement were associated with poor outcome. Mortality occurred in 30 to 40% of the patients and was more frequent in patients with rapidly developing severe neurological signs (39). Residual neurological signs were common among the survivors.

Treatment is supportive including mechanical ventilatory support for patients in a deep coma and unable to maintain airways. Ribavirin has been used in humans during the Nipah outbreak in Malaysia with equivocal results: one study suggests that ribavirin was able to reduce the mortality of acute Nipah encephalitis (6); another saw no significant difference in outcome (16). Ribavirin showed no efficacy in in vitro tests and in a guinea pig model of the disease (P. E. Rollin, unpublished data).

There are no vaccines currently available for either Hendra virus or Nipah virus.

In horses, Hendra virus is responsible for a severe pulmonary syndrome with encephalitis in some animals (22, 44, 46).

TABLE 1 Signs and symptoms of patients with confirmed Nipah or Hendra infection

Signs and symptoms	No. of patients (%) exhibiting indicated symptom				
	Nipah virus infection			Hendra virus infection	
	Goh et al., 2000 (n = 94)	Sim et al., 2002 (n = 18)	Chong et al., 2000 (n = 103)	O'Sullivan et al., 1997 (n = 1)	Selvey et al., 1995 (n = 2)
Fever	91 (97%)	17 (94%)	100 (97%)	1	2
Headache	61 (65%)	12 (67%)	90 (88%)	1	2
Dizziness	34 (3%)	8 (44%)	40 (39%)	1	2
Vomiting	25 (27%)	7 (39%)	37 (36%)	1	1
Reduced (or loss of) consciousness	20 (21%)			1	
Sore throat			21 (21%)	1	
Diarrhea		1 (5%)	21 (21%)		
Nonproductive cough	13 (14%)	3 (17%)			
Myalgia	11 (12%)	4 (22%)	48 (47%)		
Neurological signs	10 (11%)	16 (89%)	5 (5%)	1	
Mortality	30 (32%)	11 (61%)	42 (41%)	1	1
Residual neurologic deficits	14 (15%)	6 (33%)	19 (19%)		0

Experimentally infected cats develop an acute febrile disease with respiratory signs similar to those observed in horses (45). A guinea pig model of infection has been described (47). In experimental infections, gray-headed fruit bats *(Pteropus poliocephalus)* seroconverted without clinical disease (46, 47).

Nipah virus is pathogenic for several animals. In pigs, as shown during the Malaysian outbreak and in experimental infections, the virus induces a respiratory and, less commonly, a neurological syndrome. Some animals remain asymptomatic, but in these animals, as in the one showing clinical signs, virus can be found in the respiratory secretions. Nipah virus is easily transmitted to contact animals (29). Respiratory and neurological disease was also produced in cats. Nipah virus can be recovered from urine and oropharyngeal secretions (29). During the Malaysian outbreak, fatal infections were described in dogs and a Nipah serological survey found that several dogs in an area adjacent to infected pig farms had antibody (2). Models of Nipah disease have been described in hamsters (48) and guinea pigs (Rollin, unpublished).

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

Hendra and Nipah viruses are classified as biosafety level 4 (BSL-4) agents in the United States and Australia, as there is a risk of infection of laboratory personnel and appropriate precautions must be taken (3). They are also in the United States classified as Select Agents by both the U.S. Department of Agriculture and the U.S. Department of Health and Human Services and should be handled as such (see chapter 9; http://www.selectagents.gov/forms Overview.htm).

For virus isolation, serum, heparinized plasma, whole blood, or cerebrospinal fluid (CSF) should be collected during the acute, febrile stages of illness and frozen on dry ice or in liquid nitrogen. Nasal or oral swabs and bronchial wash and urine specimens could also be collected and mixed with an equal volume of buffered diluents containing serum proteins to stabilize viral infectivity prior to freezing. In fatal forms, Nipah virus could easily be isolated from different parts of the central nervous system (CNS). Specimens collected for viral isolation are also suitable for testing by reverse transcriptase PCR (RT-PCR) and TaqMan; formalin-fixed tissues and paraffin-embedded blocks are also suitable for immunohistochemical identification of viral antigens and should be conserved and shipped at room temperature. Maintenance of samples at −20°C or below is sufficient to preserve antibody, but lower temperatures are required to preserve infectivity.

Manipulation of these specimens and tissues, including sera obtained from convalescent patients, may pose a serious biohazard and should be minimized. Although no nosocomial transmissions were described in Malaysia, proper barrier nursing procedures should be implemented and personnel caring for the patient and handling diagnostic specimens should wear disposable caps, gowns, shoe covers, surgical gloves, and face masks (N99 or N100 [HEPA] filters). Procedures generating aerosols (e.g., centrifugation) should be minimized and performed only if additional protective equipment, such as a flexible plastic film isolator capable of maintaining negative pressure and HEPA-filtered exhaust, is available. For specialized procedures, the infectivity of samples may be greatly reduced, if not totally inactivated, by the addition of Triton X-100 and heating, and the samples may be safely tested by serologic or antigen capture assays in the field. Heating to 60°C for 1 h renders diagnostic specimens noninfectious and is acceptable for measurement of heat-stable substances such as electrolytes, blood urea nitrogen, and creatinine. When the equipment is available, sterilization by ^{60}Co γ-irradiation is the preferred method. Extraction of RNA from infectious samples by using the guanidinium acid-phenol method should be conducted in a laminar-flow safety cabinet, but the extracted RNA is no longer infectious and can be manipulated at BSL-2.

For all testing of infectious material, samples should be packaged in accordance with current recommendations (International Air Transport Association [IATA]; http://www.iata.org/index.htm) and forwarded, after consultation, to one of the following laboratories, which maintain BSL-4 facilities and a diagnostic capability for these agents:

1. Centers for Disease Control and Prevention, Special Pathogens Branch, Division of Viral and Rickettsial Diseases, Center for Infectious Diseases, Atlanta, GA 30333. Phone: (404) 639-1115. Fax: (404) 639-1118.
2. AAHL Geelong, Chief, Diagnostic Sciences, 5 Portarlington Road, East Geelong, Private Bag 24 Geelong, Victoria 3220, Australia. Phone: +61 (3) 5227 5115. Fax: 61 (3) 5227 5555.

DIRECT DETECTION

Electron Microscopy

Electron microscopy (EM) examination (thin-section and negative-stain preparations) shows extracellular virions appearing as tangled collections of filamentous, helical nucleocapsids surrounded by the viral envelope. Particles were pleomorphic and varied greatly in size, averaging about 500 nm in diameter (range, 180 to 1,900 nm). Negative-stain EM revealed nucleocapsids with the typical herringbone appearance that is characteristic for paramyxoviruses. These measured an average of 21 nm in diameter, with a 5-nm periodicity, and up to 1.67 μm in length. In thin-section preparations, nucleocapsids averaged 18 nm in diameter, and spikes along the viral envelope, when seen, measured 12 nm in length (17) (Fig. 1).

EM examination of CNS specimens, collected from fatal cases of Nipah infection, showed typical *Paramyxoviridae* inclusions consisting of smooth, filamentous nucleocapsids associated with dense amorphous material. These inclusions were seen mostly in neurons and occasionally within endothelial cells. In addition, unusual cytoplasmic inclusions composed of aggregates of smooth curvilinear membranes were found in neurons (49).

Pathology and Immunohistopathology

During the Malaysian Nipah outbreak, tissues were collected in several human fatal cases. Histopathologic findings included a systemic vasculitis with extensive thrombosis and adjacent parenchymal necrosis, particularly in the CNS. Endothelial cell damage, necrosis, and syncytial giant cell formation were observed in affected vessels. Intracytoplasmic eosinophilic inclusions can be seen on hematoxylin and eosin staining in neurons and other cell types (Fig. 2). The widespread presence of Nipah virus antigens was seen by immunohistochemistry (IHC) in endothelial and smooth-muscle cells of blood vessels and in various parenchymal cells, particularly in neurons (Fig. 3). Plaques with various degrees of necrosis were found in both the gray and white matter. In non-CNS organs, multinucleated giant cells with intranuclear inclusions were occasionally noted in lung, spleen, lymph nodes, and kidneys. Infection of endothelial cells and neurons as

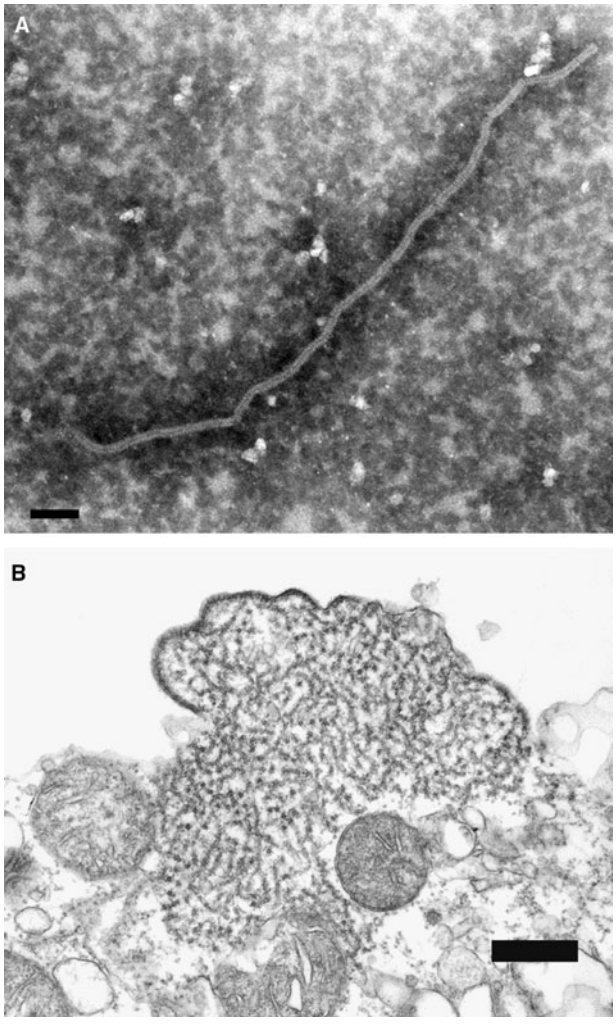

FIGURE 1 Ultrastructural characteristics of Nipah virus isolate in cell culture as seen by negative-stain (A) and thin-section (B) EM (courtesy of C. S. Goldsmith). (A) A single nucleocapsid shows the typical herringbone appearance characteristic of the family *Paramyxoviridae;* (B) Nipah virus nucleocapsids become tightly aligned along the plasma membrane as a particle prepares to bud. Scale bar, 100 nm.

well as vasculitis and thrombosis appears to be critical to the pathogenesis of this disease (24, 49).

The IHC technique is adapted from previously published hantavirus or filovirus detection (51). Briefly, 4-μm sections were predigested by proteinase K (Boehringer-Mannheim Corporation, Indianapolis, Ind.) for 15 min at room temperature and blocked with normal serum. Primary antibodies were applied for 1 h at room temperature. For anti-Hendra and anti-Nipah antibodies, the dilutions of the hyperimmune mouse ascitic fluids were 1:4,000 and 1:2,000, respectively. This step was followed by sequential application of biotinylated link antibody, alkaline phosphatase-conjugated streptavidin, and naphthol fast red according to the manufacturer's protocol (LSAB2 Universal Alkaline Phosphatase Kit; Dako Corporation, Carpinteria, Calif.). Sections were then counterstained in Meyer's hematoxylin (Fisher Scientific, Pittsburgh, Pa.).

Molecular Detection

During outbreaks, RT-PCR assays have been used successfully to detect RNA from Nipah and Hendra viruses from a variety of clinical samples including CSF, throat swabs, and urine samples (4, 7, 21). RNA can be extracted from samples by using the guanidium acid-phenol method or by using a standard commercial RNA extraction kit. RT-PCR is performed using standard conditions, with one-step RT-PCRs being preferred. PCR products are detected by agarose gel electrophoresis. The primers targeting 159- to 320-nucleotide regions of the N and M genes have given the best results with diagnostic specimens thus far (4, 21). Primer sequences can be designed to detect both Hendra and Nipah viruses or to detect each virus separately. For recent outbreak investigations, two primer pairs consisting of NVNF-4 (5′GGAGTTATCAATCTAAGTTAG′3) and NVNBR4 (5′CATAGAGATGAGTGTAAAAGC3′), which amplify a 159-nucleotide region of the N gene, and NVBMFC1 (5′CAATGGAGCCAGACATCAAGAG3′) and NVBMFR2 (5′CGGAGAGTAGGAGTTCTAGAAG3′), which amplify a 320-nucleotide region of the M gene, were used. Sequence analysis of the PCR products should be used to confirm the positive reactions, and sequence analysis allows differentiation between Hendra and Nipah viruses. In addition, phylogenetic analysis of the sequences can be used to study the evolution and transmission pathways of the viruses (4, 21).

Compared to standard RT-PCR techniques, real-time RT-PCR assays have greater sensitivity and higher throughput and are less labor-intensive and faster to perform. In addition, the TAQMAN format provides increased specificity because the identity of the amplified product is confirmed by hybridization to a target-specific, fluorogenic probe. Real-time RT-PCR assays have been developed to detect RNA from Hendra and Nipah viruses (19, 40), targeting sequences in the nucleoprotein and phosphoprotein genes. The lower limit of detection of Nipah RNA ranged from 10 (K. Hummel and P. Rota, unpublished data) to 1,000 copies of RNA (19) with excellent specificity. In addition to their critical role in diagnosis, real-time RT-PCR assays will facilitate research into the pathogenesis of Hendra and Nipah

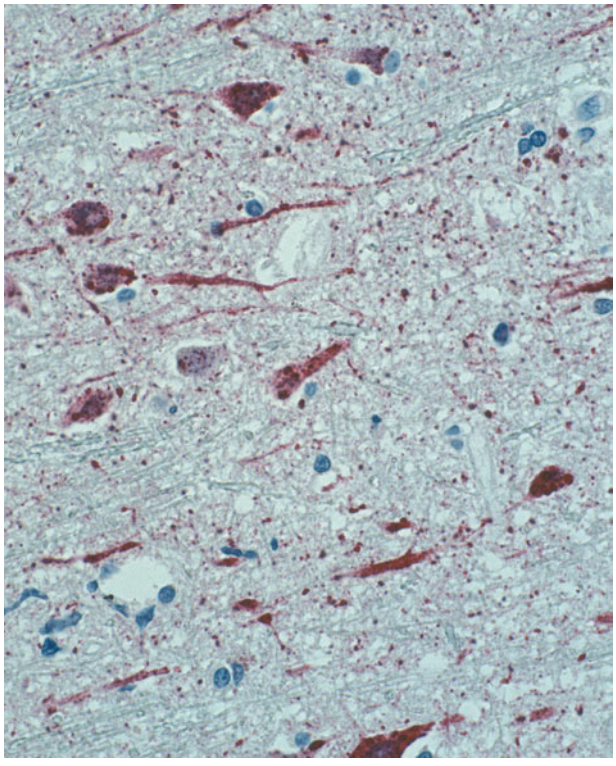

FIGURE 3 Nipah virus encephalitis: viral antigen present among numerous neurons. Note the abundance of extracellular antigen (immunoalkaline phosphatase with naphthol fast red substrate and light hematoxylin counterstain; original magnification, ×158).

viruses. For example, a real-time assay was used to determine viral loads in serum samples from experimentally infected hamsters (18).

ISOLATION PROCEDURES

Hendra and Nipah viruses are classified as BSL-4 agents in the United States and Australia, as there is a risk of infection of laboratory personnel and appropriate precautions must be taken (3). Virus isolation should be attempted only when the required laboratory containment is available.

African green monkey kidney (Vero) cells inoculated with high-titer samples contain antigen within a few days of inoculation. Cytopathic effect (CPE) is usually seen within 3 to 5 days. The CPE is noticeable by the formation of syncytia containing several nuclei. If no CPE is detected by 5 to 7 days, the sample is considered negative, but supernatant fluids should be blind passaged to confirm the absence of virus. CPE observed with Nipah virus is usually observed faster than with Hendra virus. To confirm the presence and identity of the virus, fixed cells are tested by immunofluorescence assay (see below) or supernatant fluids can be tested for evidence of viral replication by RT-PCR techniques (see above). Hendra or Nipah viruses can be reliably distinguished from each other only by neutralization tests. Other cells such as rabbit kidney (RK-13) are susceptible to Hendra and Nipah viruses. Suckling mice were susceptible by intracutaneous or intraperitoneal inoculations and died, but adult mice survived (44).

SEROLOGIC TESTS

Immunofluorescent Antibody Assay

Detection of antibodies by immunofluorescence is possible but is not routinely used by any of the reference laboratories. The preparation of spot slides with infected Vero cells would be identical to the procedure described for other viruses (26) and requires a BSL-4 facility for production.

ELISA

Enzyme-linked immunosorbent assay (ELISA) procedures for Hendra and Nipah virus-specific immunoglobulin G (IgG) and IgM have been developed and successfully used. The viruses are closely related antigenically, so Hendra or Nipah antigens could be used interchangeably in the ELISAs. Antigens are irradiated with 50 kGy prior to use under BSL-2 conditions.

IgM Detection

A Nipah or Hendra-Vero E6 cell slurry antigen was prepared in the BSL-4 laboratory and gamma-irradiated with 5×10^6 rads (50,000 Gy). A mock-infected Vero E6 control antigen was similarly prepared.

Microtiter plates were coated with goat anti-Mu chain antibody (Biosource International, Camarillo, Calif.) in coating buffer at a dilution of 1:500, held overnight at 4°C, and then washed. Fourfold serial dilutions of test sera (1:100 to 1:6,400) or CSF (1:20 to 1:1,280) in diluent and of a sample of negative and positive controls (to validate the cutoff values for the assays) were added, and the plates were incubated and washed. The Hendra or Nipah-Vero E6 cell slurry and mock-infected control were added to the top and bottom halves of the plate, respectively, at a dilution of 1:20. After incubation and washing, Nipah or Hendra hyperimmune mouse ascitic fluid was added at a dilution of 1:2,000 and the plates were again incubated and washed. Horseradish peroxidase-labeled anti-mouse IgG antibody (Biosource International) was added at a dilution of 1:2,000 before once more incubating and washing. The addition of substrate and the final incubation and wash steps were identical to those described above. A specimen is considered positive for the IgM assay if the sum of the adjusted optical densities from all of the dilutions (infected antigen less the mock-infected antigen) is >0.75 through the entire dilution series and the titer is ≥1:400 (≥1:80 for CSF).

IgG Detection

A Hendra or Nipah-Vero E6 cell lysate antigen and a mock-infected Vero E6 control antigen cell lysate were prepared under BSL-4 conditions and then gamma-irradiated as described above. Microtiter plates were again divided into positive and negative halves and coated with the respective antigens, both at a dilution of 1:1,000 as determined by checkerboard titration. Plates were kept overnight at 4°C and washed to remove unbound antigen, and fourfold serial dilutions of test sera (1:100 to 1:6,400) or CSF (1:20 to 1:1,280) were added. A sample of negative and positive controls was used to validate the cutoff values for the assays. After incubation and washing, horseradish peroxidase-labeled mouse gamma-chain-specific anti-human IgG antibody (Accurate Chemical, Grand Island, N.Y.) was added at a dilution of 1:10,000. The addition of substrate, final incubation, and wash steps were performed as described above. A specimen was considered positive in the IgG assay if the sum for the adjusted optical densities from all of the dilutions (infected antigen less the mock-infected antigen) was >0.90 through

the entire dilution series and if the titer was ≥1:400 (≥1:80 for CSF).

Nipah virus antigens have been expressed by recombinant DNA technology. These antigens, which are produced at BSL-2, have the potential to be used to configure serodiagnostic tests. So far, the extracellular domain of the G protein and the N protein virus have been expressed from recombinant baculoviruses and *Escherichia coli* (11, 12, 13, 33, 42) and have produced promising results in initial tests.

Virus Neutralization

Virus neutralization assays are the reference standard for confirmation of results obtained from ELISAs. In addition, because of antigenic differences in the G and F proteins of the viruses, neutralization is the only serologic test that can distinguish between Hendra and Nipah virus infections. The procedure involves handling infectious Nipah or Hendra viruses in a BSL-4 laboratory. Several techniques are available.

In the 50% tissue culture infective dose ($TCID_{50}$) assay, a constant predetermined dose (between 30 and 300 $TCID_{50}$ of Nipah or Hendra viruses) is allowed to react (60 min at 37°C) with varying dilutions of heat-inactivated serum to be tested (and negative and positive controls). This is then mixed with susceptible Vero cells and incubated at 37°C 5% CO_2 for 6 days. The cells are then observed for signs of CPE. The CPE in the wells can be scored by visual inspection after microscopic observation or by staining the monolayer with crystal violet. At 6 days postinfection, 10% NB formalin is added to the well and then crystal violet stain is added, allowed to absorb, and rinsed with distilled water. If the staining is to be done outside a BSL-4 facility, the plates are fixed with formalin, double bagged for removal from BSL-4, and irradiated with 2×10^6 rads before staining.

The virus control (back titration) of the test dose should give confirmation that the input dose of virus was between 30 and 300 $TCID_{50}$.

Neutralization titers of test samples are reported as the highest dilution in which cells are protected from CPE (the last well in which at least one-half of the monolayer was protected and stains purple).

A rapid immune plaque assay is also available. The technique allows the test to be performed in less time (9).

Western Blotting and Immunoprecipitation

In some cases, Western blot assays and immunoprecipitation assays have been used to confirm serologic results from ELISAs. Both Western blotting and immunoprecipitation can confirm the presence of IgG antibodies to individual structural proteins of Nipah or Hendra virus. Western blot assays are conducted by using standard sodium dodecyl sulfate-polyacrylamide gel electrophoresis (10%) and blotting techniques. No infectious Nipah or Hendra virus is required for the assays because baculovirus-expressed Nipah or Hendra virus nucleoprotein or inactivated native proteins are available for use as the test antigen and lysates of uninfected insect cells are used for the control antigen. The nucleoprotein antigens can be detected with a monoclonal antibody in the positive control reactions (P. A. Rota and B. H. Harcourt, unpublished data). To prepare radiolabeled antigen preparation for immunoprecipitation experiments, cells are infected with recombinant vaccinia viruses expressing the G, F, and N of Nipah or Hendra virus. Radiolabeling and immunoprecipitation are performed using standard conditions as previously described (41). Hyperimmune mouse ascites fluid, which recognizes all of the structural proteins of Nipah or Hendra viruses, is used as the positive control. Though this immunoprecipitation assay has been used to detect antibodies to Nipah virus in human serum samples, some samples may contain a high background of reactivity with vaccinia antigens if the patient has received smallpox vaccination.

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

As for any infectious disease, the diagnosis should be based on a combination of clinical, epidemiological, and laboratory data. Several reviews have been published on the laboratory diagnosis of Nipah and Henda virus infections in humans and animals (10, 15). The proper timing and the type of specimens collected are essential. Virus can be isolated from throat or nasal swabs, tracheal secretions, CSF, and urine at the early stage of the disease, and the excretion rate decreases in the late phase when anti-Nipah antibodies are present (8, 16). Isolation attempts could also be attempted from brain tissues collected at autopsy. Ideally any virus isolation attempt should be performed in a BSL-4 facility. In the absence of BSL-4 conditions, primary virus isolation from suspect samples could be conducted under strict BSL-3 conditions. Cell culture and the manipulation of potentially infectious specimens should be stopped with the appearance of a CPE with syncytia. Fixed cells should be stained with proper reagents to confirm the diagnosis; in case of positive results, the specimen should be transferred to an appropriate laboratory.

Molecular diagnostic methods using standard or real-time RT-PCR techniques can be used on oropharyngeal swabs or secretions, CSF, CNS or other tissues, or viral isolates in cell culture. The specimens are inactivated by adding the lysis buffer used for the first step of the RNA extraction (usually containing 4 M guanidinium isothiocyanate), and the remainder of the RNA extraction and PCRs can be performed in any BSL-2 laboratory that is equipped for these techniques. Molecular techniques can be used to confirm Nipah or Hendra virus infection in a patient or to confirm isolation in cell culture. Positive PCRs should always be confirmed by amplification of more than one target sequence and by sequencing the PCR products. This sequence information clearly identifies the virus as being either Hendra or Nipah virus and may allow use of molecular epidemiologic techniques to study viral transmission pathways between and during outbreaks. However, the sensitivity of RT-PCR for identifying cases of Hendra or Nipah will, most likely, be lower than the sensitivity of serologic testing; the timing and the type of specimen obtained and the condition and handling of the specimen will all have an effect on the quantity and quality of detectable RNA in the sample.

The ELISA IgM test has been the most important technique for serological confirmation in acute-phase patients. The rate of IgM positivity in the serum increases from 50% on the first day of illness to nearly 100% 1 week after onset. For Nipah patients, 88% of the first samples tested were positive for IgM (36). Fewer patients have IgM in the CSF at onset, but nearly all are positive by days 10 to 15. Very few patients have IgG detectable by ELISA either in the serum or in the CSF at onset. All of them have IgG in the serum by day 17 or 18. There was no difference in the prevalence of antibody between encephalitic and nonencephalitic Nipah infection for IgM and IgG.

As mentioned before, neutralization tests should be used to determine the specificity (between Nipah and Hendra) of the antibodies detected by ELISA, particularly if no virus, or virus RNA, is available to facilitate molecular typing.

In some patients, the neurological deterioration may occur fast, and the only specimens available for testing are tissues collected at necropsy; or patients may die before the appearance of detectable antibodies. In such cases, the histopathological findings and specific IHC staining are very important for confirming the diagnosis and also help to understand the pathogenesis of the disease.

The findings and conclusions in this report are those of the authors and do not necessarily represent the views of the funding agency.

Arboviruses*

ROBERT S. LANCIOTTI AND THEODORE F. TSAI

97

TAXONOMY

The term "arbovirus," a shortened form of "arthropod-borne virus," is used to describe a taxonomically diverse group of viruses that share the common feature of being biologically transmitted to vertebrate hosts by the bite of arthropod vectors (mosquitoes, sand flies, ticks, midges, etc.). This ecological grouping includes more than 500 viruses belonging to at least seven families, including the *Togaviridae, Flaviviridae, Bunyaviridae, Reoviridae, Rhabdoviridae, Orthomyxoviridae,* and *Asfarviridae* (16, 28). Over 100 of these agents have been associated with naturally acquired disease in humans and/or domestic animals. The *International Catalogue of Arboviruses* (28) also includes a number of other zoonotic viruses (i.e., hantaviruses, arenaviruses, and filoviruses) that are transmitted from animals to humans without the agency of a vector; these agents are not true arboviruses and are not included in this chapter.

DESCRIPTION OF THE AGENTS

All of the arboviruses affecting humans are RNA viruses (Table 1). Complete or partial genome nucleotide sequences have been determined for many of the medically important arboviruses, facilitating the use of nucleic acid detection techniques and the production of synthetic antigens for diagnosis and as candidate vaccines. Important antigenic determinants have been elucidated for the most important arboviruses, and virus- and group-specific monoclonal antibodies are available for taxonomic and diagnostic purposes.

Most arboviruses elaborate hemagglutinins that aggregate goose, chick, and/or human group O erythrocytes. Hemagglutination (HA) occurs optimally within a narrow and specific pH range, a property that may aid in viral identification. In general, serologic cross-relationships are most evident in hemagglutination inhibition (HI) and binding assays, e.g., enzyme-linked immunosorbent assays (ELISAs) and immunofluorescent antibody (IFA) tests, and occur to a lesser extent in complement fixation (CF) tests. These broad antigenic relationships can be refined in virus neutralization tests that differentiate individual viruses and even more specific subtype relationships through ratios of homologous and heterologous neutralization antibody titers. Genomic sequence divergence among strains of a single virus in separate geographic locations differentiates viral topotypes, which apparently result from the isolation and evolutionary divergence of these strains in distinct ecologic niches. Topotypic differences among populations of Japanese encephalitis (JE), tick-borne encephalitis (TBE), yellow fever (YF), dengue (DEN), West Nile (WN), eastern equine encephalitis (EEE), Venezuelan equine encephalitis (VEE), snowshoe hare, and LaCrosse (LAC, a serotype of California encephalitis virus) viruses, among others, have been described. Such genetic changes have been linked to differences in clinical expression of EEE, Sindbis (SIN), VEE, and St. Louis encephalitis (SLE) virus infections.

EPIDEMIOLOGY AND TRANSMISSION

The epidemiologic and clinical characteristics of the medically important arboviruses are summarized in Table 2. More comprehensive descriptions can be found elsewhere (17, 42, 52, 69). Current information on arboviral outbreaks and transmission patterns can be obtained from state health departments, from the World Health Organization (WHO) at http://www.who.org, and from the Centers for Disease Control and Prevention (CDC) at http://www.cdc.gov.

CLINICAL SIGNIFICANCE

The majority of arboviral infections in humans result in simple febrile illnesses that usually cannot be distinguished clinically from other common viral or bacterial infections. Clinical features that characterize acute arboviral fevers usually include a sudden onset of debilitating symptoms, such as malaise, extreme headache, myalgia, lumbar pain, and sometimes nausea, vomiting, and dizziness. In general, these illnesses are of relatively short duration (1 to 6 days) and resolve without sequelae, except for weakness and lethargy, which can persist for a week or more. In a few arboviral illnesses (e.g., Colorado tick fever [CTF] and Oropouche fever), a recrudescent course of fever and systemic symptoms can occur 10 to 14 days after the initial symptoms occur. In cases of Kyasanur Forest disease and Rift Valley fever (RVF), delayed syndromes of encephalitis or retinitis may follow weeks after the initial illness. Some important arboviruses, such as DEN, Ross River (RR), and WN viruses, also may produce a rash, but these

* This chapter contains information presented in chapter 103 by Theodore F. Tsai and Laura J. Chandler in the eighth edition of this Manual.

TABLE 1 Charactertistics of arboviruses

Family	Representative arboviruses affecting humans	Genome (no. of segments)	Vector(s)
Togaviridae	EEE, WEE, and VEE viruses	Positive, single-stranded RNA (1)	Mosquitoes, ticks
Flaviviridae	WN, SLE, DEN, YF, POW, and JE viruses	Positive, single-stranded RNA (1)	Mosquitoes, ticks
Bunyaviridae	LAC, Congo-Crimean hemorrhagic fever, and sandfly fever viruses	Negative- and ambisense single-stranded RNA (3)	Mosquitoes, ticks
Reoviridae	Colorado tick fever virus	Double-stranded RNA (10)	Mosquitoes, ticks
Rhabdoviridae	Vesicular stomatitis virus	Negative, single-stranded RNA (1)	Sand flies
Orthomyxoviridae	Thogoto virus	Negative, single-stranded RNA (6 or 7)	Ticks
Asfarviridae	None	Double-stranded DNA	Ticks

exanthems are not distinctive; in fact, even when outbreaks occur in epidemic proportions, diseases such as dengue fever are sometimes incorrectly diagnosed as rubella or measles. Likewise, diseases like influenza, leptospirosis, and some rickettsial infections are sometimes misdiagnosed as dengue. Several alphaviruses, such as the chikungunya, O'Nyong-Nyong, Mayaro (MAY), RR, SIN, and Barmah Forest viruses, produce an acute febrile illness with polyarthritis and exanthem that must be differentiated clinically from rubella, cytomegalovirus, parvovirus, or mycoplasma infections (63). Arboviruses can also cause congenital infections, especially when introduced into immunologically naïve populations (68).

Neurotrophic arboviruses such as JE, WN, SLE, TBE, Murray Valley, and LAC viruses cause aseptic meningitis, encephalitis, or even flaccid paralysis in only a small percentage of infected persons; most infections are asymptomatic or lead to a mild illness, sometimes with headache. Pathologically, global involvement of cortical, subcortical, and brain stem structures and spinal cord myelitis are typical in more severe forms; consequently, various neurologic presentations are possible, with combinations of coma, weakness, cerebellar and extrapyramidal movement disorders, cranial palsies, and other manifestations of bulbar dysfunction and myelitis.

Viscerotropic disease can occur with YF, DEN, RVF, and certain other arboviral infections, resulting in hepatitis and jaundice. Generalized hemorrhage and multisystem organ failure are sometimes the end results of fulminant YF, RVF, and dengue hemorrhagic fever, mimicking malaria, leptospirosis, and the viral hemorrhagic fevers produced by Lassa virus and other arenaviruses, the Ebola and Marburg filoviruses, and Crimean-Congo hemorrhagic fever virus. Although YF, RVF, and DEN viruses pose a low risk for person-to-person nosocomial transmission (e.g., through needlestick exposures), the other viruses are proven hazards to hospital and laboratory workers (40, 70).

Although more than 100 of the recognized arboviruses can cause illness in humans, the laboratory diagnosis of these infections can be simplified by first considering the patient's history of travel or exposure. Some arboviruses, such as the DEN viruses, are transmitted virtually everywhere in the tropics and subtropics, but others are much more limited in their geographic distribution. By considering the known incubation periods of the principal arboviral infections in the context of the itinerary of places and circumstances under which infection may have been acquired, the differential diagnosis can be narrowed considerably. However, microbiologists and clinicians should be mindful that arboviruses can occasionally appear unexpectedly in new geographic regions, as illustrated by the 1999 introduction of WN virus into North America and cases of chikungunya arthritis imported in 2006 to Europe from an Indian Ocean island outbreak.

Currently, there is no specific therapy available for arboviral infections; supportive care (e.g., fluid replacement, analgesics, control of convulsions, or blood products in the case of severe hemorrhage) is all that is available. The rationale for promptly establishing the laboratory diagnosis of an arboviral infection is to hasten the confirmation of other treatable conditions, to avoid unnecessary treatment, and to assist public health officials in identifying arboviral infections with epidemic potential so that appropriate control measures (e.g., vector control or vaccination) can be implemented.

COLLECTION AND STORAGE OF SPECIMENS

Other than perhaps serologic testing for WN virus infection, few primary diagnostic laboratories can justify routine arboviral diagnosis as a service; instead, most laboratories should focus on the collection of appropriate specimens for submission to a reference laboratory. Assistance with diagnosis of arboviral infections can be obtained from some commercial reference laboratories, selected university research groups, the Division of Vector-Borne Infectious Diseases of the CDC [phone: (970) 221-6400], some state public health laboratories in the United States, and the WHO Collaborating Centers for Arbovirus Reference and Research. A listing of the WHO Collaborating Centers may be found on the WHO website at http://www.bireme.br/whocc.

Most arboviruses produce a brief, low level of viremia in humans, and it is only by chance that a viral isolate can be recovered from blood in these instances. However, other arboviruses, notably DEN and YF viruses, produce higher levels of viremia ($>10^{3.5}$ PFU/ml) of sufficient duration (ca. 5 to 6 days after the onset of fever) that humans serve as hosts for epidemic transmission. From the perspective of the clinical laboratory, these infections can be diagnosed by isolating virus from blood obtained during the acute phase of illness or by detecting genomic sequences by use of nucleic acid amplification techniques (NAAT), such as reverse transcriptase PCR (RT-PCR). Viruses causing encephalitis usually can be recovered from blood only during the preneuroinvasive phase of illness, and then usually by chance. When donors are in the viremic phase of infection, both WN virus and DEN virus can be transmitted via blood transfusion or organ transplantation (8, 27, 45, 61). Retrospective testing of the donors' blood in such instances has confirmed viremia (60). CTF virus is exceptional among human arboviruses in that it infects bone marrow erythrocytic precursors, leading to infection of the erythrocyte for its lifetime; consequently, virus can be recovered from blood obtained for several weeks after clinical recovery and can be transmitted through transfusion (37, 75). TBE virus has also been transmitted by transfusion (37).

TABLE 2 Arboviruses associated with human illness by geographic region, mode of transmission, and clinical syndrome[a]

[a] Key: ○, rare or sporadic; ●, frequent, epidemic. Only arboviruses causing illness after natural infection are listed; viruses causing illness after laboratory exposure only are excluded.
[b] Perinatal illness following third-trimester infection has also been described.
[c] Transmissible by ingestion of infected milk products.
[d] Transmissible through meat of infected animals.
[e] Syndrome reported only after laboratory-acquired infection.

Viral isolates can sometimes be recovered by biopsy or at autopsy from the viscera of patients with acute YF, dengue hemorrhagic fever, or other viscerotropic arboviral infections and from brain tissue or cerebrospinal fluid (CSF) of patients with central nervous system (CNS) infections. Brain samples should be taken from several areas, including the cortex, brain nuclei, cerebellum, and brain stem. Neurotropic arboviruses can occasionally be isolated from CSF obtained by lumbar puncture during the acute stages of encephalitis or aseptic meningitis. RT-PCR has often proved to be more sensitive in detecting specific arboviral genomic sequences in brain tissue or CSF. Alphaviruses have rarely been isolated from vesicular skin lesions, the joint fluids of patients with acute polyarthritis, or the upper respiratory tracts of patients with acute febrile illnesses. Under certain circumstances, arboviruses or their antigens have been detected in urine, milk, semen, and vitreous fluid (5, 66). Clinical laboratories sometimes also receive arthropods for viral isolation. These samples can be referred in the same manner as tissues to a reference laboratory, where they can be processed for virus isolation or nucleic acid or antigen detection procedures.

A plan for dividing available tissues or fluids for viral isolation, electron microscopy, and direct detection assays of antigen and genomic sequences should be devised. Tissues should be collected aseptically and rapidly transported to the laboratory in a viral transport medium or on a moist sponge. If the aliquot for viral isolation cannot be processed within 24 h, it can be maintained at 4°C; otherwise, the sample should be frozen immediately at −70°C or stored on dry ice. Samples for virus isolation and nucleic acid detection should be kept frozen continuously, avoiding freeze-thaw cycles, which may inactivate virus or disrupt nucleic acids. The aliquot for electron microscopy should be minced and placed directly in glutaraldehyde or another fixative. Autolytic changes occur rapidly, and tissues should be fixed as quickly as possible. To prepare sections for immunohistochemical examination, a portion of the sample should be either fixed in 10% buffered formalin or, preferably, added to freezing medium and frozen. Touch preparations are less reliable. Aliquots for antigen detection by other means and for PCR should be frozen at –70°C. Samples should be shipped by express mail in double, sealed containers according to local transport regulations. Frozen samples should be shipped separately on dry ice and labeled appropriately. International shipments usually require import and/or customs permits and clearances.

Serologic studies are best done by comparing antibody titers in paired serum samples drawn during the first week of illness and 2 to 3 weeks later. A single serum specimen may be sufficient for diagnosis of certain arboviral infections for which immunoglobulin M (IgM) assays are available. Detection of virus-specific IgM in CSF is a sensitive and highly specific approach to diagnosing CNS infection, but both CSF and serum samples should be tested. IgM capture ELISAs for arboviral CNS infections transmitted in the United States are offered by several reference and some state public health laboratories. Serum and CSF samples should be collected aseptically, stored either refrigerated or frozen, and transported according to current shipping regulations. Freeze-thaw cycles may reduce antibody titers and should be avoided. Blood or serum blotted and dried on filter paper may be suitable for some serologic assays.

No specific procedures for patient preparation are required. The isolation of certain arboviruses in host systems could be inhibited in patients treated with antiviral agents, such as ribavirin, or immunomodulators, such as alpha or gamma interferon. Some preparations of gamma globulin, including preparations for intravenous use, may contain arboviral antibodies and could interfere with the isolation of arboviruses from patient specimens or with arboviral serologic tests.

DIRECT EXAMINATION

Clinical application and experience with direct arbovirus detection methods generally have been limited, and specimens should be evaluated in parallel with conventional viral isolation, molecular testing, and serologic procedures.

Electron Microscopy

When tissue is available, direct examination by electron microscopy can sometimes provide rapid evidence of an arboviral infection. Experienced observers can identify virions morphologically, often to the level of a viral family, in thin tissue sections. Visualization of togaviruses in brain tissue has helped establish a diagnosis of EEE in some reported cases. Newer techniques using confocal microscopy combined with transmission electron microscopy have been used to diagnose human flavivirus infections (11). Virions may be absent, however, from autopsy tissues of patients who died after a prolonged course of illness and from whom infection had previously been cleared.

Detection of Viral Antigens by Use of IHC or Immunofluorescence

Immunohistochemical (IHC) staining of peripheral blood mononuclear cells or tissue sections has been successful in detecting arboviral antigens in CSF and brain specimens from encephalitis patients; in the viscera of patients with YF, DEN, and other viscerotropic infections; and in joint fluids of patients with acute arthritis (14, 21). CTF virus-infected erythrocytes occasionally can be identified directly by staining a simple smear of peripheral or clotted blood. Postmortem diagnosis of arboviral infections can be made from formalin-fixed sections by using IHC staining. Formalin-fixed tissue or paraffin-embedded tissue block samples can be used. The advantage of IHC is that samples can be examined months after collection and storage. For best results, formalin-fixed specimens should be transferred to 70% ethanol after 48 h for storage. Monoclonal antibodies specific to many medically important arboviruses are available; for more obscure arboviruses, hyperimmune mouse antibodies can be employed. Antibodies and information on their working dilutions can be obtained from the CDC and other reference laboratories. Although trypsinized, formalin-fixed tissues are suitable for IFA examination, frozen sections are generally preferred because trypsinization procedures have not been standardized for all arboviruses and because success varies with the duration of formalin fixation.

Formalin-fixed tissue or paraffin-embedded tissue block samples can also be sent to the CDC or to some academic pathology groups (e.g., University of Texas Medical Branch) for detection of specific arboviruses, such as WN virus. Arrangements can be made with the CDC pathology staff [phone: (409) 639-3133] before shipping any specimen.

Antigen Capture ELISA

Antigen capture ELISAs have been developed for several arboviruses; however, the formation of immune antibody-virus complexes in DEN and YF may interfere with the detection of viral antigens in viremic blood. Although complexes can be chemically dissociated, the assays have not been shown to be clinically useful. The detection threshold

of antigen capture ELISAs for SLE, WN, and JE viruses (ca. $10^{3.5}$ PFU/ml) is sufficiently sensitive for their application in the epidemiologic surveillance of infected arthropod vectors (26, 67). Several commercial antigen assay kits are available for detection of WN, SLE, and EEE viral antigens in mosquitoes (VecTest, Medical Analysis Systems).

Nucleic Acid Detection Techniques

A number of nucleic acid amplification strategies have been developed for the detection and identification of medically important arboviruses, including standard RT-PCR (with agarose gel analysis), real-time RT-PCR using fluorescent probes, and nucleic acid sequence-based amplification (NASBA). A review of the current literature reveals that in nearly all cases, the analytical sensitivity of any of the amplification assays is equal to or exceeds that of the most sensitive viral isolation procedures performed either with cultured cells or with neonatal mice. In addition, amplification assays can provide results in a much shorter time than isolation methods while allowing for the processing of greater numbers of samples. However, the clinical sensitivity of amplification assays is highly dependent upon the dynamics of in vivo viral replication and the tissue tropism of the virus. For example, WN virus infection produces a relatively short viremia which is often low or absent at the time of clinical presentation of CNS symptoms; in one study, WN viral RNA was detected in the CSF of serologically confirmed cases only 57% of the time with a real-time RT-PCR assay with an analytical sensitivity of 0.1 PFU (32, 33). In contrast, the DEN viruses typically achieve a much higher level of viremia with a longer duration, and virus can be detected readily in serum by virus isolation or amplification methods (77). In general, amplification assays have been successful in detecting arboviruses in tissues obtained from fatal human cases when the appropriate tissue target is known and assayed (i.e., brain tissue in WN, LAC, or EEE cases, liver tissue in YF cases, etc.). A commercially available WN viral RNA detection system is approved by the U.S. Food and Drug Administration (FDA) for screening donor blood, organs, cells, and tissues (Procleix WNV assay; Gen-Probe Inc.).

The use of amplification assays for the detection of arboviruses in surveillance protocols, particularly in mosquitoes collected in the field, has become the method of choice since large numbers of samples can be tested with minimum labor and the sensitivity often exceeds that of virus isolation or antigen detection assays. With the addition of automation, amplification approaches have been used to test hundreds of mosquito specimens in a single day (57). Amplification assays have also been utilized successfully in environmental surveillance by detecting arboviruses in tissues obtained from vertebrate hosts collected in the field. WN virus detection in dead birds collected in the field and EEE virus detection in fatal equine cases are typical applications of this technology.

RNA Extraction and Purification

The majority of arboviruses of medical importance are enveloped single-stranded RNA viruses, and therefore the sensitivity and specificity of any amplification strategy are dependent on the efficient extraction and purification of the target RNA template. Highly efficient RNA extraction and purification protocols are now commercially available from a number of sources. Most of these utilize a chaotropic lysis buffer which allows for both efficient solubilization of the sample and stabilization of the RNA, followed by binding to silica, subsequent washing, and then elution in a low-salt solution. Some purification protocols have also been automated, and hundreds of samples can be processed within a single day. The use of a chaotropic lysis buffer has also enabled the efficient extraction of intact RNA from sources that were problematic in the past due to ribonuclease activity, including serum/plasma, whole blood, CSF, tissues, and homogenized ticks or mosquitoes. Ticks and mosquitoes are particularly useful for environmental surveillance of arboviruses.

RT-PCR

Standard RT-PCR-based assays (compared to real-time assays [described below]) to detect arbovirus genomic sequences have been developed for a number of the medically important arboviruses (29). Most of the assays use virus-specific primers designed to amplify a single virus species or, in a few cases, serologically related viruses (i.e., the DEN viruses). The assays typically involve RT-PCR amplification followed by agarose gel electrophoresis, with DNA visualization by staining with ethidium bromide to characterize the amplified DNA by molecular weight. Visualization of a DNA fragment of the predicted size is considered diagnostic in some cases. Because nontarget amplification in some instances can generate DNA products with similar mobilities in agarose gels to that of the predicted fragment, generating false-positive results, additional characterization of the amplified DNA is often utilized. A variety of sequence-specific technologies for detecting and confirming the identity of the amplified DNA include hybridization with virus-specific probes (e.g., Southern blot, dot blot, or microtiter plate hybridization and simultaneous detection of multiple target sequences by capture oligonucleotide macroarrays), PCR amplification with primers internal to the original primers (nested or seminested PCR), restriction endonuclease digestion of the DNA product, or nucleic acid sequence analysis (18). Virus-specific assays are available to detect the DEN, YF, JE, western equine encephalitis (WEE), EEE, SLE, VEE, MVE, Powassan (POW), TBE, and WN viruses; the California serogroup viruses; and the RR, Ockelbo, and CTF viruses, among others. In contrast to virus-specific RT-PCR assays, there are also RT-PCR amplification strategies which utilize primers designed to amplify most or all viruses within a genus. Consensus RT-PCR assays have been described for alphaviruses, flaviviruses, and the California and Bunyamwera serogroup orthobunyaviruses (30, 47, 55). When consensus primers are utilized, a sequence-specific detection method (as described above) must be employed to specifically identify the resulting DNA, since by the design of the assay, all related viruses would generate DNA amplicons of identical size.

Real-Time 5′-Exonuclease Fluorogenic Assays

Real-time fluorogenic RT-PCR assays (commonly referred to as TaqMan assays) combine RT-PCR amplification with concurrent sequence-based detection of amplified DNA, using fluorescently labeled, virus-specific DNA probes. The assays offer many advantages over standard RT-PCR, namely, increased sensitivity, increased specificity, quantification, high throughput, a decreased likelihood of cross-contamination, and rapid results. These advantages are due to the use of the fluorescently labeled internal probe, which rapidly and specifically detects amplified DNA via hybridization. Subsequent *Taq* polymerase digestion of the probe releases the 5′-labeled nucleotide and results in a measurable increase in fluorescence. This sequence-specific detection obviates the need for any postamplification characterization of the amplified DNA, resulting in a much more rapid result. In addition, the likelihood of contamination is reduced because amplified DNA is not manipulated in the laboratory, as occurs with gel

electrophoresis and standard RT-PCR. Real-time fluorogenic assays also offer the added advantage of multiplexing, the ability to detect multiple targets at the same time in the same amplification reaction mix by including additional primers and probes containing unique fluorescent dyes. Several TaqMan assays for the detection of arboviruses have been described, including assays for WN, SLE, TBE, DEN, EEE, WEE, LAC, and chikungunya viruses (31, 33, 36, 44, 74).

NASBA

Another nucleic acid amplification technology that has been used for the detection and identification of arboviruses is NASBA. The initial stage of NASBA is similar to RT-PCR in that single-stranded target RNA is copied into double-stranded DNA via virus-specific primers in an RT reaction. However, NASBA subsequently differs significantly from RT-PCR in a number of ways: the amplification reaction is isothermic (41°C), different enzymes are used (reverse transcriptase, RNase H, and T7 RNA polymerase), and the final amplification product is single-stranded RNA. In NASBA, the oligonucleotide used to prime cDNA synthesis contains the T7 promoter sequence. The resultant reverse-transcribed DNA serves as a template for transcription by T7 RNA polymerase. Amplification is generally more rapid because it is not dependent on thermal cycling. Amplified RNA can be detected by hybridization to a virus-specific oligonucleotide probe either by utilizing an electrochemiluminescence detection format or in real time by using a fluorescently labeled molecular beacon probe. Both detection approaches have been employed successfully to detect a number of arboviruses, including WN, SLE, EEE, WEE, LAC, and DEN viruses (29, 30, 70).

VIRUS ISOLATION

Many of the medically important arboviruses have caused infections in laboratory workers. The pathogenesis of infections acquired from aerosols created by pipetting tissue, homogenization, centrifugation, and other procedures may differ from that of natural infection, with the possibility of direct CNS invasion through the olfactory epithelium (46). On the basis of this experience, the joint CDC-National Institutes of Health guidelines for biosafety in microbiological and biomedical laboratories recommend biosafety level 2 to 4 containment facilities for laboratory work with arboviruses (70). The essential elements of the various biosafety levels for activities with arboviruses and laboratory animals infected with them are detailed in these guidelines (70). Some arboviruses are also designated select agents and require additional levels of security. Laboratory staff should be immunized with available arboviral vaccines. Laboratories that process CNS specimens from patients with encephalitis should consider immunizing staff with rabies vaccine as well.

Most arboviruses can be cultivated in a variety of primary and continuous cell lines, including primary duck and chicken embryo cells, primary monkey and hamster kidney cells, C6/36 *Aedes albopictus* and AP-61 *Aedes pseudoscutellaris* mosquito cell lines, and Vero, LLC-MK_2, BHK-21, CER, SW13, and PK cell lines. The time to develop cytopathic effects (CPE) as well as the pattern of CPE varies in each virus-cell system, e.g., primary duck and BHK-21 cells are rapidly destroyed by most arboviruses, while the development of CPE in monkey kidney cell lines is generally slower. AP61 and C6/36 cells exhibit nearly universal susceptibility to the mosquito-associated arboviruses, including the DEN viruses, which grow poorly in continuous monkey kidney cell lines. The mosquito cell lines, which are generally incubated at 28°C, exhibit little evidence of viral CPE, and replication must be identified by an IFA test or other means. Many alphaviruses and some flavivirus strains produce CPE or form cell syncytia in these lines, but most arboviruses do not. The majority of arboviruses are lethal to suckling (2- to 3-day-old) mice, which exhibit signs of illness, paralysis, and death within days to 2 weeks after intracerebral inoculation. Some field isolates (e.g., DEN and sandfly fever group viruses) exhibit virulence for mice only after adaptation through blind passages. Infected suckling mouse brain is still the preferred antigen for many serologic tests and for the preparation of clean, high-titer immune reagents.

Since no single isolation system detects all arboviruses, tissues, fluids, and serum collected in the acute (febrile) phase of illness should be inoculated into cultures of several cell lines, including C6/36 or AP61 mosquito cells, Vero, LLC-MK_2, or BHK-21 cells, or primary embryonic cells, and into 2- to 4-day-old suckling mice (35, 62, 78). Direct inoculation of live colony-reared mosquitoes can also be used (54). Ideally, serum specimens should be inoculated undiluted and in 10^{-1} and 10^{-2} dilutions to avoid prozone effects due to viral autointerference and antiviral antibodies present in the specimen. Tissues should be homogenized and diluted similarly on a weight-to-volume basis (10 to 20%) with a protein- and antibiotic-containing medium, e.g., phosphate-buffered saline with 0.75% bovine serum albumin and 1% gentamicin. After adsorption to the drained cell monolayer, cell cultures are fed with medium and observed daily or more often for signs of CPE. Small flasks (12.5 or 25 cm^2), tubes, or coverslips in shell vials may be used. Viral growth in C6/36 and AP61 cells does not reliably produce CPE, and these cells must be examined for viral antigen and replication by an IFA test or other means (62). When medium from infected cultures is harvested for passage or storage, fetal calf serum should be added to a final concentration of 20 to 40% before the medium is frozen at –70°C.

Intracerebrally inoculated mice (one litter of 6 to 10 mice for each dilution) should be observed twice daily for up to 2 weeks for signs of illness and death (35). Ill and dead mice should be frozen at –70°C until infected organs can be harvested and passaged in cell culture. When a bunyaviral or orthomyxoviral etiology is suspected, it is prudent to harvest livers in addition to brains since certain orthobunyaviruses and thogotoviruses replicate to higher titers in the mouse liver than in the brain.

Although NAAT have the advantages of speed and sensitivity, virus isolation remains the "gold standard" against which other methods are compared. Virus isolation can detect new or unsuspected agents, as well as those agents for which NAAT have not yet been developed. Furthermore, genetic variants and mutations can lead to falsely negative NAAT results, yet the virus may be detected in culture.

VIRAL IDENTIFICATION

While identification of arboviral isolates previously depended upon their antigenic characterization, PCR and other molecular tests are now available for many of the medically important arboviruses. Provided that sufficient sequence information is available, analysis of the PCR product can provide more specific identification of the isolates than ELISA, IFA, or other rapid serologic assays. PCR-based assays that amplify sequences conserved among medically important alphaviruses, bunyaviruses, or flaviviruses permit the assignment of an unknown virus within a broad taxon, and sequence analysis of the amplified products can give

TABLE 3 Serological assays commercially available in the United States for diagnosis of arbovirus infections

Assay type	Virus(es)	Manufacturer	FDA status[a]
IFA for IgG or IgM	WEE, EEE, LAC, SLE	Focus Diagnostics	IVD
	WEE, EEE, LAC, SLE, WN, POW	PanBio	ASR
	WN	PanBio	ASR
ELISA for IgG and IgM	WN	Focus Diagnostics	IVD
	WN	PanBio	IVD
	DEN 1-4	Focus Diagnostics	RUO
	DEN 1-4	PanBio	ASR
ELISA for IgM	WN	InBios	IVD
ELISA for IgG	WN	InBios	RUO

[a] IVD, for in vitro diagnostics; ASR, analyte-specific reagent; RUO, for research use only. Additional products available for sale outside the United States include IFAs for WN, VEE, JE, YF, and DEN viruses; rapid lateral-flow and strip immunochromatographic tests for DEN virus, and IgM and IgG ELISAs for JE virus.

their precise identification. Such omnibus primers have been reported for alphaviruses and flaviviruses and for certain groups of bunyaviruses and reoviruses (10, 15, 30). Sequence information can also be used for molecular epidemiology, including identification of source strains during outbreaks and investigation of strain relationships that may have epidemiologic or clinical importance (34).

The identity of a suspected arbovirus can often be narrowed down from information on the circumstance, source, location, or other aspects of collection (Table 2). If no particular agent is suspected, polyclonal or monoclonal antibodies against selected prototype virus strains can be used to provide a provisional identification of the agent. Antibody panels prepared against representative serogroups of viruses, such as those prepared against the suspected etiologic agents of a specific clinical syndrome (i.e., encephalitis) or against viruses present in the area where the sample was collected or the patient was infected, are particularly useful. Once the virus is provisionally identified, PCR or specific antibodies can be used to type the virus.

Any of several standard serologic tests (ELISA, IFA, HI, and CF) can be used in this preliminary phase of identification. Complete identification requires partial sequencing or serologic comparison between reactivities of antisera prepared against the new isolate and a prototype strain. The neutralization test is the preferred and accepted method for such antigenic comparisons.

When screening with broadly reactive antibodies fails to place an unknown virus within a group of arboviruses, morphologic examination of the unknown by negative-stain electron microscopy can categorize the virus within a taxon (11). Virions generally can be found in cell culture medium or directly in clinical specimens that have infectivity titers of $\geq 10^6$ PFU/ml. Although most pathology laboratories do not routinely prepare negatively stained grids, examination of thin sections of infected cell cultures can often be arranged.

SEROLOGY

In most laboratories, diagnosis of arboviral infections relies mainly on serology. The classical serologic tests, HI and CF, have been abandoned by many diagnostic laboratories in favor of IgM capture ELISA or IFA. The HI and CF tests are now mainly used in research laboratories. A number of serologic assay kits are now available commercially for specific pathogens (Table 3). In the United States, indirect IFA and ELISA reagents and kits are confined to those for arboviruses most likely to be encountered by U.S. residents. The FDA status varies for each product. In some cases, a kit may be approved for diagnostic use for serum samples but not for CSF (49). Additional products, including rapid lateral-flow and strip immunochromatogenic tests, are available for a number of arboviruses important outside the United States.

ELISA

The antibody capture format for detection of IgM in serum or CSF is more sensitive and specific than indirect methods of IgM detection (2, 7, 71). Virus-specific IgM can be detected in the sera of 90 to 95% of patients with primary DEN virus infections by the sixth day after the onset of illness (71). IgM to WN virus is usually detected in CSF 3 to 5 days into clinical illness, although up to 8 days may be required (22, 49, 65). Serum IgM appears 3 days after CSF IgM. WN virus can be detected earlier in infection by PCR or culture, but once clinical illness develops, PCR is generally less sensitive than antibody-based methods. The presence of virus-specific IgM in CSF reflects intrathecal antibody production and is considered diagnostic of recent CNS infection. In serum, a declining level of virus-specific IgM can usually be detected for several months after infection and for up to a year after infection in some cases. In WN virus infection, specific IgM antibodies have been reported for some patients for up to 2 years or more (53); therefore, a positive IgM result for a single serum sample is considered only presumptive evidence of recent infection. An analogous IgA capture ELISA for RR polyarthritis was shown to be better suited for diagnosis of recent infection because the level of virus-specific IgA declined more rapidly than that of IgM (9). In addition, IgG avidity tests on acute-phase sera have been used to discriminate between primary and secondary infections (38, 41). Low-avidity antibodies are characteristic of recent infections, whereas high-avidity IgG antibodies are seen 6 months or more after the onset of symptoms. Arboviral IgG antibodies are usually detected by an indirect sandwich method.

Heterologous reactions among antibodies to antigenically related viruses are a vexing problem in areas where several related viruses cocirculate. Cross reactions between DEN viruses and JE virus, between YF virus and the numerous flaviviruses that circulate in West Africa, and between SLE, WN, and POW viruses in the United States frequently produce overlapping values that may be uninterpretable. Serologic cross reactions of WN virus with other flaviviruses, and less frequently with bunyaviruses, enteroviruses, and cytomegalovirus, can occur, especially with serum IgG (49). Because of cross-reactivity, a positive IgM assay should be followed by a neutralization test to determine the etiology of illness.

Numerous schemes have been devised to define the threshold of a positive or significant ELISA absorbance value. Some laboratories define a positive reaction in multiples (units) of the absorbance of a weak positive specimen, an approach that controls plate-to-plate variations in specimen reactivity. An alternative approach is to define the threshold absorbance as a multiple (e.g., 5 standard deviations) above the mean absorbance of samples from a population of uninfected persons. A simple multiple of two times the absorbance of a negative control generally produces a conservative interpretation, exceeding 5 standard deviations above the mean value for negative samples.

Indirect IFA

Some laboratories use IFA for differentiation of IgG and IgM responses. Infected cells fixed onto microscope slides with multiple wells are the usual antigen substrate. Kits for detection of antibodies to the most common arboviruses in the United States are commercially available (Table 3). The kits provide multivalent slides with four (EEE, WEE, LAC, and SLE viruses) or six (WN and POW viruses in addition to the other four) infected cell spots and uninfected control cells. WN viral antigen is also available as a single analyte (40). Positive and negative sera are supplied with the kits, and all reagents are ready to use and do not have to be titrated. As with other assays, sera from persons previously infected with WN, DEN, JE, POW, or other flaviviruses may cross react with the SLE antigen in these tests and vice versa; thus, confirmation of the diagnosis should be obtained with a neutralization test.

Anti-human IgG and IgM fluorescein isothiocyanate conjugates are commercially available, but they should be titrated to ascertain their optimal working dilutions. To conserve antigen, serum samples (1:16 dilution) and CSF can be screened and then tested in further twofold dilutions to the endpoint only if positive. Positive IgM reactions should be verified as specific by ruling out the presence of rheumatoid factor (serum IgM antibodies directed against IgG).

IgM antibodies detected by immunofluorescence become detectable within a few days after the onset of illness, and IgG antibodies appear shortly thereafter. IgG antibodies detected by IFA are long-lived, paralleling the longevity of HI and neutralizing antibodies. Fourfold changes are diagnostic of recent infection, and in some circumstances, single or stable elevated titers (>1:128) may indicate recent infection. The sensitivities and specificities of the IFA and HI tests are similar. Thus, cross reactions among related flaviviruses, e.g., among SLE, WN, and DEN viruses, sometimes present a problem in interpretation.

HI Test

For the arboviruses that hemagglutinate erythrocytes, i.e., members of the families *Flaviviridae, Bunyaviridae,* and *Togaviridae* and certain members of the *Rhabdoviridae* and *Orthomyxoviridae,* the HI test is a convenient screening serologic procedure (2, 24). HI antibodies rise rapidly within the first week after the onset of illness and are long-lived, persisting at low levels for decades in some instances. These kinetics are consistent with the mixed IgM and IgG isotype distribution of HI antibodies. Gander erythrocytes are preferred, although chick and trypsinized human O erythrocytes have also been used. Inactivated sucrose-acetone extracts of infected mouse brains provide a high-titer source of antigen; for viruses such as Oropouche (ORO) and group C viruses that do not propagate to high titers in mouse brain, livers, infected-cell-culture antigens, or twice-acetone-extracted sera from infected mice or hamsters can be used. For each virus, HA is optimal within a narrow pH range of less than one-half a pH unit. Before the HI test is performed, a preliminary HA test is done to determine the specific pH optimum and the antigen titer.

Serum samples are conventionally tested at a 1:10 dilution and at further twofold dilutions to the endpoint. A fourfold change between acute- and convalescent-phase samples is diagnostic of recent infection, a titer of >1:80 may be interpreted as presumptive evidence of recent infection, and a titer of >1:2,560 is evidence of a recent secondary antibody response to flaviviral infection.

The HI test is highly sensitive in confirming an infection when adequately timed serum pairs are available, but it is considerably less useful when applied to a single serum sample. Furthermore, HI antibodies tend to be broadly reactive, recognizing common epitopes within antigenic groups or complexes. For this reason, the HI test is useful for screening unknown samples and for demonstrating group relationships among arboviruses. But, as noted before, while a primary infection may lead to a specific antibody response, repeated infections with related viruses produce increasing levels of heterologous antibodies to the related viruses, often rendering the HI test results uninterpretable.

The HI test is useful in epidemiologic surveys because of its broad reactivity and the longevity of HI antibodies and because the procedure is robust. Blood samples collected on filter paper and dried can be stored for short periods without refrigeration, mailed, and tested by HI after reconstitution. Another advantage of the HI test is that the procedure does not require species-specific reagents and can be used for wildlife and animal surveys involving sera from a variety of birds, mammals, and reptiles.

CF Test

The CF test is moderately specific and is often used to narrow the definition of a heterologous HI antibody response (59). The half-lives of CF antibodies vary, but the antibodies may persist for several years. CF antibodies to some flaviviruses (DEN, WN, JE, MAY, and YF viruses) persist for many years. Thus, some laboratories use the HI test to screen samples and the CF test to define the specificities of reactive samples. Some arboviruses, such as CTF virus, certain rhabdoviruses, and the orbiviruses, do not hemagglutinate erythrocytes, so the HI test cannot be used and the CF test is then used for primary diagnosis. Because the test is relatively insensitive, it should be used in combination with some other procedure. A fourfold change is diagnostic of recent infection, and in some circumstances, a single or stable elevated titer of 1:32 may be accepted as presumptive evidence of recent infection.

CF antibodies generally rise slowly after infection, often peaking as late as 6 weeks after the onset of illness. Convalescent-phase serum samples should be obtained 2 to 3 months after onset to ensure against missing a late-rising CF antibody response. Some individuals fail to produce detectable CF antibodies, and advanced age may be associated with a blunted, delayed, or undetectable response.

Neutralization

The neutralization test is the most specific of the common serologic procedures and is used principally to sort out heterologous reactions observed in other assays (2, 25). The presence of virus-neutralizing antibodies is also considered the best indication of protective immunity, and the response to immunization is usually monitored by following neutralizing antibody levels. Neutralizing antibodies generally become detectable within the first or second week after the onset of

illness, peak in the following 2 weeks, and decay slowly, persisting for years and often over a lifetime. Reexposures and infections with related viruses (i.e., sequential DEN virus infections) may stimulate an accelerated secondary response. Although the neutralizing antibody response is relatively specific, repeated infections with related viruses produce a progressively broader heterologous immune response, with the possible extension of cross-protection in some instances. Sometimes, as in the case of repeated flavivirus infections, these extensive heterologous reactions cannot be resolved with cross-neutralization tests.

Infectious virus is used in the neutralization test; consequently, the procedure should be performed only in laboratories capable of working safely at the appropriate biosafety level. Neutralizing antibodies are best quantitated with a plaque reduction assay, in which dilutions of heat-inactivated serum are mixed with a fixed dose of virus and incubated for 1 h at 37°C or overnight at 5°C. The longer incubation time usually gives slightly higher antibody titers (greater sensitivity). Sometimes exogenous complement is also added to the mixture. The highest serum dilution inhibiting 80 to 90% of the infectious virus dose observed in virus control wells is the endpoint. In a typical test using 100 PFU as the viral input dose, the 90% endpoint is the last well showing 10 or fewer plaques. Serum samples are generally diluted 1:5, and with the addition of an equal volume of virus, the initial test dilution is 1:10. A fourfold change in titer is considered diagnostic of recent infection.

The neutralizing capacity of a serum sample can also be measured by testing a single dilution of the serum against a series of virus dilutions. The result is expressed as the serum's log neutralization index. For viruses that do not form readable plaques, neutralization tests can also be done by inoculation of laboratory animals (i.e., newborn or weanling mice) or by a fluorescent focus technique.

Other Procedures

Rapid procedures such as dipstick, dot blot, microsphere immunoassay, and immunochromatographic tests are commercially available outside the United States for several arboviruses (Table 3). These tests have shown good sensitivity and specificity for some arboviruses, including DEN and JE viruses (3, 12, 13, 20, 72, 76), although their diagnostic accuracy may be well below manufacturers' claims (3). The assay format is usually simple and robust enough for use in primary care hospitals or outpatient facilities and in field situations where the capacity for more complex testing, such as ELISA, is not available. Further clinical evaluations are needed, but such kits may bring the capacity for serologic diagnosis within the reach of a wider range of laboratories and medical care facilities in developed and developing countries.

As stated above, heterologous serologic reactions in patients who have had repeated arboviral infections are difficult to sort out, even after all available conventional tests have been exhausted. In an attempt to improve specificity, the narrow reactivity provided by viral monoclonal antibodies has been utilized in the development of serologic tests that combine a serum sample with a virus-specific monoclonal antibody in a competitive ELISA (4, 6). Virus-specific antibodies present in the test sample block binding of the monoclonal conjugate to viral antigen, thus reducing the absorbance. Synthetic antigens, expressed as polyproteins including areas of the envelope glycoprotein or produced by proteolytic cleavage, have allowed some differentiation of flaviviral antibody responses by ELISAs, by IHC staining of expressed antigens on cell surfaces, or by Western blotting (immunoblotting). Although these techniques may be applicable to population surveys, they are still largely research techniques, and their discriminatory power for routine clinical diagnostic purposes requires further confirmation.

Recently, discrimination between primary and secondary infections was performed by using IgG avidity tests on acute-phase serum samples (38, 41). This type of determination is especially helpful for hospitalized patients with dengue fever (41).

EVALUATION AND INTERPRETATION OF TEST RESULTS

Unlike herpesviruses, adenoviruses, and other viruses that produce persistent or latent infections, nearly all human arboviral infections are acute and are terminated by viral clearance. Thus, the isolation of an arbovirus from an ill patient or detection of viral nucleic acid in blood or tissues is virtually diagnostic. However, rare subacute, progressive, and recrudescent infections and experimental models of persistent infection have been reported for TBE, WN, SLE, JE, and ORO viruses (19, 48, 50, 52, 56, 64).

Surprisingly little is known about the effect of human immunodeficiency virus (HIV) infection on the clinical course of arboviral infections or vice versa. In one case of acute dengue fever due to type 1 DEN virus in an HIV-infected adult, the HIV viral load was reduced transiently by the intercurrent infection, and the clinical course of dengue fever was unremarkable (73). In contrast, recent reports of WN virus infections from the United States have documented that immunosuppressive therapy can predispose transplant recipients and patients on chemotherapy to severe neurological disease (23, 51).

Careful consideration and planning must be undertaken in the formulation of a molecular testing algorithm for arboviruses due to the potential for cross-contamination inherent with all amplification assays. In general, a good testing algorithm for an amplification assay would include independent confirmation of all positive results by another virus detection assay, such as an alternate amplification strategy, virus isolation, antigen capture ELISA, or direct IFA. In addition, the inclusion of an internal positive control (see below) is desired to ensure that all reagents and amplification parameters are optimal for target amplification. At a minimum, all positive amplification results should be confirmed by retesting using the same technology (e.g., RT-PCR) with a different primer set. Testing algorithms must also incorporate appropriate controls to ensure against false-positive or false-negative results. Negative controls should include reaction mixes with no RNA added (reagent controls) to ensure that amplification reagents are not contaminated with target RNA or DNA, as well as RNA extracted from negative specimens (extraction controls) to monitor contamination during sample processing. Positive controls included in each assay should contain various levels of target RNA (high, medium, low, etc.) to ensure that the sensitivity of the current assay is similar to those of previous tests. The use of an exogenously added RNA target along with a corresponding amplification primer set allows for the monitoring of every amplification reaction and can detect false-negative results; this strategy is particularly useful for testing specimens that may contain inhibitors of RT-PCR (e.g., blood, mosquito lysates, etc.). In all amplification-based technologies, it is essential that proper laboratory procedures be followed to prevent cross-contamination of clinical samples

with amplified DNA (amplicon) or RNA, which would result in the generation of false-positive results. In general, there should be complete physical separation of pre- and postamplification laboratory space and equipment. Finally, clinical samples should be tested in duplicate wells, at minimum, and ideally two primer sets should be utilized in independent reactions.

Due to the possibility of cross-reactivity, serologic results should always be interpreted in view of the patient's prior residence history, exposure, and immunization record. For example, recent immigrants may have resided in regions where DEN, YF, or JE is endemic and may have antibodies to the agents of these diseases. Vaccines for YF, JE, and TBE are commercially available in the United States and abroad and are widely used in some countries or for high-risk groups (e.g., military personnel). A vaccination history should be sought from the patient because evidence of prior immunization might mitigate against certain diagnoses and because vaccine-induced antibodies can interfere with the interpretation of serologic test results. The influence of immunosuppression on antibody responses to arbovirus infections is not well characterized, but results should be interpreted with caution, and in this instance, nonserologic methods should be employed. It is known, for example, that the antibody responses of HIV-infected children to live YF virus vaccine, essentially an attenuated infection, are poorer than those of healthy control children (58).

Finally, laboratory detection of a recent arboviral infection does not necessarily secure the clinical diagnosis because concurrent infections are possible. Arboviral infections may occur coincidentally with or may predispose patients to more serious secondary infections. In a review of ~2,800 pediatric dengue fever cases in Thailand, concurrent bacteremia and other infections complicated the illness in 14 cases (43). Furthermore, acute dengue fever has also been associated with reactivation of latent human herpesvirus 6 infection (1). Dual infection with an arbovirus and a protozoan or bacterium may also occur because certain vector species participate simultaneously in several transmission cycles. *Ixodes ricinus* ticks in Europe, for example, are vectors for TBE virus, anaplasmosis, and *Borrelia* sp. and *Ixodes scapularis* ticks in the United States can transmit POW virus, *Babesia microti,* and *Borrelia burgdorferi*. Dual human infections have been reported, possibly occurring from a single, dually infected tick or after simultaneous exposure to more than one tick, each infected with a different agent (39).

Hantaviruses

CHARLES F. FULHORST AND MICHAEL D. BOWEN

98

TAXONOMY

Hemorrhagic fever with renal syndrome (HFRS) and hantavirus pulmonary syndrome (HPS, also referred to as hantavirus cardiopulmonary syndrome) are rodent-borne zoonoses caused by certain members of the virus family *Bunyaviridae,* genus *Hantavirus*. This genus presently comprises 22 species (68). Ten of these species have been causally associated with human disease. (The terms "species," "strain," and "hantavirus" have been used synonymously in the literature.)

Specific rodents (i.e., one or two closely related members of the order Rodentia, family Muridae) are the principal hosts of the hantaviral species for which natural host relationships have been well characterized. Hantaviruses are divided into three groups based upon the taxonomic assignment of their principal host(s) into one of three subfamilies within the Muridae: Murinae (Old World rats and mice), Arvicolinae (voles and lemmings), and Sigmodontinae (New World rats and mice). Murine rodents are the principal hosts of hantaviral species that are associated with severe HFRS (Table 1). Voles are the principal hosts of *Puumala virus,* which is the cause of a relatively mild form of HFRS called nephropathia epidemica. Sigmodontine rodents are the principal hosts of the hantaviral species known to cause HPS (Table 1). Many hantaviruses, particularly those associated with rodents of the subfamily Arvicolinae, have not been associated with human disease.

The degree of genetic and antigenic relatedness among hantaviral species typically correlates with the degree of (phylo-) genetic relatedness among their respective rodent hosts. This observation has been attributed to virus-host coevolution or codivergence (66, 67, 81).

DESCRIPTION OF THE AGENT(S)

Hantavirions are pleomorphic, average 100 nm in diameter, and possess a lipid-bilayer envelope (87). The envelope displays a grid-like pattern apparent when negatively stained virions are viewed by electron microscopy (Fig. 1) (64). Protruding from the lipid envelope are spikes, approximately 6 nm in length, which are formed from the virus glycoproteins, G1 and G2 (87). The virion interior contains ribonucleocapsids—segments of single-stranded genomic RNA complexed with nucleocapsid protein and L protein (an RNA-dependent RNA polymerase). The genomes of hantaviruses consist of three unique negative-sense, single-stranded RNA molecules, designated L (large, approximately 6.5 kb long), M (medium, 3.6 to 3.7 kb), and S (small, 1.6 to 2.0 kb) (83). These RNA molecules encode the L protein, the glycoprotein precursor (which is cotranslationally cleaved to yield the envelope glycoproteins, G1 and G2), and the nucleocapsid protein, respectively (2). The ribonucleocapsids display helical symmetry and form circular structures as a result of base-pairing by conserved, inverse complementary sequences at the termini of each genomic RNA (87).

EPIDEMIOLOGY AND TRANSMISSION

Hantaan virus, the prototypical member of the genus *Hantavirus,* is the cause of a severe form of HFRS that is endemic in Korea, China, and eastern Russia. *Dobrava-Belgrade virus* is an agent of severe HFRS in the Balkans and Greece. Saaremaa virus, a variant of *Dobrava-Belgrade virus,* is an agent of HFRS in Europe (100). *Puumala virus* is the agent of nephropathia epidemica, which is endemic in Finland, Norway, France, and other western European countries. *Seoul virus* is a cause of HFRS in the Old World and in the New World (53). The case-fatality rate of HFRS ranges from 0.2% *(Puumala virus)* to 15% *(Hantaan virus)*. Approximately 150,000 HFRS cases occur each year worldwide (18). The majority (100,000) of these cases are caused by *Hantaan virus* or *Seoul virus* and occur in China.

The viral species causally associated with HPS include *Sin Nombre virus, Bayou virus, Black Creek Canal virus, New York virus,* and Choclo virus in North America, and *Andes virus* and *Laguna Negra virus* in South America (Table 1). From May 1993 through February 2006, 496 HPS cases were documented in North America (Canada, the contiguous United States, and Panama; http://www.cdc.gov/ncidod/diseases/hanta/hps/noframes/epislides/episls.htm) and 1,427 HPS cases were reported from South America (Argentina, Bolivia, Brazil, Chile, Paraguay, and Uruguay; http://www.paho.org/common/Display.asp?Lang=E&RecID=1971). Undoubtedly, *Sin Nombre virus* and *Andes virus* are the major causes of HPS in North America and South America, respectively. Although there are far fewer HPS cases than HFRS cases each year, outbreaks of HPS usually are highly lethal, with case-fatality rates of 40 to 60%.

Humans usually become infected with hantaviruses by inhalation of aerosolized droplets of infectious urine, saliva, or respiratory secretions from infected rodents, or by inhalation

TABLE 1 Hantaviral species known to cause human disease[a,b]

Virus species	Natural rodent host(s)	Known geographical distribution	Human disease
Principally associated with Arvicolinae[c]			
Puumala virus	*Clethrionomys glareolus* (red bank vole) and other *Clethrionomys* spp.	Scandinavia, western Europe	HFRS
Principally associated with Murinae[c]			
Dobrava-Belgrade virus	*Apodemus flavicollis* (yellow-necked field mouse)	Balkans	HFRS
Hantaan virus	*Apodemus agrarius* (striped field mouse)	China, Korea, Russia	HFRS
Seoul virus	*Rattus norvegicus* (Norway rat) and *Rattus rattus* (black rat)	Worldwide	HFRS
Principally associated with Sigmodontinae[c]			
Andes virus	*Oligoryzomys longicaudatus* (long-tailed pygmy rice rat)	Argentina, Chile	HPS
Bayou virus	*Oryzomys palustris* (marsh rice rat)	United States	HPS
Black Creek Canal virus	*Sigmodon hispidus* (hispid cotton rat)	United States	HPS
Laguna Negra virus	*Calomys laucha* (vesper mouse)	Bolivia, Paraguay	HPS
New York virus	*Peromyscus leucopus* (white-footed mouse)	United States	HPS
Sin Nombre virus	*Peromyscus maniculatus* (deer mouse)	United States, Canada	HPS

[a] Other hantaviruses that have been associated with human disease include Saaremaa virus in Europe; Monongahela virus in the United States; Choclo virus in Panama; Bermejo, Lechiguanas, and Oran viruses in Argentina; and Araraquara, Castelo dos Sonhos, and Juquitiba viruses in Brazil. Sareemaa virus is a variant (strain) of *Dobrava-Belgrade virus,* Monongahela virus is a strain of *Sin Nombre virus,* and Bermejo, Lechiguanas, and Oran viruses are strains of *Andes virus.* The taxonomic status of Choclo, Araraquara, Castelo dos Sonhos, and Juquitiba viruses within the genus *Hantavirus* has not been determined; however, these four viruses have been associated with HPS. Sigmodontine rodents are the natural hosts of Choclo, Bermejo, Lechiguanas, and Oran viruses. The natural hosts of Araraquara, Castelo dos Sonhos, and Juquitiba viruses are not known.

of aerosolized particles of feces, dust, or other organic matter contaminated with infectious virus. The aerosol transmission of hantaviruses from rodents to humans has been well documented (46, 97). Other means of infection include contamination of cutaneous injuries with infectious virus, contact of infectious materials with mucous membranes, ingestion of food contaminated with infectious rodent secretions or excretions, laboratory-acquired infections (9, 46, 52, 57, 102), and—only in the case of *Andes virus*—contact with an HPS case during the acute phase of illness (75). Note that person-to-person hantavirus transmission has never been documented in Europe, Asia, or North America.

In nature, the risk of infection in humans depends upon occupational or recreational activities, ecological factors which affect the abundance of infectious rodents, and other variables that affect the frequency and intensity of human exposure to infected rodents and their excreta. The cleaning of closed quarters occupied by infected rodents has been repeatedly associated with an increased risk of infection (3, 20, 65, 98).

CLINICAL CHARACTERISTICS OF THE HANTAVIRAL DISEASES OF HUMANS

The clinical features of HFRS, including nephropathia epidemica, and the clinical features of HPS were reviewed recently (24, 56). Both syndromes are associated with acute thrombocytopenia and a reversible increase in vascular (capillary) permeability. A major difference between the two syndromes is that the retroperitoneum is the major site of the vascular leak in HFRS, whereas the lungs are the major site of the vascular leak in HPS.

The length of the incubation period in HFRS and in HPS usually is 2 to 4 weeks but can range from a few days to 2 months. The clinical course of HFRS can be divided into five phases: prodrome, hypotensive, oliguric, diuretic, and convalescent. Similarly, the clinical course of HPS can be divided into four phases: prodrome, pulmonary edema and shock, diuretic, and convalescent. Death in HFRS usually is due to shock in the hypotensive or diuretic phase. Death in HPS usually is attributed to hypoxia or shock in the cardiopulmonary phase.

Nephropathia epidemica and the other forms of HFRS usually include renal and hemostatic disturbances. In severe HFRS caused by *Hantaan virus* or *Dobrava-Belgrade virus,* the prodrome usually lasts 3 to 7 days; begins with an abrupt onset of high fever, chills, headache, blurred vision, malaise,

and anorexia; and then includes severe abdominal or lumbar pain, gastrointestinal symptoms, facial flushing, petechiae, and an erythematous rash or conjunctival hemorrhage. The hypotensive phase lasts from several hours to 3 days, begins with a characteristic drop in platelet number, and is followed by defervescence and abrupt onset of hypotension, which may progress to shock and more apparent hemorrhagic manifestations. In the oliguric phase, which usually lasts 3 to 7 days, blood pressure returns to normal or becomes high, urinary output falls dramatically, concentrations of serum creatinine and blood urea nitrogen increase, and severe hemorrhage may occur. Spontaneous diuresis heralds the onset of recovery, with polyuria greater than 3 liters per day. Distinct clinical phases are less obvious in nephropathia epidemica and in HFRS caused by *Seoul virus,* and visible superficial hemorrhages usually do not occur in nephropathia epidemica (53). Pathological findings in HFRS at autopsy include enlarged, congested, hemorrhagic kidneys; retroperitoneal edema; and effusions in body cavities (59).

HPS was first recognized in 1993 as a highly fatal disease in the southwestern United States (69). The original description of HPS (21) subsequently was modified to include mild infections that do not result in radiographic evidence of pulmonary disease (47). It now is recognized that HPS sometimes may include renal impairment and, at least in South America, bleeding manifestations (8, 85). The prodrome in HPS typically lasts 3 to 5 days (range, 1 to 12 days) and is characterized by fever, myalgia, and malaise. Symptoms that may occur during the prodrome include headache, dizziness, anorexia, abdominal pain, nausea, vomiting, and diarrhea. Nonproductive cough and tachypnea usually mark the onset of pulmonary edema. Fully developed HPS is characterized by rapidly progressive (time span, 4 to 24 h) noncardiogenic pulmonary edema, hypoxemia, large volumes of pleural effusion, and cardiogenic shock. Hypotension and oliguria are the result of shock; myocardial depression may occur and contribute to shock. The diuretic phase is characterized by a rapid clearance of pulmonary edema and resolution of fever and shock. Hematologic abnormalities in HPS at hospitalization include thrombocytopenia, hemoconcentration, and the presence of large, reactive (immunoblastic) lymphocytes (48, 72). Other clinical laboratory abnormalities may include elevated levels of hepatic enzymes, hypoalbuminemia, metabolic acidosis, and, in severe cases, lactic acidosis. The gross features of HPS at autopsy have been reported previously (107) and include heavy, edematous lungs and large volumes of pleural fluid.

THERAPY

Successful management of HFRS and HPS begins with prompt recognition of the disease and hospitalization of the patient. Shock in HFRS usually can be effectively managed by judicious administration of vasopressors and intravenous fluids. Intravenous ribavirin given within the first few days of the onset of clinical disease has been shown to significantly decrease morbidity and mortality in HFRS (38). The oxygen status of an HPS patient should be closely monitored so that oxygen supplementation and mechanical ventilation can be provided if required. Because life-threatening pulmonary disease and cardiogenic shock can develop rapidly in HPS, transfer to a state-of the-art critical care facility with the capacity for extracorporeal membrane oxygenation should be an early consideration. The effect of ribavirin on the course and outcome of HPS has not yet been rigorously investigated (see "Antivirals" below).

VACCINES

Inactivated vaccines have been developed in Asia for the protection of humans against HFRS. These vaccines were prepared from the brains of suckling rats or mice or from cell cultures infected with *Hantaan virus* or *Seoul virus* (14, 58, 96, 105). Hantavax (GreenCross Vaccine Corp., Seoul, Korea) and other inactivated vaccines that have been tested in humans yielded only low levels of neutralizing antibodies at 1 year after the last vaccine dose, raising concern about the duration of protection afforded by these vaccines (12, 13, 78, 95). Optimization of vaccination schedules and advances in adjuvant technology may increase the duration of immunity elicited by inactivated vaccines. Strategies for the development of new hantavirus vaccines include recombinant viruses, alphavirus replicons, and naked DNA (35, 50).

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

Hantavirus-specific RNA has been detected in and infectious hantavirus has been isolated from blood, urine, and cerebrospinal fluid samples collected just after onset of clinical disease (9). Thus, blood, serum, urine, respiratory secretions, and other biological materials from HFRS and HPS patients, especially specimens collected during the acute phase of illness, should be considered potentially infectious to humans. Laboratorians should note that laboratory-acquired infections with cell culture-adapted *Hantaan virus* have occurred in individuals who have performed centrifugation of concentrated virus (84) and that dried, cell culture-grown virus maintained at room temperature has been infectious for up to 2 days (9). The U.S. Department of Health and Human Services has recommended the following precautions for the handling of biological specimens from HFRS or HPS patients: (i) potentially infectious specimens should be handled at biosafety level 2 (BSL-2) using BSL-3 practices, (ii) all procedures that could result in splatter or aerosolization of infectious materials should be done inside a certified biological safety cabinet, and (iii) isolation of infectious hantavirus from biological specimens should be carried out in a BSL-3 facility using BSL-3 practices and procedures (84). Additionally, large-scale growth and the preparation of concentrates of hantaviruses that are pathogenic for humans should be done in BSL-4 containment facilities (84). Hantaviruses are thermolabile (86) and can be inactivated by acids, alcohols, paraformaldehyde, detergents, disinfectants that disrupt lipid membranes, and UV irradiation (9, 49, 100).

Blood, serum, or plasma samples for serology may be stored at 4°C and shipped to the diagnostic laboratory on cold-packs if there is no significant delay between collection and testing. Otherwise, these specimens should be stored at −20°C or colder and shipped on dry ice. Blood, blood clots, solid tissues, and other samples intended for RNA extraction and subsequent testing by reverse transcription-PCR (RT-PCR) or virus isolation should be stored continuously at −70°C or colder and shipped on dry ice in order to preserve the integrity of the viral RNA and infectivity of the virus. Samples should be subjected to a minimum number of freeze-thaws. Samples shipped by air should be packaged, documented, and shipped in accordance with International Air Transport Association Dangerous Goods Regulations (http://www.iata.org). In the United States, ground shipments must comply with regulations issued by the U.S. Department of Transportation (49 CFR parts 171 to 178).

DIRECT DETECTION

Laboratory assays that have been used for diagnosis of hantaviral infections in humans have not been standardized, and to date, no hantavirus diagnostic assays have received approval from the U.S. Food and Drug Administration (32). Diagnostic test kits that are commercially produced in Europe are sold "for research use only" in the United States.

Microscopy

Direct electron microscopic examination of tissues is of limited diagnostic value but has been used to detect virions and viral replicative structures in postmortem samples. Electron microscopic examination of autopsy tissues from HFRS and HPS patients found that mature virions are infrequent in tissues and can be difficult to identify due to considerable polymorphism in size and shape (41, 72, 107). Structures determined to be hantaviral inclusion bodies were seen more often than intact virions (41, 107).

Antigen

Immunohistochemistry has been used to detect hantaviral antigens in formalin-fixed tissues from patients with fatal HPS (Fig. 2) (107, 108). Polyclonal antibodies (e.g., immune sera from humans, experimentally infected rabbits or rodents, or naturally infected rodents) and murine monoclonal antibodies have been used as primary antibodies in immunohistochemistry assays. Fatal HPS is associated with the widespread distribution of hantaviral antigen in lung, liver, spleen, kidney, and heart tissues, with antigen primarily localized within endothelial cells of capillaries and other small blood vessels (107). Immunohistochemistry assays for diagnosis of hantaviral infections in humans are limited to the few institutions that have access to the appropriate primary antibodies and control (comparison) tissues.

Nucleic Acid

Since the 1993 outbreak of HPS in the southwestern United States (69), RT-PCR assays have been employed extensively to detect hantaviral RNA in clinical samples from HPS and HFRS patients. Sets of oligonucleotide primers have been designed that anneal to regions of the S and M genomic segments that are highly conserved among the hantaviruses (43, 69, 77, 103). RNA can be isolated from tissues, blood, and serum and protected from ribonuclease degradation by using methods employing chaotropic salts such as guanidinium isothiocyanate (15). RT of hantaviral RNA and subsequent PCR amplification of the resulting cDNA usually can be accomplished by using a "single-tube" format in which a single set of oligonucleotide primers is used for both enzymatic reactions. Clinical specimens rarely yield an RT-PCR product that can be visualized by UV translumination of ethidium bromide-stained agarose gels; consequently, a second "nested" PCR amplification must be performed to obtain amplicons that can be detected on gels and purified for sequencing (69). The lower limit of detection for nested RT-PCR assays for hantaviruses has been reported to be less than one viral fluorescent focus unit, or approximately 316 median cell culture infectious doses of virus per 1.0 ml (26, 37). RT-PCR assays can be used to detect hantavirus RNA in fixed, paraffin-embedded tissues (89). Real-time RT-PCR assays have been developed for some hantaviruses and are in the process of being adopted for routine diagnosis (1, 26, 101). These assays match or exceed the sensitivity of nested RT-PCR assays, with less manipulation of reaction components and shorter times to detection, and can provide precise estimates of viral load in clinical samples (1, 26, 101).

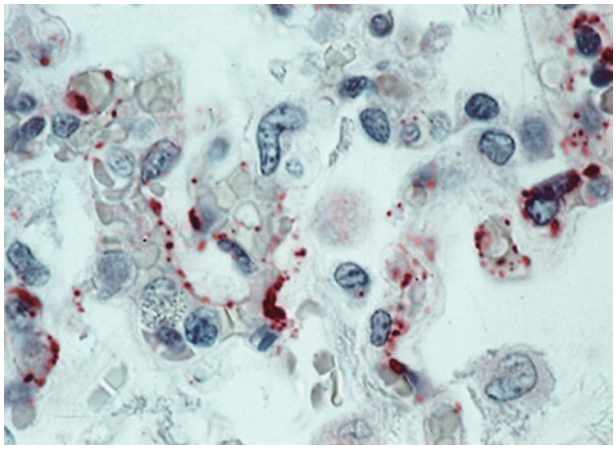

FIGURE 2 Photomicrograph of lung tissue showing hantaviral antigens in pulmonary microvasculature by using immunohistochemistry. Viral antigens are stained in red. Courtesy of Sherif Zaki, Centers for Disease Control and Prevention.

ASSAY FOR INFECTIOUS HANTAVIRUS

Compared with established RT-PCR assays for hantavirus-specific RNA, the isolation of infectious hantaviruses from blood, serum, urine, or tissues using cultured cells or live laboratory animals is substantively less sensitive and requires considerably more time. In addition, hantaviruses usually are extremely difficult to isolate from clinical materials. Thus, virus isolation is not commonly used for the diagnosis of hantaviral infections in humans.

The Vero E6 cell line (ATCC CRL-1586) has been used to isolate infectious hantaviruses from blood, solid tissue, and/or urine samples from HFRS patients and *Andes virus* from blood samples from an HPS patient. Typically, monolayer cultures of Vero E6 cells are inoculated with a crude or clarified tissue homogenate and then maintained under a fluid overlay for 10 to 14 days. Successful virus isolation may require repeated blind passages of inoculated cell culture material. Hantaviruses usually are neither cytopathic in cultured cells nor pathogenic in laboratory rodents. Consequently, detection of infection in cultured cells and in tissues of laboratory rodents often requires an indirect method, e.g., a fluorescent-antibody test for viral antigen or RT-PCR assay for hantavirus-specific RNA.

IDENTIFICATION

Historically, serological methods were used to define taxonomical relationships among the hantaviruses. Neutralization of infectivity in vitro, immunofluorescent-antibody assays (IFAs), enzyme-linked immunosorbent assays (ELISAs), and a host of other serological methods have been used to characterize hantaviruses isolated from rodents or clinical samples. The antibodies that have been used in these assays have included sera from HFRS or HPS patients (16, 54), sera from experimentally infected animals, sera from naturally infected rodents, and immune mouse ascitic fluids. Overall, serological cross-reactivity within the genus *Hantavirus* is greatest between hantaviral species principally associated with phylogenetically

closely related rodent species and usually is higher in antigen-binding assays such as IFA and ELISA than in neutralization assays. Neutralization of infectivity has been measured by plaque reduction in monolayer cultures of Vero E6 cells maintained under an overlay containing agarose and by focus reduction in monolayer cultures of Vero E6 cells maintained under an overlay containing agarose (99) or methylcellulose (4). The focus reduction neutralization test is used more widely than the plaque reduction neutralization test because some hantaviral strains do not consistently produce readily discernible plaques in monolayer cultures of cells stained with neutral red (70). Foci of infected cells (viral antigen) in the focus reduction neutralization test can be revealed by immunochemical staining (27, 91) or by chemiluminescence (30).

The use of genetic sequence data to define taxonomic relationships within the genus *Hantavirus* has become increasingly important, in part because some hantaviral species have never been adapted to growth in cultured cells and because our knowledge of the serological relationships among some of the hantaviral species is based on one strain per species. Since an RT-PCR or nested PCR product can be amplified directly from RNA isolated from clinical materials and then sequenced, analysis of sequence data (particularly from the G2 region of the glycoprotein precursor gene or the nucleocapsid protein gene) may provide the most rapid and specific means for determination of the identity of a hantavirus. Sequence data can also be used for subtyping of viruses (see next section).

TYPING SYSTEMS

Analysis of hantaviral sequence data provides the fastest and most discriminating method for hantavirus typing. An advantage of sequence data is that it is not affected by variation between different sources or lots of antibodies and antigens used in serological typing of hantaviruses (79). Additionally, sequence analysis may enable the detection of hantaviral strains that have arisen by genetic reassortment of genomic RNA segments or homologous recombination, two processes for which there is evidence in hantavirus evolution (31, 55, 92, 93). One of the criteria used to differentiate hantaviral species is at least a 7% difference in amino acid sequence identity in comparisons of complete glycoprotein precursor sequences and in comparisons of complete nucleocapsid protein sequences (68); however, there are some exceptions to this criterion (79). Analysis of sequence data also permits subtyping of hantaviruses, which often can identify geographic variants and variants associated with particular rodent-host subspecies or populations (7, 62, 80–82, 92, 101). Phylogenetic analysis of sequence data permits reconstruction of virus evolutionary trees, which have been invaluable in the establishment of virus-host relationships, virus evolutionary processes, and molecular epidemiology (34, 69, 99, 104). Microarray techniques show potential for genetic characterization of hantavirus RT-PCR products without sequencing (73).

SEROLOGY

Virtually all HFRS and HPS patients have high levels of hantavirus-specific immunoglobulin M (IgM) in serum or plasma at or soon after the onset of clinical disease (19, 42, 51, 71, 74). Measurable levels of hantavirus-specific IgM may persist as long as 6 months after the end of the acute phase of illness in nephropathia epidemica (23) and longer than 2 months after the end of the acute phase of illness in HPS (6).

Many HFRS and HPS patients have measurable levels of hantavirus-specific IgG during the acute phase of their illnesses (6, 22, 23, 42, 76). Levels of hantavirus-specific IgG increase through the end of the acute phase of illness, remain high for months to years, and then decline gradually (60). Hantavirus-specific IgG may persist as long as 10 years in HFRS cases (60) and longer than 3 years in HPS cases (106).

Neutralizing antibodies may appear during the acute phase of HFRS or HPS. A strong neutralizing antibody response early in the course of infection has been positively associated with successful recovery from HPS caused by *Sin Nombre virus* (4). High titers of neutralizing antibodies have been found in nephropathia epidemica cases 10 to 20 years after infection (36) and in HPS patients more than 3 years after infection (106).

The IgM response and IgG response in HFRS and in HPS are directed against the N protein and glycoproteins (25, 29, 33, 42, 60). The early IgM response and early IgG response are primarily directed against the N protein. The neutralizing response is directed against the glycoproteins, G1 and G2.

Antibodies (IgM and IgG) from patients infected with one hantavirus may cross-react with the nucleocapsid proteins and glycoproteins of other hantaviruses (22, 25, 40, 94). IgM and IgG in acute-phase samples can be highly reactive against the N proteins of heterologous hantaviruses (22). In contrast, IgG against G1 is more specific than IgG against the N protein (17, 42). Neutralizing antibody, even in acute- or early-convalescent-phase sera, can efficiently neutralize strains of several different hantaviral species and thus may not yield a species-specific diagnosis (61).

A variety of methods have been used for the detection of antibodies against hantaviruses in serum or plasma. These methods include high-density particle agglutination, indirect IFA, immunoprecipitation, radioimmunoassay, hemagglutination inhibition, plaque and focus reduction neutralization, Western (immuno-) blotting, μ capture (IgM capture) ELISA, and IgG ELISA. The most widely accessible serological methods for the diagnosis of hantaviral disease in humans are μ capture ELISA and IgG ELISA, which are done by many national, regional, and state public health laboratories and by some commercial reference laboratories.

The antigens used for serological assays for hantavirus-specific antibodies traditionally were prepared from cultures of virus-infected cells, concentrated virus, or tissues of naturally or experimentally infected rodents. Antigens must be rendered noninfectious prior to use, and this is usually accomplished by gamma irradiation (Co^{60} source). Heat treatment is an alternative method for making hantavirus antigens noninfectious prior to use in serological assays (86).

Recombinant nucleocapsid proteins or glycoproteins expressed in bacteria, yeasts, insect cells, or mammalian cells, as well as synthetic peptides, have been used as antigens in IFAs and ELISAs for the detection of antihantavirus antibodies (25, 28, 44, 45, 63, 88). The recombinant protein and synthetic peptide antigens can be more specific than native viral proteins in distinguishing between possible etiological agents of HFRS or HPS.

ANTIVIRALS

Presently, there are no antiviral compounds approved by the U.S. Food and Drug Administration for the prevention or treatment of HFRS or HPS. However, ribavirin (1-β-D-ribofuranosyl-1,2,4-triazole-3-carboxamide) has been shown to have activity against *Hantaan virus* (39, 90). In a double-blind, placebo-controlled study done in the People's

Republic of China, intravenous ribavirin therapy significantly reduced the morbidity and lethality of HFRS (38). In contrast, an open-label study done in the United States failed to demonstrate an appreciable effect of intravenous ribavirin therapy on the lethality of HPS (11).

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

Early diagnosis is critical to the successful management of HFRS and HPS and, at least in the case of HPS caused by *Andes virus,* implementation of appropriate isolation procedures to prevent virus transmission to health care providers and other humans. Diagnosis early in the course of disease is difficult because the hantaviral prodrome is similar to the prodrome of many other diseases. Fever and severe myalgia are prominent during the prodrome phase. These symptoms, especially in patients who develop thrombocytopenia, should lead health care providers in regions of endemicity to suspect hantaviral disease.

The laboratory criteria for diagnosis of HPS established by the Centers for Disease Control and Prevention (http://www.cdc.gov/ncidod/diseases/hanta/hps/noframes/phys/technicalinfoindex.htm) are as follows:

- Presence of hantavirus-specific IgM in persons who meet the case definition for HPS (see reference 10) or a fourfold or greater increase in titers of hantavirus-specific IgG in paired acute- and convalescent-phase serum samples
- Positive RT-PCR assay for hantavirus-specific RNA
- Positive assay for hantaviral antigens in lung, spleen, kidney, or other tissues

These criteria could be used for laboratory diagnosis of HFRS as well. Note that the extreme sensitivity of RT-PCR assays, especially those employing nested PCR or real-time PCR, predisposes these tests to generating false-positive results as a consequence of template contamination. Nucleic acid detection results should be run with the proper negative controls and confirmed by the results of tests for hantavirus-specific antibodies or antigen in clinical or autopsy specimens. Also note that proper controls for μ capture and IgG ELISAs (e.g., sera from laboratory-confirmed HPS cases) and immunohistochemical assays are essential for correct interpretation of the results of these assays. Most local laboratories do not have direct access to these materials. Thus, diagnostic testing is often limited to federal laboratories and to research institutions that have a specific interest in HFRS or HPS.

As noted previously (32), testing procedures for detection of hantaviral infections in humans have not been standardized. Thus, confidence in the results reported from individual laboratories varies substantially according to the tests used and the rigor of the standards for diagnosis. In an external quality control study for serological diagnosis of hantavirus infections involving 18 laboratories in Europe and Canada, only 53 and 76% of IgM- and IgG-positive samples, respectively, were diagnosed correctly (5).

The requirement for reporting HFRS and HPS varies from country to country and among local health agencies. In the United States, reporting of HPS cases is mandated at the state level. HPS is listed as a notifiable disease in the National Notifiable Diseases Surveillance System maintained by the Centers for Disease Control and Prevention, although reporting is not compulsory.

Arenaviruses and Filoviruses*

PIERRE E. ROLLIN, STUART T. NICHOL, SHERIF ZAKI, AND THOMAS G. KSIAZEK

99

This chapter focuses on the viral hemorrhagic fever (VHF) viruses from two taxa, the families *Arenaviridae* (8) and *Filoviridae* (66). Some, but not all, members of these viral families cause severe, frequently fatal VHF in localized areas of the world. Although exotic in North America, these viruses are important public health problems in Africa and South America and have the potential of being introduced into the United States by travelers returning from these areas. The arenavirus and filovirus pathogens have been associated with serious nosocomial outbreaks involving health care workers and laboratory personnel. A set of guidelines, *Interim Guidance for Managing Patients with Suspected Viral Hemorrhagic Fever in U.S. Hospitals,* has been recently published (http://www.cdc.gov/ncidod/dhqp/bp_vhf_interimguidance.html). Continuing isolation of new arenavirus and filovirus subtypes from new geographic locations categorizes these agents as the causes of emerging infections, whose potential importance to public health is only recently becoming recognized (44). The similarity of initial isolation, clinical management, and viral diagnostic procedures for patients with suspected arenavirus or filovirus infections is the rationale for grouping these taxonomically distinct viruses in this chapter. Viruses from other taxonomic groups, including *Bunyaviridae* and *Flaviviridae* (chapters 97 and 98), have been associated with VHF (60).

Patients with VHF frequently present with similar, nonspecific clinical signs resembling malaria, typhoid fever, and pharyngitis. A detailed travel history, coupled with a high index of suspicion and availability of definitive virologic tools, should facilitate rapid diagnosis and the timely implementation of appropriate patient isolation, clinical management procedures, and public health measures.

TAXONOMY AND DESCRIPTION OF THE AGENTS

Arenaviridae

The family *Arenaviridae* comprises 22 named viruses which have unique morphologic and physiochemical characteristics. Antigenic relationships are established mainly on the basis of broadly reactive antibody binding assays, historically the complement fixation (CF) test (9), the indirect fluorescent-antibody (IFA) test (82), and the enzyme-linked immunosorbent assay (ELISA). Both serologic and phylogenetic analyses of viral RNA divide the arenaviruses into two complexes. The lymphocytic choriomeningitis (LCM) or Old World complex contains LCM virus and the Lassa viruses, including a number of apparently benign Lassa-like viruses from Mozambique, Zimbabwe, and the Central African Republic. On the basis of RNA sequence identities, these are unique viruses rather than substrains of Lassa virus. All have been isolated from rodents of the family *Muridae.* The Tacaribe or New World complex includes Tacaribe, Junin, Machupo, Amapari, Cupixi (8), Parana, Latino, Pichinde, Tamiami, Flexal, Guanarito, Sabia, Oliveros, Whitewater Arroyo, Pirital, and Bear Canyon (20) viruses. Chapare virus is a new arenavirus isolated from a human case in Bolivia; the reservoir is still unknown (S. Olson and our unpublished data). All New World complex viruses have been isolated from rodents of the family *Muridae* subfamily *Sigmodontinae* or, for Tacaribe virus, from bats. The Old and New World arenavirus complexes are distantly related; only when very-high-titer antisera are used can cross-reactions be observed. Monoclonal antibodies with specificities for structural proteins of arenaviruses suggest that the N protein is the group-reactive determinant whereas the envelope glycoproteins (G1 and G2) are responsible for type specificity (6, 7).

The morphology of arenaviruses is distinctive in thin-section electron microscopy (55) and was the basis for first associating LCM virus with Machupo virus and ultimately associating these viruses with all the viruses in the present family. Three major virion structural proteins are usually found (7). Two are glycosylated, G1 (50,000 to 72,000 Da) and G2 (31,000 to 41,000 Da), which constitute the virion envelope and spikes and which both serve as highly type-specific neutralization targets. The third, the N protein (63,000 to 72,000 Da), is clearly associated with the virion RNA and is considered to be the nucleocapsid protein.

Four RNA species with distinct oligonucleotide fingerprints can be isolated from intact arenavirus virions. Two species are virus specific and are ambisense in coding strategy: the small (S) RNA (22S), which encodes the N and GPC, the precursor of G1 and G2; and the large (L) RNA (31S), which codes for the viral polymerase and the Z protein, a regulatory element (8). The 28S and 18S species,

*This chapter contains information presented in chapter 104 by Peter B. Jahrling, Stuart T. Nichol, Pierre E. Rollin, and Thomas G. Ksiazek in the eighth edition of this Manual.

isolated in different proportions depending on external conditions, are ribosomal.

Arenaviruses mature by budding at the cytoplasmic membrane, and host proteins are incorporated into the virion envelope. Vero cells infected with each of the viruses contain distinctive intracytoplasmic inclusion bodies, immunoreactive with anti-N but not anti-G1 or anti-G2 antibody. All arenaviruses are readily inactivated by ethyl ether, chloroform, sodium deoxycholate, and acidic media (pH less than 5). β-Propiolactone (74) and gamma irradiation (19) are both reported to inactivate arenavirus infectivity while preserving reactivity in standard serologic tests.

Filoviridae

The filoviruses, Marburg and Ebola viruses, have a common morphology and similar genomic organization and complement of structural proteins (39). Marburg and Ebola virion RNAs are nonsegmented, negative, and single-stranded RNAs, 19.1 kb long, and 4.0×10^6 to 4.5×10^6 Da. The viral genomes are linearly arranged in a manner consistent with other nonsegmented, negative, and single-stranded RNA viruses. A substantial degree of similarity to the paramyxoviruses, especially in the nucleocapsid and polymerase genes, was noted. However, comparison with other filovirus protein sequences confirms that filoviruses are distinct. Furthermore, filoviruses are sufficiently distinct by ultrastructural and serologic criteria to warrant separate taxonomic status as members of the family *Filoviridae* (40, 66).

Marburg and Ebola viruses have at least seven virus-specific structural proteins, expressed from seven genes (66). For Ebola virus, the ribonucleoprotein complex contains L (180 kDa), N (104 kDa), VP30 (30 kDa), and VP35 (35 kDa) in loose association. L is an RNA-dependent RNA polymerase, and VP35 may play a role similar to that of the P protein of paramyxoviruses and rhabdoviruses. GP (125 kDa) is the major spike protein; VP40 (a matrix protein) and VP24 make up the remaining protein content of the multilayered envelope (40, 67). The GP of Ebola virus and that of Marburg virus can be differentiated by the presence or absence of N- and O-linked glycans and by the lack in Marburg virus of the second open reading frame coding for the small/soluble glycoprotein expressed during Ebola infection in vitro and in vivo. When grown in Vero (or Vero E6) or MA-104 cells, the GP of Marburg virus is totally devoid of terminal sialic acid whereas that of Ebola virus has abundant (2–3)-linked sialic acid. Phylogenetic analysis of GP genes from filoviruses clearly separates Marburg and Ebola viruses into two genera, *Ebolavirus* and *Marburgvirus,* and, furthermore, defines one species for Marburg virus (70) and four for Ebola virus: Zaire Ebolavirus, Sudan Ebolavirus, Reston Ebolavirus, and Tai Forest Ebolavirus (formerly known as Ivory Coast Ebolavirus).

Despite their unusual morphologic properties, Marburg and Ebola viruses resemble the other lipid-enveloped viruses, including the arenaviruses, in being susceptible to heat, lipid solvents, β-propiolactone (74), formaldehyde, UV light, and gamma radiation (19). These viruses are stable at room temperature for several hours but are inactivated by incubation at 60°C for 1 h.

EPIDEMIOLOGY AND TRANSMISSION

Arenaviridae

Arenaviruses are maintained in nature by association with specific rodent hosts (Table 1), in which they produce chronic viremia and/or viruria; they are routinely isolated from blood and urine samples. Naturally occurring human disease can usually be traced to direct or indirect contact with infected rodents. Aerosol infectivity is thought to be an important natural route of infection as well. Attempts to implicate arthropod vectors have been unsuccessful, but ectoparasites taken from viremic mammalian hosts have occasionally yielded arenavirus isolates. Of the 22 named members of the family *Arenaviridae* (8, 20), 7 are known to be human pathogens.

Filoviridae

Marburg and Ebola hemorrhagic fevers are caused by taxonomically distinct viruses which form two genera, *Ebolavirus* and *Marburgvirus,* within the *Filoviridae* (66). Marburg virus was first recognized in 1967, when 31 persons in Germany and Yugoslavia became infected following contact with monkey kidneys, primary tissue cultures derived from monkeys imported from Uganda, or sick patients (51). Ebola virus first emerged in two major disease outbreaks, which occurred almost simultaneously in Zaire and Sudan in 1976. Over 500 cases were reported, with case-fatality rates of 88% in Zaire and 53% in Sudan. Despite the simultaneous emergence of Ebola virus species from Zaire (Ebolavirus Zaire EBO-Z) and Sudan (Ebolavirus Sudan EBO-S) in 1976, these isolates are distinct species by serologic and sequence analysis criteria (71). More recently, two additional, distinct, and previously unrecognized Ebola virus species have been isolated. In 1989, a new strain of Ebola virus was isolated from cynomolgus monkeys being held in quarantine in Reston, Va., following importation from the Philippines (33). This species (Ebolavirus Reston EBO-R) may be less virulent for humans than are the African filovirus strains, since four workers at the quarantine facility seroconverted to EBO-R without experiencing disease. EBO-R reappeared in monkeys exported from the Philippines to Siena, Italy, in 1992 and to Alice, Tex., in 1996 (62). In 1994, another genetically distinct species of Ebola virus (Ebolavirus Ivory Coast) was associated with disease in a human and deaths among chimpanzees in the Ivory Coast (45). In 1995, EBO-Z reappeared in Zaire and disappeared without a trace, although subsequently (1996, 2001 to 2005) a number of outbreaks have occurred in Gabon and adjacent areas of the Republic of Congo among apes and humans, some human cases being associated with exposure to infected nonhuman primates (25, 63, 76). In 2000, EBO-S was responsible for a large outbreak in Gulu, in the northwest of Uganda. Approximatively 425 persons were infected, and 53% of them died (13, 58). In Yambio (south Sudan) in 2004, 17 persons were infected by EBO-S, and 7 of them died (77). An outbreak due to Marburg virus started in 1999 and continued into 2000 in eastern Democratic Republic of Congo (76). In the spring of 2005, a large outbreak of Marburg virus occurred in Uige, northern Angola. A total of 252 cases and 227 deaths from Marburg hemorrhagic fever were reported as of 24 August 2005 (78, 79). Reservoirs of filoviruses have remained elusive despite extensive searches during and between outbreaks. Recently, fruit bats have been reported as a potential reservoir for Ebola virus (47).

CLINICAL SIGNIFICANCE

Arenaviridae

Among the known arenavirus pathogens, LCM virus produces the least severe infection (46). A modest proportion of LCM infections are subclinical. A "typical" LCM case is

TABLE 1 Currently recognized arenaviruses and filoviruses and associated human diseases

Virus, date isolated	Natural host	Geographic distribution	Naturally occurring human disease	Human laboratory infections
Old World arenaviruses				
LCM, 1933	*Mus musculus* (house mouse)	Americas, Europe	Undifferentiated febrile illness, aseptic meningitis; rarely serious	Common; usually mild, but 5 were fatal
Lassa, 1969	*Mastomys* sp. (multimammate rat)	West Africa	Lassa fever; mild to severe and fatal disease	Common; often severe
Mopeia, 1977	*Mastomys natalensis*	Mozambique, Zimbabwe	Unknown	None; little experience
Mobala, 1983	*Praomys* sp.	Central African Republic	Unknown	None; little experience
Ippy, 1984	*Arvicanthus* sp.	Central African Republic	Unknown	None
New World arenaviruses				
Tacaribe, 1956	*Artibeus* sp. bats	Trinidad, West Indies	None detected	One suspected; moderately symptomatic
Junin, 1958	*Calomys musculinus*	Argentina	AHF	Common; often severe
Machupo, 1963	*Calomys callosus*	Bolivia	BHF	Common; often severe
Cupixi, 1965	*Oryzomys gaeldi*	Brazil	None detected	None detected
Amapari,1965	*Neacomys guianae*	Brazil	None detected	None detected
Parana, 1970	*Oryzomys buccinatus*	Paraguay	None detected	None detected
Tamiami, 1970	*Sigmodon hispidus* (cotton rat)	Florida	Antibodies detected	None detected
Pichinde, 1971	*Oryzomys albigularis*	Colombia	None detected	Occasional; mild to asymptomatic
Latino, 1973	*Calomys callosus*	Bolivia	None detected	None detected
Flexal, 1977	*Oryzomys* spp.	Brazil	None detected	One recognized (severe)
Guanarito, 1989	*Zygodontomys brevicauda*	Venezuela	Venezuelan hemorrhagic fever	None detected
Sabia, 1993	Unknown	Brazil	Viral hemorrhagic fever	Two recognized (both severe)
Oliveros, 1996	*Bolomys obscuris*	Argentina	None detected	None detected
Whitewater Arroyo, 1997	*Neotoma* spp.	New Mexico, Oklahoma, Utah, California	None detected	None detected
Pirital, 1997	*Sigmodon alstoni*	Venezuela	None detected	None detected
Bear Canyon, 2002	*Peromyscus californicus*	California	None detected	None detected
Filoviruses				
Marburg, 1967	Unknown	Imported in Germany and Yugoslavia; Kenya, Zimbabwe, Democratic Republic of Congo, Angola	Fatal cases	Yes
Zaire Ebola, 1976	Unknown, bats?	Democratic Republic of Congo, Gabon, Republic of Congo	Fatal cases	Yes
Sudan Ebola, 1976	Unknown	Sudan, Uganda	Fatal cases	None detected
Reston Ebola, 1989	Unknown	Philippines, imported in United States and Italy	Fatal asymptomatic cases	Seroconversion in animal handlers
Tai Forest Ebola, 1994	Unknown	Ivory Coast	Febrile illness, survived	None detected

usually heralded by fever, myalgia, retro-orbital headache, weakness, and anorexia. Especially during the first week, prominent symptoms include sore throat, chills, vomiting, cough, retrosternal pain, and arthralgia. Rash occurs but is infrequent. In about one-third of the patients, fever recurs, coinciding with the onset of frank neurologic involvement, usually aseptic meningitis but less frequently meningoencephalitis. Complete recovery is almost always the rule. Thus, LCM infections are temporarily debilitating but rarely fatal, even when neurologic complications arise. Although recognized only recently, in utero infections with LCM virus are a cause of significant birth defects of the central nervous and ocular systems (53, 80). Fatal forms of LCM infections were reported recently following transplantation of organs from two distinct LCM virus-infected donors (14, 59).

Lassa, Junin, and Machupo virus infections are much more severe. Lassa fever patients usually present at the hospital within 5 to 7 days of onset and complain of sore throat,

severe lower back pain, and conjunctivitis. Despite the usual antimalaria treatment, these symptoms usually increase in severity during the following week and are accompanied by nausea, vomiting, diarrhea, chest and abdominal pain, headache, cough, dizziness, and tinnitus. Later, pneumonitis and pleural and pericardial effusions with friction rub frequently occur. A maculopapular rash may develop, but frank hemorrhage is seen in only a proportion of the more severe cases. Oozing from puncture sites and mucous membranes and melena are more common. Approximately 15 to 20% of hospitalized patients die. Death occurs as a result of sudden cardiovascular collapse resulting from hepatic, pulmonary, and myocardial damage. Few Lassa fever patients develop central nervous system signs, although tinnitus or deafness may develop as recovery begins. Lassa fever is a particularly severe disease among pregnant women, for whom mortality rates are somewhat higher. The disease course in children is similar to that in adults, but in infants a condition described as swollen-baby syndrome, characterized by anasarca, abdominal distension, and bleeding, is typical. Clinical laboratory studies are not usually helpful for Lassa fever; specific virologic testing is required, especially in a setting where Lassa fever is less common or where mild, atypical cases are occurring.

The clinical pictures for Argentinian hemorrhagic fever (AHF) due to Junin virus and Bolivian hemorrhagic fever (BHF) due to Machupo virus are well characterized; for Venezuelan hemorrhagic fever due to Guanarito virus, Sabia virus in Brazil, or, more recently, Chapare virus in Bolivia, less information is available (60). However, all these infections are sufficiently similar to each other to be discussed as a single entity, i.e., South American or New World Arenavirus hemorrhagic fevers. Incubation periods range from 7 to 14 days, and very few subclinical cases are thought to occur. Following gradual onset of fever, anorexia, and malaise over several days, constitutional signs involving the gastrointestinal, cardiovascular, and central nervous systems become apparent by the time patients present to the hospital. On initial examination, AHF and BHF patients are febrile, acutely ill, and mildly hypotensive. They frequently complain of back pain, epigastric pain, headache, retroorbital pain, photophobia, dizziness, constipation or diarrhea, and coughing. Flushing of the face, neck, and chest and bleeding from the gums are common. Enanthem is almost invariably present; petechiae or tiny vesicles spread over the erythematous palate and fauces. Neurologic involvement, ranging from mild irritability and lethargy to abnormalities in gait, tremors of the upper extremities, and, in severely ill patients, coma, delirium, and convulsions, occurs in more than one-half of the patients. During the second week of illness, clinical improvement may begin or complications may develop. Complications include extensive petechial hemorrhages, oozing from puncture wounds, melena, and hematemesis. These manifestations of capillary damage and thrombocytopenia do not result in life-threatening blood loss. However, hypotension and shock may develop, often in combination with serious neurologic signs, among the 15% of patients who eventually die. Survivors begin to show improvement by the third week. Recovery is slow; weakness, fatigue, and mental difficulties may last for weeks, and a significant proportion of patients relapse with a "late neurologic syndrome," which includes headache, cerebellar tremor, and cranial nerve palsies. In contrast to Lassa fever, clinical laboratory studies are frequently useful. Total leukocyte counts usually fall to 1,000 to 2,000 cells/mm^3, although the differential remains normal. Platelet counts fall precipitously, usually to between 25,000 and 100,000/mm^3. Routine clotting parameters are usually normal or slightly abnormal; however, patients with severe cases may show evidence of disseminated intravascular coagulation.

Filoviridae

Marburg and Ebola virus infections are clinically similar, although the frequencies of reported signs and symptoms vary among individuals. Following incubation periods of 4 to 16 days, onset is sudden and is marked by fever, chills, headache, anorexia, and myalgia. These signs are soon followed by nausea, vomiting, sore throat, abdominal pain, and diarrhea. When first examined, patients are usually overtly ill, dehydrated, apathetic, and disoriented. Pharyngeal and conjunctival injection is usual. Within several days, a characteristic maculopapular rash over the trunk, petechiae, and mucous membrane hemorrhages appear. Gastrointestinal bleeding, accompanied by intense epigastric pain, is common, as are petechiae and bleeding from puncture wounds and mucous membranes. Shock develops shortly before death, often 6 to 16 days after the onset of illness. Abnormalities in coagulation parameters include fibrin split products and prolonged prothrombin and partial thromboplastin times, suggesting that disseminated intravascular coagulation is a terminal event and is usually associated with multiorgan failure. Clinical laboratory studies usually reveal profound leukopenia early, sometimes moderately elevated at a later stage. Platelet counts decline to 50,000 to 100,000/mm^3 during the hemorrhagic phase.

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

Safety and Security

Arenaviruses and filoviruses are classified as biosafety level 4 (BSL-4) agents, as there is a high risk of infection of laboratory personnel and appropriate precautions must be taken (12). They are also in the United States classified as Select Agents by the U.S. Department of Health and Human Services and should be handled as such (see chapter 9 and http://selectagents.gov/formsoverview.htm). At a minimum, barrier nursing procedures should be implemented and personnel caring for the patient and handling diagnostic specimens should wear disposable caps, gowns, shoe covers, surgical gloves, and face masks (preferably full-face respirators equipped with high-efficiency particulate air [HEPA] filters) (10, 11; http://www.cdc.gov/ncidod/dhqp/bp_vhf_interimguidance.html). Gloves should be disinfected immediately if they come in direct contact with infected blood or secretions. Manipulation of these specimens and tissues, including sera obtained from convalescent patients, may pose a serious biohazard and should be minimized outside a BSL-4 laboratory (10–12). Use of Vacutainer tubes is considered safer than use of syringes and needles, which must be disassembled before their contents are transferred to another tube. Procedures which generate aerosols (e.g., centrifugation) should be minimized and performed only if additional protective measures, such as keeping the equipment in a class I or II laminar flow hood, are taken. For specialized procedures, the infectivity of samples may be greatly reduced, if not totally inactivated, by the addition of Triton X-100 and heating. Heating to 60°C for 1 h renders diagnostic specimens noninfectious and is acceptable for measurement of heat-stable substances such as electrolytes,

blood urea nitrogen, and creatinine. When the equipment is available, sterilization by ^{60}Co γ-irradiation is the preferred method. Extraction of RNA from infectious samples by using guanidinium thiocyanate (with a proper ratio, at least 1 to 5 or 1 to 10 of lysis reagents) should be conducted in a laminar-flow hood, but after extraction, the extracted RNA is no longer infectious.

Specimen Collection

For virus isolation, antigen detection, and reverse transcription (RT)-PCR, serum, heparinized plasma, or whole blood should be collected during the acute, febrile stages of illness and frozen on dry ice or in liquid nitrogen vapor. Storage at higher temperatures (above −40°C) leads to rapid losses in infectivity. Blood obtained in early convalescence for serodiagnosis may be infectious despite the presence of antibodies, and it should be handled accordingly (10–12). In addition to blood samples, throat wash specimens could also be used for virus isolation during infections with arenaviruses (Lassa, Junin, and Machupo). LCM virus may be recovered from acute-phase serum samples obtained during the first week after onset or from cerebrospinal fluid during the period of meningeal involvement and from the brain at autopsy but is rarely, if ever, recovered from throat washings or urine specimens. Marburg and Ebola viruses are usually recovered from acute-phase serum samples; various specimens including throat washings, saliva, urine, soft tissue effusions, semen, and anterior eye fluid have yielded these viruses, even when the specimens were obtained late in convalescence.

Postmortem Specimens

Lassa, Machupo, Junin, Marburg, and Ebola viruses are all readily isolated from specimens of spleen, lymph nodes, liver, and kidney obtained at autopsy but rarely, if ever, from brain or other central nervous system tissues. Notably, Lassa virus is usually isolated from the placentas of infected pregnant women. In the recent severe and fatal clinical forms observed after organ transplants, LCM virus was isolated from several organs at autopsy. Formaldehyde-fixed tissues and paraffin-embedded blocks are also suitable for histopathology and immunohistochemical identification of viral antigens and should be conserved and shipped at room temperature.

Shipping

For all testing of infectious material, samples should be packaged in accordance with current recommendations (International Air Transport Association; http://www.iata.org/index.htm) and forwarded, after consultation, to one of the following laboratories that maintain BSL-4 facilities and a diagnostic capability for these agents:

1. Centers for Disease Control and Prevention, Special Pathogens Branch, Division of Viral and Rickettsial Diseases, Center for Infectious Diseases, Atlanta, GA 30333. Phone: (404) 639-1115. Fax: (404) 639-1118.
2. U.S. Army Medical Research Institute of Infectious Diseases, Headquarters, Fort Detrick, Frederick, MD 21702-5011. Phone: (301) 619-2833. Fax: (301) 610-4625.
3. Center for Applied Microbiology and Research, Special Pathogens Unit, Salisbury, Porton Down, Wiltshire SP4 0JG England. Phone: 0980-612224. Fax: 0980-611310.
4. National Institute for Communicable Diseases, Private Bag X4, Sandringham, Johannesburg, South Africa. Phone: 27 (11) 386 6336. Fax: 27 (11) 882 3741.

DIRECT EXAMINATION

Electron Microscopy

Individual arenavirus virions are pleomorphic and range in size from 60 to 280 nm (mean, 110 to 130 nm) (Fig. 1A). A unit membrane envelops the structure and is covered with club-shaped, 10-nm projections. No symmetry has been discerned. The most prominent and distinctive feature of these virions is the presence of different numbers of electron-dense particles (usually 2 to 10), which may be connected by fine filaments. These particles, 20 to 25 nm in diameter, are identical to host cell ribosomes by biochemical and oligonucleotide analysis. Immunoelectron microscopy techniques also work well for diagnosis of arenavirus infections, although the morphology of the virions is less striking for arenaviruses than filoviruses.

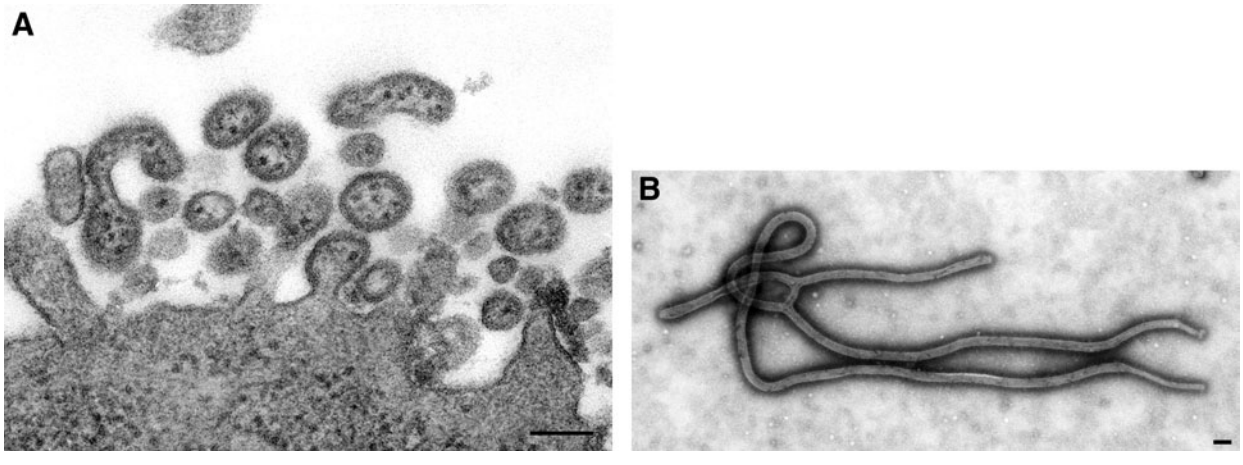

FIGURE 1 Ultrastructural characteristics of LCM and Ebola viruses as seen in tissue culture cells. (A) Lymphocytic choriomeningitis virus, an arenavirus, showing pleomorphic enveloped particles with internal ribosome-like granules; scale bar, 100 nm. (Courtesy of C. S. Goldsmith.) (B) Ebola virus isolate, a filovirus, showing enveloped filamentous particles around 80 nm wide. Some filaments can occasionally measure up to 15,000 nm in length; scale bar, 100 nm. (Courtesy of C. S. Goldsmith.)

Marburg and Ebola viruses have been successfully visualized directly by electron microscopy both of heparinized blood and urine obtained during the febrile period and of tissue culture supernatant fluids. The combination of the size and shape of the virions is sufficiently characteristic to allow a morphologic diagnosis of filovirus (21, 33, 54). The viral particles are very large, typically 790 to 970 nm long and consistently 80 nm in diameter. Bizarre structures of widely different lengths, sometimes exceeding 14,000 nm, as well as branching, circular, or "6" shapes, probably resulting from coenvelopment of multiple nucleocapsids during budding, are frequently found in negatively stained preparations (Fig. 1B) (21, 54).

Several Ebola viral inclusions are seen in thin-section electron micrographs of liver. The inclusions consist of viral nucleocapsids seen mostly in longitudinal section. Numerous viral particles are also seen in sinusoidal spaces (Fig. 2B). These virions can be differentiated and identified as Marburg or Ebola virus by immunoelectron microscopy techniques (22–24).

Antigen Detection

Immunohistochemistry

IFA staining of impression smears or air-dried suspensions of the liver, spleen, or kidney has been used successfully to detect cytoplasmic inclusion bodies associated with Marburg virus infection; clumps of Marburg virus antigen have also been observed by IFA examination of infected, dried, citrated blood smears. This approach was successfully adapted to the diagnosis of EBO-R in impression smears from blood, tissues, and nasal turbinates, as it was to the detection of Junin virus-infected cells in peripheral blood and urinary sediment. Hematoxylin and eosin staining of the liver reveals hepatocellular necrosis and numerous intracytoplasmic, eosinophilic Ebola viral inclusions, as well as sinusoidal dilatation and congestion (Fig. 2A). The development of immunohistochemical techniques for detection of filovirus and arenavirus antigens in formalin-fixed tissues has recently advanced to the point that their results are far more satisfactory than those of IFA examination of frozen, acetone-fixed sections (15, 16, 32, 83). Obtaining frozen sections for diagnosis is rarely worth the biohazard incurred, especially since the threshold sensitivity for detection exceeds 6 $\log_{10}$ PFU per g. For filoviruses, paraffin blocks of tissues are sectioned. Sections are deparaffinized, hydrated, digested with protease, and stained for the presence of viral antigens with immune rabbit serum or cocktails of murine monoclonal antibodies (32, 33, 83). Biotinylated antiserum is then allowed to react, and the product is developed with a streptavidin-alkaline phosphatase system. Substitution of other chromogens can further increase sensitivity while reducing background (15). Remarkable success was reported in the application of immunohistochemistry to the demonstration of Ebola virus

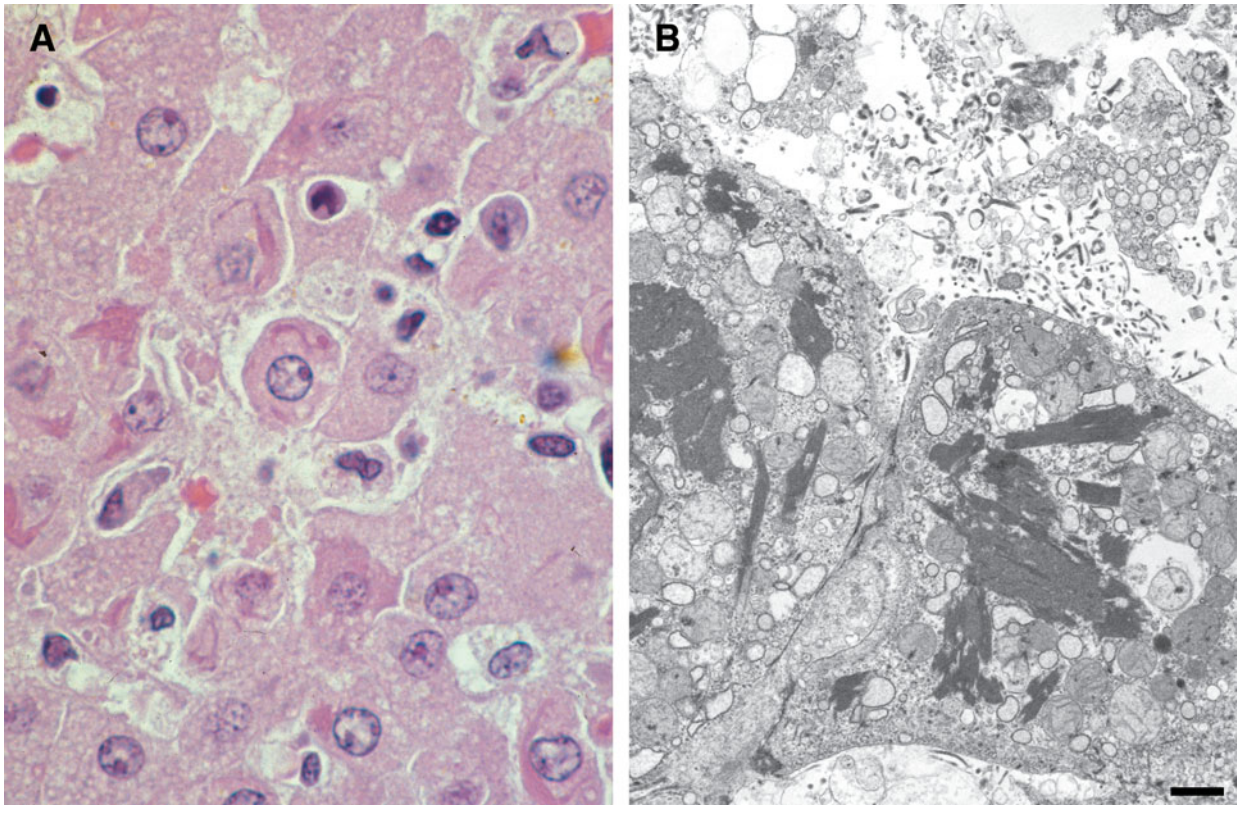

FIGURE 2 Ebola virus hemorrhagic fever. (A) Section of liver showing hepatocellular necrosis and numerous intracytoplasmic, eosinophilic Ebola viral inclusions, as well as sinusoidal dilatation and congestion. Hematoxylin and eosin stain; original magnification, ×250. (B) Several Ebola viral inclusions are seen in a thin-section electron micrograph of liver. The inclusions consist of viral nucleocapsids seen mostly in longitudinal section. Numerous viral particles are also seen in sinusoidal spaces; scale bar, 100 nm.

antigens in formalin-fixed skin biopsy specimens obtained from deceased Ebola virus patients in Zaire in 1995 (61, 83) (Fig. 3B). Immunohistochemistry was recently used to confirm the diagnosis of a fatal Lassa fever in a New Jersey patient returning from West Africa (Fig. 3A).

Antigen Capture ELISA

The recent development of an antigen capture ELISA for quantitative detection of arenavirus and filovirus antigens in viremic sera and tissue culture supernatants has facilitated the early detection and identification of these agents (2, 41, 42, 57). These tests reliably detect antigens in samples inactivated by either β-propiolactone or irradiation; therefore, they can be conducted safely without elaborate containment facilities. The threshold sensitivities for these assays are approximately 2.1 to 2.5 $\log_{10}$ PFU per ml, and so they are sufficiently sensitive to detect antigen in most acute-phase VHF viremias and to detect viruses at the concentrations present in throat wash and urine samples. Substitution of one or several monoclonal antibodies of high avidity and appropriate specificities for polyclonal sera (mostly against nucleoprotein and VP40) generally increases the sensitivities and specificities of these antigen capture ELISAs (30, 50, 56, 57, 65).

Based on the same capture principles, a rapid, colorimetric, column immunofiltration assay for the direct detection of Ebola antigen has been used in the field for the first time during an Ebola outbreak in the Republic of Congo (26).

Nucleic Acid Detection

RT-PCR followed by genome analysis is rapidly replacing identification methods based on serologic criteria and has the advantage of complete inactivation of the samples in the first extraction step. However, as RT-PCR is more prone to cross-contamination problems, we would still encourage its use in combination with traditional methods (virus isolation and/or serology). Real-time PCR combined with classical cell culture could also be used for testing antivirals against Lassa and Ebola viruses (27).

Arenaviridae

RT-PCR has also been evaluated in a small series of serum samples from Lassa fever patients in West Africa (17, 73). The sensitivity of PCR relative to conventional viral isolation

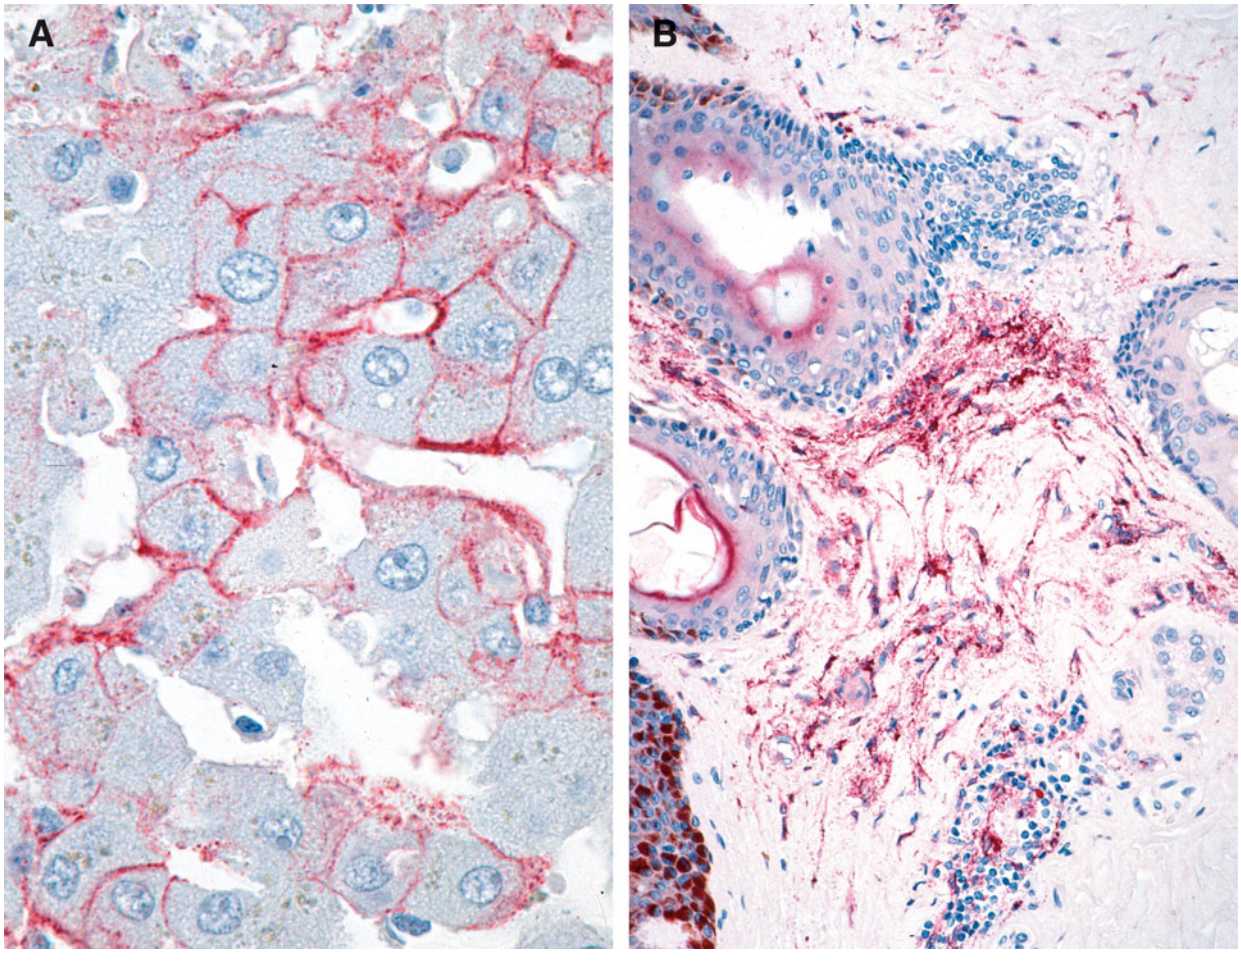

FIGURE 3 (A) By use of immunohistochemistry, abundant Lassa virus antigens are seen within the cytoplasm of hepatocytes and sinusoidal lining cells. Original magnification, ×158. (B) Skin showing massive viral burden as seen in this section immunostained for Ebola antigens; original magnification, ×50. (Immunoalkaline phosphatase staining, Naphthol fast red substrate with light hematoxylin counterstain.)

was 0.82, and the specificity was 0.68. PCR was positive throughout more of the disease course than was isolation, perhaps because of its greater sensitivity in the presence of the early antibodies associated with acute Lassa fever. Although systematic comparison with other techniques has not been made, improvement in the technique has occurred and suggests that considerable genetic variation among Lassa viruses requires the need for caution in primer design if diagnosis of infections in more than one geographic area is being considered (3–5). Real-time PCR assays are available for Lassa fever diagnostic but still lack field testing. Likewise, various strategies for RT-PCR have been devised to detect Junin virus RNA in clinical materials (3, 4, 48, 49). Some of these are reputed to be far more sensitive than conventional isolation procedures, especially in the presence of antibody. Any method which promises to be a reliable substitute for procedures that entail the manipulation of infectious BSL-4 virus deserves attention.

Filoviridae

Protocols which maximize detection are usually based on conserved sequences within the N, VP35, or L genes, while fine discrimination and phylogeny are based on the more variable GP region (68, 75). The sensitivity of RT-PCR for Ebola virus strains is similar to that of conventional isolation. During the EBO-S outbreak in Gulu, the RT-PCR-based assay was very valuable because of its ability to identify some patients prior to identification by any other available test and after clearing detectable antigen. Using NP-based real-time quantitative RT-PCR, the viral load was found to correlate with disease outcome (72). During the recent outbreak in Angola, Marburgvirus real-time PCR assays were developed and effectively applied in the laboratory in Luanda and in the field in Uige (26).

ISOLATION PROCEDURES

Cell Culture

Clinical specimens and clarified tissue homogenates (usually 10% [wt/vol]) are diluted in a suitable maintenance medium and adsorbed in small volumes to cell monolayers grown in suitable vessels, such as T-25 tissue culture flasks. If no antigen is detected by IFA by 14 days, the sample is considered negative, but supernatant fluids should be blind-passaged to confirm the absence of virus. To confirm the presence and identity of the virus, scrapped cells are tested by immunofluorescence assay and supernatant fluids could be tested by antigen capture ELISA or RT-PCR techniques.

Arenaviridae

Cocultivation of Hypaque-Ficoll-separated peripheral blood leukocytes with susceptible cells has increased the isolation frequency of Junin virus. Cocultivation of lymphocytes from spleens of experimentally infected animals has yielded Lassa virus late in convalescence, even after neutralizing antibody has appeared. The technique merits systematic development for the remaining arenavirus and filovirus pathogens.

Although historically Machupo and Junin viruses were isolated by inoculation of newborn hamsters and mice, respectively, Vero cells are approximately as sensitive and are far less cumbersome to manage in BSL-4 containment. Furthermore, Vero cells usually permit isolation and identification within 1 to 5 days, a significant advantage over the use of animals, since 7 to 20 days of incubation is required for illness to develop in the animals.

Filoviridae

The best general method currently available for isolation of filoviruses is the inoculation of appropriate cell cultures (usually Vero cells) followed by IFA or other immunologically specific testing of the inoculated cells for the presence of viral antigens at intervals. Other cell lines, including human diploid lung (MRC-5) and BHK-21 cells, also work; MA-104 cells (a fetal rhesus monkey kidney cell line) may be more sensitive than Vero cells for some strains.

Animal Inoculation

Arenaviridae

Intracranial (i.c.) inoculation of weanling mice is still regarded by some as the most sensitive established indicator of LCM virus (28), although adequate cell culture systems for the isolation of LCM virus exist. Care must be taken to use mice from a colony known to be free of LCM virus. Many LCM virus isolates produce a characteristic convulsive disease within 5 to 7 days, which is nearly pathognomonic. Brains from dead mice may be used to prepare ELISA antigens or may be subjected to IFA or immunohistochemistry staining to obtain presumptive identification. Clarified mouse brain may also be used as the antigen for confirmatory testing by neutralization or RT-PCR.

Most LCM virus strains are also lethal for guinea pigs. The pathogenicity of virulent Lassa virus strains for outbred Swiss albino mice inoculated i.c. seems to vary with different sources; mice should not be seriously considered for Lassa virus isolations.

For the New World arenaviruses, particularly Junin virus, young adult guinea pigs inoculated either i.c. or peripherally have been used. Guinea pigs die 7 to 18 days after Junin virus inoculation. Strain 13 guinea pigs are exquisitely sensitive to most Lassa virus strains and uniformly die 12 to 18 days after inoculation; outbred Hartley strain guinea pigs are somewhat less susceptible. Newborn mice (1 to 3 days old) are highly susceptible to Junin virus inoculated i.c.; newborn hamsters are believed to be more sensitive to Machupo virus.

Filoviridae

Marburg virus and the EBO-Z and EBO-S strains of Ebola virus produce febrile responses in guinea pigs 4 to 10 days after inoculation; however, none of these viruses kills guinea pigs consistently on primary inoculation, and only EBO-Z and Marburg virus have been adapted to uniform lethality by sequential guinea pig passages. EBO-Z is usually pathogenic for newborn mice inoculated i.c., but EBO-S, EBO-R, and Marburg virus are not.

IDENTIFICATION OF VIRUS

Typing Antisera

Detection of viral antigens in infected tissue culture cells (usually Vero or MA-104) permits a presumptive diagnosis, provided that the serologic reagents have been tested against all the reference arenaviruses and filoviruses expected in a given laboratory, thus permitting an interpretation of virus cross-reactions. Virus isolates in cell culture supernatant fluids or tissue homogenates are presumptively or specifically identified by their reactivity with diagnostic antisera in various serologic tests (see below). Specific polyclonal antisera are prepared in adult guinea pigs, hamsters, rabbits, rats, or mice inoculated intraperitoneally with infectious virus. Rhesus and cynomolgus monkeys that are convalescent from

experimental infections are also reasonable sources for larger quantities of immune sera. Polyvalent polyclonal "typing" sera or ascitic fluids made by immunization with a number of viruses within the families have also been useful in early identification of virus isolates and in immunohistochemistry on unknown patient materials. Diagnostic antisera produced by a single injection of infectious virus are less cross-reactive and usually have higher titers than those produced by multiple injections of inactivated antigens. To further reduce the induction of extraneous antibodies, input virus should be derived from tissues or cells homologous to the species being immunized; likewise, the virus suspension should be stabilized with homologous serum or serum proteins. Sera produced for use in the IFA tests and ELISAs should be collected 30 to 60 days after inoculation; sera for neutralization tests should be collected later. All sera must be inactivated and rigorously tested for the presence of live virus before being removed from a BSL-4 environment.

Production and use of specific murine monoclonal antibodies with fine specificities for N and GP epitopes of LCM virus, Junin virus (69), and other arenaviruses have been reported, as well as monoclonal antibodies for Lassa, Ebola, and Marburg viruses. Reference reagents for all these viruses are not generally available outside the appropriately equipped specialized laboratories.

Immunofluorescence

To process infected cells for IFA examination and presumptive identification, inoculated cell monolayers are dispersed by using glass beads or a rubber policeman or trypsinization, washed, and placed onto circular areas of specially prepared Teflon-coated slides. These "spot slides" are air dried, fixed in acetone at room temperature for 10 min, and either stained quickly or stored frozen at −70°C. Although acetone fixation greatly reduces the number of infectious intracellular viruses, spot slides prepared in this manner should still be considered infectious and handled accordingly. Gamma irradiation has been used to render spot slides noninfectious (19), with no diminution in fluorescent-antigen intensity. Alternatively, infected cells may be biologically inactivated with β-propiolactone (74). Gamma irradiation is recommended if the appropriate equipment is available.

For direct FA tests, specific immune globulins conjugated to fluorescein are used with Evans blue counterstain. Specific viral fluorescence is characterized as intense, punctate to granular aggregates confined to the cytoplasm of infected cells. Specific Marburg and Ebola virus fluorescence may include large, bizarrely shaped aggregates up to 10 μm across. Nonspecific fluorescence is rarely a problem in IFA procedures for these viruses. Detection of Marburg, Ebola, Lassa, and LCM virus antigens by the IFA test is usually considered sufficient for a definitive diagnosis, although Lassa and LCM viruses cross-react at low levels in this test. Detection of Junin or Machupo virus antigens by the IFA test constitutes a presumptive diagnosis, since these viruses can be reliably distinguished from each other only by neutralization tests. IFA formats for viral detection are more cumbersome and cross-reactive but can be used if direct conjugates are unavailable. Immunohistochemical techniques for detecting arenaviruses (15) and filoviruses (16, 32) with a variety of chromogens can also be applied.

CF Test

The CF test is rarely used now, since reliable, simplified, and more sensitive immunofluorescence, ELISA, and RT-PCR procedures have been developed. Detailed instructions for performing the CF test for arenaviruses are available (9).

SEROLOGIC DIAGNOSIS

IFA Test

Until recently, the IFA test was widely regarded as the most practical single method for documenting recent infections with Marburg and Ebola viruses or large prevalence studies (1). Preparation of spot slides with infected Vero cells is identical to the procedure described above. Some refinements to enhance reproducibility and quality between spot slides lots have been suggested (18). Although monovalent spot slides are usually desired and are prepared with cells optimally infected with a single virus, polyvalent spot slides can also be prepared by mixing cells infected with different viruses selected from these or other taxonomic groups which have similar geographic distributions (37). The BSL-4 facility requirement to produce the spot slides could be avoided by using recombinant expressing cells (29). Discrepancies in titers determined by different laboratories, or even different investigators, are common. In addition, in most of the severe and fatal forms of these diseases, the patients never develop a humoral response and die without antibodies. This technique is not recommended for acute diagnosis of hemorrhagic fevers.

ELISA for Detection of IgG and IgM Antibodies

For all intents and purposes, the immunoglobulin G (IgG) and IgM ELISAs have replaced the more subjective IFA tests as the serologic tests of choice (41, 81). ELISA procedures for Lassa virus-specific IgG and IgM have been developed and successfully used on field-collected human sera (2, 57). When this ELISA is used in combination with the Lassa antigen capture ELISA described above, virtually all Lassa fever patients can be specifically diagnosed within hours of hospital admission. A simplification of this procedure, which entails the use of infected Vero cell detergent lysate as the antigen, diluted in SerDil and adsorbed directly to the microtiter plate wells, has been developed for Ebola virus (41, 43). Test sera are serially diluted, initially 1:100, and incubated with antigen in a format analogous to the antigen capture ELISA described above. Following incubation, washing, and addition of horseradish peroxidase-conjugated anti-human serum, ABTS [(2, 2′-azinobis(3-ethylbenzthiazolinesulfonic acid)] substrate is added for color development. Species-specific conjugates allow testing of other animal species during epidemiological studies. To avoid the use of several conjugates during epidemiological studies, proteinA-proteinG conjugate can be used. More recently a competition assay using an antibody-phage indicator has been proposed but has never been used in the field (52). Samples are considered positive if the optical density at 410 nm exceeds the mean plus 3 standard deviations for the normal-serum controls. This procedure can be further modified to detect virus-specific IgM by coating the plates with anti-human IgM followed by test serum dilutions and cell slurry antigens and then using the antigen capture protocol. These IgG and IgM ELISA procedures have worked well with specimens obtained from humans during natural infection and with animals experimentally infected with Lassa, Machupo, Junin, Marburg, and Ebola viruses. A simplification of the ELISA plate procedure, substituting filter paper disks, has been reported for EBO-R (38); it appears to sacrifice some sensitivity and precision in comparison with the more

established procedures but may find application in a field setting. All of these developmental assays are sufficiently robust to warrant field testing. Recombinant full or truncated proteins have also been proposed and used as antigen for ELISAs (31, 64).

Neutralization Tests

For the arenaviruses, plaque reduction tests with Vero cells are generally used. For measuring the levels of neutralizing antibody to Lassa and LCM viruses, which are both difficult to neutralize and are poor inducers of this antibody, test sera are diluted, usually 1:10, in medium containing 10% guinea pig serum as a complement source and mixed with serial dilutions of challenge virus. Titers are expressed as a $\log_{10}$ neutralization index, defined as ($\log_{10}$ PFU in control) − ($\log_{10}$ PFU in test serum). For Junin and Machupo viruses, the more conventional serum dilution-constant virus format is normally used, although the constant serum-virus dilution format is equally useful for distinguishing among virus strains. Neutralizing-antibody responses require weeks to months to evolve but persist for years (36). Performance of these tests is restricted to laboratories equipped to handle the infectious viruses.

In survivors, neutralizing antibodies to Lassa virus first appear very late in convalescence (6 weeks or later), long after the viremia has disappeared. This pattern of early IFA and delayed neutralizing-antibody response is similar for LCM virus infections. Neutralizing antibodies against Junin and Machupo viruses become detectable 3 to 4 weeks after onset, soon after the termination of viremia. While these antibodies are thought to be important in protection against reinfection, their role in resolution of acute infections is less firmly established (34, 35).

As described above, reliable tests for measuring the levels of neutralizing antibody to Marburg and Ebola viruses are not currently available.

Western Blotting

Western blotting is feasible for demonstrating antibodies to arenaviruses and filoviruses. However, it has never been applied systematically or routinely to diagnosis, although it was proposed as a confirmatory test to supplement the IFA test for filovirus antibodies (18). Detection of the nucleocapsid (N) band plus either VP30 or VP24 was taken as diagnostic. The Western blotting procedure was further refined by miniaturization, using the Phast system sodium dodecyl sulfate-polyacrylamide gel electrophoresis and transblot apparatus (Phast Western blot system). This test is not used anymore for antibody detection.

Other Serologic Tests

Other serologic tests have been applied to diagnosis but are abandoned. They include gel diffusion for arenaviruses, CF tests, reversed passive-hemagglutination (and inhibition) test involving Lassa virus antibody-coated erythrocytes, and a radioimmunoassay using ^{125}I-labeled staphylococcal protein A for Ebola. Western blotting and radioimmunoassay procedures are used in specialized laboratories to determine the fine specificities of monoclonal antibodies and occasionally to confirm the results of serosurveys based on ELISA.

EVALUATION AND INTERPRETATION OF RESULTS

Early diagnosis of arenavirus and filovirus infection is desirable since specific immune plasma and appropriately selected antiviral drugs are in certain cases effective when treatment is initiated soon after onset. Early recognition of these infections should also trigger strict isolation procedures to prevent the spread of disease to patient contacts. In areas where specific viruses are endemic, the index of suspicion is often high and experienced clinicians may be remarkably accurate in rendering an accurate diagnosis of fully developed cases on clinical grounds alone. However, even in these areas, specific virologic and serologic tests are required to confirm clinical impressions, since many other diseases, including malaria, typhoid, rickettsial infections, idiopathic thrombocytopenia, and viral hepatitis, may masquerade as an arenavirus or filovirus infection.

Since patients with most of the severe and fatal forms of these diseases can die without developing detectable levels of antibody, timely diagnosis requires a means of detecting infectious virus or antigen in the field. The antigen capture ELISA holds promise for use in detecting clinically relevant concentrations of virus in infectious or gamma irradiation-inactivated or β-propiolactone-inactivated sera, body fluids, and tissues, and in blood and tissues of humans and nonhuman primates infected with Machupo, Lassa, Ebola, and Marburg viruses (2, 33, 41, 42, 62).

RT-PCR assays may eventually eliminate almost all need to isolate infectious virus to establish a definitive diagnosis, but virus isolation remains important for subsequent genetic and pathogenesis studies. The ability to amplify viral genomes from infected tissues, and even from formalin-fixed tissues, and to sequence the reaction products does eclipse serologic methods of identification and classification of arenaviruses (3–5) and filoviruses (70, 71). With the exception of LCM virus, which may be handled at a lower containment level, isolation attempts of these viruses should not be done outside a BSL-4 laboratory (12). A combination of several laboratory techniques should be used to confirm any clinical suspicion of hemorrhagic fevers.

Among arenavirus infections, Lassa virus is usually recovered (by isolation, antigen detection, or RT-PCR) from acute-phase sera of hospitalized patients soon after admission, frequently in the presence of specific IgM antibody, and a detectable antibody response does not necessarily signal imminent recovery; viremia frequently persists, and some patients die despite an antibody response. Junin, Machupo, and LCM viruses are recovered less frequently, and diagnosis is usually based on seroconversion. The presence of specific IgM ELISA titers in the cerebrospinal fluid of LCM patients constitutes a definitive diagnosis, and for all arenavirus infections, the presence of specific IgM antibodies is indicative of recent infection. The extent to which heterologous arenavirus infection and/or reinfection broadens antibody specificity has not been systematically evaluated for any of the available serologic tests. Neutralizing antibodies against arenaviruses persist for long periods, perhaps for life, and thus provide the most reliable basis for determining the minimum resistance of a population to reinfection. The role of neutralizing antibody in acute recovery is less clear. The protective efficacy of passively administered immune plasma is believed to be a function of neutralizing-antibody titers, and plasma should be selected on this basis, especially for Junin and Lassa fever (34).

For filoviruses, the combination of antigen detection, RT-PCR, and IgM is the most valuable for acute-case diagnosis. Because of the time required for culture and the biohazard, virus isolation data for these viruses are usually available only retrospectively. Marburg virus and Ebola viruses are usually isolated from acute-phase serum samples. A rising IgM or IgG ELISA titer constitutes a strong presumptive

diagnosis. Since IgM titers do not persist for long, a decreasing titer suggests a recent infection which occurred perhaps several months previously. The IFA test has yielded misleading results when applied to diagnostic and population-based serosurveys and should be abandoned. For unknown reasons, the filoviruses are notoriously poor inducers of neutralizing antibody. The role of neutralizing antibodies for Ebola virus protective immunity is unclear, although passively administered IgG with very high neutralizing-antibody titers conferred only partial protection to experimentally infected primates (34, 35).

The highest priority for future development is refinement of the available diagnostic tools to permit definitive virus identification in the field. PCR-based assays add another dimension to the capability of field laboratories to diagnose acute disease almost in real time. Proper tailoring of primers should permit the design of tests with the proper degree of specificity. The emergence of three new arenavirus pathogens, Guanarito, Sabia, and Chapare viruses, as well as EBO-R, Whitewater Arroyo, Pirital, and Bear Canyon viruses in the past decade, serves as a reminder that broadly reactive grouping reagents are still required to augment the newly evolving tools of PCR and capture ELISAs based on extremely specific monoclonal antibodies and gene sequences.

An investment in rapid diagnosis should result in more timely intervention with effective treatment regimens and, through implementation of appropriate public health measures, contribute to reduce the dissemination of these highly virulent viral pathogens.

Herpes Simplex Viruses and Herpes B Virus

KEITH R. JEROME AND RHODA ASHLEY MORROW

100

TAXONOMY

Herpes simplex virus (HSV) types 1 and 2, formally designated *Human herpesvirus 1* and *Human herpesvirus 2,* respectively, are members of the family *Herpesviridae.* Along with varicella-zoster virus (VZV) *(Human herpesvirus 3)* and a number of viruses affecting primarily nonhuman hosts, they constitute the subfamily *Alphaherpesviridae.*

DESCRIPTION OF THE AGENT

Historical Aspects

The herpesviruses are thought to have coevolved with their hosts (57, 58), and thus, the earliest documentation of presumptive herpes simplex infection appears shortly after the development of writing and clinical observation. The infectious nature of HSV was demonstrated in 1919 (90). The concepts of seropositivity and recurrence developed in the 1930s (15, 20). In the 1960s antigenically distinct strains (HSV-1 and HSV-2) were identified. HSV-1 and HSV-2 are two of eight known human herpesviruses (118). In addition, herpes B virus *(Herpesvirus simiae),* a cercopithecine herpesvirus, is an important zoonotic pathogen in humans (Table 1).

Genetic Structure

The linear, double-stranded genome is 152 kbp for HSV-1 and 155 kbp for HSV-2. HSV-1 and HSV-2 share 83% nucleotide identity within their protein-coding regions. The genome is organized into a unique long (UL) and unique short (US) region, each of which is flanked by inverted-repeat regions. Although significant stretches of sequence are conserved across unrelated clinical isolates, isolates can be epidemiologically linked by restriction endonuclease digestion (116, 117), PCR (92), or sequencing (103).

Virion Structure

The HSV virion is 120 to 300 nm in diameter, with a central electron-dense core containing the DNA, an icosahedral capsid consisting of 162 capsomeres surrounding the core, and a tegument layer surrounded by a spiked envelope containing viral glycoproteins that aid in attachment, penetration, and immune evasion (119). The envelope is a trilaminar, lipid-rich layer derived largely from the nuclear membrane of the infected cell. Because the viral envelope is lipid rich, the virus is readily inactivated. Lipid solvents, exposure to pH of <4, or temperatures of $>56°C$ for 30 min all eliminate infectivity (39).

Life Cycle

Viral replication begins with attachment to the target cell via cell type-dependent host receptors (129). After attachment the viral envelope and cell membrane fuse, releasing the capsid into the cell. The capsid is translocated to the nuclear pores (11, 135), and DNA is released into the nucleus. The tegument protein VP16 induces expression of the immediate early, or alpha, proteins, which in turn transactivate the expression of the early, or beta, genes. Another immediate early gene, ICP47, acts as an important mediator of immune evasion by inhibiting the loading of peptide onto major histocompatibility complex class I molecules by the transporter associated with antigen processing, or TAP (55, 62). The early genes are maximally expressed 5 to 7 h after infection and are involved in the synthesis of progeny viral DNA. DNA replication is required for optimal synthesis of the late, or gamma, genes, which are mainly structural proteins. Progeny DNA is processed and assembled into preformed capsids within the cell nucleus. The DNA-containing capsids attach to patches of the nuclear membrane that contain viral tegument proteins and viral glycoproteins. In neurons, nucleocapsids are transported anterograde to the axon terminus, where the final assembly of enveloped virus occurs (66). The replication cycle is complete within about 20 h in epithelial cells.

Immunobiology

Innate immune mechanisms such as activation of macrophages, NK cells, and interferon production play a predominant role in the control of primary infection, while both innate and adaptive immunity are important in the control of recurrences. Although both cellular and humoral immunity are thought to be important, persons with defective cellular immunity often show severe HSV infections, while those with agammaglobulinemia do not (4). $CD4^+$ T cells infiltrate mucocutaneous lesions early in lesion development (41), followed by cytotoxic T lymphocytes (81). T cells may also play an important role in controlling viral reactivation at the dorsal root ganglia (76), perhaps through the action of gamma interferon.

Functional antibody responses include complement-independent and complement-dependent viral neutralization

TABLE 1 Herpesvirus family members pathogenic to humans

Designation	Common name	Subfamily
Human herpesvirus		
1	Herpes simplex virus type 1	Alpha
2	Herpes simplex virus type 2	Alpha
3	Varicella-zoster virus	Alpha
4	Epstein-Barr virus	Gamma
5	Cytomegalovirus	Beta
6a	Human herpesvirus 6a	Beta
6b	Human herpesvirus 6b	Beta
7	Human herpesvirus 7	Beta
8	Human herpesvirus 8	Gamma
Cercopithecine herpesvirus 1	Herpes B virus or herpesvirus simiae	Alpha

(46). Immunoglobulin G (IgG), IgM, and IgA responses to individual viral proteins arise within the first weeks after infection (4). IgM wanes after 2 to 3 months, appearing sporadically thereafter, and in about one-third of patients after recurrent genital herpes episodes. Antibody titer rises may or may not occur after recurrences (113). However, IgG titers are maintained for years after primary infection.

Most epitopes are shared between HSV-1 and HSV-2. As a result, it is difficult to distinguish antibodies to HSV-1 from those to HSV-2 (3, 6). In particular, in HSV-1-seropositive patients, seroconversion to HSV-2 is accompanied by brisk anamnestic responses to HSV-1, resulting in predominant antibody titers to HSV-1 rather than to HSV-2 for prolonged periods (3). While type-specific epitopes have been demonstrated on the major viral proteins, only glycoprotein G (gG) elicits predominantly type-specific responses.

EPIDEMIOLOGY AND TRANSMISSION

HSV infections occur worldwide with no seasonal distribution. The virus is spread by direct contact with virus in secretions. Incubation periods range from 1 to 26 days. The prevalence of HSV-1 infection increases gradually from childhood, reaching 80% or more in later years (101). In contrast, the seroprevalence of HSV-2 remains low until adolescence and the onset of sexual activity. The incidence of antibodies to HSV-2 in the United States is increasing; currently about 22% of the general U.S. population is seropositive (52). The rate of seropositivity varies widely, reaching more than 50% in some demographic groups (52, 71). In general, the seroprevalence of HSV-2 is higher in the United States than in other developed countries (93, 128). Importantly, a large percentage of individuals seropositive for HSV-1 and/or HSV-2 are unaware of the infection (52). Such persons comprise an important reservoir of infection.

CLINICAL SIGNIFICANCE

Primary Infection

Most HSV-1 infections are acquired early in childhood as subclinical or unrecognized infections (131). Young children may present with classic primary HSV-1 infection characterized by gingivostomatitis, fever, and marked submandibular lymphadenopathy (131). Oral lesions progress to ulceration and heal without scarring over 2 to 3 weeks. Adolescents may present with pharyngitis and mononucleosis.

Primary infection with HSV-2 classically presents as herpes genitalis, with extensive, bilateral vesicles, fever, inguinal lymphadenopathy, and dysuria (33). Lesions ulcerate and heal without scarring within 3 weeks. Secondary lesions may develop in the second to third week. Subclinical or unrecognized primary infection with HSV-2 is common.

The proportion of primary genital infections due to HSV-1 is increasing (19), from about 10% in 1983 to 32% in 1995 (33, 137), reaching 50% or more in certain populations (115). This trend is thought to result from changing sexual practices, including increased oral-genital exposure (115). The clinical presentation of primary genital HSV-1 cannot be distinguished from that of HSV-2. However, recurrent disease (see below) is less common with genital HSV-1 than HSV-2 (33, 49), and thus, determining the infecting virus type is useful for prognostic purposes.

Latency and Recurrent Disease

Primary infection with HSV-1 or HSV-2 is followed by the establishment of latency in the dorsal root ganglia, typically the trigeminal ganglia for orolabial disease and the lumbosacral ganglia for genital disease. Periodically the virus reactivates and travels via the nerve axon to oral or genital sites, resulting in release of infectious virus and, in some cases, lesion formation. Recurrent disease has milder symptoms and a shorter time to lesion healing than primary episodes (33, 131). The frequency of HSV-2 genital recurrences varies widely among individuals, ranging from none to 12 or more per year (12) with a mean rate of 0.33 recurrences/month. Orolabial HSV-1 recurrence rates are lower, with a mean of 0.12 episodes/month, while genital HSV-1 infection occurs even less frequently (mean 0.02 episodes/month) (84). While HSV-2 may be isolated from the pharynx during primary genital herpes episodes, orolabial HSV-2 recurrences are extremely infrequent (84).

Asymptomatic or Subclinical Infection

Approximately 70 to 90% of individuals with HSV-2 antibodies have not been diagnosed with genital herpes (52). Over one-half of such persons recognize and present with symptoms after education regarding manifestations of HSV disease (54, 88). In addition, about 20% of patients presenting with first episodes of genital herpes have serologic evidence of having been infected for some time (45). These episodes most closely resemble recurrent disease, with mild symptoms. The risk of recurrence is similar for patients presenting with true primary infection and for those with first recognized recurrent episodes (45). Most patients with genital herpes have episodes of subclinical virus excretion from anogenital sites; these constitute an important source of transmission. The copy number of HSV DNA can sometimes be as high during subclinical episodes as when symptoms occur (140). Oral shedding of HSV-2 is rare, particularly outside the setting of newly acquired genital HSV-2 (84, 141).

Neonatal Herpes

The most serious consequence of genital HSV infection is neonatal herpes. Infection usually occurs during vaginal delivery when the infant is exposed to HSV in maternal secretions. The risk of maternal-to-infant transmission is 10-fold higher in mothers experiencing unrecognized primary infection during the time of labor than in those shedding HSV as a result of recurrent, subclinical reactivation. This conclusion was drawn in part from the finding that the neonatal infection rate among HSV-seronegative mothers is 54 per 100,000, 26 among mothers with only HSV-1 antibody, and 22 among all mothers with HSV-2 antibody (18, 111). Transmission of

HSV-1 occurs at a significantly higher rate than that of HSV-2 (18). Nevertheless, the relative preponderance of recurrent genital HSV-2 disease means that most cases of transmission occur during HSV-2 recurrences.

Infected neonates can present with HSV disease localized to the skin, eyes, and mucosa or more serious central nervous system (CNS) or disseminated disease but often have nonspecific presentation (82). The mortality rate for untreated neonates with disseminated disease exceeds 70%. Early diagnosis and antiviral therapy while disease is localized to the skin can substantially reduce the morbidity and mortality associated with neonatal infections (78, 146, 147). PCR should be used to test cerebrospinal fluid (CSF), plasma, and peripheral blood mononuclear cells (44).

Herpesvirus CNS Disease in the Immunocompetent Host

HSV is the most common cause of fatal sporadic encephalitis in the United States (105). HSV encephalitis presents as fever, behavioral changes, and altered consciousness, resulting from localized temporal lobe involvement. Without treatment, mortality exceeds 70%, and few survivors recover normal neurologic function. Early treatment with acyclovir reduces morbidity and mortality; however, residual neurologic impairment is common (59). HSV PCR of CSF is the test of choice, being far more sensitive than culture (27, 47).

Genital HSV may be followed by sporadic meningitis or recurrent meningitis (Mollaret's syndrome) characterized by headache, fever, photophobia, and lymphocytic pleocytosis (123). The condition is self-limiting and typically resolves within 1 week (149a). HSV also can be associated with myelitis, radiculitis, ascending paralysis, autonomic nerve dysfunction, and possibly Bell's palsy.

Ocular Herpesvirus Infections

HSV is the most common viral cause of corneal infection in the United States, affecting 400,000 to 500,000 people (42, 108). Most corneal HSV infections are limited to the epithelial layer, causing characteristic branching ulcerations, pain, photophobia, and blurred vision. HSV epithelial keratitis responds well to oral or topical therapy (see below). Such superficial infections heal without loss of vision. HSV infection may extend to the corneal stroma leading to scarring and opacification of the cornea. Stromal HSV infections respond favorably to a combination of corticosteroids and topical or oral antivirals (75).

Herpes in the Immunocompromised Host

Immunosuppressed individuals with defective cell-mediated immunity frequently develop symptomatic HSV disease. HSV infections in such individuals can be severe, with extensive mucocutaneous necrosis and involvement of contiguous tissues leading to esophagitis or proctitis. HSV occasionally disseminates to multiple organs, leading to meningoencephalitis, pneumonitis, hepatitis, and coagulopathy. Disseminated infections require intravenous antiviral therapy and monitoring for development of antiviral resistance.

Antiviral Therapy

Several antiviral drugs including acyclovir, valacyclovir, penciclovir, and famciclovir are now widely used to treat mucocutaneous and genital herpes (24) and for long-term suppression of recurrent episodes. These drugs are selectively activated by the viral thymidine kinase and have minimal side effects. Suppressive therapy reduces the risk of viral transmission between HSV-discordant partners (36). *N*-Docosanol, a nonprescription topical medication, and topical acyclovir are used for the treatment of herpes labialis. HSV conjunctivitis, blepharitis, and dendritic keratitis are treated either topically with trifluridine, idoxuridine, or vidarabine or orally with acyclovir, valacyclovir, or famciclovir (75). In cases with stromal involvement the addition of topical corticosteroids reduces the persistence of inflammation (75). Neonatal herpes, herpes encephalitis, and severe infections in immunocompromised patients require prompt intravenous antiviral therapy (43). Foscarnet, a viral DNA polymerase inhibitor, is reserved for acyclovir-resistant herpes infections (77).

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

Lesions or Mucocutaneous Sites

Specimens require special viral transport medium (VTM) and controlled temperature to retain optimal infectivity for culture (7). VTM is made of balanced salt solutions such as Hanks' balanced salt solution, Stuart's medium, Leibovitz-Emory medium, veal infusion broth, or tryptose phosphate broth buffered to maintain a neutral pH. Protein-stabilizing agents such as gelatin or bovine serum albumin are added as well as antibiotics to prevent bacterial overgrowth (130). Most VTM are inappropriate for bacterial or chlamydial transport. However, Multi-Microbe Medium (M4-RT) from MicroTest (Lilburn, Ga.) can be used for bacterial, chlamydial, or viral specimens. In one comparison study, Bartel's VTM (ViraTrans; Trinity Biotech, Bray, Ireland), cell culture medium (Dulbecco's with bovine serum albumin and gentamicin), and tryptose phosphate broth did not preserve HSV infectivity as well as Richards' VTM or Virocult Medium (Medical Wire and Equipment, Cleveland, Ohio) (69).

Samples should be shipped cold (on ample ice packs) but not frozen. Prolonged (>48 h) storage should be at –70°C. HSV stability is reduced 2- to 10-fold at 22°C compared with 4°C; in one study, median half-lives of four strains held in Richard's VTM was 72 days at 4°C but only 8 days at 22°C. With other transport media, half-lives ranged from 0.5 to 4 days at 22°C and from 1 to 180 days at 4°C (69).

Necrotic debris or exudate should be removed from mucosal sites (endocervix, anogenital areas, conjunctiva, and throat) or lesions with a cotton swab prior to sampling. The area must be vigorously rubbed with Dacron, rayon, or cotton swabs on aluminum shafts to ensure that infected cells at the base of the lesion are collected. Calcium alginate swabs and swabs with wooden shafts inhibit infectivity (38, 130). Swabs are then broken off into VTM for transport.

A single transport vial may provide specimen for both viral culture and direct antigen detection tests. Alternatively, slides for direct fluorescent-antibody (FA) detection can be prepared immediately after collection by gently spreading the material on a swab in a thin layer over a clean microscope slide. The slide is air dried and fixed in cold acetone before transport.

Collection for DNA Amplification (PCR)

Special collection and handling methods are essential to avoid contamination of the specimen with exogenous viral DNA (31). For lesions or mucocutaneous sites, a dedicated specimen should be collected with a Dacron swab in VTM or digestion buffer (120). CSF does not require special handling. Blood from neonates is collected in lavender-topped tubes (EDTA) for PCR of peripheral blood mononuclear cells and plasma (44). Specimens for PCR can be maintained

at 4°C for up to 72 h, but longer storage should be at –20°C (31, 70, 142).

Other Samples

Fluids such as tracheal aspirates should be collected aseptically and transported without VTM. Urine should be collected by clean catch and refrigerated before transport. Once in the laboratory, urine is diluted 1:1 with culture medium. Corneal samples are obtained with a no. 15 scalpel blade, and cells are suspended in VTM. Tissue is placed in VTM in a sterile container. Prolonged storage of tissue requires immersion in sterile 50% neutral glycerol in saline or, alternatively, in culture medium with 5% fetal bovine serum. Fresh tissue samples can also be frozen, sectioned, applied to slides, and fixed in acetone.

DIRECT EXAMINATION

Detection of virus in patient samples without an intervening culture amplification step provides the most rapid diagnosis. Immunostaining methods to detect antigen require less expertise than cytopathic effect (CPE)-based culture methods and are usually less expensive than culture.

Tzanck Test

Changes that are characteristic for HSV are sometimes visible in fixed, stained cells from lesions (Tzanck preparations) or cervical scrapings (Papanicoalaou stains) (100) or in hemotoxylin and eosin stains of fixed tissue. Enlarged or degenerating cells, syncytium formation, chromatin margination, a "ground glass" appearance of the cytoplasm, and nuclear inclusions are typical of HSV-infected cells. These methods are widely available but lack sensitivity and specificity (34). Virus-specific methods are preferred.

Fluorescent-Antibody Detection (DFA or IFA)

For FA detection, slides are prepared with cells from the patient's specimen and fixed with acetone (7). Cells are coated with antibody preparations against HSV-1 and HSV-2 or against type common epitopes. If the antibodies are linked to a fluorophore such as fluorescein isothiocyanate, the test is a direct fluorescent-antibody assay (DFA). If bound anti-HSV antibodies are detected with secondary antibodies conjugated to fluorophore, the test is an indirect fluorescent-antibody assay (IFA). Same-well testing can be performed using antibody conjugates with different fluorophores for HSV-1 and HSV-2 (see Table 3) (25). DFA is 10 to 87% as sensitive as culture, with higher sensitivity from vesicular lesions and poor sensitivity from healing lesions (85). DFA is far less sensitive than PCR (37).

Antibodies give their own distinct patterns (see Table 3). For example, HSV-1-infected cells have a halo of apple-green fluorescence with monoclonal antibodies from MicroTrak (see Fig. 2B). Staining patterns require skill to interpret; nonspecific staining can be distinguished from staining of viral antigen by a trained reader.

Cytospin DFA

An effective modification of DFA employs a cytocentrifuging step to apply cells from the sample to slides for subsequent DFA testing. The cytospin step results in better adherence of cells to the slides and fewer inadequate specimens than what is obtained with drip application methods (87) while allowing a <2-h turnaround time. The sensitivity of cytospin DFA has been reported to be higher than that of culture for detecting HSV from swab specimens (87), while other researchers, using different DFA antibody and cell culture systems, reported sensitivity of 31% versus culture (122).

EIA

Enzyme immunoassay (EIA) is rapid and amenable to automation. Sensitivity can be as good as culture for diagnosis from lesions (32) or as low as 35% in asymptomatic patients (16, 136). Dako USA (Carpinteria, Calif.) currently markets an amplified enzyme-linked immunosorbent assay (ELISA) based on monoclonal antibodies to HSV-1 and HSV-2 (IDEIA).

Direct DNA Detection

In situ hybridization or solution hybridization methods are not as widely used as IFA or DFA. These tests use DNA or RNA probes, some of which are type specific. The hybrid capture method (Digene Corp.) used a cocktail of RNA probes targeting type-common or type-specific regions of the HSV genome. DNA/RNA hybrids were then detected by ELISA (40). The sensitivity of direct hybridization methods is limited (approximately 1×10^5 copies/ml for the Digene assay), and thus, these approaches have been largely replaced by PCR (see below).

PCR-Based Detection Methods

The most sensitive method for direct detection of HSV is the PCR (127). Precautions to prevent contamination of the sample and the inclusion of frequent negative controls within the assay are critical (83, 86). Some laboratories include isopsoralens or uracil-*N*-glycosylase in their PCR amplifications, preventing the amplification of PCR products in subsequent reactions.

The likelihood of laboratory contamination by amplicon is reduced with the new real-time PCR detection systems (see below) that eliminate the need for postamplification manipulation of the PCR product. Laboratories performing PCR testing should participate in a regular proficiency testing program, such as the Nucleic Acid Amplification ID survey from the College of American Pathologists (http://www.cap.org). It is important to consider performance data, including test turnaround times, before selecting a provider of DNA amplification testing.

Primer Selection and HSV Typing

Depending on the primers and detection methods, PCR can be set up to detect both HSV-1 and HSV-2 (120) or to allow distinction of HSV-1 from HSV-2 (79, 120). PCR primers have been described amplifying portions of many HSV genes, including those encoding thymidine kinase (U_L23), DNA polymerase (U_L30), DNA binding protein (U_L42), and glycoproteins B, C, D, and G (U_L27, U_L44, U_s6, and U_s4, respectively) (133). Distinction of HSV-1 and HSV-2 can be achieved using type-specific primers or probes, melting curve analysis, restriction enzyme analysis, or direct sequencing. At our institution, we detect both HSV-1 and HSV-2 by PCR using a real-time detection system (see below) with the type-common gB forward primer CCG TCA GCA CCT TCA TCG A, reverse primer CGC TGG ACC TCC GTG TAG TC, and probe CCA CGA GAT CAA GGA CAG CGG CC (70).

Detecting PCR Products

Methods to detect PCR products include intercalating agents such as ethidium bromide, Southern blot hybridization, and liquid hybridization (29, 65, 120). Of these, liquid

hybridization gives the greatest sensitivity (64). The herpes simplex 1/2 consensus assay and the herpes consensus generic (which can detect HSV-1, HSV-2, VZV, Epstein-Barr virus, cytomegalovirus, and HHV-6) (Argene) detect amplification product by hybridization with biotinylated probes (14). The Light Diagnostic HSV OligoDetect assay uses a biotinylated primer set to generate the amplification product, which is then denatured and captured on microtiter plates via hybridization with an immobilized oligonucleotide probe. A recent improvement has been the development of HSV assays using real-time detection of PCR products (51, 70, 74, 102). These systems allow constant monitoring of the amount of PCR product by detection of a fluorescent signal generated as PCR product accumulates. The Cepheid HSV Non-typing ASR utilizes primers directed to the HSV type 1 and type 2 polymerase gene to generate a 92-bp amplicon, which is then detected using a specific fluorophore (6-carboxyfluorescein [FAM])-labeled probe. The Cepheid HSV Typing ASR uses primers targeting the glycoprotein D gene of HSV-1 and the glycoprotein G gene of HSV-2, which are then detected with FAM- and Alexa 532-labeled probes, respectively. The LightCycler-HSV 1/2 Detection Kit (Roche) uses a pair of detection probes designed such that hybridization to PCR product brings a donor fluorophore into proximity with an acceptor fluorophore, allowing fluorescence of the acceptor (94). In addition to the commercial assays, a large number of laboratories offer in-house-validated assays using various real-time detection approaches. Real-time systems decrease the likelihood of laboratory contamination and allow more accurate quantification than is possible with older quantitative-competitive assays (120). The ability to quantitate virus may be useful in monitoring response to antiviral therapy, particularly in HSV encephalitis or neonatal herpes infections (1).

ISOLATION PROCEDURES

Culture

Virus detection methods including culture and modified culture are used to diagnose mucocutaneous, genital, and ocular lesions (Table 2). Conventional culture uses cells that are permissive for HSV-1 and HSV-2 as well as other viruses that may be of diagnostic importance. Inoculated cells are examined frequently for CPE (see below). In our laboratory, 95% of HSV isolates produce CPE by day 5; only 5% require 5 to 14 days. Mink lung cells, rhabdomyosarcoma cells, human diploid fibroblasts such as MRC-5 and WI-38, and human epidermoid carcinoma lines such as HEp-2 and A549 are commercially available (68, 72).

Direct comparisons suggest that test sensitivity can be markedly affected by the cells used, particularly with a low-titer HSV inoculum. Mink lung cells are reportedly more sensitive than MRC-5 cells, while Vero cells have had low sensitivity reported even with high-titer isolates (150).

CPE

Infected cells develop cytoplasmic granulation and then become large, round, and refractile. Clusters or foci of infected cells appear early after inoculation in diploid fibroblast or epidermoid carcinoma lines (Fig. 1). CPE in A549 cells is characterized by syncytium formation, particularly with HSV-2 (68). Cells then lyse and detach from the substrate with eventual destruction of the monolayer.

IDENTIFICATION AND TYPING

Other viruses, as well as toxic factors in specimens, can mimic the CPE of HSV (Fig. 2A). Confirmation of putative HSV CPE is accomplished using commercially available polyclonal

TABLE 2 Selected diagnostic tests for HSV

Syndrome	Sample	Laboratory tests	Comments
Oral or genital lesion	Swab in VTM	Culture, shell vial FA, cytospin FA PCR	Viability must be preserved. Cell architecture must be maintained.
Recurrent genital symptoms; culture negative	Serum Serum Serum Capillary blood	WB HerpeSelect ELISA HerpeSelect Immunoblot Captia ELISA HSV-2 *biokit* Rapid HSV-2	Limited availability. Good confirmatory test. FDA approved; Focus (Cypress, Calif.) FDA approved; Focus (Cypress, Calif.) Trinity Biotech (Bray, Ireland) Biokit USA (Lexington, Mass.); point-of-care, FDA approved; HSV-2 only
Neonatal herpes	CSF; blood in EDTA Eye, mouth, nasal, and rectal swabs	PCR Culture, FA, PCR	Collect separate CSF for PCR. Blood in EDTA (purple top)
Ocular herpes	Swab in VTM	Culture, FA, PCR	Clinical presentation may be sufficient for diagnosis.
Conjunctivitis; dendritic corneal ulcers	Corneal scraping	Culture, FA, PCR	
Encephalitis	CSF	PCR	Culture far less sensitive than PCR.
Recurrent lymphocytic meningitis	CSF	PCR	

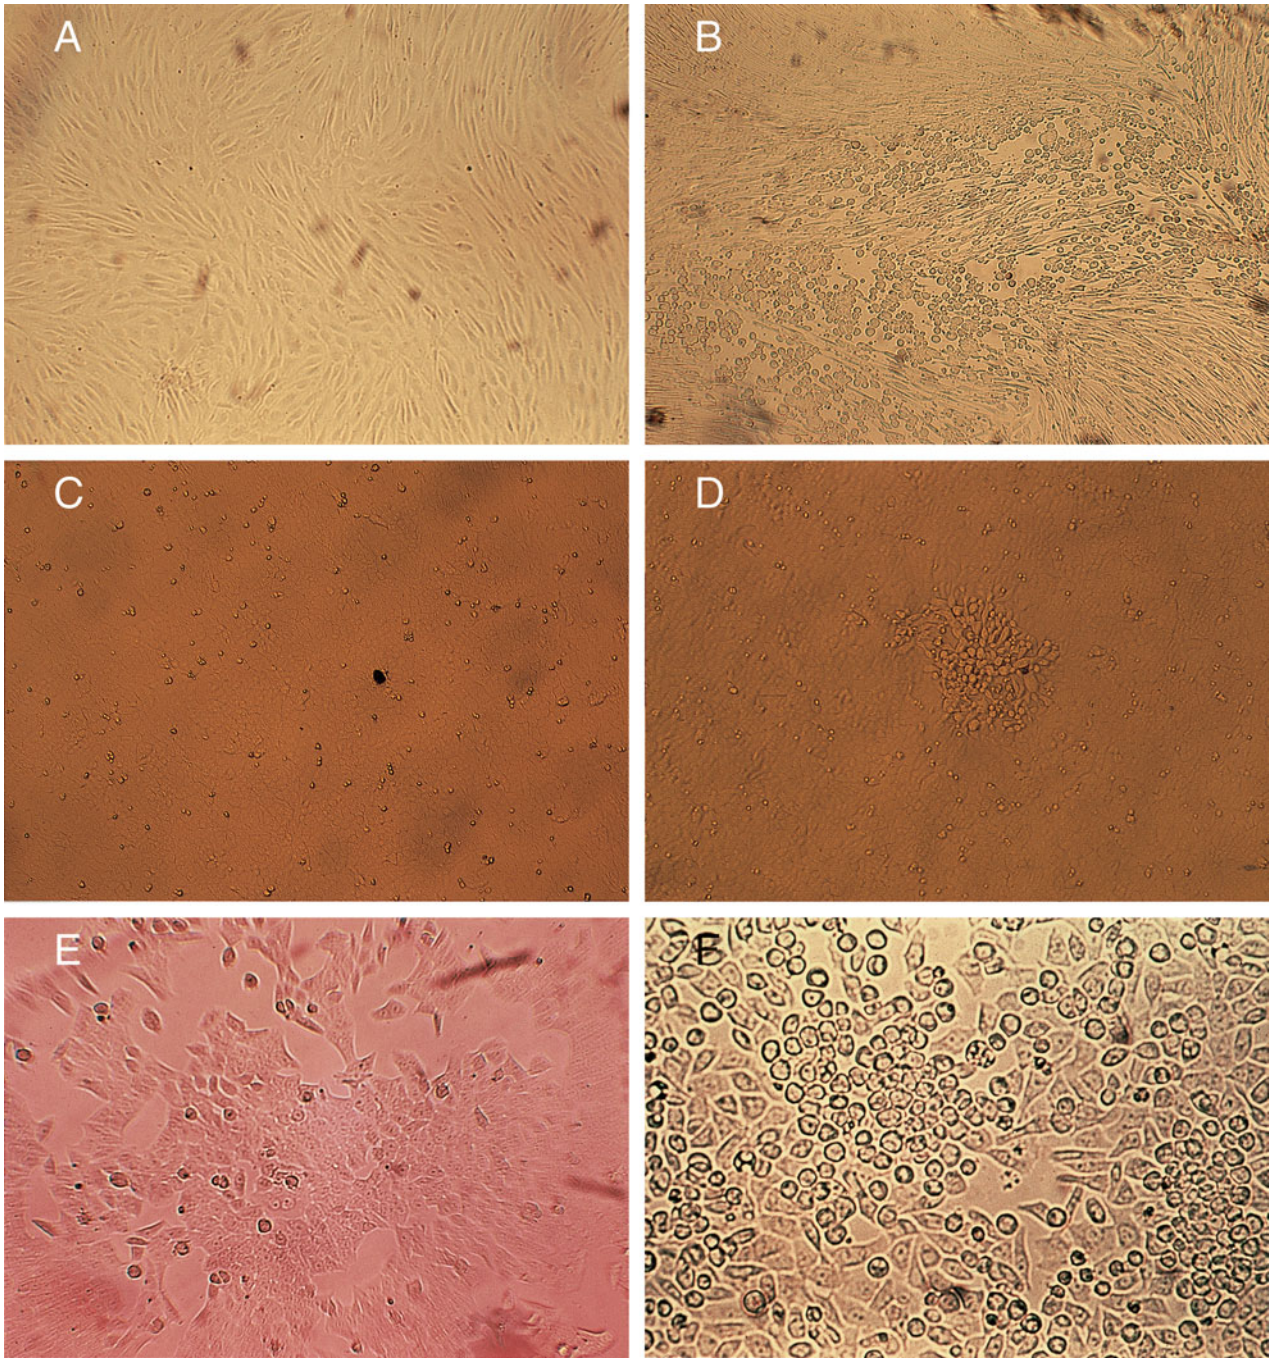

FIGURE 1 (A and B) Normal and HSV-1-infected human diploid fibroblasts, respectively (magnification, ×400). (C and D) Normal and HSV-2-infected mink lung cells, respectively (magnification, ×100). (E and F) Normal and HSV-2-infected HEp-2 cells, respectively (magnification, ×400).

or monoclonal antibodies against type-common or type-specific epitopes. The most widely used reagents are fluorescein conjugated for use in fluorescent-antibody tests (Table 3 and Fig. 2B). Trinity Biotech and Diagnostic Hybrids, Inc. (Athens, Ohio) both supply these reagents. SimulFluor HSV/VZV (Chemicon, Temecula, Calif.) can detect and type HSV as well as VZV from a single sample. Peroxidase-conjugated antibodies against HSV-1 and HSV-2 are also used in in situ EIA formats (150).

Spin-Amplified Culture

Spin amplification methods reduce the time required to detect HSV in culture by detecting viral proteins before CPE develops (150). The most widely used technique involves centrifuging the sample onto monolayers of cells on coverslips that are placed in the bottom of small vials ("shell vials") or in the wells of flat-bottomed plates. After 16 to 48 h of incubation, the coverslips or plates are subjected to antigen detection tests for HSV (25). When compared to standard

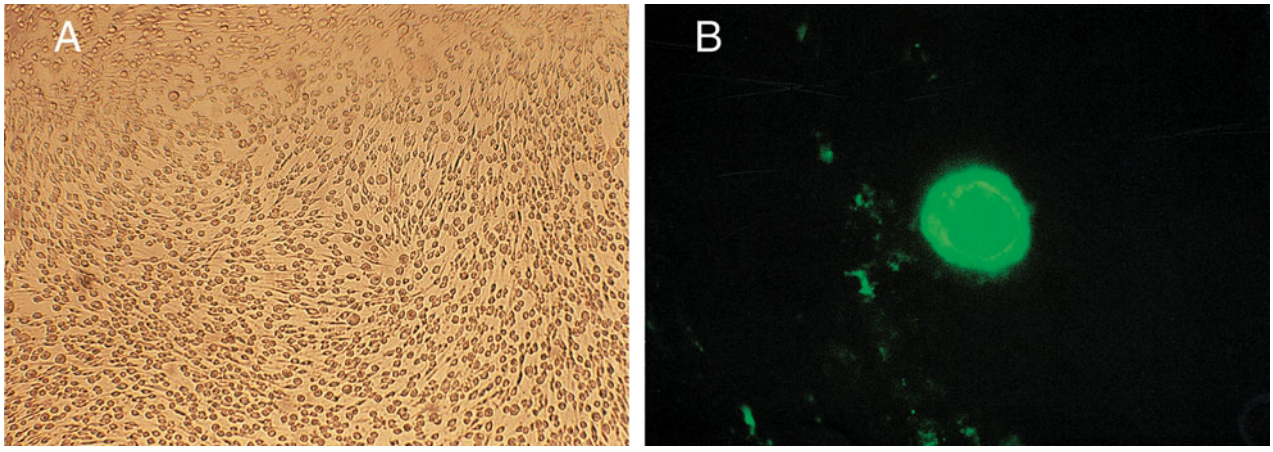

FIGURE 2 (A) Toxicity in human diploid fibroblasts (magnification, ×100). (B) HSV-2 DFA confirmatory test.

culture, reported sensitivity ranges from 71 to 97% (50, 110, 149). Sensitivity is affected by time of incubation before staining, with 48 to 72 h yielding more positives than 16 to 24 h. The cell line also affects sensitivity, with mink lung or A549 cells having greater sensitivity than MRC-5 cells (110).

Mixed FreshCell (Diagnostic Hybrids, Inc.) is a combination of CV-1 and MRC-5 cells in a shell vial format to detect a large number of human viruses including HSV-1 and HSV-2. Combined with immunodetection tests and spin amplification, this approach is intended to provide a rapid definitive diagnosis of HSV-1, HSV-2, or VZV from lesions.

Genetically Altered Cell Lines

The enzyme-linked virus inducible system (ELVIS) is based on BHK cells with a reporter gene for β-galactosidase that is driven by the promoter from the HSV-1 UL39 gene. Other viruses do not transactivate this promoter (132). Infected cells express the reporter gene, resulting in a color change visualized by light microscopy (132). The ELVIS-Id (Diagnostics Hybrids, Inc.) system allows HSV-positive cells to be tested for the presence of HSV-1 or HSV-2 (107). ELVIS-based systems can have sensitivity comparable to that of standard culture (107) and spin-amplified cell culture (89).

SEROLOGIC TESTS

Because nearly all HSV structural proteins have extensive antigenic cross-reactivity, only IgG tests based on the type-specific HSV gG accurately distinguish HSV-1 and HSV-2 antibodies (3, 9, 95). Tests based on crude antigen mixtures are still on the market from Wampole Laboratories (Cranbury, N.J.), Zeus Scientific (Raritan, N.J.), and DiaSorin (Minneapolis, Minn.) and have unacceptably low sensitivity and specificity, especially for detecting new HSV-2 infections in patients with prior HSV-1 infections (3, 95). Type-specific IgM tests are not available. FDA-approved IgM tests decrease the time to detecting seroconversion in new infections but cannot accurately distinguish new from established infections (99). Tests for HSV-2 antibody avidity can discriminate accurately between first episodes (low avidity) and recurrent episodes (high avidity) in most cases. However, overlapping avidity values occur in the mid-range (97).

WB

The HSV Western blot (WB) used by the University of Washington laboratory uses nitrocellulose blots prepared with human diploid fibroblast-infected cell proteins. WB detects antibodies to multiple viral proteins, including those to the type-specific glycoprotein gG-2 (2). About 20% of sera must be preabsorbed against Sepharose beads coated with HSV-1 or HSV-2 proteins and retested to give definitive results (5). This combination of tests gives a very accurate determination of HSV-1 versus HSV-2 antibody status (2).

Commercial Type-Specific G-Based Assays

The following tests use gG as the target antigen: HerpeSelect ELISA and HerpeSelect immunoblot tests from Focus Diagnostics (Cypress, Calif.; formerly MRL). These

TABLE 3 Monoclonal antibodies for HSV-1 and HSV-2 detection, confirmation, and typing by immunofluorescence

Reagent	Source	Comments
SimulFluor	Chemicon International, Inc., Temecula, Calif.	HSV-1: whole-cell stain (apple green); HSV-2: cytoplasmic or membrane stain (yellow); simultaneous testing for both HSV-1 and HSV-2
PathoDx	Diagnostics Products Corp./Viromed, Minneapolis, Minn.	HSV-1: cytoplasmic or whole-cell stain; HSV-2: nuclear stain
MicroTrak	Trinity Biotech, Jamestown, N.Y.	HSV-1: nuclear staining; HSV-2: strong nuclear stain, with speckled cytoplasmic staining

tests have been approved by the FDA for detection of HSV-1 or HSV-2 antibodies in adults and in pregnant women. The Captia ELISA for either HSV-1 or HSV-2 by Trinity Biotech was recently FDA cleared. A point-of-care test, *biokit* Rapid HSV-2 assay (Biokit USA, Lexington, Mass.) or SureVac-HSV-2 (Fisher HealthCare), was FDA approved under the original brand name, POCkit-HSV-2, for use with capillary blood.

The Focus and Biokit tests perform as well as or better than other gG-based tests in clinically defined populations and can be used for serum or plasma (9, 26). When compared with the University of Washington Western blot, HerpeSelect ELISA for HSV-1 had 91 to 96% sensitivity with 92 to 95% specificity. HerpeSelect Immunoblot had 99 to 100% sensitivity with 93 to 96% specificity. For HSV-2, HerpeSelect ELISA had 96 to 100% sensitivity with 96 to 97% specificity while HerpeSelect Immunoblot for HSV-2 had 97 to 100% sensitivity and 94 to 98% specificity. The POCkit-HSV-2 test from Diagnology (now Biokit USA) had 93 to 96% sensitivity with 95 to 98% specificity in comparison tests (9).

Median time to seroconversion is approximately 3 weeks for HerpeSelect-HSV ELISA (10) and about 2 weeks for the biokit-HSV-2 assay (8).

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

Laboratory results are best interpreted in the context of the patient's presentation and history and with the knowledge of the natural history of HSV infection.

Interpretation of Virus Detection Tests

Interpretation of positive test results also depends upon the specificity of the test. Specificity of culture is virtually 100% if confirmatory tests are performed. In situ techniques for antigen detection (FA or immunoperoxidase staining of infected cells) have better specificity than other antigen detection methods because the cell's staining pattern allows the technologist to confirm that the signal is specific (Table 3). Finally, PCR for HSV is most reliable when closed system methods are used and laboratory practices are strictly met to avoid contamination of specimens with exogenous HSV DNA. Given these caveats, in practice positive cultures are highly diagnostic in patients with lesions due to gingivostomatitis, genital herpes, or ocular infections. Positive FA tests from lesions or ocular swabs are considered reliable. HSV found in the central nervous system, in tissues, in blood, or in the eye by culture or PCR techniques is diagnostic. Positive cultures or positive PCR tests in symptomatic infants at 1 to 3 weeks of life are highly diagnostic (78).

For other patients, interpretation of a positive viral detection test requires caution. For example, respiratory secretions from immunocompromised patients may contain HSV in addition to the causative agent such as respiratory syncytial virus, parainfluenza virus, or adenovirus. The laboratory should be engaged in working up this type of specimen in appropriate viral isolation systems and appropriate antigen detection tests to identify the relevant pathogen. HSV may also be shed concurrently with other pathogens from oral or anogenital sites or may not be the cause of the episodic syndrome that triggered testing. Syphilis and chancroid are the most likely alternative causes of genital ulcers in the United States. In a series of patients with genital ulcers other than those typical of herpes (vesiculopustular lesions), 65% had only herpes detected while 20% had both syphilis and herpes detected (96). HSV results from such patients need to be interpreted in the context of laboratory test results for other pathogens in the differential diagnostic list (61). Symptoms of HSV gingivostomatitis or genital infection can be mimicked by noninfectious syndromes, such as Stevens Johnson syndrome, as well as by infectious agents. Because of the sporadic nature of asymptomatic HSV shedding, swabs of oral or anogenital sites may yield positive HSV culture, PCR, or antigen test results when the underlying cause of disease is not herpes.

Positive cultures or PCR results from skin, conjunctival, mouth, or nasal swabs from neonates less than 24 h old may reflect maternal virus, not neonatal infection. Neonates born to mothers found to be shedding HSV from the genital tract at labor and delivery may be tested 24 to 72 h after birth; a likely time frame for receiving maternal culture results. Most babies with neonatal herpes present between 9 and 14 days of life (147), well beyond the time frame during which maternal viral contamination would be a problem.

False-negative tests may occur because of poor technique in sampling (not obtaining infected cells), because of prolonged transport time or exposure of samples to high ambient temperature (reducing viability for culture) or because the specimen has low levels of virus. Recurrent episodes yield lower titers of virus for shorter periods (33). In many cases, a combination of tests or repeated testing is the most sensitive approach. Performing both culture and FA tests can increase sensitivity by 20% or more from genital lesions; repeating testing at a later recurrence nearly doubles the sensitivity (85). PCR is the most sensitive test available and is the test of choice for herpes encephalitis, disseminated neonatal herpes (see below), and, increasingly, diagnosis of anogenital herpes (140). However, in areas without local PCR testing, direct or indirect FA methods and culture may yield more timely results. Antiviral therapy should be started empirically if disseminated herpes, neonatal herpes, or encephalitis is suspected.

Interpretation of PCR Results

PCR has adequate sensitivity to detect shedding of HSV in individuals with asymptomatic infection or negative cultures (139) and also to detect HSV in CSF, a specimen with a low yield of HSV by culture. The sensitivity of HSV PCR for HSV encephalitis is about 96%, while specificity is 99% (13). Similarly, PCR has about three times the sensitivity for genital HSV-2 detection both from lesions and during periods of subclinical shedding (140). PCR can remain positive for several days after HSV lesions become negative by culture (29). PCR positivity in this case probably represents infectious virus below the limit of detection by culture, and PCR positivity is quickly lost in the absence of active shedding (138). False negatives can occur in PCR, due to reaction failure or the presence of inhibitors in clinical specimens (21, 114). It is therefore critical that only negative reactions accompanied by positive internal controls be accepted as true negatives (30). Importantly, a negative PCR result for HSV does not rule out HSV disease, since specimens taken very early or late in the course of disease may not have viral DNA (112). This is especially true in pediatric populations; for example, in one series nearly 25% of infants with CNS HSV infections had negative CSF PCR results (78). In patients with CNS HSV infections, HSV PCR may become negative after about 7 days of antiviral therapy (13). The persistence or reemergence of virus after antiviral therapy has been associated with a poor clinical outcome (80).

Quantitative PCR may be useful in monitoring the response to antiviral therapy. Successful antiviral therapy is associated with a decline in viral load in the CSF (1, 48, 114,

148). Quantitation of HSV may also have prognostic value; patients with >100 copies/μl (100,000 copies/ml) of CSF were reported to have worse outcome than patients with lower levels (48). However, other groups have reported no association between CSF viral load and clinical outcome (114, 148).

Interpretation of Type-Specific Serology

Type-specific serology is useful when culture or other virus detection methods are not available or when specimen collection or transport is inadequate. Serology based on gG-1 and gG-2 is vital for diagnosing subclinical and unrecognized HSV infections. In fact, many experts believe that better recognition of genital HSV-2 infections by increased use of accurate gG-based serologic tests could help slow the spread of genital herpes (17, 35, 60).

As with other herpes laboratory tests, serology tests based on gG must be ordered and interpreted with care. First, due to the low specificity of non-gG-based commercial tests, it is important to determine that a gG-based test was used. If so, a positive test for HSV-2 antibodies for a patient with genital lesions is highly likely to be a true positive. A positive HSV-2 antibody test for a patient without a history compatible with genital herpes may be false positive and should be confirmed by a different type-specific test (98). Negative HSV-2 test results for a patient with symptomatic genital disease may indicate genital HSV-1; no test can distinguish between antibodies elicited by oral versus genital HSV-1. False-negative tests may also occur because the patient is seroconverting; sera drawn 4 to 6 weeks later should be tested. IgM tests based on gG-1 and gG-2 are not available commercially. The available IgM tests cannot distinguish new from established symptomatic episodes with sufficient accuracy and are not recommended (99). However, avidity tests based on the Focus ELISA may be useful to identify recent infection (97).

The role of type-specific serology in pregnancy is controversial. Determining that a woman is HSV-2 seropositive early in pregnancy has been recommended so that treatment options can be considered and careful checks for lesions can be performed at delivery (17). Further, because the risk of herpes transmission to the neonate is 10-fold higher when maternal infection is acquired late in pregnancy, serologic screening of pregnant women and their partners has been recommended to identify seronegative women at risk of acquiring herpes (17). If a herpes culture from the anogenital region is positive at labor or delivery, a negative maternal type-specific serology indicates high risk (30 to 50%) for neonatal herpes. A positive maternal serology by WB indicates a lower risk of transmission (1 to 3%).

HERPES B VIRUS

Description of the Agent

Herpes B virus is similar to HSV in terms of genome size and structure and in terms of virion morphology. Herpes B virus DNA has 161 ± 12 kbp (91) and is extremely (approximately 75%) G+C rich.

The replication cycle of herpes B virus is very similar to that of HSV. Herpes B virus is detectable as soon as 6 h postinfection, and titers of virus stabilize by 24 to 36 h (63). At least nine herpes B virus glycoproteins have been identified, and at least two of these share antigenic determinants with glycoproteins B and D of HSV (104). As an enveloped virus, herpes B virus can be inactivated by lipid solvents, UV light, or heat, and thus, cell-free virus is inactivated rapidly in the environment.

Clinical Significance

Herpes B virus is the simian counterpart to HSV in Old World monkeys of the genus Macaca, including the rhesus, cynomolgus, Japanese, Taiwan, and stumptail macaques. The virus can affect the oropharynx or genital areas and is spread between animals via biting, sexual activity, or other close contact (144, 145). The seroprevalence of herpes B virus among macaques in the wild is unknown, but among animals housed in outdoor breeding corrals the seroprevalence is approximately 22% before 2.5 years of age, rising to more than 97% among animals 2.5 years or older (143). Primary infection in the macaque is often asymptomatic, but the virus establishes latency and can reactivate. Reactivation can be triggered by stress, such as the transition of animals from freedom to captivity, or crowded conditions. Recurrent disease in macaques is typically characterized by vesicular lesions of the tongue and buccal mucosa, progressing to ulceration. Encephalitis is rare but can occur. Asymptomatic shedding of virus can occur.

In 1932 a researcher was bitten by a macaque and developed ascending myelitis and encephalitis culminating in death. Herpes B virus was subsequently described (56, 121). About 40 cases of herpes B virus infection in humans have been described in the literature. Humans can be infected via animal bites, mucosal or eye exposure (23), inoculation of broken skin, needle sticks, or, potentially, via aerosols. The possibility of herpes B virus transmission makes macaques unsuitable as pets (106). Safety precautions for workers with close contact with macaques have been summarized recently (67).

Herpes B virus disease is severe in humans, with a mortality rate of 70% or higher without treatment. The first symptoms usually appear 3 to 5 days after exposure (although they can appear up to several weeks later) and include a localized vesicular lesion at the site of inoculation, erythema, and edema. Lymphangitis and lymphadenopathy follow, with fever, myalgia, vomiting, and cramping. Neurologic signs develop quickly, starting with meningeal irritation, diplopia, and altered sensation, progressing to paralysis, altered mentation, respiratory depression, seizures, and death within 10 days to 6 weeks. Human-to-human transmission appears to be extremely rare (22). Asymptomatic infection in humans also appears to be rare. In one study of over 300 primate handlers (of whom more than 150 had a history of exposures), none had antibody to herpes B virus (53).

Acyclovir is effective against herpes B virus, although the 50% effective dose is 10-fold higher than for HSV. Ganciclovir is somewhat more effective than acyclovir (151), although clinical experience with ganciclovir is limited. Foscarnet has also been used in some cases (23). Postexposure therapy can often prevent the development of acute disease (67). The preferred drug for postexposure prophylaxis is oral valacyclovir, due to its improved bioavailability (28). Clinical disease necessitates intravenous antiviral therapy. Intravenous therapy should be continued until symptoms resolve and two or more viral cultures are negative after having been held for 10 to 14 days, at which time therapy can be switched to oral antivirals (28). Reactivation and relapse have occurred in some patients upon cessation of antiviral therapy. Many clinicians therefore recommend continuing oral antiviral therapy indefinitely.

Collection, Transport, and Storage of Specimens

Because herpes B virus should be propagated only under biosafety level 4 conditions, diagnostic specimens are best handled by specialized reference laboratories (see below). Special precautions should be taken by other laboratories so

that herpes B virus specimens are not confused with HSV specimens and thus cultured under lower biosafety conditions, since amplification of virus in culture increases the risk to laboratory personnel.

Reference Laboratories for Herpes B Virus

Lesion swabs should be taken from each collection site by using a separate, sterile Dacron or cotton swab with wooden or plastic shafts. Swabs or biopsy tissue should be placed into separate tubes containing 1 to 2 ml of VTM. Specimens should be stored on dry ice or at <–60°C until shipped. Advice regarding proper specimen collection and submission of specimens for herpes B diagnosis can be obtained from the National Institutes of Health B Virus Resource Laboratory, Atlanta, Ga., phone (404) 651-0808, or from their website http://www.gsu.edu/bvirus.

Identification of Virus and Serodiagnosis

Herpes B virus can be cultured in monkey kidney and chick embryo cells. A characteristic CPE similar to that of HSV is seen, with polykaryon formation and intranuclear Cowdry type A inclusion bodies. Confirmation of herpes B virus in culture can be done using monoclonal antibodies or molecular techniques. PCR for herpes B virus (109, 124, 125, 126) is generally preferred over culture for diagnostic purposes, since it is comparatively rapid and highly sensitive and specific and avoids the need to amplify infectious virus to high titers.

Serodiagnosis of herpes B virus infections has been complicated by extensive cross-reactivity with HSV-1 and HSV-2. However, a competitive ELISA that allows discrimination of antibodies to herpes B virus, HSV-1, and HSV-2 has been developed (73). Serologic testing can be useful for evaluation of potentially infected animals involved in human exposures and for screening research animals. Serial determinations of serostatus from potentially exposed individuals are also useful adjuncts for diagnosis (23).

Varicella-Zoster Virus

ANNE A. GERSHON, JINGXIAN CHEN, PHILIP LaRUSSA,
AND SHARON P. STEINBERG

101

TAXONOMY

Varicella-zoster virus (VZV) is a member of the *Herpesviridae.* It is classified as an alphaherpesvirus along with the herpes simplex viruses (HSV). It has been designated human herpesvirus 3 by the International Committee on Taxonomy of Viruses.

DESCRIPTION OF THE AGENT

VZV has a morphology typical of the *Herpesviridae* (12). It has a linear double-stranded DNA genome of approximately 125,000 bp ([80 ± 3] × 10^6 Da) that exists as four isomers. The genome encodes at least 70 open reading frames (ORFs) and consists of a 67 × 10^6-Da long unique DNA segment, U_L, and a 3.4 × 10^6-Da short unique sequence, U_S. Each unique sequence is flanked by internal and terminal repeats (Fig. 1). The virion has a diameter of 150 to 200 nm and consists of an inner icosahedral capsid composed of 162 capsomeres surrounded by a tegument and of an envelope composed of two or more membranes. The envelope contains essential lipid; therefore, virus infectivity is inactivated by lipid solvents. The viral genome encodes nonstructural and structural proteins, including at least seven glycoproteins (gps), designated E, B, H, I, C, K, and L, which are at least partially analogous to the gps of HSV (20, 22). Unlike HSV, VZV has no glycoprotein D (gD). The gps are required for viral attachment and penetration of host cells. Immune recognition of gps and other virion components results in humoral and cellular responses to VZV. Immunity to nonstructural antigens undoubtedly also plays a role in host defense.

There are at least three distinct VZV genotypes based on nucleotide analysis (83). Antigenic variation, however, of VZV isolates has not been demonstrated. Restriction enzyme profiles of VZV isolates reveal that (i) there are no detectable differences between varicella and zoster isolates from the same individual (23), (ii) the agent is remarkably stable after passage in vitro and in vivo, and (iii) non-epidemiologically related strains may be differentiated with molecular assays (54). VZV shares major antigens with herpesviruses that produce varicella-like disease in various simian species (15), and it appears to share minor antigens with HSV (67).

EPIDEMIOLOGY AND TRANSMISSION

VZV is a highly cell-associated virus that is spread through the body by cell-to-cell contact. However, during acute infection, highly infectious cell-free VZV is produced in skin vesicles, accounting in large part for the high degree of contagion of varicella and zoster (9). VZV spreads by the airborne route and infects the respiratory mucosa; the source of most of the airborne virus is the vesicular skin lesions. Humans are the only natural host for VZV, so there is no animal reservoir for this virus.

CLINICAL SIGNIFICANCE

Varicella (chicken pox) and zoster represent different clinical manifestations of VZV infection. Varicella occurs most frequently in children and is characterized by a generalized vesicular exanthem often accompanied by fever. Zoster (shingles) usually occurs in adults or immunocompromised patients and consists of a painful, circumscribed eruption of vesicular lesions with accompanying inflammation of associated dorsal root or cranial nerve sensory ganglia. Varicella is the primary infection with VZV, whereas zoster is a secondary infection due to reactivation of latent VZV in sensory and cranial nerve ganglia. The following observations indicate that zoster results from reactivation of latent virus rather than reintroduction of virus into the host: (i) zoster does not exhibit the seasonal prevalence seen with varicella (late winter and spring in temperate climates); (ii) zoster does not occur commonly in parents of young children with chicken pox; (iii) latent virus is detectable in the sensory ganglia of autopsy specimens as indicated by the presence of VZV DNA (51), RNA (37, 49), and certain latency-associated proteins (50); and (iv) viruses causing the primary infection and subsequent zoster are the same as demonstrated by molecular studies of VZV isolates from patients with zoster after either natural chicken pox or varicella vaccination (73). Studies after natural varicella or immunization indicate that reinfection and reactivation of VZV may occur in the absence of clinical symptoms and that second attacks of clinical varicella are infrequent but may occur (24, 53). VZV infection may cause severe or fatal disease in individuals who are receiving immunosuppressive therapy or who have abnormalities in cell-mediated immune responses. Progressive, generalized varicella may occur in as many as 30% of children who acquire chicken pox while receiving chemotherapy and radiotherapy for cancer, with mortality of 7% (18).

VZV infections can be treated with acyclovir (ACV), and disease can be prevented by vaccination. Live attenuated

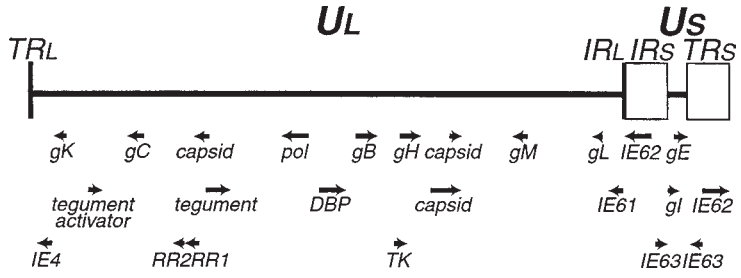

FIGURE 1 Diagram of the structure of the VZV genome. The linear double-stranded DNA consists of a long unique segment, U_L, of approximately 100 kbp, and a short unique sequence, U_S, of approximately 5.4 kbp, flanked by internal and terminal repeats of 6.8 kbp (TR_S and IR_S) and repeats flanking U_L (TR_L and IR_L). The ORF and direction of transcription (arrows) of some of the important genes are indicated below the map. RR, ribonucleotide reductase; DBP, DNA binding protein. Reprinted from reference 20.

varicella vaccine derived from the Japanese Oka strain was licensed in the United States for routine use in susceptible healthy persons in 1995. Since licensure, the incidence of varicella has decreased in sentinel counties in the United States by 71 to 84% (72). Approximately 15% of vaccinated individuals may develop "breakthrough" varicella caused by wild-type (WT) virus months to years after vaccination (23) because the vaccine is not 100% protective. However, it is 97% protective against severe disease (82). Vaccine-induced zoster is rare but has been reported in healthy and immunocompromised patients (45, 73). Infection of highly susceptible patients can be prevented through administration of varicella immunoglobulin.

Although the clinical presentations of varicella and zoster are likely to be easily recognizable to medical personnel, clinical symptoms such as rash may be diagnostically deceiving. Eruptions caused by VZV and HSV can be confused with each another. In one study, 13% of patients diagnosed as having zoster were found to have HSV infection on laboratory testing (36). The diagnosis of acute VZV disease is best made by testing vesicular skin lesion specimens rather than by determining relative antibody levels in acute- and convalescent-phase sera. Discrimination between VZV infection and other causes of vesicular eruptions such as enteroviruses, bacterial agents, and hypersensitivity reactions may also be necessary. Rapid diagnosis of suspected infection is important in a number of situations so that appropriate medical management such as antiviral therapy or passive immunization with varicella immunoglobulin prophylaxis for high-risk exposed persons can be initiated. These settings include (i) immunocompromised patients and their contacts, (ii) uncommon presentations such as pneumonia or encephalitis, (iii) some cases of breakthrough after vaccination, (iv) suspected reactions in the days to weeks following vaccination, and (v) zoster sine herpete, the presentation of cutaneous pain in a dermatomal distribution in the absence of a rash.

It is possible, although potentially inaccurate and slow, to diagnose acute VZV infection by measurement of immunoglobulin (IgM) titers to VZV; these determinations may have false-positive and false-negative results. Antibodies to VZV after varicella begin to be detected only after onset of rash, usually within 3 days. Titers of IgG rise for about 10 days and then fall, but not to susceptible levels in most cases. Zoster develops despite the presence of VZV antibodies, often in high titer. Serology thus is not the best way to diagnose acute VZV disease.

Determination of VZV serostatus may be helpful in several settings other than acute disease. Determining immune status is useful for guiding the management of exposed, high-risk immunocompromised individuals. It may also be useful for healthy adults with no history of varicella. Only approximately 25% of such individuals are susceptible (21); however, these susceptible adults have an increased risk of developing severe varicella. Adults raised in countries with tropical climates are also at increased risk of varicella compared to those from countries with temperate climates (18). Ideally, measurement of antibodies to VZV could be used to determine whether immunization has been successful in vaccinees, but available serologic tests are not sensitive enough for this purpose (see below).

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

To make a laboratory diagnosis of acute VZV infection, the presence of the virus or one of its products should be demonstrated in tissues or fluids obtained from the patient. Specimens usually examined for VZV are smears of vesicular lesions, skin scrapings, vesicular fluid, and tissues obtained at autopsy. Detection of VZV in affected tissues or fluids is diagnostic because asymptomatic patients do not shed virus. Tests to detect VZV and acceptable specimens are shown in Table 1 (29). Depending upon the individual circumstances, it is optimal to obtain material for immunofluorescence (IF) staining, PCR, and/or culture. If insufficient material is available for all determinations, IF and/or PCR is preferred and virus isolation may be forgone. A few diagnostic laboratories no longer use culture for diagnosis because IF and PCR are faster, less expensive, and more accurate.

Smears of Cellular Material from Lesions

To obtain specimens from lesions, a sterile needle is used to lift off the top of a vesicle. A sterile swab moistened in sterile transport medium is then used to vigorously swab the base of the lesion, applying enough pressure to collect epithelial cells without causing bleeding. Swabs can be placed in viral transport medium and taken rapidly to the laboratory where the laboratory personnel will prepare the slides by using methods such as vortexing and cytospin to concentrate cellular material. Alternatively, for direct detection of antigens, lesion material can be applied directly to slides at the bedside (11). Slides can then be transported to the laboratory for fixation and staining. It is essential that lesion

TABLE 1 Diagnostic tests for acute VZV infection[a]

Test	Comments
PCR	Becoming the diagnostic standard. Useful with scabs and skin lesions several days old, when culture is negative. Most sensitive assay. Useful for CSF, other body fluids, and tissues. Used to differentiate between WT and vaccine VZV disease in vaccine recipients. Rapid results (1–2 days).
DFA	Commercial kits available to use with fluorescein-conjugated monoclonal antibody to VZVgE. Results potentially available within a few hours. Possible to distinguish rapidly between HSV, VZV, and poxviruses (which would yield negative results).
Culture	Traditionally the diagnostic gold standard. May take up to 1 week for CPE. Positive only in the first 1–2 days of rash.
Serology	Limited value; requires 7–10 days between acute- and convalescent-phase sera. IgM may yield false-positive or false-negative results.

[a] Adapted from Hambleton and Gershon (29).

specimens contain a large number of infected epithelial cells for successful detection of antigen.

The time between specimen collection and testing is particularly critical for successful VZV isolation because the virus is very labile and infectivity is transient. Lesions present on skin for more than 4 days rarely yield infectious virus, but scrapings may give positive results by IF and/or PCR (5, 11, 16, 38, 40, 47, 52, 58, 82). Crusts from lesions do not yield infectious virus and are not suitable for IF staining or other specific antigen detection methods. However, crusts are very useful for PCR and may be expected to yield positive results in VZV infection.

Vesicular Fluid

Vesicular fluid contains cell-free virus. This material is therefore suitable for a variety of diagnostic assays (Table 1) but not for IF staining (due to its lack of cellularity). Fluid can be collected into capillary pipettes or syringes or on swabs. For culture, collection on swabs is least preferable. Virus collected on swabs is less stable than in vesicle fluid. In addition, medium used for specimen transport or virus elution during swab processing may impede recovery due to dilution and loss of virus infectivity.

Tissue

Smears of autopsy tissue for IF staining are prepared by excising three or four pieces of autopsy tissue about 10 to 15 mm in size, holding the tissue with forceps, and gently pressing the cut surface to the clean area of a slide. A series of impressions is made over an area 30 to 40 mm in length. Three or four slides should be prepared from each specimen. The slides are dried at room temperature for 15 to 20 min, fixed in cold acetone for 10 min, and stained by IF as described below. Suspensions of tissue are prepared for virus isolation as described in chapter 80. Skin biopsy material, for example, from a vesicular lesion, can be fixed, paraffinized, sectioned, and then stained with anti-VZV antibodies for demonstration of VZV antigens. Tissue samples can also be used for PCR analysis, but this will require nucleic acid extraction prior to amplification.

Blood (Buffy Coat) and CSF

Virus has been isolated from buffy coat cells (3, 55) and extremely rarely from cerebrospinal fluid (CSF) (35) from immunocompetent and immunocompromised patients. Demonstration of VZV in CSF by PCR appears to be more sensitive and useful than culture (33, 38, 52, 58, 63, 77, 89, 92). Whole blood should be promptly submitted to the laboratory in sterile anticoagulant other than heparin, for example, EDTA. CSF should be sent in a sterile tube.

Storage and Transport of Specimens

Specimens for virus isolation attempts should be inoculated into suitable cell cultures as soon as possible after collection. If inoculation must be delayed (ideally for no longer than 12 h), specimens may be transported or held (preferably in transport medium) on wet ice or in a refrigerator at 2 to 8°C. For longer storage, freezing at −70°C (or on dry ice) is required to preserve virus for isolation. Refrigeration is preferred for smears to be examined for viral antigen, but it is not necessary for cytological examination or for PCR. Specimens from vesicular lesions may be infectious; thus, suitable precautions should be taken in packing and storage to protect postal and laboratory personnel.

DIRECT DETECTION

Microscopy

For cytological examination of smears from vesicular lesions (Tzanck smears), cellular material from the base of vesicular lesions is collected and processed as described above. Prepared slides are fixed with methanol and stained with Giemsa stain buffered to pH 7.0 to 7.2. Microscopic examination reveals the presence of multinucleated giant cells with altered chromatin patterns (Fig. 2). Multiple viral capsids in the nucleus of the infected cell appear as eosinophilic intranuclear inclusions. This appearance is characteristic of infection with either VZV or HSV. Due to the availability of PCR and IF, this nonspecific technique is rarely useful today and cannot be recommended.

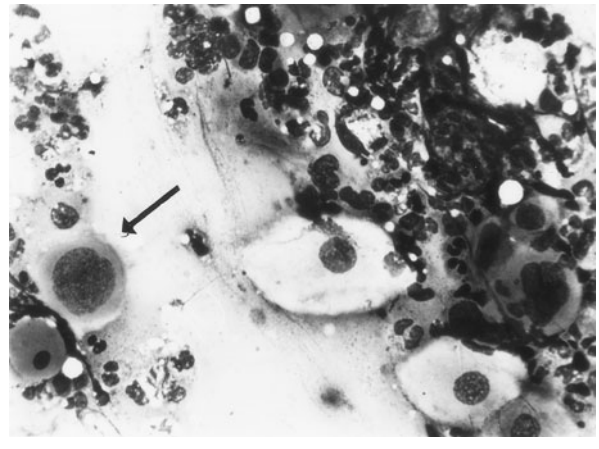

FIGURE 2 Giemsa-stained preparation of material from the base of a vesicular lesion. Magnification, ×102. The arrow indicates a giant cell with a folded nucleus characteristic of VZV or HSV.

Vesicular fluids can be examined by electron microscopy (EM), but it is not possible to differentiate between different herpesviruses by this method. The main diagnostic use of EM is to distinguish between a herpesvirus and agents such as poxviruses. To prepare slides for negative staining, a drop of the specimen is placed on a grid and blotted with filter paper. A drop of 3% phosphotungstic acid (prepared in distilled water buffered to neutrality with 1 N KOH) is then added and blotted. The specimen should be examined in an electron microscope as soon as possible. The demonstration of virus with typical herpesvirus morphology (Fig. 3) identifies the etiological agent as a member of this group and distinguishes it from the poxvirus group, but it does not provide a specific diagnosis of VZV infection. For confirmation of results, vesicular fluid can be fixed with glutaraldehyde and centrifuged. The pellet is then dehydrated and embedded in epoxy resin for examination by standard EM.

Antigen Detection by IF Staining

To prepare slides from swabbed lesions submitted in viral transport medium (VTM), swabs are vortexed in the original transport tube to release collected cells. The swab is discarded, and tubes are centrifuged to concentrate cells. Supernatant is decanted, and cells are resuspended in a small volume of phosphate-buffered saline (PBS). Cell suspensions are applied directly to slides or by using a cytospin. Most laboratories utilize Teflon-coated slides for this purpose. If individual direct IF staining for VZV and HSV is to be performed, at least three slides should be made. Slides are fixed in cold acetone for 15 min and air dried.

Slides of lesion specimens can be stained by the direct method using conjugated antibodies or with indirect methods (unlabeled anti-VZV antibodies followed by labeled secondary antibody). Monoclonal antibodies, which are preferred, have overcome problems previously encountered with immune VZV serum including the presence of unwanted antibodies to cellular proteins (19, 86). The use of human sera of uncertain antibody content is considered unreliable because these sera may contain antibodies to other human herpesviruses such as HSV and cytomegalovirus (CMV), from which it is important to distinguish VZV.

Direct fluorescent-antibody (DFA) staining is more specific than indirect staining, due to the potential for nonspecificity when more than one antibody is used in IF. Directly labeled antibodies to VZV gps are available from commercial sources such as Merifluor (Meridian Biosciences, Cincinnati, Ohio). There is extensive diagnostic experience with commercially produced monoclonal antibodies to VZV gE. In one study involving 133 patients, 79 (56%) specimens were positive for VZV: 40 (51%) by DFA alone, 2 (3%) by culture only, and 37 (47%) by both culture and DFA (11). The sensitivity of DFA was 97.5% (77 of 79) and 49.4% (39 of 79) for viral culture. Both procedures were highly specific. Rapid differentiation between HSV and VZV by simultaneously using antibody pools labeled with different fluorophores on a single cell spot such as SimulFluor reagents has been reported (8, 71). Slides with wells are commercially available (Trinity Biotech, Co., Jamestown, N.Y.) and highly convenient. Commercial monoclonal antibodies are usually supplied at working concentrations. Antibodies from noncommercial sources require titration against VZV-infected smears to determine appropriate concentrations for use in staining protocols. Working dilutions of these immune conjugates are usually prepared in PBS.

For staining, conjugated antibody is applied to the slide in a volume sufficient to cover the lesion smear (about 0.05 ml). Positive and negative control slides for VZV should also be stained with each conjugate as controls for conjugate reactivity and specificity. After addition of antibody, slides are incubated in a humidified atmosphere at 18 to 25°C for 30 min, rinsed twice in PBS (5 min for each rinsing), rinsed once in distilled water, and then air dried. Commercial mounting medium or buffered glycerol solution (9 parts glycerol and 1 part PBS) and a coverslip are then placed over the stained cells.

Examination with a fluorescence microscope at a magnification of ×100 to ×400 should reveal specific staining of 3+ to 4+ intensity, especially associated with the cytoplasm of the rounded epithelial cells. Positive specimens should contain two or more cells with typical apple green fluorescence (Fig. 4). Vesicular lesion specimens containing too few basal epithelial cells for definitive examination should be reported as unsatisfactory rather than negative.

Unconjugated mouse monoclonal antibodies can be used for indirect detection of VZV in clinical specimens. When using the indirect method, it is essential to use a conjugate against mouse immunoglobulins that is free from nonspecific reactivity with human tissue and serum components. This is determined by testing dilutions of the conjugate against infected and uninfected cell smears in the absence of intermediate mouse antibodies. The appropriate working dilutions of the VZV reagent and the anti-mouse globulin conjugate are determined by preliminary titration.

Nucleic Acid Amplification

Molecular methods are immensely practical for demonstrating VZV infection, and they are becoming the standard for diagnosis. In the past few years there has been a veritable explosion in publications concerning molecular techniques to identify VZV infections. Although the virus has been demonstrated using in situ hybridization (1, 74), this technique is

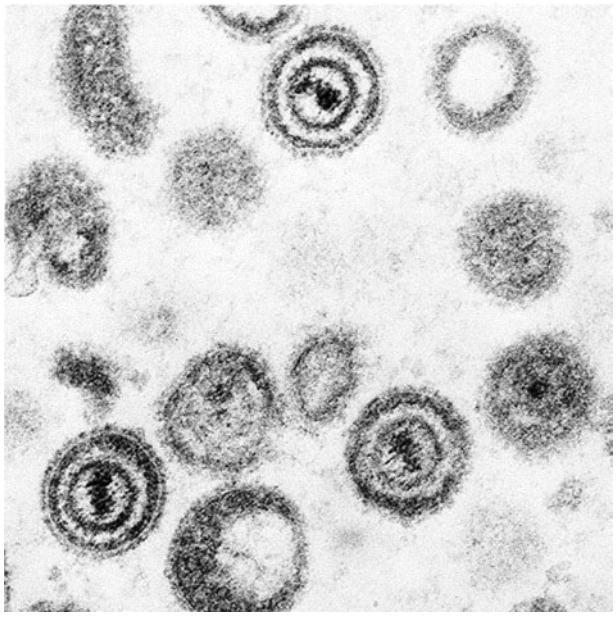

FIGURE 3 Electron micrograph of VZV. The specimen was obtained from a skin vesicle from an infant on day 1 of varicella. Magnification, ×100,000. Reprinted from *Cell* (9) with permission of Elsevier.

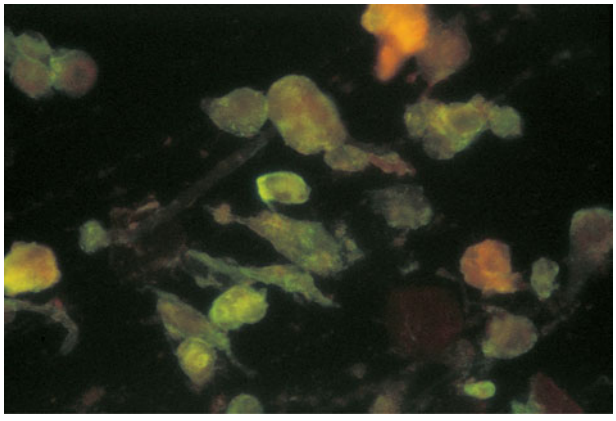

FIGURE 4 IF assay for detection of VZV antigens. A swab was obtained from an unroofed skin vesicle from a patient with a localized unilateral vesicular rash, from which a smear was made. The specimen was fixed and stained with monoclonal antibody to VZV gE. Numerous VZV positive cells are shown, establishing the diagnosis of zoster. Magnification, ×200.

not nearly as well developed nor as practical as nucleic acid amplification by PCR. Nucleic acid amplification is more sensitive than virus isolation partly because infectious virus is more labile than viral DNA (42, 70, 78, 81, 82).

PCR has been employed successfully for VZV detection from skin scrapings and vesicular fluid (4, 5, 16, 42, 44, 47, 70, 78, 81, 82, 85), respiratory and ocular secretions (10, 63, 78, 81, 84), blood (32, 76, 77, 84), and CSF (10, 13, 33, 38, 52, 58, 63, 77, 89, 92). Because PCR is often used to distinguish between vaccine and WT VZV infections, ORFs 54, 38, and 62 have been developed as popular amplification targets.

Many conventional PCR methods have been described (4, 7, 16, 33, 39, 40, 42, 47, 48, 52, 58, 89); however, homogeneous (real-time) PCR methods have quickly become the new standard due to faster processing time, decreased labor and expense, lower risk of laboratory contamination with amplicons, and comparable sensitivity to conventional PCR (6, 32, 70, 77, 78, 81, 84, 85). Table 2 describes information from published real-time PCR methods for VZV.

A significant advance associated with real-time PCR is the multiplex assay, used for simultaneous diagnosis of VZV and other viruses from a single specimen (10, 13, 52, 58, 76, 77). Real-time PCR assays have been employed to determine VZV viral loads in blood, a technique which may prove to be useful in the management of immunocompromised patients (32, 84).

Reagents for VZV DNA amplification by conventional (multiplex herpesvirus PCR; Argene, Inc., North Massapequa, N.Y.) and real-time PCR (Qiagen Diagnostics, Valencia, Calif.) are commercially available. Table 2 indicates published methods used for DNA extraction prior to amplification. Internal controls spiked into samples have been used to determine the efficacy of DNA extraction and if extraction has removed inhibitors of thermostable polymerases (6, 78). It is possible to purchase quantified VZV DNA for use as positive controls. Potential sources are Advanced Biotechnologies, Inc. (Columbia, Md.) and Zeptometrix Corp. (Buffalo, N.Y.).

Molecular methods for discriminating between WT and vaccine (Oka) strains directly in patient specimens have been developed (39, 42, 63, 73, 82). Such assays are useful in distinguishing the causes of rash in a number of settings including possible vaccine reactions (17, 73) and the rarely observed transmission of vaccine virus from healthy (41, 62, 73) or leukemic vaccinees (31) to varicella-susceptible contacts. Molecular typing has been reported for the rare identification of Oka-mediated herpes zoster in a vaccinated immunocompromised patient (45).

Conventional PCR assays with restriction fragment length polymorphism (RFLP) analysis of ORF6 and a combination of ORFs 38 and 54 (ORF38/54) (Table 3) have been described (39, 79). In a recent comparison of different typing methods it was found that BglI and PstI do not distinguish between parental Oka and Oka vaccine. In addition, inconsistent patterns of ORF62 BssHII and ORF6 AluI RFLP were found in vaccine preparations and vaccine-derived rashes. ORF62 SmaI and NaeI RFLPs, however,

were present in all vaccine preparations and vaccine-derived rashes, but not in all WT viruses tested. Therefore, SmaI and NaeI sites can be used successfully to identify rashes caused by varicella vaccine (60).

Real-time PCR assays based on sequence polymorphisms in ORF62 (7, 48) and ORF38 (80) have also been published. Such molecular assays reflect differences between circulating VZV strains; however, none have been identified as vaccine virus-attenuating mutations. The molecular basis for Oka vaccine strain attenuation is still under investigation. Because VZV varies in different geographical locations (60), analyses of ORFs 6 and 62 have been useful in Japan, while those involving ORF38/54, ORF62, and ORF38 are especially useful in western countries (59, 65) (Table 3).

ISOLATION

Host Systems

Diploid human cell lines or primary human cell cultures are the most sensitive host systems for isolation of VZV from clinical materials. Human fetal diploid kidney or human fetal diploid lung (HFDL) cells have been found to be highly satisfactory for primary isolation of VZV and are available from commercial sources (see chapter 81). Some laboratories have used human foreskin fibroblasts for isolation of VZV, but their sensitivity, compared to that of HFDL cells, is uncertain. Primary monkey kidney cells and embryonic guinea pig cells support growth of VZV but are less sensitive than HFDL cells. A549 cells, a human cell line of lung carcinoma cells, are sometimes used in the clinical laboratory in preference to HFDL (11, 64). MeWo cells, a human melanoma cell line, support growth of VZV (28), but plaques are more difficult to identify than those in fibroblast cultures. Cell cultures are initiated with Eagle minimal essential medium prepared in Hanks' or Earle's balanced salt solution (BSS) and supplemented with 10% heat-inactivated (56°C for 30 min) fetal bovine serum. Inoculated cell cultures are maintained in Eagle minimal essential medium prepared in Earle's BSS supplemented with 2% inactivated fetal bovine serum. Although this medium maintains the cultures for 14 days without a fluid change (a period usually sufficient for the development of a specific viral cytopathic effect [CPE]), a change of medium at least once a week is preferable. VZV cannot be isolated in mouse or embryonated egg host cell systems.

Virus Subpassage and Storage

Infectious VZV remains in close association with the host cell in cell cultures, and therefore it is necessary to use virus-infected cells rather than culture fluids as an inoculum for serial propagation of the virus. Trypsin-dispersed infected cells are most suitable for subpassage of VZV. The medium is removed from cell cultures in which CPE involves approximately 50% of the cell sheet and rinsed briefly with PBS, and about 1 ml of 0.25% trypsin solution is added to each tube culture. After the cells begin to round up (usually after 60 s at room temperature), most of the trypsin is removed, and the small amount of residual trypsin is distributed over the monolayer. As soon as the cells detach from the surface, they are dispersed in the original volume of growth medium and inoculated into fresh cell cultures.

Virus in infected cells can be stored in the frozen state if the viability of the cells is maintained through the use of a cryoprotective agent such as dimethyl sulfoxide (DMSO) in the freezing medium. Infected cells are dispersed with trypsin as described above and then suspended in 80% heat-inactivated fetal bovine serum and 20% DMSO. Infectious virus can be recovered after storage at −70°C for 18 months or more, but infectivity is preserved more effectively by storage of the infected cells in liquid nitrogen. High-titer cell-free virus prepared by sonic treatment of infected cells is stable at −70°C in Hanks' BSS for at least 5 years, although titers decrease with time (68).

IDENTIFICATION

Presumptive Identification

Presumptive identification of VZV may be made on the basis of cells in which virus grows and CPE. Unlike HSV, VZV fails to produce CPE in rabbit or hamster kidney cell cultures. Initially, VZV CPE consists of small, discrete crescent-shaped foci of rounded and swollen refractile cells (Fig. 5). CPE may appear from 2 to 14 days after inoculation of the cultures with clinical materials, but in most instances it is first apparent after 3 to 7 days. The foci of infected cells enlarge and may slowly involve much of the monolayer. The spread of infection can be accelerated by trypsin treatment and replating.

VZV CPE is more focal in nature and progresses more slowly than that of HSV. The specimen source and clinical presentation should usually prevent confusion between VZV and human CMV. However, it may be necessary to distinguish between these herpesviruses if isolations are made from tissue specimens. Production of CPE by CMV generally is slower and more focal in nature than that produced by VZV. Unlike CMV, VZV usually produces CPE in primary monkey kidney cells after initial isolation.

Specific Identification

Identification of VZV isolated in cell cultures is performed by direct IF staining when the inoculated cultures show distinct plaques. Trypsin-dispersed cells from an infected tube culture are suspended in 3 ml of PBS with 2% fetal bovine serum, and cells are sedimented by centrifugation at 1,000 × *g* for 5 min. Cells are resuspended in 0.2 ml of PBS and spotted onto slides. Alternatively, slides can be prepared using cells that have been scraped into a small volume of PBS after monolayers are washed twice with PBS. The slides are fixed and stained as described above for antigen detection by DFA. Positive-control slides should be included in each run. Positive results are based upon staining of 3+ to 4+ intensity with the VZV conjugate. Infected cells can be easily distinguished from uninfected cells by using the Evans blue counterstain reagent that is included in commercial kits.

FIGURE 5 CPE of VZV in human fetal diploid lung (HFDL), showing a characteristic viral plaque. Magnification, ×100.

Identification of VZV Isolates by Use of Shell Vials

The shell vial method is a combination technique involving virus culture and early specific identification of virus with monoclonal antibody prior to development of obvious CPE. It is more rapid and sensitive for VZV detection than conventional tube culture (26, 66, 87). The disadvantages of this method include the lack of a viable isolate after the virus has been identified and the inability to identify other viruses in clinical specimens. Therefore, some clinical laboratories may also inoculate standard tube cultures during specimen processing if a virus resistant to antivirals is suspected.

Shell vials containing coverslips with monolayers of human diploid fibroblast cells are commercially available from many sources. One useful product is H&V Mix (Diagnostic Hybrids, Athens, Ohio). This is a proprietary mix of CV-1 and MRC-5 cells sold in shell vial and plate format for the detection of HSV, VZV, and CMV (30). Swabs or vesicular fluids are diluted in approximately 1 ml of medium, and 0.2 ml is inoculated directly into shell vials from which medium has been removed. Vials are centrifuged for 40 min at 700 × *g* at room temperature. After centrifugation, 2 ml of maintenance medium is added to each vial. One set of positive and negative controls should be set up daily. Vials can be incubated at 35 to 37°C for 1 to 3 and 5 days. HSV can be detected after 24 h of incubation, but VZV usually takes an additional day, and CMV may not be obvious for 5 to 7 days. After incubation, the vials are washed twice with 1 ml of PBS and monolayers are fixed in 2 ml of cold acetone for 10 min. Coverslips are either stored at −70°C or used immediately. For staining, one vial is incubated with 1 or 2 drops of commercial fluorescein-conjugated monoclonal antibody to VZV (see "Antigen Detection by IF Staining" above for reagents) for 15 to 30 min at room temperature or 37°C. The vials are washed with PBS twice and quickly rinsed with distilled water once. The coverslips are removed from the vials, air dried, and placed cell side down on microscope slides in mounting medium. Positive results are based on staining of 3+ to 4+ intensity with the VZV conjugate.

Preparation of Control Slides for IF Staining

Control slides are required for IF staining for antigen detection in lesion smears, for identification of viral isolates, and as an antigen substrate for antibody assays. Negative control slides are prepared from uninfected monolayers. Positive control slides are prepared using stock virus that has been subpassaged two or three times to increase infectivity. Fresh monolayers are infected with subpassaged virus, and cells are harvested when cultures show about 50% CPE, usually 24 h after inoculation. Infected and uninfected cells are dispersed with trypsin, suspended in 0.1 M PBS (pH 7.2 to 7.5) with 2% fetal bovine serum, and sedimented by centrifugation by 1,000 × *g* for 5 min. The supernatant fluids are removed, and the packed cells are resuspended in PBS with 2% fetal bovine serum, using a volume of 0.01 ml per tube culture or 0.4 ml per 32-oz (ca. 0.95-liter) flask culture. Smears approximately 5 mm in diameter are made from this cell suspension by placing small drops (approximately 0.025 ml) on microscope slides or by using a cytospin apparatus. The smears are dried at room temperature, fixed with cold

acetone for 10 min, and then dried at room temperature. Smears can be stored at −70°C until they are used. Before staining, the smears are ringed, if necessary, with a liquid embroidery pen, wax pencil, or diamond pen to retain the conjugate.

SEROLOGICAL METHODS

Serological tests are used for laboratory diagnosis of varicella or zoster infections and for determining immunity status to varicella. Serologic testing is particularly useful for adults who have no history of varicella, since over 75% have detectable VZV antibody and therefore presumably experienced mild or subclinical varicella.

Today, viral diagnostic laboratories are using mainly enzyme immunoassays (EIAs) as their principal serological tool. Alternative methods for serodiagnosis of VZV infections are indirect IF with fluorescent-antibody staining of membrane antigens in VZV-infected cells (FAMA) (88), anticomplement immunofluorescence (ACIF) staining (57), and latex agglutination (LA) (21, 75). Neutralizing antibody to VZV can be assayed by plaque reduction techniques with cell-free virus obtained by sonic treatment of infected human diploid cells (69); however, this is primarily a research rather than a routine diagnostic tool.

The FAMA assay is generally considered the "gold standard" for VZV serological procedures. The sensitivity and specificity of other serologic assays have been compared to those of FAMA in a few studies. In one study of healthy adults, the sensitivity, specificity, positive predictive value, and negative predictive value of EIA compared to FAMA were 86.1, 98.6, 98.9, and 82.1% (14). FAMA and LA assays are also more sensitive than EIA for demonstration of antibodies after vaccination (21, 61, 75). In a study of vaccinated adults, the sensitivity and specificity of EIA (VIDAS Varicella-Zoster IgG; bioMerieux, Hazelwood, Mo.) were 74 and 89% compared to those of FAMA (61). It is noteworthy that 10% of adults were positive by EIA but negative by FAMA prior to vaccination in this study, suggesting that this EIA is less specific than FAMA.

FAMA and LA results have correlated well with resistance or susceptibility to infection in clinical settings (18). In a study comparing FAMA with LA, approximately 80% of 77 sera from healthy adults tested were seropositive up to 11 years after vaccination; there were no significant differences between the rates of positivity of LA and FAMA (21). A newly developed IF antibody assay using a cell line of lung carcinoma infected with VZV has been described and compares favorably with FAMA (64). While it is sensitive, the FAMA method is somewhat cumbersome. Other disadvantages include the requirement for live unfixed VZV-infected cells and the lack of automation.

Traditionally for serodiagnosis of infection, acute- and convalescent-phase sera must be analyzed in the same test run. A fourfold or greater increase in IgG antibody titer between acute- and convalescent-phase sera is considered diagnostically significant. For EIAs, however, fourfold increases in antibody are not measured. Values for significant increases in antibody titer must be determined on an individual basis for each particular assay. For commercial kits, the diagnostically significant increase is determined by the manufacturer and provided in the instruction manual. In varicella, antibodies are usually demonstrable within several days after onset of rash, and they reach a peak 2 to 3 weeks later. The antibody increase is usually more rapid in zoster, and antibodies are detectable at the time of rash onset.

EIAs

A number of EIAs are commercially manufactured and have been evaluated (14, 43, 61). A few examples of some commercial tests are VZV ELISA (Zeus Scientific, Raritan, N.J.), VZV IgG ELISA (Trinity Biotech, Bray, Ireland), VIDAS immunoassay system (BioMerieux, Durham, N.C.), VZV EIA (Panbio, Sinnamon Park, Queensland, Australia), and VZV ELISA (Walpoole Labs, Princeton, N.J.). The main advantages of these assays are their automated formats and availability. Assays are performed according to the manufacturer's package inserts. In general, these tests are fairly specific; however, because they are relatively insensitive, some adults with immunity to varicella may be misidentified as susceptible to chicken pox. False-positive tests have also been reported (61). EIAs are more effective for screening individuals (especially adults) who might have had previous natural varicella than for identifying persons who have responded to immunization. It is not uncommon for a vaccinee to have a negative EIA but have antibodies to VZV detectable with a more sensitive test.

FAMA Test

For the FAMA test, serial twofold dilutions of serum are made in PBS beginning at 1:2 in a 96-well round-bottom microtiter plate. Heat inactivation of serum is not required and should not be done since it may lead to nonspecific results. Cells infected with VZV are harvested when they exhibit 50 to 75% CPE. Medium is poured off the cultures, and the cells are scraped into any remaining medium and centrifuged at 700 × *g* for 2 min. The cells are taken up in PBS (about 1.5 ml/150 cm^2 flask) and dispersed in 0.025-ml aliquots into microtiter plates containing dilutions of serum. Cells are then incubated for 30 min at room temperature in a moist chamber. PBS is then added to fill the wells, and the plate is centrifuged at 1,000 × *g* at 4°C for 10 min. PBS is removed by rapidly flipping the plate upside down, and the washing step is repeated. A working dilution of fluorescein-labeled anti-human immunoglobulin (0.025 ml) is added to each well, and plates are incubated for 30 min at room temperature. This assay may also be used to measure specific VZV IgG, IgM, or IgA antibody by using corresponding fluorescein-labeled anti-human conjugates. After two washing steps, a drop of buffered glycerol (9 parts glycerol to 1 part PBS) is added to each well, and the cells are removed with an aspirator and placed on microscope slides. The cells are covered with a glass coverslip, which is sealed with nail polish. The slides are then examined by fluorescence microscopy. The antibody titer is the highest dilution of serum yielding membrane fluorescence.

The sensitivity of this assay is likely due to the preservation of VZV glycoprotein antigen conformation on the surface of infected cells. These structures are probably altered by fixation, leading to decreased sensitivity by other methods. A modified FAMA assay in which cells are briefly fixed in dilute glutaraldehyde (0.075% for 60 s at 0°C) and stored at −70°C has, however, been described (90). The advantage of this particular method is that virus-infected cells may be stored, and a continuous culture for VZV is not required in the laboratory. A positive FAMA test from a seropositive individual is shown in Fig. 6.

ACIF Test

The ACIF method has a sensitivity comparable to those of FAMA and LA, permitting examination of serum dilutions as low as 1:2 or 1:4, and avoids nonspecific reactivity indirect IF staining (57). The advantage of the ACIF test is its

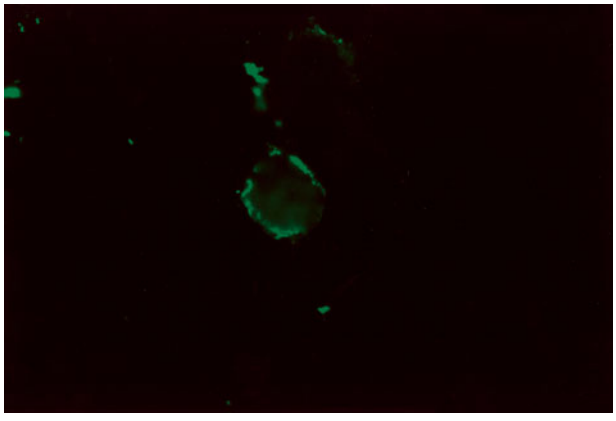

FIGURE 6 Positive FAMA test for VZV antibodies. Note surface staining of unfixed HFDL infected with VZV. Positive results of ≥1:4 are consistent with immunity to VZV. Magnification, ×525.

specificity; its disadvantages include the inability to automate the test, the high degree of training required to perform it, and the inability to distinguish between IgG and IgM against VZV.

LA Assay

The LA method is a commercial assay (VZVScan; Becton Dickinson, Sparks, Md.) that uses emulsified latex particles coated with VZV gps (21, 75). Prior to the test, all reagents stored at 4°C are warmed to room temperature. Serial twofold dilutions of sera are made in 1-cm-diameter flat circles on a wax-coated 10- by 12-cm card supplied by the manufacturer, and the serum is spread evenly over the circle. A 0.025-ml drop of latex emulsion is added to each circle directly from the supplied reagent bottle. The card is briefly rotated by hand and placed on a mechanical rotator for 10 min at 90 to 110 rpm in a moist chamber. Circles are then examined for agglutination (obvious clumping of the latex particles) using a high-intensity desktop lamp. To screen for immunity status, it is recommended that sera be tested at 1:4 and 1:40 dilutions, although the package insert specifies an initial dilution of 1:2. A titer of 1:4 is more consistent with immunity to varicella in our experience. A positive reaction in one or both wells is highly correlated with immunity to varicella. If possible, sera (particularly from adults) that are negative at screening dilutions should be retested at dilutions of 1:4 to 1:64 to avoid false-negative results due to prozone phenomena. In our experience, testing of serial dilutions is more likely to provide an accurate assessment of immunity to varicella. False-positive reactions are rare (75). To diagnose VZV infection, serial twofold dilutions of acute- and convalescent-phase sera are tested beginning at a dilution of 1:4. In convalescent-phase specimens, care must be taken to make certain that high antibody titers such as those greater than 1:4,096 are not missed due to a prozone effect. Thus, if a negative result is seen in a convalescent-phase serum specimen, the serum should be retested using higher serum dilutions. The chief advantages of the LA test are its simplicity, low cost, and the rapidity with which it may be performed (15 to 30 min). Its disadvantages include lack of automation, inability to demonstrate IgM, requirement for training to correctly interpret the appearance of agglutinated latex, and the occurrence of prozone reactions in 1 to 5% of sera.

ANTIVIRAL SUSCEPTIBILITIES

Methods to detect viruses resistant to ACV have not been standardized and are not widely performed. Most VZVs are sensitive to 1.0 to 2.0 μg/ml concentrations of ACV (reported range, 0.3 to 10.8 μg/ml) (2). VZV isolates that are resistant to ACV are unusual but have been described, particularly from patients with underlying human immunodeficiency virus infection who have received multiple courses of ACV for frequent recurrences of VZV infection (34, 46, 56). One ACV-resistant Oka strain virus has been described, from an immunocompromised patient with a chronic form of zoster following immunization (45).

EVALUATION AND INTERPRETATION OF RESULTS

Demonstration of virus growth, specific antigen, or other viral products such as DNA in skin lesion material or autopsy tissue is diagnostic of active VZV infection, since asymptomatic shedding, as occurs with some of the other herpesviruses such as HSV and CMV, is not known to occur. The presence of VZV IgM in serum is suggestive but not definitive of acute VZV infection because false positives occur.

The combination of IF staining and/or PCR is used in some laboratories as the first line for rapid diagnosis. Obtaining smears from vesicular lesions for IF staining should be attempted wherever feasible, because this method is more rapid and sensitive than culture (11, 82, 91). PCR is more sensitive than IF (82). Studies have shown virus isolation, even in optimal cell culture systems, to be less sensitive than IF staining or PCR on lesion materials for diagnosis of VZV infection (5, 27, 82). Infectious virus persists for a shorter length of time in vesicles and is more labile than viral particles and antigens. The lability of viral infectivity in vesicular lesions and the host immune response that inactivates virus in the skin with time probably both contribute to the difficulty of virus isolation. Shell vial methods are a practical alternative to tube culture since they are more sensitive and rapid, providing significant information within 24 to 48 h.

Currently the disadvantages of VZV PCR include false-positive reactions due to contamination of specimens with previously amplified VZV DNA (a problem commonly encountered with PCR in general) and the somewhat limited availability of commercial reagents. These drawbacks are minor and easily managed, so virus isolation and IF are being increasingly supplanted by PCR for diagnosis of VZV infection.

In the absence of a similar rise to HSV antigen, a ≥4-fold increase in IgG titer to VZV antigen in convalescent serum or a significantly increased titer by EIA is diagnostic of a current VZV infection. However, a high proportion (up to one-third) of individuals with primary HSV infections who have experienced a prior VZV infection show a heterotypic antibody response to VZV antigen, making the differentiation between VZV and HSV infection difficult in the absence of clear-cut clinical findings. Thus, not only is serology slower than IF and PCR for diagnosis of VZV infection, but also it is less reliable. The best method for diagnosis of acute VZV disease today, including possible rashes associated with varicella vaccination, continues to be by demonstration of the virus, its antigens, or its DNA.

Although negative results by FAMA, ACIF, LA, and EIA are reliable indicators of susceptibility to varicella, the occurrence of clinical varicella in a few individuals with low titers of VZV antibody demonstrated by FAMA and ACIF indicates that low levels of antibody demonstrable by these

sensitive methods are not always a reliable indication of protection against clinical illness. This is particularly true for immunocompromised patients. Patients who have received blood transfusions may have falsely positive FAMA tests for some months. Occasional second attacks of varicella can occur in VZV-seropositive healthy individuals. Detection of serum antibody to VZV by FAMA in healthy individuals has correlated with protection in up to 96% of persons in one study (25). More recently, similar accuracy levels of the FAMA and LA assays have been demonstrated with healthy subjects (21, 75). In general, testing sera from immunocompromised persons for antibodies to VZV may be less reliable for determining immunity status to varicella than simply asking the patient whether he/she had previous varicella. In contrast, testing sera from healthy individuals, particularly adults with no history of varicella, is a useful and reliable means to identify persons susceptible or immune to varicella.

The work described in this chapter was supported in part by grants AI 24021 and AI 127187 from the National Institute of Allergy and Infectious Diseases.

Human Cytomegalovirus

RICHARD L. HODINKA

102

TAXONOMY

Human cytomegalovirus (CMV), formally designated human herpesvirus 5 (HHV-5) by the International Committee on Taxonomy of Viruses, is a member of the family *Herpesviridae,* which includes herpes simplex virus types 1 (HHV-1) and 2 (HHV-2), varicella-zoster virus (HHV-3), Epstein-Barr virus (HHV-4), and human herpesviruses 6, 7, and 8. It is classified in the subfamily *Betaherpesvirinae* with cytomegaloviruses of other animal species based on its tropism for salivary glands, slow growth in cell culture, and strict species specificity. Human CMV is the type species of the genus *Cytomegalovirus,* and its name is derived from the enlargement of cells (cyto = cell, mega = large) infected by the virus. Regions of genome sequence homology between CMV and herpesviruses 6 and 7 have been identified, and HHV-6 and HHV-7 are now classified with CMV among the betaherpesviruses.

DESCRIPTION OF THE AGENT

Complete CMV particles have a diameter of 120 to 200 nm and consist of a core containing a 235-kb linear double-stranded DNA genome, an icosahedral capsid with 162 capsomeres, an amorphous tegument or matrix, and a surrounding phospholipid-rich envelope. Electron microscopic features of CMV include virions morphologically indistinguishable from those of other herpesviruses, a high ratio of defective viral particles, and the presence of spherical particles called dense bodies. Viral replication occurs in the nucleus of the host cell and involves the expression of immediate-early (α), early (β), and late (γ) classes of genes. The viral envelope is formed as assembled nucleocapsids bud from the inner surface of the nuclear membrane.

Molecular virologic techniques have been used to study variation among CMV strains. DNA-DNA reassociation kinetics analysis has shown that various CMV strains have considerable homology to AD-169, a standard laboratory strain; restriction endonuclease analysis has shown that DNAs from various strains have similar but distinctive fragment migration patterns. These studies suggest that CMV strains are closely related to each other, more so than are herpes simplex virus types 1 and 2. Antigenic heterogeneity among CMV strains has been detected in cross-neutralization and other serologic assays, but evidence for distinct serotypes is limited.

CMV is inactivated by a number of physical and chemical treatments, including heat (56°C for 30 min), low pH, lipid solvents, UV light, and cycles of freezing and thawing.

EPIDEMIOLOGY AND TRANSMISSION

CMV has a worldwide distribution and infects humans of all ages, with no seasonal or epidemic patterns of transmission. The seroprevalence of CMV increases with age in all populations and ranges from 40 to 100%; the virus is acquired earlier in life and the prevalence is highest among lower socioeconomic groups in crowded living conditions. CMV can be transmitted vertically and horizontally, and infections are classified as being acquired before birth (congenital), at the time of delivery (perinatal), or later in life (postnatal).

Most infections are acquired by direct close personal contact with individuals who are shedding virus. Since CMV has been detected in many body fluids, including saliva, urine, breast milk, tears, stool, vaginal and cervical secretions, blood, and semen, it is clear that transmission can occur in a variety of ways. Prolonged shedding of virus after congenital or acquired CMV infection contributes to the ease of virus spread; virus may be excreted for weeks, months, or even years following a primary infection.

Transplacental infection of the fetus can occur following primary or recurrent infection of a pregnant woman, but the risk of CMV transmission to the fetus and the rate of symptomatic fetal infection are much higher with primary maternal infection. Newborns can also acquire infection at the time of delivery by contact with virus in the birth canal. Nearly 10% of women shed CMV in the genital tract at or near the time of delivery, and virus is transmitted to approximately 50% of the newborns. Such infants begin to excrete virus at 3 to 12 weeks of age but usually remain asymptomatic. Mother-to-infant transmission of CMV through breast milk is very common; low-birth-weight premature infants are at greatest risk for developing disease. Of children who attend day care centers and enter as toddlers, 20 to 70% experience CMV infection over a 1- to 2-year period. Infection is usually asymptomatic, but the children may transmit CMV to their parents and other caregivers, posing a risk to an unborn fetus if a woman is pregnant at the time. In adolescents and adults, sexual transmission of CMV may occur and is an important route of CMV spread.

Similar to infections with other herpesviruses, primary infection with CMV results in the establishment of a persistent or latent infection. The sites of latent infection are thought to include various tissues, endothelial cells, and leukocytes. Therefore, CMV can be transmitted by blood transfusion and organ transplantation. Reactivation of the virus can occur in response to different stimuli, particularly immunosuppression.

CLINICAL SIGNIFICANCE

CMV infections are common and usually asymptomatic in otherwise healthy children and adults; however, the incidence and spectrum of disease in newborns and in immunocompromised hosts establish this virus as an important human pathogen.

CMV infection has been detected in 0.2 to 2.5% of newborn infants and is the most common identified cause of congenital infection. Fewer than 5% of congenitally infected infants develop symptoms during the newborn period; possible manifestations range from severe disease with any combination of intrauterine growth retardation, jaundice, hepatosplenomegaly, petechiae, thrombocytopenic purpura, myocarditis, pneumonitis, central nervous system abnormalities, and chorioretinitis to more limited involvement. Symptomatic infants may die of complications within the first months of life; more commonly, they survive but are neurologically damaged. It is now recognized that even congenitally infected infants who are asymptomatic at birth may develop hearing defects or psychomotor and/or intellectual disabilities later in life. Thus far, it appears that perinatally infected infants do not develop late neurologic sequelae of infection.

The vast majority of immunocompetent children and adults who acquire CMV infection postnatally remain asymptomatic. In high-risk premature newborns infected as a result of blood transfusions, morbidity and mortality can be significant and hepatosplenomegaly, thrombocytopenia, atypical lymphocytosis, and hemolytic anemia have been described. Symptoms in young adults can mimic the infectious mononucleosis syndrome caused by Epstein-Barr virus and include prolonged fever (persisting for 2 to 3 weeks), malaise, an atypical lymphocytosis, and mild hepatitis without the production of heterophile antibody. More recently, a link between CMV infection in the immunocompetent host and atherosclerosis has been suggested, and there is growing evidence that CMV is a contributing factor to vascular disease in certain individuals (for a review, see reference 74).

CMV infections are frequent and occasionally severe in children or adults with congenital or acquired defects of cellular immunity, such as patients with AIDS, cancer patients (particularly those with leukemia and lymphoma receiving chemotherapy), and recipients of solid-organ and bone marrow transplants. Infections in these patients may be due to reactivation of latent virus or primary infection or reinfection with exogenous virus, which may be introduced by blood transfusions or by the grafted organ. Symptoms tend to be most severe after primary infection; however, reactivation infection or reinfection in a severely immunocompromised host may also cause serious illness. Active infection usually occurs between 1 and 4 months after transplantation, when patients are at the height of their immunosuppression, or when $CD4^+$ lymphocyte counts drop below 50 cells/μl for individuals infected with the human immunodeficiency virus. The frequency and severity of CMV infection in organ transplant recipients are variable and depend on the type of transplant, the source of the donated organ, the immune status of the recipient, and the duration of the immunosuppressive therapy. The major symptoms in these patients usually include fever, malaise, lethargy, myalgia or arthralgia, leukopenia, thrombocytopenia, and hepatitis. Specific organ damage may lead to pneumonitis in recipients of lung or heart-lung transplants; the development of myocarditis, retinitis, or accelerated vascular damage and atherosclerosis after cardiac transplantation; hepatitis and pancreatitis in liver and pancreas transplant recipients, respectively; and gastrointestinal disease. CMV infection in transplant recipients has also been associated with delayed or failed bone marrow engraftment, an increased incidence or severity of graft-versus-host disease, and an increased risk of graft rejection in solid-organ transplants. Death may occur as a result of various complications, including bacterial and fungal superinfections. CMV infection, particularly when associated with pneumonitis, is an important cause of morbidity and mortality after bone marrow transplantation. In patients infected with human immunodeficiency virus, CMV is an important cause of fever, sight-threatening retinitis, encephalitis, polyradiculomyelopathy, and gastrointestinal infections including esophagitis, gastritis, and ulcerative colitis.

Antiviral drugs, including ganciclovir, valganciclovir, foscarnet, cidofovir, and fomivirsen, have been licensed by the U.S. Food and Drug Administration (FDA) for treatment of CMV retinitis in immunocompromised hosts, particularly in patients with AIDS. Ganciclovir, its oral prodrug, valganciclovir, valacyclovir, cidofovir, and foscarnet have been used with or without immunoglobulin products containing CMV-specific antibodies in various strategies as universal prophylaxis, preemptive therapy, and treatment for CMV disease in transplant recipients (for a review, see reference 84). Experience in using these antiviral drugs in the settings of congenital and perinatal CMV infection is limited. There are currently no licensed vaccines available for prevention of CMV disease. A number of candidate vaccines have been developed and are in various stages of preclinical and clinical evaluation (for a review, see reference 91).

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

At present, a variety of methods are available for use in the diagnosis and management of patients infected with CMV. These include isolation of the virus in cell culture, histologic and cytologic techniques, assays for the direct detection and/or quantification of viral proteins or nucleic acids, serologic tests, and phenotypic and genotypic tests to screen for antiviral drug resistance. The selection of assays to perform and the choice of specimen(s) to be tested depend on the patient population and clinical situation and the intended use of the individual tests. In the immunocompromised host, virologic or serologic detection of CMV indicates infection but does not establish whether the infection is responsible for symptomatic illness. CMV is ubiquitous, and there is a high rate of asymptomatic excretion in patients who never progress to disease. Reactivation of latent virus is also common, and other pathogens are simultaneously present in patients with overt disease. To implicate CMV as the cause of an illness, laboratory confirmation of active infection in an appropriate clinical setting is required.

Specimens for Direct Detection

Tissue specimens, respiratory secretions, urine sediment, cerebrospinal fluid (CSF), amniotic fluid, and peripheral blood

leukocytes have been used for the direct detection of CMV antigens or nucleic acids. Whole blood, plasma obtained from anticoagulated whole blood, serum obtained from clotted blood, or purified peripheral blood leukocytes have all been used to quantitate CMV DNA in molecular amplification assays (20, 72, 83, 97). There is considerable debate about which blood compartment is best suited for the detection of CMV DNA. The most experience to date is with peripheral blood leukocytes and plasma. More recently, whole blood has been shown to yield the highest levels of CMV DNA of all blood compartments examined (83) and may represent the most practical specimen for laboratories to process for use in the diagnosis and monitoring of CMV disease since it requires little processing prior to extraction of the DNA. Also, delays in sample preparation can result in lysis of leukocytes after blood collection, which may result in inaccurate quantitation of CMV DNA if either whole blood, purified leukocytes, or plasma is used as specimen sources (88). A potential limitation for the use of whole blood is the possibility of variation in leukocyte counts from patient to patient; this may lead to erroneous quantitative measurements if fluctuations in cell numbers are not taken into consideration. Plasma or serum may be preferable in neutropenic patients who may have inadequate numbers of leukocytes for testing. For the CMV antigenemia assay, a total of 4 to 7 ml of whole blood is usually recommended for collection, but at least 10 ml of blood may be required for patients with severe neutropenia (e.g., absolute neutrophil counts of less than 200/mm^3). Any type of anticoagulated blood can be used, including blood collected in heparin, EDTA, sodium citrate, or acid citrate dextrose, although the most extensive experience has been with using heparin or EDTA. The blood should be kept at 4°C during storage and transport and should be processed within 6 to 8 h of collection for accurate and reliable quantitation of the viral load and within 24 h and no later than 48 h for qualitative testing (59). A decrease in quantitative antigenemia levels after storage of blood specimens for 24 to 48 h has been described, although most positive specimens remain positive after this time when held at 4°C (11, 59). Specimens for molecular amplification should be stored at 4°C immediately after collection and then promptly transported to the laboratory for processing. Single-use aliquots of processed specimens should be placed in multiple cryovials for testing and storage. By being processed in this manner, specimens are not frozen and thawed repeatedly and are never returned to the original specimen cryovial, thereby avoiding possible degradation of the DNA and cross-contamination of specimens, respectively. If not tested immediately, specimens should be promptly frozen and stored at –70°C. Impression smears, frozen sections, or formaldehyde-fixed and paraffin-embedded material can be used for in situ hybridization or histopathologic examination of tissue specimens.

Specimens for Virus Isolation

CMV can be isolated from a variety of body fluids; however, urine, respiratory secretions (e.g., saliva, throat washings, and bronchoalveolar lavage fluid), and anticoagulated whole blood (leukocytes) are most common for diagnostic purposes. Urine specimens should be clean-voided specimens. Because excretion of CMV in urine is intermittent, increased recovery of the virus is possible by processing more than one specimen. In the evaluation of immunocompromised patients, blood leukocyte cultures are particularly useful. Detection of CMV in leukocytes is often a better indicator of symptomatic CMV infection than is shedding of virus in urine or respiratory secretions. Bronchial washings and tissue biopsy and autopsy specimens, particularly of lungs, kidneys, spleen, liver, brain, and retinas, also can be processed for virus isolation. Recovery of CMV from tissues is strong evidence for organ involvement. All tissue specimens should be placed in a suitable viral transport medium immediately after collection. The details of specimen collection and processing are given in chapter 80. Since CMV loses infectivity when subjected to freezing and thawing, specimens for virus isolation should be kept at 4°C in an ice-water bath or refrigerator until they can be used to inoculate cultures, preferably within a few hours after collection. When prolonged transport times are unavoidable, infectivity is reasonably well preserved for at least 48 h at 4°C. In general, it is never a good idea to hold specimens for CMV isolation at room temperature and specimens should be transported to the laboratory as quickly as possible after collection to maintain viability of the virus. If freezing the specimen is necessary, an equal volume of 0.4 M sucrose-phosphate added to the specimen helps preserve viral infectivity. All frozen specimens should be stored at −60 to −80°C or in liquid nitrogen. Loss of virus infectivity occurs if specimens are stored at −20°C.

Specimens for Serologic Testing

Single serum specimens are useful in screening for evidence of past infection with CMV and for identifying individuals at risk for CMV infection. This approach is especially helpful in testing sera from organ transplant donors and from donors of blood products that are to be administered to premature infants or bone marrow transplant patients. For serologic diagnosis of recent CMV infection, paired sera should be obtained at least 2 weeks apart when testing for immunoglobulin G (IgG) antibody. The acute-phase serum sample should be collected as soon as possible after onset of illness and tested simultaneously with the convalescent-phase serum sample. If congenital infection is suspected, both maternal and infant sera should be submitted. Detection of IgM in a single serum specimen may be beneficial. Testing saliva or oral fluids for CMV-specific antibodies has been suggested as a noninvasive alternative to the collection of blood from children (1). In patients with CMV neurologic disease, CSF may be tested for viral antibody if paired with a serum specimen collected on or close to the same date.

DIRECT EXAMINATION

Histopathologic Testing

Histologic examination of Wright-Giemsa-, hematoxylin and eosin-, or Papanicolaou-stained lung or other biopsy specimens can be useful in the diagnosis of localized CMV organ disease. Characteristic large cells (cytomegalic cells) with basophilic intranuclear inclusions and, on occasion, eosinophilic cytoplasmic inclusions can be seen in routine sections of biopsy or autopsy material (Fig. 1). The nuclear inclusion has the appearance of an "owl's eye" because it has marginated chromatin that is typically surrounded by a clear halo that extends to the nuclear membrane. The presence of characteristic cytologic changes suggests CMV infection and correlates with active disease in most cases, although additional virologic or serologic confirmation is suggested. Overall, histopathologic diagnosis of CMV disease involves time and labor and is relatively insensitive, and since CMV can infect tissues without producing morphologic changes, failure to find typical cytomegalic cells does not exclude the

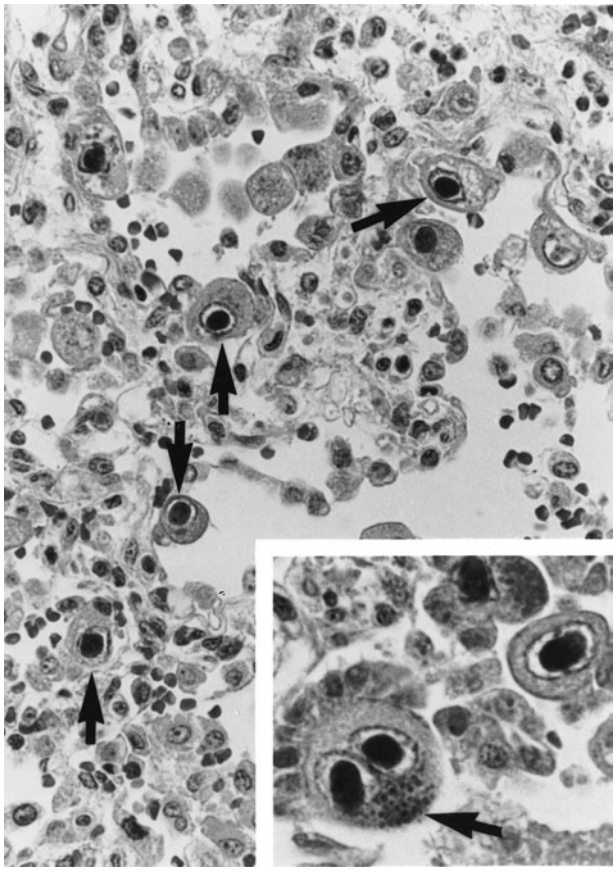

FIGURE 1 Fixed hematoxylin-eosin-stained lung tissue from a patient with interstitial pneumonia. Note the numerous giant cells that possess large intranuclear inclusions surrounded by characteristically clear halos (arrows). Less pronounced granular inclusions may also be present in the cytoplasm (inset). (Courtesy of Eduardo Ruchelli.)

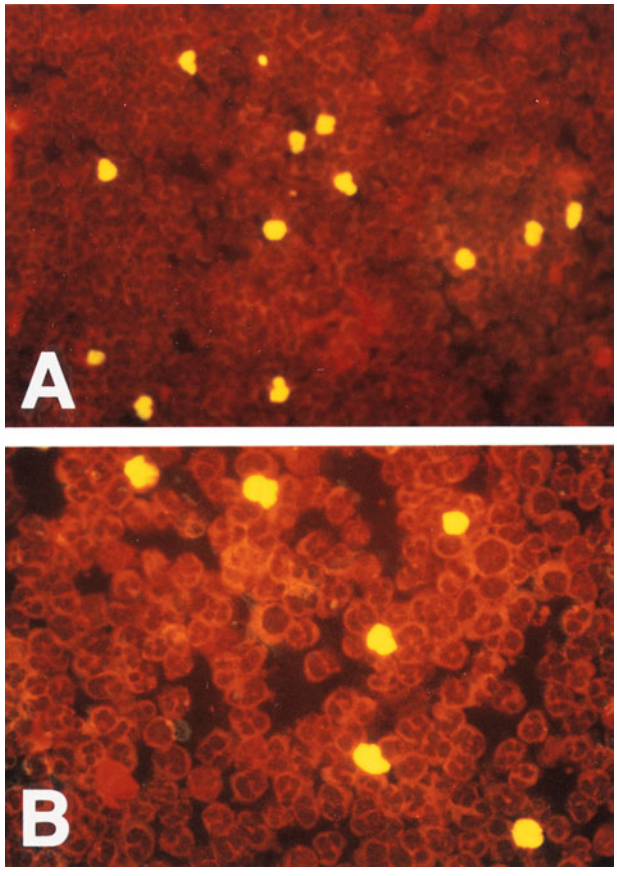

FIGURE 2 CMV antigen-positive polymorphonuclear leukocytes. Note the nuclear staining when a monoclonal antibody directed against pp65 is used. (A) Magnification, ×100; (B) magnification, ×400.

possibility of CMV infection. The sensitivity of histopathologic testing can be increased somewhat by using immunohistochemical staining to detect CMV antigens or in situ hybridization to detect CMV nucleic acids. A major obstacle to tissue diagnosis of CMV is the need to perform invasive procedures to obtain specimens for testing.

Antigenemia Assay

The CMV antigenemia assay is widely used for the direct detection and quantitation of CMV from blood leukocytes (102, 103, 106, 107) in recipients of solid-organ and bone marrow transplants and individuals infected with human immunodeficiency virus (HIV). There have been numerous studies comparing the performance of this assay to conventional and shell vial culture isolation of CMV from blood (for a review, see reference 10). The antigenemia assay is a sensitive, specific, and rapid method for the early diagnosis of CMV infection and can be used for routine monitoring of patients at high risk for severe CMV disease. The test is relatively simple to perform and is based on immunocytochemical detection of the 65-kDa lower-matrix phosphoprotein (pp65) in the nuclei of peripheral blood leukocytes (Fig. 2). By using this assay, CMV can be detected before the onset of symptoms and the viral load can be quantified to assist in predicting and differentiating CMV disease from asymptomatic infection (36, 58). The procedure has also been used to evaluate the efficacy of antiviral therapy (39, 105), to prompt the institution of preemptive therapy, and to detect CMV in leukocytes of CSF from AIDS patients with infections of the central nervous system (86). The pp65 protein has also been found in endothelial cells circulating in the blood of immunocompromised patients, and some investigators have suggested that infection of these cells is associated with organ involvement and more advanced disease (37, 87). The results of the antigenemia assay correlate well with the quantitative detection of CMV DNA in leukocytes or plasma in molecular amplification assays (13, 34).

In the antigenemia assay, leukocytes (mainly polymorphonuclear leukocytes) are enriched from freshly collected whole blood by sedimentation with dextran. More recently, a method for direct lysis of erythrocytes and subsequent isolation of leukocytes from whole blood has been described (48). This modification allows for a shorter total assay time and the capability of processing more specimens. Following sedimentation, the remaining erythrocytes are lysed with ammonium chloride, the granulocytes are counted in a hemocytometer or automated cell-counting instrument, and a known number of cells (usually 2×10^5 although variations of 5×10^4 to 10^6 cells have been used) are cytocentrifuged onto microscope slides. The cells are fixed with formaldehyde or

paraformaldehyde and then permeabilized with the nonionic detergent Nonidet P-40 and stained with suitable monoclonal antibodies directed against CMV pp65. These processes are followed by incubation of the cells with a fluorescein isothiocyanate-labeled secondary antibody diluted in a counterstain. Slides are read by microscopy at ×200 to ×400 magnification. Positive results are viewed as homogeneous apple green fluorescence within the nuclei of infected cells. Quantitative results are usually expressed as the number of antigen-positive cells per total number of leukocytes evaluated. No absolute CMV antigenemia values or breakpoints for symptomatic disease have been established for interpretation of quantitative testing; they appear to be different between patient populations. Therefore, it is important to monitor patients and observe relative rises and/or falls in the level of antigen-positive cells in multiple blood specimens collected over time. The presence of small numbers of antigen-positive cells generally indicates asymptomatic infection, whereas increasingly larger numbers are more strongly associated with clinically significant disease. In patients with severe immunosuppression (e.g., after allogeneic bone marrow transplantation), however, even very small numbers of antigen-positive cells may be significant. For transplant recipients, the frequency and extent of monitoring vary with the institution and from one transplant population to another and depend on the medical approach taken to manage CMV infection and disease (for a review, see reference 84).

The major advantages of the antigenemia assay are that it is more sensitive than either conventional tube or shell vial cultures for the detection of CMV from blood; it can be completed in 2 to 4 h, providing same-day turnaround of results; and the procedure can be readily modified for quantitative measure of the viral load. The assay has the disadvantages of being labor-intensive and time-consuming, particularly when large numbers of specimens are being processed; and it should be performed by personnel with experience in immunocytochemical techniques. Considerable time, effort, and expertise are needed in isolating and counting cells, adjusting the cell concentration to 10^6/ml before preparing the slides for staining, and then reading the stained slides. Also, interlaboratory variability exists with regard to the exact procedures used to perform the antigenemia assay and there is a definite need for assay standardization (35, 101, 108). Commercial kits containing monoclonal antibodies and other reagents needed to perform the antigenemia assay are available (Table 1). Several of these assays have been licensed by the FDA, and comparative studies have demonstrated equivalent performances (25, 57, 60, 99, 109).

Molecular Amplification

Molecular amplification assays are progressively replacing nonmolecular assays for the diagnosis and monitoring of CMV infections. PCR is currently the most widely used molecular method for the detection of CMV DNA and mRNAs. Many laboratory-developed and some commercial qualitative assays (64, 96) are available, and the sensitivity and specificity of PCR for diagnosis of active CMV infection have been evaluated (22, 51, 75, 92, 114). Amplification has been performed with a variety of primer pairs from the immediate-early antigen 1, the major immediate-early antigen, glycoproteins B and H, the EcoRI D fragment, the HindIII X fragment, pp65, pp67, and the major capsid protein gene fragments. In several studies, the sensitivity of the assay was increased by amplifying genomic regions from both the immediate-early and the late CMV genes or by using nested primers to a single gene fragment. The use of both gene fragments enabled the detection of a variety of clinical isolates, indicating that strain variability is not a limiting factor for PCR diagnosis of CMV. PCR has been used successfully to detect CMV DNA in a variety of clinical specimens from organ transplant recipients, patients with AIDS, and infants with congenital infection. It also has been used for the continued surveillance of

TABLE 1 Available CMV antigenemia assays

Manufacturer	Product name	Recommended blood collection and processing			Cell separation technique	No. of cells per slide	Monoclonal antibody used	Total assay time (h)	FDA license[a]
		Amount (ml)	Anticoagulant used	Storage conditions					
Biotest Diagnostics, Denville, N.J.	CMV Brite	5–10	Heparin or EDTA	20–25°C for 6–8 h	Dextran sedimentation	1.5×10^5	C10/C11	4–5	Yes
	CMV Brite Turbo	3–5	EDTA	20–25°C for 6–8 h	Direct erythrocyte lysis with NH_4Cl	2.0×10^5	C10/C11	2	Yes
Argene, North Massapequa, N.Y.	CINAkit Rapid Antigenemia	7	Heparin or EDTA	2–8°C for up to 24 h	Dextran sedimentation or direct erythrocyte lysis with NH_4Cl	2.0×10^5	1C3 + AYM-1	4–5 or 2	Yes

[a] FDA license for qualitative testing only.

immunocompromised patients and for evaluation of the therapeutic efficacy of antiviral drugs (38, 39, 103).

Of concern with PCR for CMV diagnosis is whether the test can distinguish between active disease and asymptomatic infection or latency. CMV viremia is considered to be the best predictor of CMV disease, and CMV DNA has been successfully detected in whole blood, purified peripheral blood leukocytes, plasma, and serum by PCR (38, 92, 97, 103). However, PCR is extremely sensitive and the qualitative detection of CMV DNA in these specimens has limited value in predicting symptomatic disease and in monitoring the success of antiviral therapy in immunocompromised patients. CMV DNA can be detected in blood by PCR in the absence of disease and can be found for weeks or months after successful therapy of symptomatic patients (5, 39, 98). At present, the clinical significance of results provided by qualitative PCR is unclear, but the method appears to be useful in certain settings. These include diagnosis of less common forms of CMV infection, such as detection of CMV in CSF of patients with encephalitis or polyradiculomyelitis, in urine, tissue, amniotic fluid, or fetal blood for diagnosis of congenital CMV infection; in the aqueous or vitreous humor in patients with CMV retinitis, and in the blood of patients at high risk of severe infection, such as CMV donor-positive, recipient-negative transplant patients, so that antiviral therapy can be started early in the course of infection. Also, a negative result from qualitative PCR of blood has a high negative predictive value for ruling out systemic CMV disease.

Similar to the antigenemia assay, measuring the level of CMV DNA in blood appears necessary to predict and diagnose CMV disease (for reviews, see references 10 and 50). Consequently, a number of quantitative and semiquantitative molecular assays have been developed and a variety of kits and analyte-specific reagents are now commercially available. These include target and signal amplification methods such as conventional PCR (12, 13, 16, 17, 94) and real-time quantitative PCR (20, 30, 42, 46, 47, 63, 66, 71, 89), branched-chain DNA technology (18, 28), and a solution hybridization antibody capture assay (17, 69, 90). The performances of individual assays have been compared to the antigenemia assay and culture (12, 16, 69, 90, 94) as well as to each other (4, 7, 78, 82, 104, 111). Overall, these molecular methods provide quantitative results comparable to those obtained by the antigenemia assay; they are also more sensitive than culture for detecting CMV infection and can detect CMV before the onset of clinical symptoms. It has been shown that transplant recipients and AIDS patients with active CMV disease have higher levels of CMV DNA and that a rapid rise in the CMV DNA copy number correlates with the presence of symptoms and drug failure during treatment (18, 23, 31, 34, 117). Also, Rasmussen et al. (81) have determined that quantitation of CMV DNA from peripheral blood leukocytes can be used to identify HIV-infected patients at risk for development of symptomatic CMV retinitis. It has also been determined that immunocompromised patients with CMV disease have more CMV DNA in either plasma or leukocyte fractions than do patients without disease but that the level of CMV DNA in leukocytes is higher than that in plasma (34, 118). Quantitation of CMV in plasma, therefore, may be less sensitive for monitoring CMV infection, although a positive result may correlate better with active disease. As in the antigenemia assay, absolute CMV DNA levels or breakpoints for symptomatic disease have not been determined, and it is currently more important to monitor the relative changes in DNA levels from serial blood specimens collected over time. Quantitative PCR methods for the estimation of CMV DNA levels in CSF, amniotic fluid, tissue, and urine of CMV-infected patients have been described (4, 28, 29, 85, 93), but more research is needed to assess the clinical relevance of quantitating CMV DNA from these specimens. It has been shown that the prognosis of congenital CMV infection may be directly related to the amount of CMV in the urine of an infected neonate and that quantitating CMV DNA in the CSF of AIDS patients may help determine if disorders of the central nervous system are attributed more to CMV than to the direct effects of HIV or other opportunistic pathogens.

As an alternative to using quantitative assays, reverse transcriptase PCR assays have been used to demonstrate that qualitative amplification of specific CMV mRNA transcripts that are expressed only during active infection may make it possible to identify the patients at greatest risk for developing symptomatic infection (6, 43, 54, 73). Commercial assays involving nucleic acid sequence-based amplification have been developed, and the diagnostic value of monitoring the expression of CMV immediate-early and late pp67 mRNA has been evaluated for blood leukocytes and CSF specimens (8, 9, 17, 32, 33, 45, 116). Assays used to detect CMV mRNA are usually less sensitive than other methods, but they have a high specificity for diagnosing CMV disease.

In general, molecular assays for the detection and quantification of CMV DNA are sensitive, specific, and reproducible and significantly reduce the time necessary to report results that may have an impact on the care and management of patients. They differ in the types of specimens used, the nucleic acid target selected, the choice and design of suitable oligonucleotide primers and probes, optimization of specimen extraction and PCR amplification conditions, the controls and quantitative standards used, the method chosen to detect and/or quantify the amplified product, and the number of DNA copies reported from one laboratory and method to another. Many of the assays require additional validation, and there is a definite need for standardization of both the qualitative and quantitative test methods. Most methods also have the distinct disadvantages of being technically demanding and expensive and requiring considerable technical expertise to perform. These concerns have diminished as many of the steps involved in molecular testing are now being automated. Ultimately, the clinical utility of these assays will depend on their accuracy, reproducibility, precision, ease of use, cost, and predictive value. Molecular methods, however, are proving to be valuable additions to the analytical tools already being used to provide a rapid diagnosis of established disease, identify patients at risk of developing disease, assess the progression of disease and the risk of relapse, direct the initiation of preemptive therapy, monitor the response to therapy, and predict viral resistance and treatment failure.

Other Direct Detection Methods

Electron microscopy, exfoliative cytology, and molecular dot blot and in situ hybridization techniques have also been used for the direct detection of CMV from tissues, bronchoalveolar lavage specimens, blood leukocytes, cervical secretions, and urine sediments. An enzyme-linked immunosorbent assay and a dot immunoperoxidase assay involving antisera to viral proteins have also been used for the direct detection of CMV antigens from clinical specimens. Overall, these methods lack sensitivity and are not used routinely in most clinical laboratories.

ISOLATION PROCEDURES

Processing of Specimens

Adjustment of urine specimens to pH 7.0 with 0.1 N NaOH or 0.1 N HCl is recommended to reduce toxicity to cell cultures. Centrifuging urine specimens to obtain sediment-enriched samples has been advocated but is usually unnecessary. Sediment-enriched urine samples from renal transplant recipients may produce toxicity more frequently than do uncentrifuged urine samples.

A number of procedures for obtaining peripheral blood leukocytes have been described. However, density gradient centrifugation with either Ficoll-Hypaque or a mixture of sodium metrizoate and dextran 500 (PMN; Robbins Scientific, Sunnyvale, Calif.) is most suitable for a clinical laboratory. Fresh blood collected in the presence of heparin, sodium citrate, acid citrate dextrose, or EDTA may be used. Both mononuclear cells and granulocytes are efficiently separated from erythrocytes in a single step. The procedure is rapid and easy to perform, and the reagents are commercially available. Compared with traditional sedimentation methods, the technique results in a greater number of virus isolates and an increased yield of infectious foci or plaques. Alternatively, the direct lysis procedure described above may be used, although a reduced ability to culture CMV following direct erythrocyte lysis has been reported (56).

Respiratory, biopsy, autopsy, and other specimens are processed as described in chapter 80. All specimens are treated with antibiotics before inoculation of cell cultures. Portions of specimens not used to inoculate cell cultures should be mixed with equal volumes of 0.4 M sucrose-phosphate and frozen at −70°C or in liquid nitrogen; some infectivity may be preserved if further isolation attempts are necessary.

Cell Cultures

Human fibroblasts best support the growth of CMV and therefore are used for diagnostic purposes. Acceptable fibroblast cultures include those prepared from human embryonic tissues or foreskins and serially passaged diploid human fetal lung strains such as WI-38, MRC-5, or IMR-90. Diploid fibroblast cells should be used at a low passage number, since they may become less susceptible to CMV infection with increasing cell generations. Several of these fibroblast cell lines are commercially available. CMV can infect and replicate in certain human epithelial cells, but its growth is limited. CMV infection of nonhuman cells can occur but leads to abortive replication with expression of only immediate-early genes and proteins.

Isolation of Virus in Conventional Tube Culture

Specimens to be tested are added in a volume of 0.2 ml to duplicate tubes of confluent fibroblasts maintained in Eagle minimal essential medium with 2% fetal bovine serum. Alternatively, the tubes are drained of medium, the inocula are absorbed for 1 h in a stationary position or by centrifugation at 700 × *g* for 45 min at 30 to 33°C, and then fresh medium is added. After inoculation, the tubes can be rolled or kept stationary at 37°C. At 24 h later, the medium is changed in tubes inoculated with urine or leukocyte specimens. Thereafter, and for other types of specimens, the medium is changed once a week or more frequently as the pH of the culture medium changes or if toxicity appears. When toxicity necessitates passage of the culture, cells rather than culture medium should be passaged, since CMV remains cell associated. Cells are removed by addition of 0.25% trypsin–0.1% EDTA to the monolayers and incubation at 37°C for approximately 1 min. When the cells detach, Eagle minimal essential medium with 2% fetal bovine serum is added, and the cells are used to inoculate fresh tubes. Tubes are examined for cytopathic effect (CPE) daily for the first 5 days and then twice a week for at least 4 weeks for most specimens (6 weeks for leukocyte specimens). Control, uninoculated cultures are handled in the same manner as those inoculated with clinical specimens.

The time of appearance and the extent of CPE depend on the amounts of virus present in specimens. In cultures inoculated with urine from a congenitally infected newborn, CPE may develop by 24 h and progress rapidly to involve most of the monolayer if the virus titer in the urine is extremely high. More commonly, foci of CPE, consisting of enlarged, rounded, refractile cells, appear during the first week, and progression of CPE to surrounding cells proceeds slowly (Fig. 3). In cultures inoculated with urine or respiratory specimens from older individuals, CPE usually appears within 2 weeks. Leukocyte cultures may not become positive until after 3 to 6 weeks. The usual slow progression of CPE in cultures inoculated with clinical specimens is due, at least in part, to limited release of virus into extracellular fluid. With strains of CMV that have been serially passaged, including laboratory-adapted strains, greater amounts of extracellular virus are released and CPE progresses more rapidly.

For storage of fresh isolates, monolayers exhibiting CPE are treated with trypsin-EDTA and the cells obtained are suspended in Eagle minimal essential medium with 10% fetal bovine serum and 10% dimethyl sulfoxide and then frozen at −70°C. Infectivity can be better maintained for long periods by storage in liquid nitrogen.

Identification of Isolates

In some laboratories, CMV isolates are identified solely on the basis of characteristic CPE and host cell range. However, viruses such as adenovirus and varicella-zoster virus occasionally produce a CPE indistinguishable from that of CMV. Thus, suspected CMV isolates are best confirmed by an immunofluorescence assay (IFA) using monoclonal or polyclonal antibodies that are available from a variety of commercial sources. The appearance of typical nuclear fluorescence of infected cells indicates the presence of CMV. PCR or other molecular amplification methods also can be used for confirmation of suspected isolates.

Spin-Amplification Shell Vial Assay

The spin-amplification shell vial assay as described by Gleaves et al. (41) has been used extensively as a rapid culture method for the detection of CMV in clinical specimens. The technique is based on the amplification of virus in cell cultures after low-speed centrifugation and detects viral antigens produced early in the replication of CMV, before the development of CPE. Even low titers of virus present in specimens are easily amplified and rapidly detected, within 24 h. Monoclonal antibodies are commercially available and have been used for the detection of CMV early antigens. In situ hybridization with commercially available DNA probes to CMV has also been used.

MRC-5 fibroblast cells are grown to confluency on 12-mm round coverslips in 1-dram (3.7-ml) shell vials and inoculated with 0.2 ml of specimen. Shell vials of MRC-5 cells can be obtained commercially or prepared in the laboratory. Monolayers should be inoculated within 1 week after preparation, since older monolayers demonstrate decreased sensitivity to CMV and increased toxicity (27). Pretreatment of the monolayers with dexamethasone, dimethyl sulfoxide, or these agents plus calcium may increase the sensitivity of the cells to CMV infection (112, 113), although other investigators have been unable to confirm these results (26). Two vials should be inoculated for urine, tissue, and bronchoalveolar lavage fluid specimens, and three should be inoculated for blood specimens (77). Alternatively, disruption of purified leukocytes by sonication before their use in the shell vial assay may increase the sensitivity of CMV detection from blood (115). Increasing the frequency of blood collection and the volume of blood obtained also may enhance the diagnostic yield of the shell vial assay from this specimen (76). After inoculation, the vials are centrifuged at 700 × *g* for 40 min at 25°C and then 2.0 ml of Eagle minimum essential medium containing 2% fetal bovine serum and antibiotics is added. The cultures are incubated at 37°C for 16 to 24 h, fixed with acetone, and stained. A longer incubation time may be used, but the time should be determined by each laboratory on the basis of individual experience, reagents, staining technique used, and whether monolayers are purchased or prepared in the laboratory. Uninfected and CMV-infected monolayers are included as negative and positive controls, respectively. Mink lung (ML) cells, a nonhuman continuous cell line, are comparable to MRC-5 fibroblasts for the detection of CMV in clinical specimens by shell vial culture (40, 67). A distinct advantage in using ML cells is that this cell line can be propagated and passaged in the laboratory for a long time without a decrease in susceptibility to CMV. Significantly less toxicity and an increase in the number of CMV-positive nuclei were also observed with ML cells. Coverslips are scanned at ×200 to ×250 magnification, and specific staining is confirmed at ×400 to ×630. Positive cells contain apple green fluorescent nuclei against a red cytoplasmic background. Staining of immediate-early antigen appears as an even matte green fluorescence with specks of brighter green (Fig. 4A). Viral inclusions (owl's eyes) may be visible in the nuclei (Fig. 4B).

The spin-amplification shell vial assay has been a valuable adjunct to conventional virus isolation. It has the important features of being rapid, sensitive, and specific. However, skilled technical personnel and close attention to the quality of specimens, monolayers, and reagents are required for optimum performance.

SEROLOGIC DIAGNOSIS

A variety of tests with high sensitivities and specificities are available for the detection of antibodies to CMV (for an overview, see reference 49). In deciding which test to perform, one should consider such factors as the number of specimens to be tested, the patient population, cost, turnaround time, equipment needs, and ease of performance. The method that is chosen depends on the needs of individual laboratories. For small-volume laboratories, IFA or passive latex agglutination tests may be more cost-effective and practical, while enzyme immunoassays (EIA) may be more suitable for laboratories with higher volumes of specimens. Overall, detection of CMV-specific IgM or determination of a positive seroconversion can be useful for the diagnosis of primary CMV infection in certain clinical settings, and the screening of blood and organ donors and recipients plays an important role in preventing the transmission of latent CMV to patients at high risk for severe CMV disease.

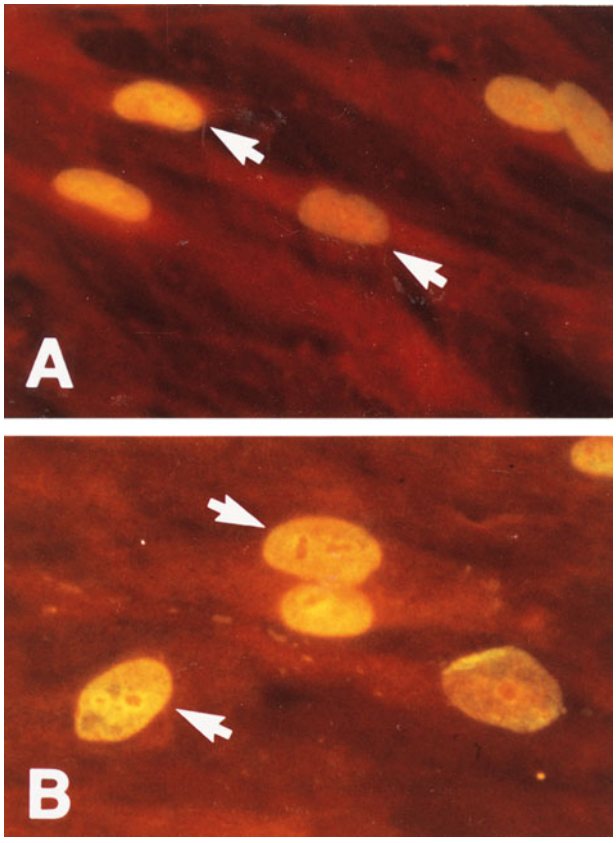

FIGURE 4 Demonstration of CMV early antigens in the nuclei (arrows) of infected MRC-5 cells following shell vial culture and IFA staining. Staining of immediate-early antigen appears as an even matte green fluorescence with specks of brighter green (A). Viral inclusions (owl's eyes) may be visible in the nuclei (B). Magnification, ×400.

EIA

Over the years, EIA have largely replaced other traditional methods for detecting antibodies to CMV. The main advantages of the EIA are that it is rapid, sensitive, and specific (68, 70, 79). In addition, multiple specimens can be handled daily at a relatively low cost. Kits that detect CMV IgG are available from a number of commercial sources. The kits are easy to use, and the manufacturers have provided detailed instructions. All the materials necessary to perform the assay are included, and the reagents are stable with time. Some

companies also provide a spectrophotometer and automated plate washer, which otherwise must be purchased separately at considerable expense. The development of robotics technology has led to the commercial availability of both fully automated and semiautomated EIA instruments, including sample dispensers, diluters, washers, and spectrophotometers with complete computer programming and generation of written reports.

IFA

Indirect and anticomplement IFA are commonly used methods for detecting CMV antibodies (53, 80). In the indirect IFA, dilutions of test serum are incubated with virus-infected cells that have been fixed to a glass microscope slide. Specific antibody-antigen complexes are detected using an anti-human antibody conjugated with fluorescein isothiocyanate and fluorescence microscopy. Anticomplement immunofluorescence is similar to the indirect IFA. It differs, however, in that the test serum is first heat inactivated to remove endogenous complement activity and then incubated with virus-infected cells on glass slides. Complement is added and bound by any specific antigen-antibody complexes that have formed. A fluorescein-labeled anticomplement antibody is then added; it binds to the C3 component of complement, and the slides are read using a fluorescence microscope. IFAs are useful and inexpensive methods that offer the advantages of speed and simplicity for the qualitative and quantitative detection of CMV antibodies. Commercial kits are readily available, or antigen-coated slides and labeled secondary antibodies can be purchased separately. The major disadvantages of IFA systems are that they require a fluorescence microscope and darkroom for examining slides and that extensive training is needed to read and interpret the test results.

Passive Latex Agglutination Test

The passive latex agglutination test provides a simple, rapid, and inexpensive means of detecting antibodies to CMV in human sera and plasma (3, 52, 68, 70). A suspension of latex particles coated with viral antigens is mixed with a test serum and allowed to incubate with rotation for a short time. The antigen-coated particles clump and produce agglutination in the presence of CMV-specific antibody; the agglutination is visible to the naked eye. The procedure detects both IgG and IgM antibodies but does not differentiate between the two classes of immunoglobulins. The assay can be completed in 10 to 15 min and does not require extensive washes, long incubation times, or expensive equipment. The main disadvantages are that agglutination patterns can be difficult to discern and readings are subjective. Commercial kits are readily available.

CMV IgM Antibody Measurements

Current methods for measuring CMV IgM antibodies include IFA and EIA. The procedures are essentially the same as those used to detect IgG antibodies, except that anti-human IgM antibodies labeled with suitable markers are used. A recognized pitfall of CMV IgM assays is the occurrence of false-positive and false-negative reactions. False-positive reactions occur when sera contain unusually high levels of rheumatoid factor in the presence of specific CMV IgG (21). Rheumatoid factor is an immunoglobulin, usually of the IgM class, that reacts with IgG. It is produced in some rheumatologic, vasculitic, and viral diseases, including CMV infection. IgM rheumatoid factor forms a complex with IgG that may contain CMV-specific IgG. The CMV IgG binds to CMV antigen, carrying nonviral IgM with it; in this setting, a test designed to detect IgM will produce a false-positive result. False-negative reactions occur if high levels of specific IgG antibodies competitively block the binding of IgM to CMV antigen. Therefore, it is highly recommended to separate IgM and IgG fractions before testing to decrease the incidence of both false-positive and false-negative IgM test results.

Rapid and simple methods for the removal of interfering rheumatoid factor and IgG molecules from serum have been developed. These include gel filtration, affinity chromatography, selective absorption of IgM to a solid phase, and removal of IgG by using hyperimmune anti-human IgG, staphylococcal protein A, or recombinant protein G from group G streptococci. Serum pretreatment methods are now incorporated in the procedures of commercially available IFA and EIA kits, which have resulted in more-reliable IgM tests. More recently, reverse capture solid-phase IgM assays have been used as an alternative approach to avoiding false-positive or false-negative results. This method uses a solid phase coated with an anti-human IgM antibody to capture the IgM from a serum specimen, after which competing IgG antibody and immune complexes are removed by washing. The bound IgM antibody is then exposed to specific CMV antigen, and an enzyme-conjugated second antibody and substrate are added. The development and use of recombinantly derived CMV proteins as a source of antigenic substrate also have greatly improved the performance of IgM assays (55, 110).

Although the detection of CMV-specific IgM may be useful in the determination of recent or active infection, the results should be interpreted with caution. Because IgM does not cross the placenta, a positive result from a single serum specimen from an infected newborn is diagnostic. However, there may be a lack of or delay in production of IgM in the newborn. Testing for the presence of CMV-specific IgM antibody beyond the newborn period is usually not recommended since IgM antibody can appear in both primary and reactivated CMV infections and can persist for extended periods after a primary infection. This complicates the interpretation of test results, particularly for pregnant women or immunocompromised patients, and may not be predictive of recent or active infection. Similar to newborns, immunocompromised individuals also may have a delay in IgM production or may be unable to mount a significant IgM antibody response. Lastly, patients with Epstein-Barr virus-induced infectious mononucleosis may produce heterotypic IgM responses, resulting in false-positive CMV IgM test results.

IgG Avidity Assay

The detection of CMV-specific IgM in maternal serum is not predictive of transmission to the fetus, since fewer than 10% of pregnant women who are positive for CMV IgM actually give birth to a congenitally infected infant. More recently, it has been suggested that finding low-avidity CMV-specific IgG antibody in CMV-IgM-positive pregnant women may improve the diagnosis of recent primary CMV infection and may have prognostic value with regard to fetal infection (44, 61). In solid organ transplant recipients, it has also been shown that a delay in the development of high-avidity CMV-specific IgG antibody correlates with prolonged antigenemia and a poor prognosis (62). Measurements of CMV-specific IgG avidity are accomplished by conventional EIA protocols, with one modification. Following the addition of patient serum to antigen-coated wells and prior to the addition of the conjugated secondary antibody, any CMV-specific IgG bound to the antigen source is treated with a

denaturing agent such as urea to determine the strength, or avidity, of the binding. Avidity levels are expressed as the percentage of IgG bound to the antigen when test results are generated and compared in the presence and absence of the urea pretreatment step. CMV-specific IgG of low avidity is produced during the first weeks to months following primary infection, whereas IgG antibody of increasingly higher avidity is produced with past or nonprimary infections.

Other Serological Tests

Complement fixation, immune adherence hemagglutination, indirect hemagglutination, and the neutralization test are other serologic tests used to measure CMV antibody. These methods are currently performed in only a limited number of diagnostic laboratories; some of the procedures have the disadvantages of being insensitive, poorly standardized, and relatively labor-intensive and time-consuming.

ANTIVIRAL SUSCEPTIBILITY TESTING

Resistance of CMV to ganciclovir has been reported in immunocompromised patients, particularly patients with AIDS receiving long-term ganciclovir treatment for CMV retinitis. Ganciclovir-resistant clinical isolates have also been recovered from bone marrow and solid organ transplant recipients and a patient with chronic lymphocytic leukemia. Although foscarnet is the alternative therapy for ganciclovir-resistant CMV infections, clinical CMV isolates resistant to foscarnet alone or in combination with ganciclovir resistance have been described. The mechanisms of resistance to ganciclovir in CMV include mutations in the catalytic domain of the UL97 phosphotransferase gene, leading to a deficiency in drug phosphorylation, and alterations in the UL54 viral DNA polymerase gene; the latter is also responsible for resistance to foscarnet (for a review, see reference 24). Ganciclovir-resistant CMV isolates with mutations in the UL54 gene are generally cross-resistant to cidofovir, and isolates resistant to ganciclovir, foscarnet, and cidofovir have also been reported.

The described emergence of antiviral drug resistance has led to a definite need for in vitro antiviral susceptibility testing. Laboratory confirmation of drug resistance is essential for defining the mechanisms of antiviral resistance, for determining the frequency with which drug-resistant CMV mutants emerge in clinical practice, for predicting treatment failure and identifying cross-resistance to other antiviral agents, for instituting the most appropriate alternative therapy, and when evaluating new antiviral agents. A number of phenotypic and genotypic assays have been described for testing the susceptibility of CMV to antiviral agents (for an overview, see references 65 and 100). Phenotypic assays measure the ability of CMV to grow in cell culture in the presence of various concentrations of antiviral drug, and they generally require isolation and passage of the virus in cell culture before testing begins. The activity of the antiviral agent against the replication of the virus is measured by one of many methods, including the inhibition of viral plaque formation or virus-induced CPE; a decrease in the production of viral antigens, enzyme activities, or total virus yield; and a reduction in viral nucleic acid synthesis. With each method, results are expressed as the drug concentration that causes a 50% inhibition in the growth of the virus. Genotypic assays have been used to screen CMV isolates for the identification of mutations in the CMV UL97 phosphotransferase gene and the UL54 DNA polymerase gene that confer resistance to ganciclovir and/or foscarnet (2, 19, 95). These assays normally involve using PCR for amplification of specific viral genes and direct sequencing of the amplified products; some assays use specific probes to detect selected mutations or use restriction endonuclease digestion of amplified products to identify alterations in the viral genome known to be associated with viral resistance to a given viral agent. Phenotypic assays offer the distinct advantage of being a direct measure of CMV susceptibility to any antiviral drug and can provide data on the concentration of drug needed to inhibit viral replication. However, phenotypic assays for CMV are cumbersome, labor-intensive, and expensive and have long turnaround times. Genotypic assays offer speed and efficiency in analyzing large numbers of CMV isolates and may allow an earlier detection of the emergence of drug resistance than phenotypic assays. Current genotypic assays, however, detect only known drug-resistant mutations, and the results may be confounded by the presence of mutations that have no bearing on drug resistance. Phenotypic assays are still required to identify drug-resistant viruses with novel mutations for antiviral resistance. The overall complexities of phenotypic and genotypic assays make either method less than routine for most clinical laboratories.

REPORTING, EVALUATION, AND INTERPRETATION OF RESULTS

There are a number of points to consider when choosing which tests to perform for the detection of CMV. Conventional tube cultures are highly specific and can detect unexpected viruses, but are generally too slow and insensitive to have an impact on clinical decision making when considering CMV as the primary pathogen. Shell vial cultures decrease the time required for detecting CMV in culture, but the sensitivity varies by specimen type and from laboratory to laboratory. Cultures also are often positive in the absence of true CMV disease; this is particularly true when screening urine or respiratory specimens for CMV, where shedding of CMV is common during asymptomatic infection and is usually not suggestive of more severe illness. Isolation of CMV in culture may be useful for postpartum and in utero diagnosis of congenital CMV infection and tissue invasive disease, and CMV isolates are also needed for phenotypic antiviral susceptibility assays.

In the immunocompromised host, the use of direct detection methods to diagnose CMV disease is most beneficial for patient care. In this regard, most clinical virology laboratories have largely replaced their conventional tube and shell vial culture systems with CMV antigenemia assays or molecular methods for accurate CMV detection and/or quantification from blood. Quantitative measures of CMV pp65 antigen or CMV DNA or qualitative detection of CMV mRNA can provide a rapid diagnosis of established disease, identify patients at risk of developing disease, assess the progression of disease and the risk of relapse, direct the initiation of preemptive therapy, monitor the response to antiviral therapy, and predict treatment failure and the emergence of drug-resistant virus. Histopathologic examination can be useful in immunocompromised hosts for the diagnosis of tissue invasive disease, although the procedures involve considerable time and labor and are of moderate sensitivity and specificity. Also, detection of CMV in tissue specimens must be interpreted with caution, since other pathogens may also be present; when dual infections are documented, the relative importance of each pathogen in producing clinical illness may be difficult to determine.

The isolation of CMV from urine, respiratory secretions, or other body fluids within the first 3 weeks of life is the traditional means of confirming the diagnosis of congenital infection in newborns. Urine is the preferred specimen because it contains greater amounts of virus, and the virus therefore grows quickly in culture. PCR has also been used to find CMV DNA in urine of congenitally infected infants, and viremia in infants with congenital infection has been detected by the antigenemia assay and PCR. Attempts to isolate or detect virus from maternal blood leukocytes and from amniotic fluid and fetal tissue by molecular- and/or antigen-based tests may provide useful information for prenatal diagnosis of congenital CMV infection (for a review, see reference 85). While such prenatal testing is a sensitive indicator of maternal or fetal CMV infection, positive results do not predict which infants will have disease. Recently, it has been demonstrated that elevated levels of CMV DNA in blood during early infancy is associated with hearing loss in newborns with symptomatic and asymptomatic congenital CMV infection (14, 15). Infants not previously tested but found to be excreting virus after 3 weeks of age may have either congenital or acquired infection. Standard serologic or virologic tests do not differentiate between these possibilities.

In general, serologic tests for CMV-specific IgG antibody have limited value for the diagnosis of acute infection since the results are obtained retrospectively and are not predictive of disease. Also, the transplacental passage of maternal IgG antibody confounds the diagnosis of CMV infection in the neonate, and immunocompromised hosts may not mount a normal immune response or they may have been given blood transfusions or intravenous immunoglobulins that contain detectable CMV IgG antibodies. Nonetheless, a history of seroconversion from a negative to a positive IgG antibody response to CMV is diagnostic of primary infection and may be beneficial in evaluating a pregnant woman with symptoms of viral disease. For pregnant women with preexisting CMV-specific IgG and/or IgM antibody, however, IgG avidity testing may be more helpful in distinguishing primary from nonprimary infections and for predicting CMV transmission to the fetus. Use of the IgG avidity assay in immunocompromised hosts may have value in detecting those at highest risk for CMV disease. Whenever possible, serologic diagnoses of CMV infection should be confirmed by other virologic methods. CMV-specific IgG serologic assays play a more important role in the determination of an individual's immune status to CMV. Detection of CMV-specific IgG in a single serum specimen indicates exposure to CMV at some time in the past. Negative serum antibody titers may exclude previous CMV infection. In the evaluation of an organ donor and recipient, a seronegative recipient who receives an organ or blood products from a seropositive donor is at increased risk for developing primary CMV infection and serious disease. Knowing the serostatus of the donor and recipient is therefore important in determining the treatment or prophylaxis to be used and in considering the type of donor and blood products to be given.

The application of virologic methods, including conventional and shell vial culture, rapid direct-detection assays, and serologic testing, should be combined with clinical assessment of the patient to provide an accurate, reliable diagnosis of CMV infection and disease and to allow subsequent prompt, appropriate patient management and timely intervention with specific antiviral therapy. There is a particular need to differentiate CMV infection from graft rejection in transplant patients, since the administration of potent immunosuppressive antirejection drugs during active CMV infection can result in life-threatening disease.

Epstein-Barr Virus

ANNIKA LINDE AND KERSTIN I. FALK

103

TAXONOMY

The Epstein-Barr virus (EBV), also known as human herpesvirus 4, belongs to the subfamily *Gammaherpesvirinae* in the *Herpesviridae* family.

DESCRIPTION OF THE AGENT

EBV has the morphology of a herpesvirus, with 162 capsomeres in icosahedral arrangement surrounded by a lipid-rich envelope. It has a double-stranded 172-kbp DNA, which is linear in the mature virion and circular and episomal in latently infected cells. The genome consists of a series of unique sequences alternating with internal repeats, all sandwiched between two terminal repeat elements. These are joined during circularization. Integration of viral DNA into host chromosomal DNA has been shown, mainly in lymphoblastoid cell lines (46).

EBV primarily infects B cells, which carry the receptor for EBV, the CD21 complement receptor. It has the ability to transform precursor and mature human B lymphocytes to lymphoblastoid cell lines. B cells are the site of latency, but epithelial cells, not expressing the receptor, are the main producers of progeny virus. Also monocytes may be productively infected by EBV, and the infection may affect the virus-host interaction (33, 71). In the B cells, the EBV nuclear antigens (EBNA), EBNA 1, EBNA 2, EBNA 3 (also referred to as EBNA 3a), EBNA 4 (EBNA 3b), EBNA 5 (EBNA LP), and EBNA 6 (EBNA 3c) and latent membrane proteins (LMP 1 and 2A and B) can be expressed. Three types of B-cell latency have been defined, based on their varying expression of the latency-associated proteins (58). EBNA 1 is always present. In addition, all latently infected B cells contain high copy numbers of EBV-encoded RNAs, known as EBER1 and EBER2. These are nonpolyadenylated RNAs with unknown functions. In vitro, EBV has been propagated only in B lymphocytes from human and subhuman primates (46).

EPIDEMIOLOGY AND TRANSMISSION

Transmission of EBV occurs by salivary or sexual contact (13, 19, 68). Virtually everyone becomes infected with the virus at some time. Primary infections occur during the first decade of life in areas with crowded living conditions and poor hygiene. In industrialized countries at least 50% of the population becomes EBV seropositive before puberty. Familial transmission of EBV infections is common (31). Infectious virus and viral genomes can be detected in materials from the oropharynx of the majority of seropositive individuals, including infectious mononucleosis (IM) patients (20). Detectable, infectious virus and viral DNA in saliva are more common in immunosuppressed than in immunocompetent persons (54). Viral DNA is detectable by nucleic acid amplification techniques (NAAT) in leukocytes, both from healthy carriers and from IM and immunosuppressed patients. However, except in immunocompromised patients, EBV transmission via blood products is not of clinical importance. EBV strains may be classified into types A and B (sometimes referred to as types 1 and 2) based on the polymorphism of their EBNA genes. Serology and PCR investigations indicate that both types have worldwide distribution, although type A appears to be more prevalent than type B and is the dominant type in IM (75). Dual infections with both types are not uncommon. In immunosuppressed individuals, coinfection by multiple strains of EBV has been demonstrated (30).

CLINICAL SIGNIFICANCE

IM

Primary EBV infections are mostly asymptomatic, especially in early childhood. Around 50% of primary infections in young adults are associated with classical IM. This is a self-limiting, lymphoproliferative illness, ranging from mild to severe (65). The clinical manifestations of primary EBV infections are mainly immunomediated (44). The various traits of IM are presented in Table 1. The incubation time is 30 to 50 days, and the disease generally lasts 1 to 4 weeks. However, protracted illness and tiredness for up to a year are not uncommon. Complications (Table 1) are frequent and can sometimes be the only sign of the primary infection. Very rare fatalities can occur due to splenic rupture, overwhelming infection, or hemophagocytic lymphohistiocytosis. In adults, the last is often associated with EBV reactivation and lymphoma (42). In immunocompromised patients, the primary infection often becomes severe and may be lethal. The severity of IM, the many atypical manifestations, and its similarity to malignant disease often warrant a laboratory confirmation of primary EBV infection. Mononucleosis can also be induced by other agents, such as cytomegalovirus

TABLE 1 Conditions and malignancies verified or suggested to be associated with EBV

Condition	Clinical traits
Nonmalignant	
Classic IM	Fever, malaise, pharyngitis, tonsillitis, lymphadenopathy, periorbital edema, hepatomegaly, splenomegaly, lymphocytosis with atypical lymphocytes and elevated liver enzymes
Complications of IM and other nonmalignant manifestations	
Hematological	Anemia, thrombocytopenia, granulocytopenia, hemophagocytic lymphohistiocytosis
Neurological	Meningoencephalitis, cranial nerve palsies, Guillain-Barré syndrome, seizures, mononeuritis, myelitis, psychosis
Visceral	Pericarditis, myocarditis, airway obstruction, laryngitis, epiglottitis, tracheitis, interstitial pneumonia, hepatitis, splenic rupture, splenic pseudotumor
Skin/epithelium	Exanthema, mosquito bite hypersensitivity, oral hairy leukoplakia, genital ulcers
Other	Chronic active EBV infection
Malignant/premalignant conditions	
High degree of association	Burkitt's lymphoma, posttransplant lymphoproliferative disorders, peripheral NK/T-cell lymphomas, peripheral NK/T-cell lymphomas including skin localizations, leiomyosarcoma in immunosuppression, lymphoepithelioma-like gastric carcinomas
Varying degree of association	Non-Hodgkin lymphoma, Hodgkin's disease, salivary gland and other head and neck tumors
Possible association	Gastric adenocarcinomas, breast cancer
Genetic	X-linked lymphoproliferative syndrome

(CMV), adenovirus, and *Toxoplasma gondii,* and etiologic differentiation may have important implications for treatment. To verify the diagnosis may also be cost saving since many other examinations may be avoided (5).

EBV and the Immunocompromised Host

In immunocompromised patients, EBV reactivations are associated with a number of lymphoproliferative disorders (LPD), ranging from benign, polyclonal hyperplasias to oligoclonal or monoclonal, malignant lymphomas (28, 53). The lymphomas are often localized to the brain or intestine. The risk of posttransplant lymphoproliferative disorders (PTLDs) is around 1% in hematopoietic stem cell transplant recipients and varies from 1 to 20% in solid organ recipients, depending on the type of organ. Risk factors for PTLD are EBV-seronegative recipients with seropositive donors; young age; long-standing, severe T-cell depletion of donor cells or recipient; transplantation of small intestine as well as heart, lung, and liver; CMV infection; and high degree of mismatch (11). In late-stage AIDS, the risk for LPD is also very high. EBV also may play a role in rare leiomyosarcomas, occurring in immunocompromised children (72). In oral hairy leukoplakia, replicating EBV is found in the oral epithelium. The lesions appear as white patches at the border of the tongue, mainly in human immunodeficiency virus-infected patients (88).

X-linked lymphoproliferative syndrome (XLP) is a rare, inherited immunodeficiency, involving primarily T and natural killer (NK) cells (25). Affected boys become symptomatic after exposure to EBV, developing acute fatal IM or lymphoproliferative disorders and/or dysgammaglobulinemia. The gene responsible for XLP is the SH2 domain containing 1A (SH2D1A). Multiple mutations of that gene have been identified in XLP (59, 83). Untreated, the disease is eventually lethal, but transplantation and gene therapy are possible therapeutic approaches, making the identification of affected persons important (25).

EBV-Associated Tumors

EBV is associated with a variety of tumors not related to obvious immunosuppression (62, 86). In >95% of endemic Burkitt's lymphoma and nasopharyngeal carcinoma (NPC), 40 to 50% of Hodgkin's disease, 2 to 16% of gastric adenocarcinoma, >90% of T/NK lymphomas, and 44 to 93% of lymphoepithelioma-like carcinomas, EBV genomes have been found in tumor cells. EBV-associated tumors are frequently preceded by detectable EBV genomes in serum or cerebrospinal fluid (CSF) and increased virus load in peripheral blood mononuclear cells. The reason for this is not clear. The EBV latency is different in different kinds of tumors. Burkitt's lymphoma has latency I, Hodgkin's disease and NPC have latency II, and PTLD, like lymphoblastoid cell lines, has latency III (58).

PROPHYLAXIS AND TREATMENT

There is no registered vaccine against EBV, but two approaches have been tried. One is to use glycoprotein (gp) 340 to induce neutralizing antibodies; the other is to use peptide vaccines based on major histocompatibility complex class 1-restricted epitopes of latent genes (56, 93). A gp340 vaccine is presently in clinical trials. Nucleoside analogues such as acyclovir, ganciclovir, and famciclovir, as well as the pyrophosphate analogue foscarnet, inhibit replication of EBV. Treatment of IM with nucleoside analogues results in termination of viral shedding but does not affect the symptoms, probably since these are mainly immunomediated (1, 89). Of immunomodulators, cortisone has been systematically tried against IM and may be beneficial for impending airway obstruction. Gamma interferon treatment is useful only in patients lacking this cytokine (65). The pathophysiology behind hemophagocytic lymphohistiocytosis is hypercytokinemia, and treatment with combinations of cyclosporin, methothrexate, anti-thymocyte globulin, and etoposide has been tried with some success (42).

For LPD treatment, anti-CD20 monoclonal antibodies and EBV-specific cytotoxic T lymphocytes are cornerstones (27). Adoptive transfer of cytotoxic T lymphocytes may also be beneficial in other EBV-associated malignancies (16). Despite lack of proof that antivirals have any beneficial effect, immunomodulation is almost always combined with nucleoside analogues in treatment of EBV-associated malignancies. Since the presence of EBV in tumors may have therapeutic consequences, the demonstration of the virus in tumors can be of vital importance (80).

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

Virus Isolation and Antigen Detection

For isolation of excreted virus, 5 to 10 ml of throat gargle fluid, collected in serum-free tissue culture medium or Hanks' balanced salt solution, is satisfactory. Five to 10 ml of heparinized blood is needed for culture to detect EBV-transformed B lymphocytes. The same material can be used for antigen detection in B cells by immunostaining. Blood specimens should be processed as soon as possible, although refrigeration for up to 24 h is acceptable for antigen detection. Storage at room temperature is preferable for lymphocyte transformation assays. Fresh biopsy specimens or thin (5-μm) cryosections are preferred to formalin-fixed material for antigen detection in other tissues.

Nucleic Acid Detection

Whole blood (collected in EDTA; heparin may inhibit the PCR), leukocytes, serum, and plasma are useful materials for monitoring of EBV presence and of viral load by NAAT. The choice of material is dependent on the clinical condition of the patient (Table 2). There is no agreement on whether leukocytes, whole blood, or serum or plasma should be used for monitoring EBV lymphoproliferative disease. Leukocytes and blood give higher sensitivity for EBV detection, while serum or plasma gives higher specificity for EBV-associated disease. The amount needed varies depending on the technique used at the individual laboratory, but it is advisable to send at least 1 ml of serum or plasma or 3 ml of whole blood. If the initial volume available is less than required, the material may be diluted, but this lowers test sensitivity. Blood specimens should be processed as soon as possible. If transport time is less than 24 h, whole blood can be kept at room temperature until separated. The separated materials can thereafter be stored at 4°C for a few days. If leukocytes or serum or plasma is to be used, the material should be separated before freezing. Whole blood can be frozen without further processing. For long-term storage, freezing at –70°C is recommended. For detection of EBV by DNA hybridization in peripheral blood lymphocytes, 5 to 10 ml of blood collected in heparin or EDTA is needed. CSF is useful for diagnosis of EBV-associated central nervous system disease, though the relation of EBV DNA to disease is not completely elucidated (15, 81). CSF is also useful for diagnosis of EBV-associated brain tumors in immunosuppressed patients. Sterile CSF without additives should be sent and can be stored in the same way as serum. The amount of CSF needed for NAAT varies depending on the amplification technique used at the laboratory. Though sometimes as little as 10 to 20 μl is sufficient for one examination, it is advisable to send at least 0.5 ml. Tissues to be examined for viral nucleic acids and antigens by NAAT should be collected aseptically and refrigerated in saline or balanced salt solutions. Suitable for this purpose are lymph nodes, spleen, liver, brain, and biopsy specimens of tumors. Fresh, frozen, but also paraffin-embedded specimens may be used.

Serodiagnosis

Only a single acute-phase serum sample is required for serodiagnosis in most cases. The amount needed varies depending on the method(s) used in the individual laboratory. Fifty microliters or even less may be enough, but it is advisable to send 1 to 5 ml. Convalescent-phase serum collected 1 to 2 months after onset is occasionally needed if ambiguous results were obtained for the first sample. Plasma can be used, but serum is preferable. Plasma and serum titers should not be compared to determine changes over time. Aseptically collected serum can be stored at 5°C for several months. For long-term storage, freezing at –20 or –70°C is recommended.

TABLE 2 Materials and methods to be used for diagnosis and monitoring of disease caused by EBV, for identification of EBV-associated malignancies, or for verification of EBV association in already diagnosed tumors

Suspected EBV-associated condition	First-choice method	Suitable material	Second-choice method	Suitable material
IM	Serology	Serum	PCR[b]	Serum or plasma
LPD outside CNS[a] immunosuppressed patients	Quantitative NAAT	Whole blood, serum or plasma, leukocytes	In situ hybridization and/or antigen detection	Tumor biopsy specimen
CNS lymphoma in immunosuppressed patients	Quantitative or qualitative NAAT	CSF	In situ hybridization and/or antigen detection	Tumor biopsy specimen
Nasopharyngeal carcinoma	Serology	Serum	Quantitative or qualitative NAAT	Plasma or serum
XLP	Genetic analysis	Cells	Serology	Serum
Other EBV-associated tumors	In situ hybridization and/or antigen detection in tumor cells	Biopsy specimen	Quantitative or qualitative NAAT[b]	Plasma or serum

[a] CNS, central nervous system.
[b] Still not fully evaluated, but promising in preliminary reports.

DIAGNOSTIC METHODS

Direct Detection

Electron Microscopy

Electron microscopy is not an appropriate diagnostic technique for EBV, since latency is the norm and virions rarely are present in sufficient amounts in infected tissues.

Antigen Detection

EBNA 1 is the only antigen expressed in all EBV-infected cells. Staining for EBNA 1 in tissues and cell lines by anticomplement immunofluorescence (ACIF) with carefully selected polyclonal sera or a monoclonal antibody (29, 61) has been the main method used for detection of EBV. For differentiation between latent and lytic infection and for characterization of type of latency associated with different EBV-associated tumors, immunohistochemistry is widely used (39, 61). A number of investigational-use antibodies against both latent and lytic antigens are available (29, 66, 90, 96). In practice, staining for EBNA 2 and LMP 1 is sufficient to define the form of latency (61). However, detection of nucleic acids is more sensitive if knowledge of the mere presence of EBV is desirable.

Nucleic Acid Techniques

Molecular techniques are important tools for detection of EBV RNA and DNA in clinical specimens. For the clinical laboratory, the choice of which EBV nucleic acid technique to use is dictated by the availability of methods and specimens, as well as the medical questions to be answered. A variety of methods, such as in situ hybridization on frozen or paraffin-embedded sections, cyto-hybridization on cell suspensions, dot blot hybridization, Southern blot hybridization, or NAAT, may be used (17, 32, 34, 91, 92). Today, NAAT methods are probably the most commonly used tools for detection of EBV and can be performed on many different clinical specimens (Table 2) after RNA or DNA extraction. A variety of primers, probes, and techniques have been presented (35). Two general-purpose probes are widely used for EBV detection. The conserved BamHI W region, coding for a long internal repeat sequence of EBNA 1, is present in multiple copies in EBV-infected cells. Probes targeting this region have maximal sensitivity in both DNA hybridization and genome amplification assays on clinical samples (10, 91). Also the LMP 1 gene is conserved and suitable for NAAT primers (19). In situ NAAT can detect one EBV genome in formalin-fixed and paraffin-embedded tissue or in whole blood (85). Quantitative real-time PCR is probably the most popular method today for monitoring EBV in patients at risk for PTLD (53). The Namalwa cell line, containing two integrated EBV copies per cell, is frequently used as a standard for determination of the number of EBV copies in a sample (19). Since increases in genome levels often signify a pathological process, the criteria for a significant increase must be determined by establishing the expected interassay variation by repeated examination of the same material (70, 79). Different statistical calculations can be used to determine the limit. A variation of 0.5 $\log_{10}$ (threefold) is often used as indication of a change that is above the expected interassay variation. Appropriate controls for contamination and inhibition should always be included. Participation in external quality control programs is important to ensure the sensitivity, specificity, and correct quantification (see evaluations at http://www.QCMD.org).

Like NAAT, in situ hybridization and cytohybridization require small amounts of sample. They can also be combined with immunohistochemical staining, and they are ideally suited for the detection of EBV in tumor tissues. Sequence-specific RNA or DNA in a single cell can be detected by in situ hybridization, also allowing for cellular localization of the EBV infection. Both RNA and DNA probes can be used for hybridization (55, 60). The EBER1 and EBER2 genes, each coding for a small RNA expressed in high (10^6 to 10^7) copy numbers, were found to be highly sensitive in detecting latently infected tissues and tumors (67). The blot techniques require larger samples but are useful when multiple analytic probes are needed.

Isolation Procedures

EBV isolation is not a routine method but may be important for research purposes. For EBV isolation, freshly fractionated human cord blood lymphocytes are inoculated with cell-free and filtered saliva or throat gargle specimens and monitored for 4 weeks (1). Individual viral isolates can be characterized by molecular techniques, on the basis of polymorphism of the EBNA 2 and 3 genes. In addition, the sizes of many of the EBNA proteins (EBNA 1 to 6) are strain dependent. Each isolate induces proteins with distinctive patterns by Western blotting, thus allowing the fingerprinting or "EBNo-typing" of each virus (31).

Serologic Tests

Heterophile Antibodies

Serologic testing is still the method of choice for the diagnosis of primary EBV infections (38, 40, 64, 68). For patients with classical IM, demonstration of Paul-Bunnell heterophile antibodies is diagnostic and no further testing is necessary (66). In-house Paul-Bunnell assays are rarely used at present. Instead, rapid qualitative agglutination or immunochromatographic assays for heterophile antibodies are widely available. They are all intended for laboratory and point-of-care use and are effective for 80 to 85% of the IM patients (6, 50). However, performing the agglutination assays may be unsuitable for persons without laboratory training, since the evaluation of a true positive agglutination result demands some experience. A strict adherence to the procedure described by the manufacturer concerning the time frame within which to read results is required, since spontaneous agglutination always appears over time. Also in comparative studies, immunochromatographic assays have performed better than agglutination assays (6).

EBV-Specific Antibodies

Around 15 to 20% of patients with EBV IM lack heterophile antibodies, and for these, EBV-specific serology is necessary for confirmation of the diagnosis. Traditionally, in the qualified virus laboratory, antibodies to four antigen complexes are measured, including the virus capsid antigen (VCA), a combined assay for the diffuse component of the early antigen (EA/D) and the early antigen-restricted component (EA/R) and the EBNAs. In addition, differentiation of immunoglobulin G (IgG), IgM, and sometimes IgA to VCA is made. The development of the antibody profile for evaluation of the EBV serological status of a patient with suspected mononucleosis is presented (Fig. 1). The immunofluorescence assay (IFA) methods are still the "gold standard" in EBV serology, but a large number of serologic assays using different methodologies are in use today. Commercially available kits are of three types: IFA, enzyme-linked immunosorbent assay (ELISA), and immunoblot assays. IFAs have fairly uniform performance characteristics as a group, principally because the cell substrates provided by various suppliers

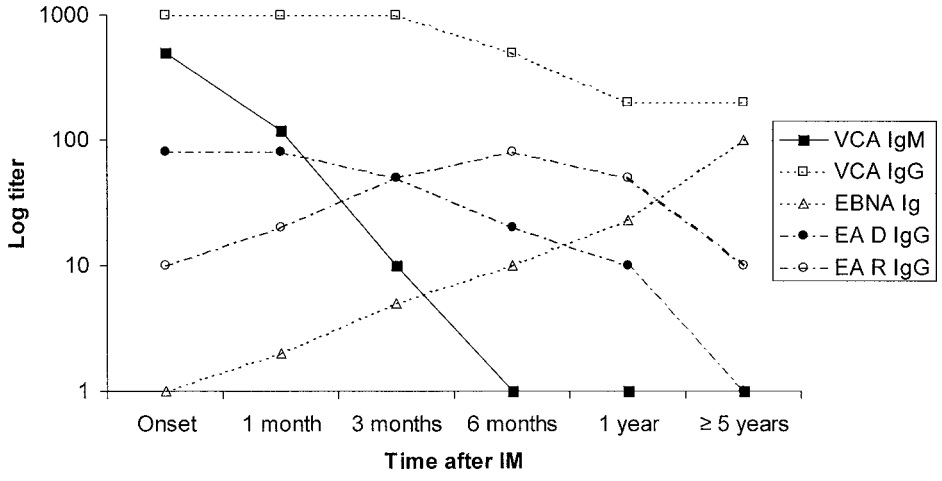

FIGURE 1 Development of titers to some EBV antigens over time after primary infection, as measured by IFAs using cell-bound antigens. Although marked interpatient and interlaboratory variation in titers occurs, the figure gives the characteristic development of titers in relation to each other.

are similar. The performance of ELISAs is much more variable, due to the plethora of antigen preparations used in the different kits. They range from cell extracts to recombinant or fusion proteins and synthetic peptides (40). Therefore, the reference criteria for interpretations established for the IFAs (Table 3) may not apply to all ELISAs, even when the antigens are referred to by the same name. For example, EBNA is a complex of several large, native proteins detected in Raji cells by ACIF, whereas the same designation may be given to a single oligopeptide deduced from EBNA 1 or an EBNA 1 recombinant protein in ELISAs. Recombinant proteins and peptides, however, are easier to standardize than cell-grown antigens, and possibly assays using synthetic antigens will be more widely used in the future.

There are many published evaluations of varying quality concerning the performance of commercial ELISAs (6, 21, 22, 26, 41, 84). Lack of standardization for the evaluations, batch-to-batch variation of some assays, and varying names and distributors of the assays in different countries and over time, as well as different demands, economy, and routines at individual laboratories, make it impossible to provide firm advice as to what brand to choose. In general, before selecting an assay, one must ascertain that it has been thoroughly investigated and related to reference IFA methodology. Examination of a series of consecutive clinical samples should be performed to determine the sensitivity and specificity in each laboratory setting, and a selection of problematic sera (mainly sera from patients with other herpesvirus infections and from patients with autoimmune diseases) should also be examined. Further, to ensure batch-to-batch stability, internal serum controls, apart from the controls provided by the manufacturers, and participation in external quality control programs, are necessary.

Antibodies against Individual EBV Antigens

VCA

The main VCA is a 150-kDa protein, but p18 and p23 proteins are also included in the VCA complex and used for serology (40). Thus, what is called VCA in reality is a mixture of antigens expressed by the P3HR1 cell line entering the lytic phase, to which human sera react (68). VCA-ELISAs containing antigens from infected cells have been available for a long time, and assays using affinity purified antigen still perform better than ELISAs with recombinant or synthetic antigens (22). Recently, ELISAs and line blot assays using recombinant VCA proteins (p23-p18) and a peptide (p18) have been reported to perform adequately in relation to IFAs (8, 41, 87).

TABLE 3 Typical EBV serological profiles under different conditions[a]

Condition	Presence of antibodies to antigen and Ig isotype[b]:						
	VCA, IgG	VCA, IgM	VCA, IgA	EA/D, IgG	EA/R, IgG	EBNA, Ig	EBNA 1, IgG
Seronegative	−	−	−	−	−	−	−
Ongoing primary infection	++	+++	+	+	±	−	−
Recent primary infection	++	+	+	+	+	±	−
Past infection	+	−	±	−	±	+	+
Chronic active EBV infection	+++	+	++	++	+	±	±
NPC	+++	−	+++	+++	+	+++	+++
XLP	±	−	−	−	−	−	−

[a] The most frequently employed antigens and Ig isotypes are included.

[b] −, antibodies completely absent; ±, antibodies absent or present in low titers; +, antibodies present; ++, antibodies present in elevated titers; +++, antibodies present in strongly elevated titers.

EBV Early Antigens

Anti-EA/D and EA/R antibodies are traditionally measured with Raji cells, activated by, e.g., phorbol ester and sodium butyrate, to enter the lytic phase. Ethanol fixation eliminates the EA/R complex, and cells fixed in ethanol are used for studies of EA/D antibodies, but separation of EA antibodies is seldom made for diagnostic purposes today. ELISAs with cell-derived and recombinant EA proteins are available, but especially the EA IgM assays are often lacking somewhat in both specificity and sensitivity (6, 84).

Anti-EBNA

The ACIF assay or assays with equally high sensitivity must be used to detect the low concentration of EBNA antibodies by IFAs. ELISAs can be made more sensitive than ACIF, but they have been adjusted to be of sensitivity similar to that of ACIF since the late seroconversion to EBNA 1, as measured by ACIF, is an important part of diagnosis. The complement-fixing antibodies detected by ACIF may be of almost any Ig isotype and should be referred to as EBNA Ig. The EBNA staining pattern is nuclear and should be present in all EBV-infected cells. The preparations should contain cells from an EBV-negative lymphoblastoid cell line, or EBV-negative cells could be incubated in parallel staining, to ensure that the nuclear staining is not due to antinuclear factors present in the patient's serum.

Commercial ELISAs containing cell-derived EBNA antigen or recombinant EBNA 1 antigen are available. The recombinant antigen assay containing p72 has ≥95% sensitivity and specificity compared to the ACIF assay for total EBNA Ig (23, 84). The same antigen is used in line blot assays. Antibody responses to individual EBNA components can be measured using ACIF with transfected cell cultures (18).

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

Diagnosis of EBV IM (Table 3)

Heterophile Antibodies

High levels of heterophile antibodies are seen during the first month of IM, normally followed by a rapid decrease. As a rule, in typical cases, a positive assay for heterophile antibodies is sufficient confirmation of a primary EBV infection. False-positive results are found mostly in individuals with low but persisting levels long after their primary illness. However, other viral infection agents such as CMV may also cause false-positive results, especially in the agglutination assays. False negatives (mean, 10 to 15%) are the rule among young children (82) but also occur in adolescents and adults. For these patients, EBV-specific serologic testing is needed.

Antibody Reactivity against Various EBV Antigens

Most IM patients have peak titers of both IgG and IgM antibodies to various antigens belonging to the EBV lytic phase (VCA and EA) by the time they consult their physicians but lack antibodies to the EBNA antigens, as measured by the standard ACIF assay using Raji cells (Fig. 1). IgM VCA starts to disappear after 4 weeks, and the levels of IgG VCA decline with time. However, IgG VCA persists for life, and its presence is the most reliable test for EBV seropositivity. The EBV status of the patient can generally be determined from a single serum sample by measuring antibodies to a panel of EBV-associated antigens. The characteristic antibody profile is sufficiently distinct in at least 90 to 95% of the cases to allow classification as to whether the patient (i) is still susceptible to EBV, (ii) has a current primary infection, (iii) has had a recent primary infection (within 2 to 3 months), (iv) has a past infection, or (v) may be having reactivated EBV infection (Table 3).

A cost-effective, stepwise analysis of sera for serologic diagnosis of heterophile-negative IM could start with analysis for antibodies to EBNA 1 (47). These antibodies normally do not appear until 6 weeks after onset of IM, and the assay should be negative in acute IM (37). They are maintained for life but have been reported to be of low titer and sometimes undetectable in EBV-seropositive children (82) even without recent primary infection. With severe immunosuppression, the anti-EBNA titers may gradually decrease but rarely disappear entirely. Only sera with no or very weak EBNA 1 reactivity need to be further examined and analyzed for IgG and IgM to VCA. If both are positive, a primary EBV infection is confirmed. Diagnosis of primary EBV infections should not rely only on the detection of IgM-VCA since both false-positive and false-negative results occur in IgM VCA testing. The former is mostly due to the presence of rheumatoid factor (36), other herpesvirus infections, and antinuclear factors (49). False negatives may result from late collection of serum samples or insufficiently sensitive methods. Some ELISAs use EA instead of VCA for confirmation, but the EA IgM ELISA especially has a low specificity (84). Inclusion of measurement of IgG to EA by IFA may increase the diagnostic discrimination concerning EBV IM, but the use of commercial assays with inclusion of the p18 protein or Western blots including an array of proteins may be more valuable (40). Further, avidity indices of VCA IgG antibodies can add information, especially if serum is drawn late after onset of disease and EBNA antibodies have already appeared (4, 74). In a laboratory using Western blot routinely for other agents, a commercial blot method could be used for primary screening for EBV IM, or as a second line, after the exclusion of EBNA-positive patients. It can also be combined with avidity testing, and may then be of sensitivity and specificity equal to those of the IFA reference methods (4, 22). EBNA 1 to EBNA 2 titer ratios were used for some time to verify chronic or complicated EBV infections (37, 47). However, no clear association can be made between the anti-EBNA 1 to EBNA 2 ratio and the duration or nature of illness, and the significance of antibodies to other EBNA components is still not firmly settled.

The interpretation of the specific antibody status must always be related to the condition of the patient, above all to the immunological status. In immunocompetent individuals, only three interpretations are relevant in routine diagnostics: primary infection, past infection, and EBV susceptibility (23). In Table 2, the methods of choice depending on the condition of the patient and the suspected EBV-related disease are presented.

The exact titers to each EBV antigen and the time needed to develop a full spectrum of antibodies vary widely between individuals. Significant changes in EBV antibody titers can be demonstrated only with the consecutive samples analyzed in the same assay. In general, the antibody titers to the various antigens are remarkably stable after adolescence in immunocompetent individuals. Significant changes in titers are seldom seen except during the early acute phase of the infection. Many apparently completely healthy individuals may maintain EBV antibodies at high levels throughout life (95). High titers alone are therefore not diagnostic of EBV-associated disease, but the combination of very low or absent EBNA 1 antibodies and high titers to other EBV antigens indicates a pathological virus-host relationship (63). Whether EBV is the cause of disease or immune aberrancies induced by the disease

cause an asymptomatic EBV reactivation, however, is always difficult to establish. Each laboratory not using well-characterized, commercial assays must establish its own range of "normal" titers in healthy, EBV-seropositive individuals. Titers need to be established using the laboratory's own microscope and other equipment and healthy donor sera. Due to the complexity of EBV serology, written interpretations of results should be sent to the clinicians.

EBV can be detected by NAAT in serum in most IM patients until around 2 weeks after onset of disease (3, 20), but the role of NAAT in the routine diagnosis of IM is not established. The main problem is that EBV genomes may be detected in healthy individuals. The level is normally low (20), but studies of blood from healthy donors indicate that temporary increases in levels may occur quite frequently (51, 57).

Chronic Active EBV Infections

During the 1980s, the diagnosis of chronic EBV (7) infection was given to patients with a variety of diffuse symptoms, often dominated by fatigue and fever. The EBV diagnosis was based mainly on the finding of antibodies to EA. There now seems to be a general agreement that symptomatic EBV reactivations are very uncommon. The term "chronic active EBV infections" could be given to rare, severe EBV-associated conditions, often ending in EBV-associated malignancies or other diseases with lethal outcome (63, 73). The serologic profile should be similar to what is found in primary EBV infection. However, most likely due to long-standing antigen stimulation during chronic reactivation, VCA and EA/D IgG titers are usually higher than during primary infection and may reach extremely high levels. VCA IgM titers may be very low or undetectable (Table 3).

EBV-Associated Malignancies and XLP

For patients with chronic conditions other than malignancies affecting the host-EBV balance, profiles of EBV antibodies compatible with EBV reactivation are already established by the time most patients seek clinical diagnosis. Their EBV serological profiles do not undergo observable change. Whether there is a relation between EBV and the symptoms or the EBV reactivation is an asymptomatic consequence of their immune disorder is seldom possible to discern. EBV serology for these patients is not clinically indicated. In nasopharyngeal carcinoma, elevated antibody levels of various isotypes to a variety of antigens, e.g., VCA and LMP 2 (48), LMP 1 (94), thymidine kinase (12), ZEBRA (14), and EBNA 1 (9), have been identified. The assays could be used for screening of high-risk populations. Positive findings should lead to close examination of the nasopharynx. Maintenance of high antibody levels after treatment correlates with a bad prognosis. The best-documented antibodies for monitoring are VCA IgA antibodies. The presence of EBV DNA in plasma has recently been suggested as a more reliable marker, both for diagnosis and monitoring of NPC (52, 76, 77). However, DNA detection is expensive, and serology may still be more suitable for the large-scale general screening that may be indicated in affected geographic areas.

Monitoring for EBV-associated lymphoproliferative disease in transplant recipients is indicated for those at high risk (see above). The EBV serostatus should always be clarified before transplantation since seronegativity is one risk factor. Thereafter, serology is of little value since the heavy immunosuppression of transplant recipients prevents adequate antibody formation. Monitoring of viral load by NAAT is the method of choice (69). NAATs detect EBV in some asymptomatic persons, and cutoff levels for significant viral loads must be defined for each patient group and for each material. Saliva and leukocytes have low predictive value for disease, since in healthy seropositive individuals, EBV genomes can be detected in saliva (20, 54), and there may be up to 1 to 50 EBV-infected B cells in 1 million B cells (45). Detectable EBV genomes in serum or plasma are a more reliable sign of a pathological virus-host relationship (2, 78). However, any immunocompromised patient may lack EBV-associated symptoms despite detectable EBV in these materials. Irrespective of the material, diagnostic cutoffs at low copy numbers give low specificity for tumor development, while a high cutoff gives low sensitivity (24). A significant increase in genomes is a relatively strong marker for an ongoing pathological process and is an indication for the need for a further search for EBV-associated malignancies in at-risk patients. Since the disease and also its treatment have severe consequences, additional easy-to-use but more precise markers for risk of PTLD would be valuable.

EBV-positive CSFs from HIV-infected individuals have been reported to be significantly associated with primary central nervous system lymphoma (10), but the findings have not been fully verified in recent studies (43). In nonimmunocompromised individuals it is found in EBV encephalitis, but the specificity for EBV-associated disease is not 100% (81). For unambiguous laboratory diagnosis of possible EBV-associated lymphoproliferation or other malignancies, detection of EBV genomes by amplification should be complemented by other laboratory data, such as in situ immunohistochemical detection of LMP 1 or EBERs in hyperplastic or neoplastic cells.

XLP is very rare, but the severity and the heredity of the disease make it important to identify. Typically, these patients do not develop EBNA antibodies, and usually they have low titers to other EBV-associated antigens in comparison to other patient groups with chronic lymphoproliferative diseases. The ultimate diagnosis rests on genetic analysis for mutations in the SH2D1A gene domain, and such analysis should certainly be performed in the few cases where the questions may arise.

Human Herpesviruses 6, 7, and 8

PHILIP E. PELLETT AND GRAHAM TIPPLES

104

The viruses discussed in this chapter are *Human herpesvirus* 6 variants A and B (HHV-6A and HHV-6B), *Human herpesvirus* 7 (HHV-7), and *Human herpesvirus* 8 (HHV-8; Kaposi's sarcoma-associated herpesvirus). These viruses cause diseases that are clinically significant primarily in small children and in immunocompromised patients (Table 1). The clinical challenges relate to differential diagnosis, identification of efficacious therapies, and discrimination between their adventitious and etiologic associations. Diagnostic challenges include a lack of licensed diagnostic kits and limited commercial availability of specific reagents. This leaves it up to the local laboratory to devise in-house assay validations and quality control and quality assurance programs that meet regulatory requirements. A limited array of laboratory assays for these viruses is available through commercial reference laboratories; the information provided here will help in deciding when such assays are needed, choosing the most appropriate test, and interpreting test results.

HHV-6

Taxonomy

HHV-6A and HHV-6B are the most closely related pair of known herpesviruses that warrant designation as individual species (75). Along with HHV-7, which is somewhat more distantly related, these viruses comprise the *Roseolovirus* genus of the betaherpesvirus subfamily. Roseoloviruses share many features of their genomic architecture and genetic content, the ability to replicate and establish latent infections in lymphocytes, associations with febrile rash illnesses in young children, and being opportunistic pathogens in immunocompromised patients. For convenience we will frequently refer to HHV-6A and HHV-6B collectively as HHV-6.

Description of the Agent

Like all herpesviruses, HHV-6 virions consist of four concentrically arranged major components: a double-stranded DNA genome (160 to 170 kb) that is contained in the core of an icosahedral capsid, which is surrounded by a proteinaceous tegument, all of which is surrounded by a lipid bilayer envelope that is studded with a variety of virally encoded proteins and a sprinkling of cellular proteins. The viral genomes encode approximately 100 unique genes.

Epidemiology and Transmission

Epidemiology

Collectively, HHV-6A and HHV-6B are highly prevalent, with seroprevalences in many populations exceeding 90% (30). Most individuals become infected by the age of 2 to 3 years (98). HHV-6B is the main source of the nearly universal early childhood HHV-6 infections, and HHV-6A prevalence may exceed 50% by adulthood.

Tissue Distribution

The cell surface receptor for HHV-6 is CD46, a widespread cell surface antigen. HHV-6B DNA has been detected in as many as 90% of peripheral blood mononuclear cell (PBMC) specimens, >80% of brains, >90% of tonsils (in epithelial cells of tonsilar crypts), and 40 to 90% of saliva or oral fluid specimens; it has been detected less frequently in skin, lungs, endomyocardial biopsy specimens, goblet cells and histiocytes in the large intestine, and cervical fluids. During primary infection in young children, HHV-6A was found by PCR in 2.5% of PBMCs and in 17% of cerebrospinal fluid (CSF) specimens, while HHV-6B was found in 99% of PBMCs and 86% of CSF specimens (some specimens were coinfected) (42). The median salivary viral level of HHV-6 increased from approximately 10^3 copies of HHV-6/ml at 1 week postinfection to 10^5 copies of HHV-6/ml by 8 weeks postinfection (98). HHV-6A DNA has been detected in over one-half of lung and skin specimens, mostly in conjunction with HHV-6B. In a study of adult brains, 28% were positive for HHV-6A and 75% were positive for HHV-6B (some were dually positive) (18). In bone marrow transplant recipients, HHV-6A and HHV-6B were both detected in plasma, while HHV-6B was the variant detected in PBMCs (68). A small percentage of individuals (0.5 to 1%) harbor germ line integrated HHV-6A or HHV-6B genomes, and thus all of their cells are positive for viral DNA, which may be a source for the occasionally detected persistence of high levels of HHV-6 DNA in serum (92).

Latency and Persistence

Other than during the acute phase of roseola, HHV-6 can seldom be detected by culture, even though its DNA can be intermittently detected in most children by PCR, and transcripts can be occasionally detected in asymptomatic children (~1% of specimens) (14). This suggests that a true

TABLE 1 Disease associations

Virus	Age at primary infection	Principal disease associations	
		Primary infection	Immunocompromised patients
HHV-6A	?	Occasional roseola	Disseminated infections, CMV-like and CMV-associated disease, pneumonitis, graft loss
HHV-6B	<2 yr	Most roseola, related febrile/rash illness	Disseminated infections, CMV-like and CMV-associated disease, pneumonitis, graft loss
HHV-7	>50% by 2 yr	Occasional roseola	CMV-like and CMV-associated disease
HHV-8	During childhood in Africa; postadolescence in the United States and Europe	?	KS, MCD, PEL, acute bone marrow failure in transplant recipients

latent infection is established in PBMCs. Latent HHV-6 has been detected in monocytes, their $CD34^+$ bone marrow progenitors, and in PBMC-derived dendritic cells. HHV-6 DNA is more frequently detected in salivary glands than in saliva, in contrast with HHV-7, which is frequently detected in both the gland and the fluid.

HHV-6A was reactivated in 53% of patients in an intensive care unit for medical or surgical indications or trauma (79). Extensive HHV-6 activity (variant not determined) was also seen in another study of intensive care unit patients who were experiencing multiple organ failure syndrome (33); there was no linkage of viral activity to disease severity or outcome in either study. Stress-induced HHV-6 activity thus represents a possible confounder of studies of the relationship between the virus and specific disease, as well as a possible subsequent contributor to the pathogenic process.

Transmission

HHV-6B primary infection typically occurs within a matter of months of the waning of maternal antibody, transmission likely being via saliva. Asymptomatic congenital transmission has been documented (at a rate of approximately 1%), one-third of these infections being with HHV-6A (41). Breast milk is not a significant vehicle for transmission. Little is known of HHV-6A transmission.

Clinical Significance

Infections with HHV-6 are generally mild or subclinical in immunocompetent individuals, but clinically important disease does occur and can be severe in immunocompromised persons.

Primary Infection

HHV-6 primary infection causes roseola (roseola infantum, sixth disease, exanthem subitum) in approximately one-quarter of children. While HHV-6B is the predominant etiologic agent of roseola, rare cases of HHV-6A-associated roseola or febrile illness have been reported. About 90% of children are symptomatic at the time of primary infection, with specifically associated symptoms including fever (58%), fussiness (70%), rhinorrhea (66%), diarrhea (26%), rash (31%), and roseola (24%) (98).

Classic roseola symptoms include an abrupt rise in temperature (39 to 40°C), which persists for 2 to 5 days. Fever abatement coincides with the onset of a maculopapular rash (only rarely vesicular) (Fig. 1), similar to measles and rubella, which resolves in 1 to 3 days. The initial appearance of the rash is on the neck, behind the ears, and on the back, followed by spread to the rest of the body, usually excluding the face and distal extremities. The illness lasts 2 to 7 days, usually with no sequelae. Other clinical symptoms may include palpebral edema, and suboccipital, postauricular, and cervical lymphadenopathy prior to rash onset.

Primary HHV-6 infection may also present as fever without rash or rash without fever. Less common but more severe forms of primary HHV-6 infection may include a body temperature of >40°C, respiratory tract distress, tympanic inflammation, diarrhea, and convulsions. Primary HHV-6 infection, with or without clinical roseola, accounts for a significant proportion of febrile seizures in young children who

FIGURE 1 Child with roseola during primary HHV-6B infection. Photo courtesy of Stephen Dewhurst, University of Rochester. Previously published in reference 36.

are taken to emergency departments (91). However, there were no seizure cases among 130 prospectively monitored children who had laboratory-confirmed primary HHV-6 infection (98), which suggests that relatively few primary infections result in seizures. Other serious but rare complications reported for HHV-6 primary infections include hepatosplenomegaly, Gianatti-Crosti syndrome (an acrodermatitis of childhood that has also been associated with hepatitis B virus and Epstein-Barr virus [EBV] infections), bulging fontanels, aseptic meningitis, encephalitis (perhaps 1% of meningitis and encephalitis cases) (91), seizures and poor neurologic outcome following congenital infection, or disseminated fatal infection.

Primary HHV-6 infection in adults is rare but can be severe. Clinical presentation in these cases may include mononucleosis-like illness, prolonged lymphadenopathy, and fulminant hepatitis.

Immunocompromised Patients

Under immunocompromised conditions, such as in the transplantation setting, or in AIDS patients, HHV-6 can reactivate, sometimes causing disease.

Transplant Recipients

HHV-6 reactivation occurs in approximately one-half of bone-marrow transplant recipients and one-third of solid organ transplant recipients (30). There appears to be a temporal pattern of HHV-6, HHV-7, and human cytomegalovirus (HCMV) reactivation for solid organ transplant recipients, with the median times posttransplantation being 20 days, 27 days, and 36 days, respectively (30).

HHV-6 is a consistent, low-to-moderate frequency contributor to posttransplant illness that can sometimes be severe, and its activity might be both a marker of and contributor to immune suppression (88). In bone marrow and stem cell transplant recipients, HHV-6 has been associated with encephalitis/encephalopathy, pneumonitis, delayed engraftment, erythematous papular rash, fever, CMV-like disease, graft-versus-host disease, seizures, hepatitis, diarrhea, and bone marrow suppression (reviewed in references 13, 30, and 95). In solid organ transplant patients, HHV-6 has been associated with encephalitis, pneumonitis, graft-versus-host disease, fungal disease, and bone marrow suppression. HHV-6B is detected more frequently than HHV-6A in transplant patients. Partitioning of HHV-6A into plasma and HHV-6B into both plasma and circulating lymphocytes (68) suggests that studies that focused on one or the other of these compartments may have missed part of the story.

Human Immunodeficiency Virus (HIV)-Infected Patients

Although HHV-6 infects and replicates in $CD4^+$ T cells, no specific role has been established for HHV-6 in AIDS; some interesting data suggest possible pathogenic interactions (26, 51, 75).

Infections in the Brain

HHV-6 can grow in neuronal cells, and neurological symptoms are clearly associated with primary infection. Numerous studies have shown that HHV-6 is a common inhabitant of the brain, and there have been many suggestions of a possible involvement of the virus in multiple sclerosis (MS) (25). While many studies have seen associations between the virus and disease in a subset of patients and others have found no difference between cases and controls, no study has shown an inverse association, which would be expected if the results were simply random. In addition, the more precisely linked the specimens have been to diseased tissue (e.g., microdissected lesions versus CSF versus serum), the stronger the associations have been. Thus, while the HHV-6–MS association is still a research question, it may soon be of greater relevance to diagnosticians, and some physicians and patients request such testing. Improved and standardized assays and validated controls are needed to allow proper comparison of research results, and potentially for monitoring patients.

In addition to the established etiologic role of JC polyoma virus in progressive multifocal leukoencephalopathy (PML), HHV-6 was more frequently detected in archival brain tissues from PML cases than in control tissues using in situ PCR and immunocytochemistry (64). In contrast, active HHV-6 infection as detected by HHV-6 PCR in CSF was not detected in a study of AIDS patients with progressive multifocal leukoencephalopathy (29).

Other Clinical Manifestations

Drug Hypersensitivity Syndrome

Exposure to various drugs occasionally results in a severe and sometimes fatal reaction variously known as drug hypersensitivity syndrome, drug rash with eosinophilia and systemic symptoms, and anticonvulsant hypersensitivity syndrome. The illness is characterized by rash, fever, and internal organ involvement. In a number of these patients, HHV-6 reactivations have been identified by very large increases in HHV-6 immunoglobulin G (IgG) antibody titers 3 to 4 weeks after onset (93). It remains to be seen whether HHV-6 contributes to either initiation or exacerbation of the events or whether either antiviral therapy or HHV-6 monitoring might be useful.

Rosai-Dorfman Disease

Rosai-Dorfman disease (histiocytosis with massive lymphadenopathy) patients have had increased HHV-6 antibody titers, HHV-6 DNA detected by in situ hybridization, and strong immunohistochemical staining for HHV-6 antigen in abnormal histiocytes.

Other Diseases

There is no conclusive evidence for an association between HHV-6 and malignancy or chronic fatigue syndrome, but the lingering possibility of an association with the latter leads to frequent requests for HHV-6 diagnosis. In our opinion, such information is of little clinical value.

Collection, Transport, and Storage of Specimens

For virus isolation, blood should be collected in an anticoagulant (such as heparin) and processed through a Ficoll gradient within 24 h; cells for virus isolation should not be frozen. After isolation, HHV-6-infected cells (both primary cells and cell lines) can be stored in standard cryopreservation media. Saliva specimens can be collected for virus detection (e.g., by PCR) by various methods, including filter paper strips (97), oral swabs, throat swabs, and expectorated saliva. Serum, plasma, and cells intended for PCR can be shipped frozen.

Direct Detection

Direct detection of HHV-6 can be done by in situ hybridization and in situ PCR (12, 71) and by immunohistochemistry (IHC) (55, 67). While those methods have their niches, the

most common method of direct detection is by PCR. The sensitivity of PCR is of particular value for the detection of HHV-6, given that even during periods of viral activity, viral DNA can be at a relatively low concentration relative to cellular DNA. A multitude of PCR strategies that utilize numerous HHV-6 genomic targets have been published. No genomic target or strategy has emerged as clearly superior; more needs to be done to compare and standardize methods. The list of methods includes single-target and multiplex PCR strategies, qualitative and quantitative assays, and methods that target either DNA (PCR) or RNA (reverse transcriptase [RT]-PCR). HHV-6A and HHV-6B can be readily distinguished by using variant-specific PCR primers, amplimer size differences, variant-specific hybridization probes, restriction enzyme analysis of PCR amplimers, or by melting curve analysis using real-time PCR.

Qualitative PCR for HHV-6 in the clinical laboratory can be set up as a component of a herpesvirus multiplex PCR assay that enables simultaneous analysis for multiple human herpesviruses (46, 49, 78). When multiplex assays are used, it is important to consider the clinical management implications and clinical significance (or lack thereof) of positive results for viruses that would not normally be included in the differential diagnosis.

Quantitative PCR (from whole blood or PBMCs) is particularly useful for the determination of baseline viral load levels in transplant patients, with significant increases above baseline indicating active infection. A LightCycler-based assay that quantitates and discriminates among HHV-6A, HHV-6B, and HHV-7 has been described (81).

We suggest the use of quantitative real-time assays that incorporate a coamplified positive control and allow the HHV-6 variants to be distinguished. Nested-PCR strategies are to be avoided because of the problem of contamination control. Important variables that need to be carefully standardized and then incorporated into the sensitivity calculation and interpretation are the amount of material initially lysed to prepare the template (e.g., volume of fluid or number of cells) and then the amount of this material that is included in each reaction (63). Sources for commercial PCR testing are listed in Table 2. Quantitated HHV-6A and HHV-6B DNA for use as PCR controls is available from Advanced Biotechnologies (Columbia, Md.).

Isolation Procedures

Although HHV-6 can be isolated from PBMCs by cocultivation of patient PBMCs with stimulated human umbilical cord blood lymphocytes (CBLs) (8, 31), primary isolation from clinical specimens is not routinely done in the clinical diagnostic laboratory. The primary cell culture medium consists of RPMI-1640, 10% fetal bovine serum, 100 U of penicillin per ml, 100 μg of streptomycin per ml, and 0.29 mg of L-glutamine per ml. Cells are cultured at starting densities of 10^6 cells per ml. Ficoll-purified primary CBL are first stimulated for 2 to 3 days at 37°C, 5% CO_2 in cell culture media containing 0.01 mg of hydrocortisone/ml and 2 μg of phytohemagglutinin/ml. Stimulated CBLs are then cocultured with an equal volume of Ficoll-purified patient PBMCs in the medium described above, except that the PHA is replaced with recombinant interleukin-2; interleukin-2 concentrations used in various laboratories range from 0.1 to 5 U/ml. Cultures are monitored daily for cytopathic effect (CPE). Typical HHV-6 CPE consists of loss of CBL clumping, the appearance of large balloon-like cells, and syncytium formation. After 7 to 10 days the culture is passaged into freshly stimulated CBLs. Cultures that remain healthy after another 7 to 10 days are considered negative. HHV-6 infection should be confirmed by immunofluorescence or PCR, as described below.

Isolates from primary CBL cultures can be adapted for propagation in continuous cell lines as follows: HHV-6A isolates in HSB-2 or J-JHAN cells, and HHV-6B isolates in Molt-3 cells. HHV-6B strain Z29 grows well in Molt-3 cells of the NIH lineage but not in Molt-3 cells from the ATCC lineage. Culture conditions are similar to those used for propagation in primary cells. Propagation of HHV-6 can be moderately tricky; more extensive procedural details are provided elsewhere (8, 9, 72). It is important to monitor cultures by an immunofluorescence assay (IFA) in addition to CPE. Nonoptimal culture conditions can lead to extensive CPE but little virus production.

Identification

Electron Microscopy

HHV-6 virions have typical herpesvirus morphology by electron microscopy: approximately 200-nm-diameter spherical enveloped virions, containing a 90- to 110-nm icosahedral capsid with an electron-dense core surrounded by an amorphous tegument.

MAbs

Numerous monoclonal antibodies (MAbs) are available (both commercially and from research laboratories) that react with both HHV-6A and/or HHV-6B. MAbs are useful

TABLE 2 Some commercial sources for HHV-6, HHV-7, and HHV-8 testing

for confirming cell culture CPE for HHV-6 infection, for antigen detection assays, and for flow cytometry. Well-characterized commercially available antibodies include MAbs against p41 (DNA polymerase accessory factor) and gp116/54/64 (glycoprotein B) (both from Advanced Biotechnologies, Inc.), and a B variant-specific MAb against the tegument protein 101K/p100 (Chemicon International, Temecula, Calif.). MAbs are also used for IHC analysis, such as in brain sections from patients with MS or in lymph node biopsy specimens. Although not all MAbs react well with antigens that have been fixed and then embedded in paraffin, the MAbs described above against gp116/54/64 and 101K are useful for such specimens. A list of published antibodies, their targets, variant specificity, and commercial sources is provided in reference 3.

Typing Systems

HHV-6A and HHV-6B can be typed through the use of variant-specific MAbs and variant-specific PCR assays (described above).

Serologic Tests

Numerous enzyme-linked immunosorbent assay (ELISA) methods for detecting HHV-6 antibodies have been described. Most are based on the use of lysate from HHV-6-infected cells; purified viral antigens can also be used. The most sensitive HHV-6 antigen in immunoblot assays (IgG and IgM) is a virion protein of approximately 100 kDa, designated either p100 or 101K. IFA is commonly used for the detection and quantification of HHV-6-specific IgM and IgG antibodies. Recent versus past infections can be discriminated through the use of IFA-based avidity antibody tests. Maturation from low- to high-avidity HHV-6 antibody following primary HHV-6 infection takes approximately 5 months. Antibody avidity testing can also be used to differentiate between HHV-6 and HHV-7 primary infections (90). Neutralizing antibodies typically become detectable 3 to 8 days following the onset of fever during primary infection. Sources for commercial antibody testing are listed in Table 2. Research antibody test kits (IFA and ELISA) are available from Advanced Biotechnologies and Biotrin (Dublin, Ireland). Slides and control sera are available from Panbio Diagnostics (Columbia, Md.) and Bion Enterprises (Des Plaines, Ill.).

Sensitivity and Specificity

ELISA-based methods are generally thought to be more sensitive than IFA, but this is not always true in practice and may depend on whether the definition of sensitivity is endpoint titer or simply detection of infection.

Specificity issues for HHV-6 serological methods involve cross-reactivity between HHV-6A, HHV-6B, HHV-7, and CMV (13, 90). Current serological methods based on whole infected cells as antigen do not differentiate between HHV-6A and HHV-6B antibody responses. Although adsorption studies have demonstrated the presence of cross-reactive antibodies to HHV-6 and CMV, the cross-reactivity is generally not sufficient to confound methods based on HHV-6 whole-cell lysates. The simultaneous rise in antibodies to both HHV-6 and CMV seen in some patients is not fully understood; it may be due to varying combinations of simultaneous activity of both viruses and some individuals responding to cross-reactive antigens. Limited cross-reactivity has also been found between HHV-6 and HHV-7 antibody responses; adsorption methods and antibody avidity can be used for differentiation (90).

Antiviral Susceptibilities

Antiviral treatment of HHV-6 has been reviewed in depth (30). The clinical circumstances for which antiviral intervention for HHV-6 might be appropriate include HHV-6 reactivation in immunocompromised individuals. There are presently no antivirals licensed for specific treatment of HHV-6; however, an approach similar to that for HCMV has been used. The best in vitro antiviral sensitivities and selectivities have consistently been for foscarnet, cidofovir, and ganciclovir. Similar to the mechanism of ganciclovir resistance for HCMV, there is in vitro and in vivo evidence that mutations in the HHV-6 U69-encoded protein kinase or the HHV-6 DNA polymerase gene can cause HHV-6 ganciclovir resistance.

Evaluation, Interpretation, and Reporting of Results

Methods used in the clinical virology laboratory must be thoroughly evaluated in the relevant clinical context (e.g., febrile and/or rash illness in children under 3 years of age, and specific forms of disease in immunocompromised individuals such as transplantation patients) to assess sensitivity, specificity, and positive and negative predictive values. Whether using in-house or commercial assays, the panel of specimens used in the evaluation should be validated with respect to a "gold standard" test or marker, such as virus isolation or seroconversion.

Laboratory diagnosis of HHV-6 is challenging given the many biological and molecular similarities between HHV-6A, HHV-6B, and HHV-7; the association between CMV and HHV-6 reactivation; and the need to differentiate between primary and reactivation disease. Also, other than for roseola and related febrile rash illnesses in children, the profiles of viral markers and immunologic responses during the course of HHV-6 primary infection and reactivation are still not well defined (11, 22). With these limitations, the interpretations of laboratory results for the detection of primary HHV-6 infections and the detection of active HHV-6 infection (which includes both primary and reactivation) are presented in Table 3. We also refer the reader to the elegant treatment of this issue by Ward (90).

Primary Infection

The following definitions have been used to diagnose HHV-6 primary infection: (i) antibody seroconversion between acute- and convalescent-phase serum or plasma specimens (collected 2 to 4 weeks apart); (ii) detection of HHV-6-specific low avidity antibodies in serum or plasma (90); (iii) a positive PCR result from whole blood and IgG-negative plasma within 5 days of disease onset in children older than 3 months of age (to avoid problems with maternal antibodies; some recommend 6 months) (22); (iv) a PCR-positive blood and PCR-negative saliva taken during the acute phase of disease (27); (v) positive serum IgM and/or serum PCR, when both have been evaluated (to improve on the lower sensitivity of testing for each marker alone) (11); and (vi) detection of IgM antibodies in the absence of IgG antibodies. Assaying only for IgM is of limited value for this purpose, given that approximately 5% of adults are HHV-6 IgM positive at any time and the window of IgM positivity is poorly defined. Primary HHV-6 infection almost always occurs in children before 2 to 3 years of age. Thus, in cases when clinical symptoms are compatible with roseola (the illness most commonly associated with HHV-6 primary infection in young children), a serum specimen that tests positive for both IgM and IgG

could indicate primary infection if the blood was collected after the IgG response developed; avidity testing could clarify the diagnosis in this case. Quantitative PCR assays are preferred because they allow identification of individuals with extraordinarily high viral loads that may be due to germ line integrated viral DNA, which can conceivably lead to positive serum or plasma specimens that are diagnostically ambiguous (92). Further evaluations and standardization of diagnostic algorithms are needed.

Active Infections

The following criteria have been considered to be diagnostic for detecting active infections, which include both primary infections and reactivations: (i) virus isolation from PBMCs (the gold standard); (ii) a significant rise in antibody titers (>4-fold) between acute- and convalescent-phase serum or plasma specimens; (iii) a positive serum or plasma PCR result for HHV-6 DNA (the low sensitivity of this marker suggests that it should not be relied on as the only marker); (iv) quantitative PCR from whole blood or PBMCs with results above a defined threshold level (e.g., transplant patients routinely monitored to determine baseline HHV-6 viral load; a significant increase in viral load is indicative of reactivation); and (v) detection of spliced HHV-6 mRNA by RT-PCR (69). Yoshikawa et al. (96) suggest that a combination of RT-PCR detection of immediate early and late genes provides optimal sensitivity and specificity for confirming active HHV-6 infections. In many circumstances, the final diagnosis is strengthened by analysis of paired acute- and convalescent-phase specimens.

Individuals with Constitutively High Viral Loads

Approximately 1% of individuals harbor exceptionally high HHV-6 loads in their PBMCs (approximately one copy per cell equivalent of DNA), apparently due to germ line HHV-6 integration. No HHV-6-linked immunologic deficiency, disease, or unusual virologic activity has yet been observed in such individuals. This circumstance can be difficult to detect in acellular fluids but often leads to striking results when a cell-derived template is analyzed in a quantitative PCR assay. This reinforces the need to monitor serial specimens; if all are positive and the viral load is very high and constant, this may well represent integrated virus that could be irrelevant to the event being examined.

HHV-6 Testing in the Clinical Setting

Clinical testing for HHV-6 should be limited to circumstances for which there has been a well-characterized association between the disease and HHV-6 infection and when the results of a given test will be diagnostically informative. For example, HHV-6 IgG or IgM serology in an adult done at a single time point is of limited diagnostic value. Clinical scenarios where HHV-6 testing could be considered include primary infection in children under 3 years of age and primary infection or reactivation in immunocompromised individuals such as AIDS patients or transplantation patients, those with mononucleosis-like syndromes, and meningitis and encephalitis cases. Still relevant in some parts of the world, HHV-6 has been identified as the cause of rash illness incorrectly diagnosed as measles infection. The possibility of primary HHV-6 or HHV-7 infection should be considered when febrile and/or neurologic illness occurs shortly following routine immunizations; such illness may be incorrectly attributed to the vaccine (90).

Further studies are needed to improve our understanding of the associations between HHV-6 and disease and to improve the quality of HHV-6 diagnostic testing.

HHV-7

Taxonomy

Because of the relative similarity of its nucleotide sequences, genomic architecture, and biology with those of HHV-6A and HHV-6B, HHV-7 is included as a member of the *Roseolovirus* genus of the betaherpesvirus subfamily (75).

Description of the Agent

Like all herpesviruses, HHV-7 virions consist of four concentrically arranged major components: a double-stranded DNA genome (145 kb) that is contained in the core of an icosahedral capsid, which is surrounded by a proteinaceous tegument, all of which is surrounded by a lipid bilayer envelope that is studded with a variety of virally encoded proteins and a sprinkling of cellular proteins. HHV-7 genomes carry approximately 100 unique genes.

Epidemiology and Transmission

Epidemiology

HHV-7 seroprevalence in healthy adults in Europe, Japan, and the United States ranges from 60 to 90%. Following waning of maternal antibody, HHV-7 seroprevalence rapidly increases to over 50% by 2 years of age and then progresses toward the adult level over the remaining years of childhood.

Tissue Distribution

Although its in vitro host range is restricted to lymphocytes, HHV-7 has a broad cellular host range in vivo. One of its cellular receptors is the lymphocyte antigen, CD4; other receptors must be involved in the infection of other cell types. HHV-7 lytic antigens have been detected in salivary gland acini, lungs, skin, and mammary glands, and more sporadically in liver, kidney, and tonsils (48). HHV-7 DNA has been detected by PCR in PBMCs, salivary glands, and gastric mucosa. The virus has seldom been detected in brain tissues. Infectious HHV-7 has been occasionally isolated from PBMCs during roseola and is easily isolated from the saliva of healthy adults. HHV-7 shedding in the saliva is associated with younger age and low HHV-7-specific antibody titers (45). The ability to detect HHV-7 DNA in uncultured lymphocytes by PCR, along with the inability to detect infectious virus in the absence of T-cell activation, suggests that the virus is latent in PBMCs. Macrophages represent another potential reservoir (99).

Transmission

HHV-7 can be cultured from the saliva of ~75% of healthy adults, with viral loads frequently exceeding 10^6 genomes per ml. While the most plausible route of transmission is via saliva, HHV-7 has also been detected in breast milk, urine, and cervical secretions. In contrast to HHV-6, congenital transmission of HHV-7 has not been documented (41).

Clinical Significance

Primary Infection

HHV-7 causes perhaps 5% of roseola cases, as well as other febrile illness in children. In one small study, HHV-7 appeared to cause milder roseola than HHV-6 in terms of mean and maximum fever, fever duration, and duration of rash. However, other studies suggest a rate of central nervous system complications during HHV-7 primary infections equal to or higher than with HHV-6 (91). HHV-7 neurologic involvement includes hemiplegia and febrile seizures.

TABLE 3 Diagnostic methods for HHV-6, -7, and -8

Virus	Method	Approach	Advantages	Limitations	Clinical availability	Key reference(s)
HHV-6	Virus isolation	Cocultivate PBMCs with stimulated primary CBLs	Gold standard for active infection	Slow, need for ongoing access to umbilical cord blood	Not practical in the routine clinical lab	8, 9, 31, 72
	Antigen detection	Use of HHV-6A, -6B variant-common and variant-specific MAbs against p41/p38, gp116/54/64, gp82/105, 101K for IHC and culture confirmation	Specific, readily available reagents	Primarily described for research studies, not clinical testing	Commercially available MAbs	3
	Serology	IgM and IgG; NT, immunoblot, IFA, ACIF, ELISA; major antigen: p100/101K		Single IgG-positive results are uninformative; clinical significance of IgM in individuals >3 yr of age is questionable.	Practical for clinical labs; commercially available	11, 13
		Antibody avidity	Clear identification of primary infections	Best with acute and convalescent specimens	Avidity test not commercially available	90
	PCR	Qualitative and quantitative		Optimal target not determined; assays not standardized; quantitation threshold not determined or standardized	Practical for clinical labs; commercial assay available	Numerous methods reported in the literature
		PCR from PBMCs or plasma/serum		Not able to unequivocally differentiate latent from active infections for PBMC/whole-blood PCR.		11, 22, 27
		RT-PCR from PBMCs to detect active infections	Confirms active infection	Not standardized	Not commercially available	
		Herpesvirus multiplex	Convenient for the lab	Clinicians may not want testing done for all human herpesviruses because of interpretation and clinical utility issues.		46, 49, 78
HHV-7	Virus isolation	Cocultivation of PBMCs with stimulated primary CBLs; inoculation of CBLs with saliva from healthy and ill patients	Gold standard for active infections	Not practical in the routine clinical lab		8
	Antigen detection	Several, including against pp85; for IHC and culture confirmation			Commercially available MAbs	7
	Serology	IgM and IgG			Commercially available materials	7
		NT, immunoblot, IFA, ELISA; major antigen: pp85				10, 85
		Antibody avidity	Clear identification of primary infections	Best with acute and convalescent specimens		90
	PCR	Qualitative and quantitative PCR from PBMCs or plasma/serum			Practical in the clinical lab; commercial testing is available	6

	Herpesvirus multiplex	Convenient	Clinicians may not want testing done for all human herpesviruses because of interpretation and clinical utility issues.		46, 49, 78
HHV-8					
Virus isolation	Not available				
Antigen detection	MAbs against K8.1, ORF59, LANA; for IHC	Distinguish KS from clinical mimickers		MAbs are commercially available.	21, 43, 74, 80
Serology	Mostly IgG			Reagents, research kits, and testing are commercially available.	19, 66
	IFA based on unstimulated (latent) or stimulated (lytic) PEL cells; also immunoblot and ELISA				20, 23, 53, 61, 82, 83
	Neutralization assay				50
	Major lytic antigens: ORF65 and K8.1; major latent antigen: LANA-1				21, 43, 74, 80
PCR	Qualitative and quantitative				19, 63, 76
	Herpesvirus multiplex		Clinicians may not want testing done for all human herpesviruses because of interpretation and clinical utility issues.		46, 78

Immunocompromised Patients

HHV-7 becomes latent in lymphocytes following primary infection and can reactivate in immunocompromised hosts such as transplantation recipients and AIDS patients. In bone marrow, liver, and renal transplant patients, simultaneous CMV and HHV-7 activities have sometimes been associated with clinical events (see the corresponding HHV-6 section above), and a case of fatal HHV-7-associated encephalitis has been reported, but overall, HHV-7 infections are not frequent contributors to posttransplant illness.

Like HIV, HHV-7 uses CD4 as its major cellular receptor. In vitro, HHV-7 can inhibit HIV infection, possibly due to receptor interference. There is no clear evidence of a role for HHV-7 in AIDS progression.

Interstitial Pneumonia

HHV-7 DNA was detected more frequently and at higher loads in affected tissues from nonimmunocompromised patients with interstitial pneumonia (94). Further study is required to fully evaluate the significance of this observation.

Pityriasis Rosea

Data are inconsistent for an association between HHV-7 and pityriasis rosea (24).

Collection, Transport, and Storage of Specimens

The methods described above for HHV-6 are appropriate for HHV-7.

Direct Detection

By electron microscopy, HHV-7 virions have appearances typical of herpesviruses. One MAb (anti-HHV-7 pp85) is commercially available (Advanced Biotechnologies), and other MAbs are available upon request from some research laboratories (7). The most widely used qualitative PCR primer set for HHV-7 was described by Berneman et al. (6); others have also been described, but their performances have not been compared. Qualitative PCR for HHV-7 can be included in a herpesvirus multiplex setup (46, 49, 78). Quantitative PCR methods for HHV-7 include a LightCycler-based assay that discriminates among HHV-6A, HHV-6B, and HHV-7 (81). An HHV-7 RT-PCR system has not been described but could be useful for detecting active virus replication. Sources for commercial PCR testing for HHV-7 are listed in Table 2. Quantitated DNA for use as a PCR control is available from Advanced Biotechnologies.

Isolation Procedures

HHV-7 isolation can be accomplished using the methods described above for HHV-6 but is not used for routine clinical diagnosis. HHV-7 isolates initially propagated in primary cell culture or previously adapted HHV-7 strains (e.g., strain SB) can be grown in SupT1 cells in a manner similar to that used for the propagation of HHV-6 in continuous cells (8).

Identification

MAbs can be useful for confirming cell culture CPE when attempting virus isolation, especially to rule out CPE due to HHV-6, for IHC, and for immunoelectron microscopy. The PCR methods described above provide sensitive, specific, and rapid ways to unambiguously identify the virus.

Typing Systems

Biologically meaningful subtypes of HHV-7 have not been identified.

Serologic Tests

HHV-7 serologic assays include neutralization tests, immunoblot, immunoprecipitation, IFA (commercially available reagents), and ELISA (reviewed in reference 7). In one comparison of IFA, immunoblot, and ELISA, the overall performances of the three assays were quite similar, there being a small sensitivity advantage for the ELISA and a specificity advantage for the immunoblot assay (10). As described above, antibody avidity testing for both HHV-6 and HHV-7 allows differentiation between HHV-6 and HHV-7 primary infections as well as recent and past HHV-7 infections (90). Slides and control sera are available from Panbio Diagnostics and Advanced Biotechnologies.

Antiviral Susceptibilities

HHV-7 antiviral sensitivities are similar to those for HHV-6 and CMV, ganciclovir, foscarnet, and cidofovir being much more inhibitory than acyclovir (32). Drug-resistant HHV-7 has not been identified, but given the widespread use of ganciclovir for therapy of CMV and "CMV disease," it will likely occasionally emerge. Therapeutic regimens have not been defined; for transplant recipients they may ultimately be linked to strategies for dealing generically with betaherpesvirus activity.

Evaluation, Interpretation, and Reporting of Results

There are no circumstances that warrant routine single-agent monitoring for HHV-7 activity, but its inclusion in multiplex assays may prove to be of value in monitoring children with suspected encephalitis and/or febrile convulsions (especially in association with recent vaccination) (91) and transplant recipients. The main issues for HHV-7 diagnostic testing are distinguishing HHV-6 from HHV-7, differentiation of primary HHV-7 infection from reactivation, and distinguishing latent and active infections. Many of the same considerations for interpretation and reporting of results described for HHV-6 apply to HHV-7. Differentiating HHV-6 from HHV-7 can be done both by molecular analysis (e.g., PCR) and through the use of specific antibodies. Combinations of methods, as described for HHV-6, can also be used for HHV-7 laboratory diagnosis.

HHV-8

Taxonomy and Description of the Genus

HHV-8 is a member of the *Rhadinovirus* genus of the gammaherpesvirus subfamily. Gammaherpesviruses, which include EBV, are characterized by being able to replicate and establish latency in lymphoblastoid cells.

Description of the Agent

Like all herpesviruses, HHV-8 virions consist of four concentrically arranged major components: a core double-stranded DNA genome (165 kb) that is contained in the core of an icosahedral capsid, which is surrounded by a proteinaceous tegument, all of which is surrounded by a lipid bilayer envelope that is studded with a variety of virally encoded proteins and a sprinkling of cellular proteins. HHV-8 genomes carry approximately 80 unique genes.

Epidemiology and Transmission

Epidemiology

The global distribution of HHV-8 is uneven (reviewed in reference 65). In much of Africa, HHV-8 seroprevalence exceeds 50%, whereas in most of Europe, the United States, and Japan, seroprevalence is less than 10%. Seroprevalence is in the range of 30 to 50% in men who have sex with men (MSM) in the United States and Europe. The reasons for the population-based disparities are likely to be due to differences in child-rearing and family practices, sexual behaviors, and possibly viral and/or host genotypes. In Africa, the virus is frequently acquired early in life, in a maternally linked manner. In the United States, prevalence rises after adolescence. At least four major HHV-8 genotypes are in global circulation (100).

Tissue Distribution

Other than in the context of Kaposi's sarcoma (KS), HHV-8 DNA or antigens have seldom been detected in immunocompetent individuals, even if they are seropositive. The circumstance where the virus has been detected most often in immunocompetent individuals is in the saliva of HIV-negative MSM. In HIV-positive MSM, viral DNA can be detected in essentially all KS lesions, over 50% of saliva or oral fluid specimens, around 30% of PBMC specimens, about 10% of semen specimens, and less frequently in other types of specimens. In KS lesions, the virus is present mainly in spindle cells, mostly in a latent form, with scattered lytically infected cells. Although ordinarily restricted in its tissue distribution, the virus is capable of replicating in many cell types.

Latency and Persistence

In AIDS patients the virus has been detected in CD19-positive B cells. In PBMCs from patients with or at risk for KS, the HHV-8 concentration can be so low as to preclude reliable detection by PCR. The virus has been detected in a variety of tissues, especially in immunocompromised patients, but generally with methods that cannot discriminate between latent and lytic infections. Evidence for persistence of HHV-8 in immunocompetent seropositive individuals comes from organ transplant recipients who subsequently developed KS (16); at the time of their transplant, they most likely already harbored the virus that caused their KS.

HHV-8 latency has been extensively studied in cell culture systems that employ primary effusion lymphoma (PEL) cell lines that harbor HHV-8. In such cell lines, under ordinary culture conditions the virus is in a latent state in >95% of cells, with 1 to 5% of cells being in a lytic state. Treatment of such cultures with inducing agents such as a phorbol ester, sodium butyrate, or the HHV-8 lytic inducer gene encoded by open reading frame 50 (ORF50), rapidly induces lytic replication in 10 to 30% of cells. Only a handful of HHV-8 genes are transcribed during latency, including the ORF73 gene that encodes the major latency-associated nuclear antigen 1 (LANA-1), v-cyclin, and the highly expressed K12 (kaposin, also known as *nut*-1 and T0.7); transcripts of the latter are sensitive diagnostic targets.

Transmission

Most HHV-8 transmission is probably via oral fluids, although questions remain as to precisely how this might occur (44). Some transmission may also occur via breast milk and semen. In Africa, the virus is typically acquired in a maternally linked manner early in life, possibly via a traditional practice such as premastication of food or use of saliva to soothe bloodsucking-arthropod bites. Sexual transmission probably occurs in Africa but does not appear to be the major route. Among MSM, HHV-8 seropositivity is linked to a variety of sexual risk factors. Inconsistent linkages have been observed with various forms of anal sex (34, 62). In some studies, HHV-8 seropositivity has been linked to injection

drug use and blood transfusion (35); screening of blood products is under discussion but does not appear to be imminent. A suitable screening assay is not available.

Clinical Significance

Primary Infection

Little is known of primary HHV-8 infection. There are likely to be significant differences between healthy children, immunocompetent adults, and immunocompromised patients. HHV-8 DNA has been detected in febrile children in areas where the virus is endemic. Among 15 HIV-negative MSM who seroconverted to HHV-8, diarrhea, fatigue, localized rash, and lymphadenopathy were sometimes noted in association with primary infection (89). Seroconversion was contemporaneous with PCR positivity in PBMCs and development of cytotoxic T-lymphocyte responses to HHV-8 lytic proteins. For immunocompromised patients, acute illness has been associated with apparent HHV-8 primary infection, including KS, fever, arthralgia, lymphadenopathy, splenomegaly, and cytopenia (56, 70).

KS

The four major epidemiologic forms of KS are all associated with HHV-8: (i) African endemic KS, which primarily affects children with or without HIV infection; (ii) Mediterranean or classic KS, which affects older men from specific regions of Mediterranean Europe who have no known immunologic dysfunction; (iii) transplant-associated or idiopathic KS, which affects approximately 1% of solid organ transplant recipients in the United States; and (iv) AIDS-associated KS, which is the most common AIDS-associated neoplasm and the most aggressive form of the disease. KS incidence has decreased substantially but has not been eliminated since the advent of highly active antiretroviral therapy.

KS is characterized by reddish brown plaque or nodular lesions on the skin of the trunk or the extremities and in the oral cavity (oral KS), as well as on internal organs (visceral KS). The disease can be disfiguring, disabling, and life-threatening. KS lesions are characterized by networks of vascular slits, spindle-shaped cells of endothelial origin, extravasated red blood cells, and purplish deposits of hemosiderin. HHV-8 is present in the spindle cells, lytically in a small percentage and latently in the remainder. Immortalized KS cells have not been identified despite numerous attempts.

PELs

PELs are a rare (approximately 3% of AIDS-non-Hodgkin's lymphomas) but frequently aggressive subset of a class of lymphomas known as body-cavity-based lymphomas. PELs occur as lymphomatous effusions in body cavities, seldom disseminate beyond the cavity of origin, have cell morphologies between those of large-cell immunoblastic lymphoma and anaplastic lymphoma, express CD45 and associated antigens, have clonal immunoglobulin rearrangements suggesting B-cell origin but seldom express B-cell antigens, have infrequent c-*myc* rearrangements or alterations in other cellular oncogenes, are frequently infected with EBV, and harbor HHV-8 in every cell (17). These lymphomas have a poor prognosis.

MCD

Multicentric Castleman's disease (MCD) is a multicentric angiofollicular B-cell hyperplasia that occurs in germinal centers of lymph nodes. The disease has systemic manifestations that include fever, fatigue, recurrent lymphadenopathy, hepatosplenomegaly, bone marrow plasmacytosis, and polyclonal hypergammaglobulinemia. HHV-8-associated MCD occurs predominantly in HIV-infected individuals. Within the mantle zone of the germinal centers, HHV-8 is present in scattered B cells. HHV-8-associated MCD has a poor prognosis. Plasmablastic lymphoma has developed in patients who have the plasmablastic form of MCD.

Disease in Transplant Recipients

Organ transplant recipients have significantly elevated risk for developing KS (reviewed in reference 65). KS risk is highest in regions where HHV-8 seroprevalence is highest. In most cases, the virus causing the disease was probably reactivated from a prior infection in the transplant recipient, but graft-derived infections have been documented (5, 16, 56, 73). In renal transplant recipients, in addition to cutaneous KS, parenchymal KS infiltration has led directly to marrow aplasia with plasmacytosis, fever, splenomegaly, cytopenia, marrow failure, graft failure, and disseminated KS (56, 59). PELs (one in association with KS) have been reported following cardiac transplants (37, 47), as has apparently donor-derived fatal disseminated KS in liver transplant recipients (58).

The association between organ transplantation and adverse clinical manifestations of HHV-8 infections in the transplant setting defines an imperative to devise clinically useful approaches to their diagnosis, prevention, and treatment.

Other Diseases

HHV-8 has been associated with several other diseases. For some (e.g., angioimmunoblastic lymphoproliferative disease, oral plasmablastic lymphomas, and some cutaneous disease), further work is required to more firmly establish an etiologic association. In the case of multiple myeloma, the association with HHV-8 has been extensively studied, with the weight of the evidence being that the virus has little to do with the disease. Likewise, the initial observations of an association between HHV-8 and primary pulmonary hypertension have not been confirmed in subsequent studies by others. HHV-8 was detected in tissues from patients with idiopathic pulmonary fibrosis, but so were several other viruses. It remains to be determined whether the association is specific. An important part of establishing etiologic associations is consistency of association, a criterion that generally requires both agreement between laboratories and agreement when different populations are examined.

Collection, Transport, and Storage of Specimens

Conventional methods can be used for collection and storage of serum or plasma for serology. For preparation of lymphocyte DNA for PCR, blood should be collected in anticoagulant (not heparin) and PBMCs should be purified on a Ficoll gradient. Oral fluids can be collected for PCR by the methods described above for HHV-6. Biopsies are used for pathologic analyses that may include standard hematoxylin- and eosin-stained cytopathic examination, PCR on total DNA extracted from a section, in situ PCR, or IHC. Standard methods can be used for the preparation of such specimens.

Isolation Procedures

Reliable systems have not been developed for primary culture of HHV-8 from KS lesions. Ascitic fluids from PEL patients have been used as the source for deriving PEL cell lines.

Identification

HHV-8 is readily identified by PCR, hybridization with nucleic acid probes that target abundant transcripts (84, 86),

and MAbs. By electron microscopy, HHV-8 virions have a morphology similar to that of other herpesviruses, but this method is seldom applied to clinical materials.

The PCR primer sets described in the initial description of HHV-8 remain in wide use for qualitative PCR on specimens of all types (19). Nested PCR has been used, but the potential for false positives is higher and seems to outweigh the possible sensitivity increase (76). Numerous systems have been described for quantitative PCR. Because of the low frequency of circulating HHV-8-infected lymphocytes and low viral copy number in latently infected cells, important variables for PCR from blood specimens include the number of cells in the initial lysis and the total quantity of resulting DNA included in the PCR (63). Sources of commercial PCR testing are listed in Table 2. Quantitated DNA for use as a PCR control is available from Advanced Biotechnologies.

KS can be readily distinguished from its mimickers such as benign vasculoproliferative lesions and tumors that have a prominent spindle cell component by IHC employing a MAb to the HHV-8 LANA-1 encoded by ORF73 (21, 43, 74, 80). Antigen retrieval methods can influence sensitivity. IHC appears to be more specific for identifying KS than is PCR or RT-PCR, which has sometimes been positive for angiosarcoma specimens.

Typing Systems

HHV-8 genotyping is based predominantly on the sequence of the highly variable K1 gene sequence (100). HHV-8 genotypes have been associated with the global migration of the virus in association with human migration but have not been specifically associated with any of the major forms of the disease or conclusively associated with pathogenic variation.

Serologic Tests

Latent versus Lytic Antigens

EBV and HHV-8 share two biologic properties relevant to their serodiagnosis: (i) in vivo, they maintain their latent state in circulating lymphocytes and (ii) in vitro, they are propagated in cell lines in which the virus is present in a latent form in >95% of cells, but in which the lytic cycle can be induced in 10 to 30% of cells by treatment with an inducer such as a phorbol ester or sodium butyrate. Latency is regulated in part by chromatin-associated proteins that are significant antigens: EBNA in the case of EBV and LANA-1 for HHV-8. In addition, a handful of other HHV-8 proteins that are expressed only during the lytic cycle have been identified as significant serologic antigens. The most useful of these lytic antigens are encoded by ORF65 and ORFK8.1 (65). Sources for commercial antibody testing are listed in Table 2. IFA and ELISA antibody test kits are available from Advanced Biotechnologies and Biotrin.

IFA

The two main varieties of IFA in use for detection of HHV-8 antibodies are based on (i) uninduced PEL cell lines that target LANA-1 and (ii) lytically induced PEL cell lines. Latent fluorescence is primarily restricted to the nucleus, while lytic fluorescence is predominantly cytoplasmic. An important consideration is the serum dilution. Although a dilution of 1:10 has been used in some studies, in most cases this has led to unacceptable loss of specificity. Most laboratories have settled on dilutions in the range of 1:40 to 1:100 for IFA.

In addition to PEL cell lines that express complex mixtures of HHV-8 antigens, IFAs have been developed based on single defined antigens expressed via recombinant Semliki Forest viruses. Occasionally, false positives in the lytic IFA are due to antigenic cross-reactivity between the EBV and HHV-8 versions of the conserved herpesvirus protein, glycoprotein B.

Immunoblot

Immunoblot assays have been developed based on uninduced or induced PEL cells, as well as on purified bacterially or baculovirus-expressed LANA-1, ORFK8.1, and ORF65.

ELISAs

The most widely used HHV-8 ELISAs are based on purified virions (20, 23, 61), purified bacterially expressed ORF65 (83), and synthetic peptides based on ORF65 and ORFK8.1 sequences (53, 82). These assays have the obvious virtue of high throughput and objective evaluation of individual specimens relative to a defined cutoff but are less sensitive than lytic IFA.

IgG and IgM

Little attention has been paid to serologic methods for identifying and discriminating recent from past infection, such as detection of IgM or antibody avidity.

Neutralization Assays

A neutralizing antibody assay based on inhibiting infectivity of a recombinant HHV-8 that has been engineered to express green fluorescent protein in infected cells has been developed (50). The assay was used to demonstrate the potential importance of neutralizing antibody titers in preventing KS.

Sensitivity, Specificity, and Interassay Agreement

Assessment of the specificity and sensitivity of HHV-8 serologic assays has been complicated by several issues that revolve around the problem of unambiguously identifying individuals who are truly positive or negative for the virus. It has been a challenge to identify the most appropriate cutoff in the absence of true gold standard specimens. Healthy blood donors are often defined as HHV-8 negatives, although some of them are likely to be positive for the virus, and KS patients are frequently regarded as true positives, even though some may be seronegative. Specimens from individuals in groups of relatively greater or lesser risk for being positive or negative for the virus have been used to generate a receiver-operating characteristic (ROC) curve that allowed selection of assay cutoffs with various combinations of sensitivity versus specificity (61). A classification tree was used to define serostatus based on different interpretive algorithms applied to five assays (40); the best combined sensitivity and specificity was obtained by defining individuals as seropositive if they had strong reactivity in the ORFK8.1 enzyme immunoassay (EIA) or moderate reactivity in the same assay and were positive by a latent IFA. Latent class analytic methods were used to estimate the sensitivity and specificity of three assays (EIAs to ORF65 and ORFK8.1 and a latent IFA) in the absence of prior knowledge of truth (39). There was only modest agreement among the assays, with the ORFK8.1 EIA being the most sensitive and specific. Corchero et al. (28) bootstrapped gold standards by ROC analysis of results obtained at several serum dilutions in an IFA based on ORFK8.1 expressed via a recombinant Semliki Forest virus and then compared several assays on the basis of the area under ROC curves generated relative to the carefully defined standards; assays based on lytic antigens were superior to latent antigen assays. In an evaluation of 18 different assays, there was no clear delineation of assay quality between assays based on latent versus lytic antigens (82). The four assays with the best sensitivity

and specificity included a latent and a lytic IFA and EIAs based on bacterially expressed K8.1 or peptides derived from ORF65 and ORFK8.1. In a comparison of several laboratory-specific algorithms for HHV-8 serodiagnosis, some of which employed more than one assay to arrive at their final result, all approaches identified all KS patient specimens as being seropositive, and there was high agreement that most blood donor specimens were seronegative, but there was only modest agreement about which blood donor specimens were positive, with no approach being clearly superior (77).

Antiviral Susceptibilities and Therapy

The main forms of standard therapy for KS include highly active antiretroviral therapy (immune reconstitution and possibly reducing HIV cofactor effects), local and systemic cytotoxic and tissue-destructive regimens, and immune enhancement by alpha interferon (2, 4, 52, 87). HHV-8 is exquisitely sensitive to cidofovir and is also sensitive to ganciclovir and foscarnet. Although in small trials the therapeutic effect of these agents has been equivocal, in large retrospective analyses, foscarnet or ganciclovir used for controlling other herpesvirus infections has been associated with lower KS risk (60), possibly due to these agents being more effective in preventing than in treating KS. Therapeutic algorithms employ a stepped approach based on the extent of disease and rate of progression, with therapeutic options ranging from local to systemic to palliative.

Because cases of PEL and MCD are so rare, there have been no controlled therapeutic trials. Case reports suggest potential utility of anti-CD20 MAb therapy for both diseases (which may exacerbate KS [57]), ganciclovir for MCD (15), and cidofovir plus alpha interferon for PEL.

Evaluation, Interpretation, and Reporting of Results

We anticipate an expanded role for clinical microbiology and pathology laboratories in the management of HHV-8-related illness. A major part of the cohort of susceptibles and already affected individuals is currently under clinical scrutiny related to their HIV infection, and our understanding of the utility of various virologic and immunologic markers as prognostic indicators is rapidly expanding. In addition, consideration is being given to whether donors and recipients should be matched with respect to HHV-8 status or whether the HHV-8 status of the transplant recipients should be monitored to allow for heightened surveillance for KS and other HHV-8-associated disease.

KS

While KS has ordinarily been diagnosed on the basis of clinical or histologic presentation, as mentioned above, LANA-1-based IHC is of value in establishing a definitive diagnosis of KS. An area of active research is identification of markers for progression to KS (1, 38, 54). The major risk identified thus far is being dually positive for HHV-8 and HIV. There is movement toward a consensus that sensitive serologic tests are the best tools for identifying HHV-8-infected individuals from single specimens, with subsequent PCR monitoring of blood for the appearance of viral DNA as a harbinger of KS. This has not risen to the level of being a practice guideline.

PEL and MCD

Biopsies, cell smears, or lysates of either fluid or solid specimens from suspected cases of PEL or MCD can be analyzed for the presence of HHV-8 by any of the array of in situ molecular diagnostic tools described above.

Adenoviruses*

CHRISTINE ROBINSON AND MARCELA ECHAVARRIA

105

In 1953, Rowe and colleagues described an agent which they named "adenoid degeneration agent" that induced spontaneous degeneration of cultures prepared from adenoids of children (59a). In 1954, Hilleman and Werner cultivated a similar agent from respiratory samples from military recruits which they called "RI-67" (35a). The two viruses were subsequently shown to be related, and in 1956 the term adenovirus was proposed to acknowledge their initial source. Epidemiological studies soon identified the virus as the major cause of acute respiratory disease (ARD) in military recruits and of many other clinical entities. In the mid-1960s, adenoviruses were found to cause tumors in rodents, prompting studies that revealed fundamental processes of molecular biology but failed to link the virus convincingly to human cancer. Currently adenoviruses are again under scrutiny as vectors for gene therapy and as pathogens in immunocompromised patients.

TAXONOMY

Adenoviruses are widespread in nature and have been isolated from humans and many animals. They belong to the *Adenoviridae* family, which has been recently subdivided into four genera: *Aviadenovirus, Atadenovirus, Siadenovirus,* and *Mastadenovirus*. The *Mastadenovirus* genus, from the Greek "mastos," meaning breast, infects mammals. Six of the approximately 19 *Mastadenovirus* species (formerly called subgenera) infect humans and are designated A through F, with species B further subdivided into subspecies B1 and B2 (Table 1). Each human adenovirus species contains multiple serotypes, with 51 human serotypes distinguished to date (14).

DESCRIPTION OF THE AGENT

Adenoviruses are medium-sized, nonenveloped icosahedral viruses 70 to 90 nm in diameter (Fig. 1). Each particle contains a single linear, double-stranded DNA molecule of about 36 kb containing approximately 40 genes (13). Major transcription units include early genes E1A, E1B, E2, E3, and E4, genes expressed later in the early phase (IX and IVa2), and late genes (L1 to L5). One or more (depending on the serotype) virus-associated (VA) nontranslated genes are also described.

The protein capsid is formed by 252 capsomeres. The 240 hexons are grouped into 20 triangular faces, with one penton at each of the 12 vertices. Each penton consists of a base and the fiber, a rod-like projection of variable length with a terminal knob that interacts with cellular receptors. The hexon has antigenic sites common to all human adenoviruses. These sites reside within the capsid, so neutralizing (protective) antibodies are not formed. Hexons also contain type-specific sites which induce neutralizing antibodies. Fibers have type-specific and some species-specific antigenic determinants and are responsible for hemagglutination (HA) in vitro.

Adenoviruses interact with cells in at least three different ways. Productive infection occurs mostly in epithelial cells and begins by attachment of the fiber knobs to cell surface molecules such as CAR, the coxsackie-adenovirus receptor, although other molecules are used by some serotypes. Virus particles are then internalized, pentons are removed, and DNA cores move to the nucleus, where viral DNA replication ensues. Structural proteins synthesized in the cytoplasm then move to the nucleus and form capsids which encase the DNA and aggregate into crystalline arrays (Fig. 2A). From 10,000 to over a million viral particles are produced per cell, only 1 to 5% of which are infectious. Latent or persistent infections occur primarily in the lymphoid mucosal tissue at sites such as the tonsils and adenoids, where they are maintained by unknown mechanisms and infrequently produce virus (25). Transformation occurs primarily in rodent cells infected with species A serotypes, which integrate into the host genome and induce cellular replication without producing infectious virus.

EPIDEMIOLOGY AND TRANSMISSION

Adenovirus infections are common and ubiquitous. From 1 to 5% of all respiratory infections and 5 to 15% of acute diarrheal infections are due to adenoviruses. Children are especially susceptible. The prevalence of adenovirus respiratory infections in children ranges from 2 to 14% and may be higher during outbreaks (23, 74). Many (30 to 70%) respiratory illnesses in unvaccinated new military recruits are adenovirus associated as well. The incidence of all infections is higher in crowded closed settings such as day care centers, boarding schools, geriatric facilities, military training camps, and hospitals. Intrafamilial infections are common.

* This chapter contains information presented in chapter 91 by Paul D. Swenson, Göran Wadell, Annika Allard, and John C. Hierholzer in the eighth edition of this Manual.

TABLE 1 Properties of the 51 human adenovirus serotypes by species characteristics[a]

Species	Serotype(s)	Oncogenic potential	% G+C	HA		Fiber length (nm)
				Rhesus	Rat	
A	12, 18, 31	High	47–49	–	±	28–31
B1	3, 7, 16, 21, 50	Weak	50–52	+	–	9–11
B2	11, 14, 34, 35	Weak	50–52	+	–	9–11
C	1, 2, 5, 6	None	57–59	–	±	23–31
D	8–10, 13, 15, 17, 19, 20, 22–30, 32, 33, 36–39, 42–49, 51	None	57–60	±	+	12–13
E	4	None	58	–	±	17
F	40, 41	None	52	–	±	~29

Adenovirus infections are frequent in immunocompromised patients (34). Before highly active antiretroviral therapy (HAART) was introduced, adenoviruses were isolated from 7 to 29% of gastrointestinal and urinary tract specimens from human immunodeficiency virus (HIV)/AIDS patients. Even higher frequencies were observed using molecular methods (16). Most isolates were species D serotypes rarely detected in other situations (14). These viruses probably arose from reactivation of endogenous virus at mucosal sites in the gut, concurrent infection with other serotypes, and recombination, resulting in new serotypes. HAART has dramatically reduced the incidence of all infections, including adenovirus, in these

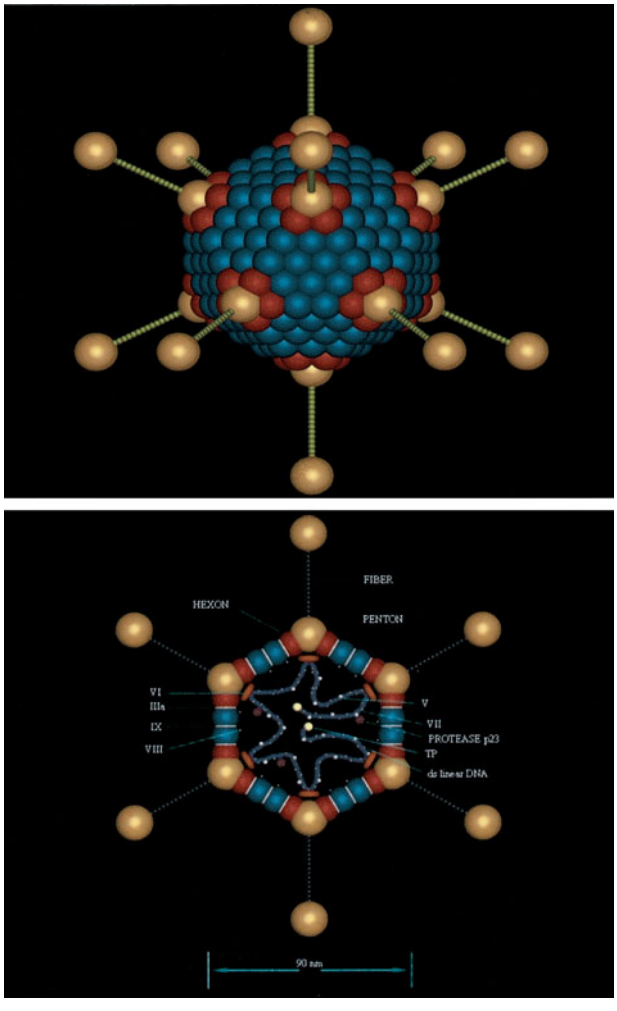

FIGURE 1 Model of adenovirus particle. (Top) Exterior; (bottom) interior.

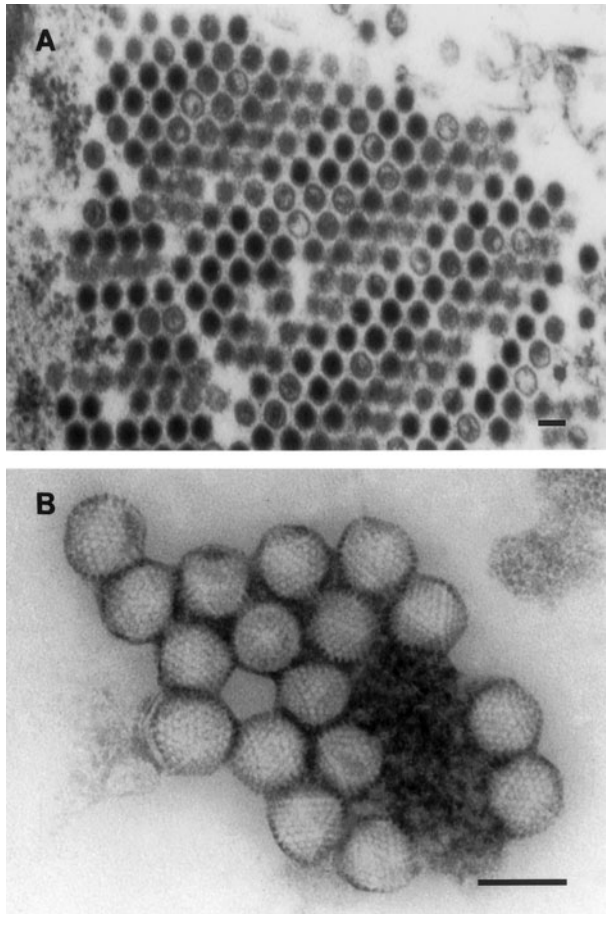

FIGURE 2 Ultrastructure of adenovirus particles. (A) Transmission EM of hepatocyte nucleus containing complete (dark) and empty (clear) adenovirus particles; (B) direct EM of a cluster of adenovirus particles in stool from a child with diarrhea. Bar = 100 nm.

patients. Adenovirus infections are, however, increasingly reported for solid-organ transplant and bone marrow transplant (BMT) recipients. The incidence is highest in pediatric BMT patients, with 5 to 47% of individuals affected depending on age and conditioning regimen. Most infections are probably due to reactivation of latent or persistent virus from mucosal sites. Viruses from species A, B, and C, the species most likely to establish latent or persistent infection, are commonly recovered.

Most adenovirus infections occur in the first few years of life. By age 10, a majority of individuals have been infected with one or more serotypes (23). About half of all infections are asymptomatic. There is no obvious difference in susceptibility by gender or ethnic group. Infections occur worldwide, with some differences in serotypes in other parts of the world. Disease patterns vary by serotype and type of host (Table 2). Respiratory infections are usually caused by species B, C, and E, with serotypes 1, 2, 5, and 6 causing endemic infections and serotypes 4, 7, 14, and 21 causing small epidemics, mostly in winter to early summer. Epidemics of ARD in military recruits typically occur in the winter and spring and are associated with serotypes 4 and 7. Large epidemics of keratoconjunctivitis are due mostly to serotypes 8, 9, and 37. Smaller outbreaks of serotypes 3, 4, and 7 occur in the summertime associated with contaminated swimming pool water. Adenovirus-associated gastroenteritis is endemic and is caused primarily by serotypes 40 and 41, also known as the "enteric adenoviruses." Sporadic and endemic infections occur year-round.

Transmission is primarily by the respiratory or fecal-oral routes. Airborne transmission occurs by small-droplet and, to a lesser extent, large-droplet aerosols. Fecal-oral spread probably accounts for most infections. Virus is also spread by contaminated fomites, fingers, ophthalmic solutions, and airborne particulates. The mode of transmission among new military recruits is thought to differ from that among civilians and similarly congregated college students (18). Spread is also facilitated by resistance of the virus to gastric secretions, bile, and pancreatic proteases, permitting passage of virus through the stomach and replication in the intestine. Prolonged virus shedding from various body sites aids transmission as well. Adenoviruses can be isolated from the throat and respiratory secretions of adults with upper respiratory tract infections for up to a week and from the eye for several weeks after recovery. Children shed nonenteric adenoviruses, especially the lower-numbered serotypes, for 3 to 6 weeks in the throat or stool following respiratory tract or generalized illness. Virus can be isolated intermittently from stools of children for 18 months or longer following an adenovirus infection, but this is uncommon (9). In contrast, enteric adenoviruses are rarely recovered more than a few weeks after recovery from gastroenteritis. No well-designed studies have examined shedding of adenoviruses in stools of immunocompetent adults. Immunocompromised patients shed virus longer than immunocompetent individuals.

TABLE 2 Adenovirus diseases, associated serotypes, hosts, and suitable specimens[a]

Disease	Associated serotype(s)		Frequent hosts	Specimens
	Frequent	Infrequent		
URI[b]	1–3, 5, 7	4, 6, 11, 14, 15, 18, 21, 29, 31	Infants, children	NP[c] aspirate or swab, throat swab
LRI[d]	3, 4, 7, 21	1, 2, 5, 7, 8, 11, 35	Infants, children, IP[e]	NP aspirate or swab, BAL sample, lung tissue
Pertussis syndrome	5	1–3, 12, 19	Children	Throat swab
ARD	4, 7	2, 3, 5, 8, 11, 14, 21, 35	Military recruits	Throat swab, BAL sample, lung tissue, NP aspirate or swab
Acute conjunctivitis	1–4, 7	6, 9–11, 15–17, 19, 20, 22, 37	Children	Conjunctival swab or scraping
Acute hemorrhagic conjunctivitis	11	2–8, 14, 15, 19, 37	Children	Conjunctival swab or scraping
Pharyngoconjunctival fever	3, 4, 7	1, 2, 5, 6, 8, 11–17, 19–21, 29, 37	Children	NP aspirate or swab, throat swab, conjunctival swab or scraping
Epidemic keratoconjunctivitis	8, 9, 37	2–5, 7, 10, 11, 13–17, 19, 21, 23, 29	Individuals of any age	Conjunctival swab or scraping
Gastroenteritis	40, 41	1–3, 5, 7, 12–18, 21, 25, 26, 29, 31	Children	Stool
HC	11	7, 21, 34, 35	Children, IP	Urine
Hepatitis	1–3, 5, 7	4, 31	Infants, children, IP	Liver tissue, blood
Myocarditis	7, 21		Children	Heart tissue, blood
Meningoencephalitis	7	1–3, 5, 6, 11, 12, 32	Children, IP	Brain tissue, CSF
Venereal disease	2, 37	1, 5, 7, 11, 18, 19, 31	Teens, adults	Lesion swab
Disseminated disease	1, 2, 5, 11, 34, 35	3, 6, 7, 14, 21, 29–31, 37–39, 43, 45	IP, newborns	Blood, BAL sample, urine, involved tissue

[a] Modified from reference 35 with permission of the publisher.
[b] URI, upper respiratory illness.
[c] NP, nasopharyngeal.
[d] LRI, lower respiratory illness.
[e] IP, immunocompromised persons.

CLINICAL SIGNIFICANCE

The spectrum of adenovirus-associated disease is broad due to the many serotypes and their distinct tissue tropisms, although there is some overlap (Table 2). Most infections affect the respiratory tract, eyes, and gastrointestinal tract, with lesser involvement of the urinary tract, heart, central nervous system, liver, pancreas, and genital tract. Disseminated disease is also reported.

Most respiratory tract infections occur early in life and are self-limited and mild. The incubation period is 2 to 14 days. Usual signs and symptoms are fever, nasal congestion, coryza, pharyngitis, cervical adenopathy, and cough, with or without otitis media. An exudative tonsillitis clinically indistinguishable from infection with group A streptococcus is described. Lower respiratory infections such as bronchitis, bronchiolitis, croup, and pneumonia can be severe and sometimes fatal, particularly in children under 2 years of age. Long-term sequelae can include bronchiectasis, bronchiolitis obliterans, and unilateral hyperlucent lung. Higher mortality rates are associated with some genotypes and when extrapulmonary manifestations occur. Adenoviruses have been associated with a pertussis-like syndrome, although the virus can also be isolated from *Bordetella pertussis*-positive patients as well.

Although adenovirus-associated ARD is uncommon in civilian adults, frequent outbreaks in young military recruits were noted beginning in 1953. Symptoms included febrile cold-like illness, pharyngitis with tonsillitis, bronchitis, and pneumonia. Hospitalization rates were as high as 50% in some outbreaks, and some fatalities occurred. Live adenovirus vaccines directed against serotypes 4 and 7, the most common serotypes involved, were introduced in 1980 and significantly reduced morbidity and mortality. In 1996, vaccine production was discontinued and the problem recurred. Although current outbreaks are not as severe as in the prevaccine era, ARD is still a significant problem among U.S military recruits. Reintroduction of the vaccine to the military is planned. Interestingly, adenovirus type 4 is uncommonly associated with respiratory disease in civilians. No vaccine is available for nonmilitary populations.

Ocular adenovirus infections are common. The most frequent manifestation is acute follicular conjunctivitis, which is usually superficial and resolves completely in a few weeks. Pharyngoconjunctival fever is a follicular conjunctivitis accompanied by upper respiratory tract symptoms, fever, lymphadenopathy, pharyngitis, and malaise. Epidemic keratoconjunctivitis is a more serious infection that starts with conjunctivitis but progresses to painful edema of the eyelids, sometimes followed by corneal erosions and infiltrates. Symptoms may resolve in 2 weeks, although reduced vision, photophobia, and foreign-body sensation may persist for months to years. Epidemics of acute hemorrhagic conjunctivitis similar to those caused by enterovirus are also described.

Gastroenteritis due to enteric serotypes 40 and 41 has an incubation period of 3 to 10 days. Diarrhea is usually watery and nonbloody, lacks fecal leukocytosis, and lasts for a mean of 10 days. Mild fever, vomiting, and abdominal pain may occur. Respiratory symptoms are noted in some studies. Immunocompetent children recover uneventfully, although infants with ileostomies or colostomies can have prolonged symptoms. Rare fatalities occur in immunocompromised patients. Gastrointestinal syndromes associated with nonenteric adenoviruses include intussusception, acute mesenteric lymphadenitis, and appendicitis.

Clinical manifestations in immunocompromised patients depend on the underlying disease or affected organ system, patient age, and virus serotype (34). Mortality rates of 12 to 70% are reported for pediatric solid-organ transplant or BMT recipients (11). Pneumonia, hepatitis, colitis, pancreatitis, and disseminated disease are observed. Hemorrhagic cystitis (HC) can be especially severe and may signal the start of dissemination (20). In liver transplant recipients, adenovirus typically causes hepatitis with mortality rates as high as 53%. In renal transplant recipients, the predominant symptom is HC, with a 17% fatality rate. In the post-HAART era, clinical manifestations in HIV/AIDS patients are uncommon until immune system deterioration occurs. Even terminally, the clinical significance of adenovirus detection in HIV/AIDS patients can be unclear due to infection with other opportunistic pathogens.

Less common clinical manifestations include severe and frequently fatal neonatal disease, meningoencephalitis and encephalitis, acute myocarditis in otherwise healthy individuals or associated with cardiac transplant rejection, and venereal diseases including genital lesions and urethritis (2, 62, 66, 71). The role of adenoviruses in fetal demise remains unclear (7). Adenovirus type 36 can cause obesity in animals, but the relevance of this finding for humans is uncertain.

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

Adenoviruses are readily detected from affected sites early in the course of illness. Suitable specimens depend on the patient's symptoms (Table 2). Cell-rich specimens such as nasopharyngeal aspirates or stool are usually preferred over swabs. When tissue is unavailable and deep-seated infection is suspected, specimens from multiple sites (e.g., respiratory, stool, and urine) or blood can be helpful (11, 61). To detect seroconversion, paired serum specimens should be collected, the first one during the acute illness and the second one 2 to 4 weeks later.

Recovery is optimal if specimens are collected as soon as possible after the onset of symptoms and kept cold (2 to 8°C) during transport. Infectivity is well stabilized by most commercial viral transport media (VTM), although studies comparing traditional and newer formulations are lacking. Some VTM, like Microtest M4 (Remel, Lenexa, Kans.), are compatible with molecular and antigen assays as well as culture. This medium also preserves infectivity of some serotypes for 5 days at ambient temperature (59). Specimen processing should occur within 2 to 3 days of collection whenever possible. Plasma or serum should be separated within a few hours after collection to avoid hemolysis and white blood cell degeneration. Specimens, virus isolates, or DNA extracts can be frozen at −70°C indefinitely with minimal loss of activity. Long-term storage in self-defrosting freezers and repeated freeze-thaw cycles will ultimately reduce infectivity and degrade virus DNA.

Adenoviruses are highly resistant to inactivation. Most serotypes are stable at 36°C for a week, at room temperature for several weeks, and at 4°C for several months. Infectivity is retained for several weeks on paper or in saline and for over a month on nonporous surfaces. Strict adherence to conventional safety practices such as use of personal protective equipment and biological safety cabinets, disinfection of work surfaces, and hand washing will minimize laboratory infections. Avoid hand-to-eye or hand-to-mouth contact due to the affinity of adenoviruses for mucosal and ocular tissue. Treatments that destroy infectivity include 1 min of a 1:5 dilution of household bleach, heating to 56°C for 30 min or 60°C for 2 min, and autoclaving. Serotype 4 is especially heat

resistant. Alcohol-based hand gels destroy infectivity, although up to 2 min of contact can be required. Variable inactivation occurs with iodine, UV light, and formaldehyde. Viral DNA can be detected long after infectivity is destroyed.

DIRECT DETECTION

Microscopy

Adenovirus-infected cells can be visualized by light microscopy as "smudge cells" in histologically stained tissues, fluid sediments, or cultures. These late-stage infected cells contain solitary, central, basophilic nuclear inclusions composed of viral particles. Other forms of inclusion are described but are less frequently observed. The inclusions of cytomegalovirus, herpes simplex virus, or polyomavirus can resemble adenoviral inclusions, so further evaluation is recommended to avoid misdiagnosis (41). In situ hybridization, immunohistochemistry, or PCR can identify adenovirus in fixed tissue.

The characteristic morphology of adenovirus particles permits detection by electron microscopy (EM) without the need for further identification. In typical transmission EM, fixed tissue fragments are thin sectioned, negatively stained, and then examined for crystalline arrays of virus particles usually found in the nucleus (Fig. 2A). In direct EM, fluid clarified by low-speed centrifugation is similarly stained and examined for clusters of particles (Fig. 2B). Sensitivity is improved by ultracentrifugation of virus onto EM grids (Airfuge; Beckman Coulter Inc., Fullerton, Calif.), by prior aggregation of virus with antihexon antibodies, or by other concentration techniques (30). Direct EM was historically used to detect adenoviruses in urine and respiratory secretions, but other methods are more sensitive and practical. Direct EM is still used at some centers to detect viruses in stool, including the enteric adenoviruses.

Antigen Detection

Antigen detection is widely used for diagnosis of adenoviral respiratory and gastrointestinal tract infections because it is rapid and reasonably sensitive. Most current assays identify conserved regions of the hexon protein and use monoclonal antibodies (MAbs). Immunofluorescence (IF) and enzyme immunoassay (EIA) are common approaches. Many products for antigen detection are commercially available (Table 3).

The major application of IF is detection of virus in respiratory tract specimens. Washes, aspirates, or swabs containing exfoliated ciliated columnar epithelial cells from the posterior nasopharynx should be collected. Touch preparations of fresh tissue or frozen or trypsin-treated, formalin-fixed tissue sections can also be used. Conjunctival or throat swabs should be evaluated by more sensitive techniques such as culture or PCR. A typical assay is performed by depositing spots of washed cells onto a glass slide, followed by acetone fixation, staining with fluorochrome-labeled MAbs, and examination under a fluorescence microscope. A satisfactory specimen should contain more than 50 virus-susceptible cells. Indirect IF can be used, but newer direct stains provide excellent and rapid results (40). Positive cells should display

condensed nuclear or granular cytoplasmic staining (Fig. 3). Staining can be performed with an adenovirus-specific MAb or a pool of MAbs for adenovirus, respiratory syncytial virus, influenza A and B viruses, and parainfluenza virus (70). Dual infections can be identified using MAb pools. Pools are also economical if the laboratory sees little adenovirus, but confirmatory stains with the individual components are needed if the pool stain is positive. The sensitivity of adenovirus IF in respiratory specimens is 40 to 60% compared to culture. This is lower than the rate of detection of most other respiratory viruses. Higher values (70 to 75%) can be obtained using cytocentrifugation, which hastens drying and improves readability and specimen adequacy (40). The specificity of IF is very good (>99% in most studies).

The major application of EIA is detection of virus in stool. Genus-specific tests and type-specific assays for serotypes 40 and 41 are commercially available (Table 3). Most EIAs utilize microtiter plates and adenovirus-specific MAbs as capture and detector reagents (33). Color produced by an enzyme-substrate system conjugated to the detector MAb is then read visually or by spectrophotometer. The sensitivity of most enteric adenovirus EIAs compared to 293 cell culture or EM is >90% but can be lower if variants are circulating (63). The specificity is usually >97%. Genus-specific assays are sensitive (>95%) when stool is used. The sensitivity is lower (65 to 75%) with respiratory tract and eye specimens. Urine has the lowest detection rate (5, 26). Occasional false-positive reactions occur.

Other antigen detection tests include immunochromatography (IC), which is convenient when small numbers of specimens are tested. In IC, the specimen migrates laterally along a membrane strip, antigen binds to virus-specific antibodies, and a colored line develops within minutes. The sensitivity of a commercially available adenovirus IC assay with nasopharyngeal specimens tested at the bedside was 84% compared to culture and PCR, and 95% when the same specimens were retested in the laboratory (24). Another antigen detection assay is latex agglutination (LA), which is used primarily for genus-specific detection of adenovirus in stools. LA has a sensitivity similar to that of EIA, although up to 13% of specimens may yield uninterpretable results (28). Infrequently used antigen tests include time-resolved fluoroimmunoassay, radioimmunoassay (RIA), counterimmunoelectrophoresis (CIE), and complement fixation (CF).

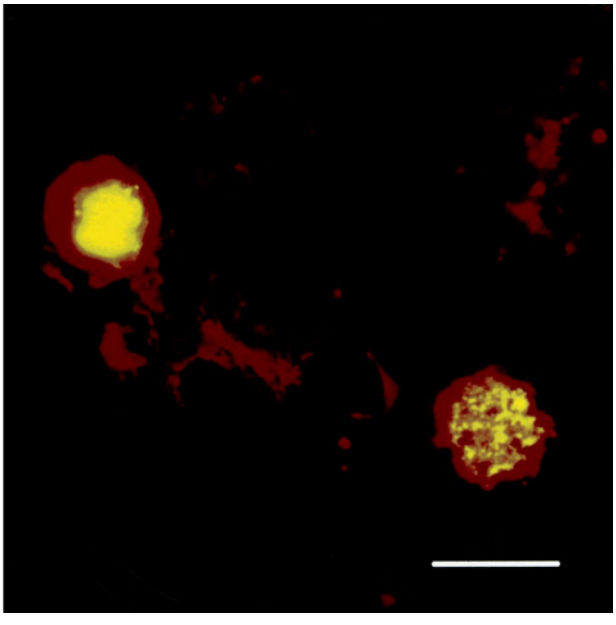

FIGURE 3 Adenovirus antigen demonstrated in two cells of a nasopharyngeal aspirate by direct IF using a rhodamine-conjugated antibody (yellow). Bar = 40 μm.

Nucleic Acid Detection Techniques

Detection of the viral genome is highly sensitive and especially applicable when noninfectious virus is present, when the viral load is too low to be detected by culture, or when results are needed quickly. Adenovirus DNA has been detected in virtually all clinical samples, so specimen selection depends largely on the associated disease (Table 2).

Many techniques have been used to detect adenovirus DNA. A simple early method was visualization of enteric adenovirus DNA as a 36-kb band on a gel after lysis of stools from children with diarrhea (51). Assays using extracted DNA and hybridization to isotope- or enzyme-labeled DNA probes increased the sensitivity, specificity, and applicability to other specimen types. Dot blot hybridization was often used for this purpose (39). In situ hybridization on tissue samples remains useful for diagnosis and studies of pathogenesis (48).

PCR is currently the most accepted detection method, with both conventional and real-time assays used. Sensitivities approach or exceed that of culture. Most assays use degenerate or nondegenerate primers from the hexon gene, the fiber gene, or the VA RNA I and II regions. The hexon gene consists of three different segments: a central variable region with seven hypervariable regions and two highly conserved regions flanking the central one. The conserved regions are most often used in generic PCR (12, 16, 32). The fiber gene contains regions that are conserved within and variable between species. Several PCRs with species-specific fiber gene primers are described (56). Multiplex primers flanking the VA RNA coding regions are also used (73).

Conventional adenovirus PCR typically takes 1 to 2 days, most of which is dedicated to detection. Methods for detection include ethidium bromide-stained gels, solid- or liquid-phase hybridization to labeled probes, time-resolved fluorometry, or hybridization to probes in microtiter plates. Single and multiplex PCRs are described. Multiplex conventional assays can detect adenovirus species A to F individually, together, or as a component of a panel for respiratory viruses (55, 56, 73). Plasma, urine, and stools of immunocompromised patients, ocular specimens from patients with conjunctivitis, throat swabs from ill military recruits and their environment, serum and respiratory tract specimens from healthy children with acute infection, heart biopsy samples, and polluted water have been tested (1, 16–19, 66, 73). Several conventional PCR kits are commercially available (Table 3).

Real-time PCRs provide qualitative and quantitative results within hours with less labor and fewer opportunities for contamination than conventional assays. Several real-time adenovirus PCRs have been developed, initially for BMT patients but recently for other patient populations as well (12, 15, 32, 43, 65). In general, more than one set of primers and several probes are necessary to detect all serotypes. Many specimen types have been assessed, but blood is the most frequently evaluated specimen in most laboratories. Plasma or serum is recommended to avoid variations due to low levels of viral DNA in white blood cells (WBC) of some healthy subjects and fluctuations in WBC counts, especially in BMT patients (12). Nevertheless, whole blood has been used in some studies.

Currently quantitative real-time adenovirus PCR has several limitations. First, universal standards are lacking for assay calibration and interlaboratory comparisons. Purified, titered adenovirus particles and DNA from several serotypes of species C can be purchased (Advanced Biotechnologies Inc., Columbia, Md.) but are not recommended as standards until their exact DNA concentration and stability are independently validated. Second, there is no universally accepted primer-probe combination for uniform detection and quantitation of all serotypes, although recent studies are promising in this regard (12, 15). Variable results among laboratories are therefore expected. A new European adenovirus PCR proficiency survey series available to U.S. subscribers (Quality Control Program for Molecular Diagnostics; European Union Concerted Program for Quality Control, Glasgow, Scotland) may soon provide data about optimum assay design. Until these issues are resolved, viral loads for clinical intervention should be determined locally. Meanwhile, it may be preferable to report viral kinetics (the relative change in adenoviral load over time) rather than absolute viral loads (42).

To verify a new adenovirus PCR, the limit of detection should be defined using several serotypes of each species, at a minimum. Wild isolates and prototypes should be tested to avoid false-negative results or misquantitation due to unanticipated polymorphisms (16). Dilutions of quantitated virus stocks spiked into negative samples can be used to generate standard curves. This approach can also be used to make positive controls. Plasmids containing inserts of the target region are also useful to create standard curves, but these should be added after extraction because loss can occur with some protocols. In general, the serotype best matching the primers and probe is used as the working standard. Analytic specificity should be evaluated by testing microorganisms likely to be present in the specimen types submitted. Clinical specificity should be carefully assessed because low levels of adenovirus DNA can be detected in a small proportion of specimens from healthy controls (22, 25, 32, 43). Published guidelines recommend testing sufficient known positive and negative specimens to have confidence in the test (54). Specimens for this purpose can be verified as adenovirus positive or negative by culture, pathology, careful clinical follow-up of the patient of origin, or a combination of methods. Archived specimens are frequently used for convenience and economy.

ISOLATION PROCEDURES

Isolation produces progeny for further studies and is reasonably sensitive. It therefore remains the "gold standard" but can be slow and plagued by overgrowth with unwanted organisms or cell death due to toxicity. All specimens are suitable for routine culture (Table 2), although enteric adenoviruses are optimally detected by nonculture methods. Blood rarely yields virus except by PCR, probably due to the presence of neutralizing antibody. Isolates can sometimes be obtained by culture of buffy coat or of WBC purified through Ficoll-Hypaque density gradients.

Adenoviruses can be isolated in conventional tube culture or centrifugation culture (CC). Growth is best in human epithelial cell lines. For culture of nonenteric serotypes, the A549 cell line is recommended because it supports adenoviruses and other viruses well (67). Other suitable cell lines are HEp-2, HeLa, and KB. Human diploid fibroblasts are less sensitive. Nonhuman cells such as Vero and primary monkey kidney cells containing simian virus 40 will recover adenovirus, although the yield is low. Recovery is not optimal in simian cells and human fibroblasts, but these cells are in widespread use and frequently detect adenoviruses. Enteric adenoviruses grow best but inconsistently in Graham 293 cells, a continuous line of adenovirus type 5-transformed HEK cells (72). Other serotypes replicate in these cells as well. Limited growth of enteric adenoviruses can occur in A549, HEp-2, KB, and other cell lines (57).

Inoculated tubes should be incubated at 35 to 36°C in stationary racks and read every other working day. Rolling offers little advantage. The speed with which cytopathic effect (CPE) develops depends on the cell type, serotype, and concentration of virus in the specimen. Epithelial cells typically develop adenovirus CPE in 2 to 7 days, although up to 28 days can be required in simian cells, in human fibroblasts, or with slow-growing serotypes. Most diagnostic laboratories retain tubes for 2 weeks. If 28 days is used, cells should be maintained in good condition by scraping them into the culture medium and subpassage onto fresh cells at 10 to 14 days (35). Cells with suspicious CPE that does not progress should be disrupted and reinoculated into sensitive cells such as A549.

Typical CPE usually begins at the edge of the monolayer and then progresses until grape-like aggregates of swollen, refractile cells form (Fig. 4B). Aggregation may not occur with subgroup D viruses. Other forms of CPE, such as web-like flattening with serotypes 3 and 7, are also described (45).

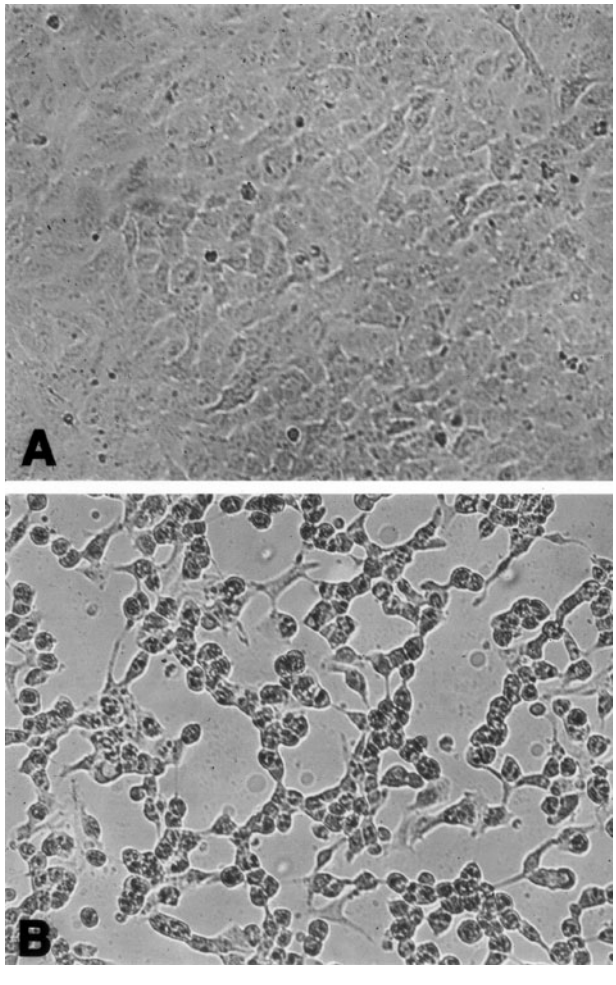

FIGURE 4 Adenovirus CPE in A549 cells. (A) Uninfected cells; (B) advanced adenovirus CPE. Magnification, ×100.

Glycolytic activity may also increase, resulting in excretion of acid and a color change of the medium. As infection progresses, cells may become highly granular and detach completely from the surface. The CPE of adenoviruses can be confused with that of herpes simplex virus or cytomegalovirus. Viable epithelial cells in bronchoalveolar lavage (BAL) specimens or in subpassages can produce colonies of rounded cells on the monolayer that also resemble adenovirus CPE. All presumptive adenovirus isolates should therefore be definitively identified.

For high-titered isolate preparations, infected cells and fluid should be frozen and thawed rapidly several times. Rapid CPE, also known as "lysis from without," can occur within hours after inoculation with concentrated extracts of infected cells. It is due to interaction between adenovirus free penton base and cellular adhesion molecules and can be prevented by further dilution of the inoculum or by using a different preparation.

Adenoviruses can be detected rapidly by CC. In this technique, specimens are centrifuged for 15 to 60 min onto cells growing on coverslips in shell vials or in microtiter plates. One to 5 days later, IF is performed to detect intracellular hexon antigen, typically before significant CPE develops (21). Adenovirus-specific antibody or a MAb pool to simultaneously detect adenoviruses and other respiratory viruses can be used (58). Isolates can be obtained if the culture medium is removed prior to staining. Detection of adenoviruses in CC stained at 2 days is only 50 to 85% compared to tube culture at 14 days. This detection rate is lower than for most other respiratory viruses. For maximal adenovirus recovery, tube culture or CC stained at 5 days is recommended. CC is insensitive for detection of enteric adenoviruses.

A mixture of A549 and mink lung cells has become popular to expand the type of respiratory viruses detected by individual CC. This mixture recovers influenza and parainfluenza viruses well, but adenovirus recovery is more variable. In an initial study, in-house-prepared CC of the mixture identified all adenovirus-containing specimens identified by A549 CC alone after overnight incubation (36). Most laboratories, however, use a commercially prepared mixture of the same cells (R-Mix; Diagnostic Hybrids Inc., Athens, Ohio). We and others find that only about half of all adenovirus-positive specimens identified by CC of A549, HEp-2, or RMK cells are detected by R-Mix CC, even after 2 days of incubation (76).

IDENTIFICATION

All isolates with adenovirus CPE should be definitively identified before a report is generated. For diagnostic work, genus-specific identification is usually sufficient. Most immunologic or molecular methods for direct detection are suitable for this purpose. Identification by IF is used most frequently because it is simple and rapid, and the reagents can be used for direct detection as well. Some smaller labs may prefer IC, but laboratories with larger test volumes may prefer EIA. LA and PCR can be used as well. Other procedures used historically include CIE, RIA, DNA hybridization, and CF. For identification by IF, cultures should be harvested when 25 to 50% of the cells show CPE. Depending on the cell line and assay used, more extensive degeneration may be required to obtain sufficient soluble material for analysis. On occasion CPE-positive variants or new serotypes cannot be identified. In this situation, EM of infected cells, HA, restriction enzyme analysis (REA), or DNA sequencing can aid identification.

TYPING SYSTEMS

Typing is used primarily for epidemiological investigations, for studies of pathogenesis, or to reveal the cause of an unusual or especially severe infection. Serologic or molecular typing can be performed. Serologic typing requires an isolate and detects differences in epitopes on the fiber gene and hexon gene. Molecular typing can be performed on isolates and on the original specimen. Differences in DNA sequences of the fiber gene and hexon gene are typically determined, although nontranscribed regions can be interrogated as well. The two systems differ fundamentally in target, so results do not always concur. Each provides a different view of virus structure.

Serologic typing provisionally determines the species of an isolate by HA (Table 1), or if the isolate is from stool, by a species F (serotype 40 or 41) EIA. Serotyping by HA inhibition (HAI) or serum neutralization (SN) is then performed, using antisera that define each serotype of that species. The HAI assay is easier, but SN is the primary arbiter of serotype. Most SN assays are tedious so modifications are made, such as the use of intersecting pools of antibodies to reduce the number of individual reactions. There are three major SN assays: a conventional 7-day test in human epithelial cells (or 293 cells for stool isolates); a 3-day test in monkey kidney cells, which is the most simple and rapid assay; and a 5-day microneutralization test using Vero cells (35). Interpretation is not always straightforward, as when HAI and SN fail to agree with intermediate species D variants containing the fiber gene of one serotype and the hexon gene of another. Yet serotyping remains the gold standard by which newer systems are evaluated. Other serologic methods include an immunoperoxidase technique, immune adherence HA, and indirect IF with serotype-specific antisera.

Molecular typing is increasingly performed because it is rapid, utilizes molecular equipment and expertise now in many laboratories, and does not require expensive and difficult-to-obtain antisera. The REA method was initially used. It can be applied to purified virus, virus-infected cells, or stools from children with diarrhea (3, 10). The starting material is first lysed and then digested with restriction endonucleases (e.g., SmaI), and then serotype- and/or genotype-specific band patterns are visualized after agarose gel electrophoresis. Unfortunately strains that defined the initial REA patterns are no longer circulating, so patterns of currently obtained adenoviruses may be uninterpretable. Coinfections can also cause ambiguous results. REA is still useful for presumptive identification of new serotypes, for identification of genotypes (e.g., 7h or 7d2) associated with severe disease, or to confirm results obtained by other means (14, 29). Other approaches include detection of single-stranded confirmation polymorphisms and heteroduplex mobility analysis (68).

Typing by PCR is now preferred by many laboratories. This method begins by amplification of extracted DNA from an isolate or purified virus, using a generic or multiplex species-specific PCR and hexon gene or fiber gene primers. The serotype is then indicated by measurement of product length, sizes or DNA sequence of fragments generated after cleavage with restriction enzymes, or DNA sequence. Early PCR-based methods required high concentrations of starting material. Newer methods can be applied directly to clinical specimens, although nested PCR may be required to obtain sufficient product for analysis (4). Some schemes detect only limited number of serotypes, whereas others are more comprehensive and can demonstrate coinfections (49, 60). Direct comparison among these methods is lacking.

SEROLOGIC TESTS

Most primary infections are accompanied by a fourfold or greater rise in adenovirus immunoglobulin G (IgG) and a less predictable IgA response. Virus-specific IgM appears in only 20 to 50% of cases (37, 50). The IgG response in older children and adults typically begins 7 to 10 days after infection, but it can be delayed for months in children and may never appear in immunocompromised individuals or in superficial infections. An IgM response can occur when virus reactivates. Both genus- and serotype-specific antibodies appear. Children often have a single serotype-specific response because their exposure to multiple serotypes is limited. Up to 25% of adults, however, raise heterologous antibodies, often to multiple serotypes within the same species as the infecting serotype. Neutralizing antibodies usually persist a decade or more in relatively undiminished titer, probably maintained by periodic reinfection, reactivation, and heterotypic anamnestic antibody responses. Complement-fixing antibodies typically disappear about a year after infection.

Serodiagnosis requires detection of an IgM response or documentation of at least a fourfold rise in IgG between acute- and convalescent-phase specimens. Acute- and convalescent-phase sera should be tested simultaneously for greatest accuracy. The choice of assay is based on its use. For clinical work, a generic test like CF or EIA for IgG or IgM is usually selected. Some reference laboratories offer these assays, and kits are commercially available as well (Table 3). Both CF and EIA use hexon antigen-rich preparations and detect genus-specific antibody responses. Historically CF was the most widely used generic test. It is well standardized, reagents can be readily acquired or made, and it is inexpensive, especially if antibodies to other pathogens are simultaneously assessed. A major drawback of CF is sensitivity. Fewer than half of all infections in children and immunized adults and 50 to 70% of infections overall are detected by CF. Sensitivity also varies with the infecting virus and serotype used as the antigen. EIA is therefore preferred for greater sensitivity and to detect different immunoglobulin classes (37).

Serotype-specific antibody tests are infrequently used for diagnostic work. They are valuable, however, to pinpoint serotypes responsible for a cluster of infections when viral isolates are unavailable, for diagnosis of illnesses typically associated with a limited number of serotypes, or for studies of the immune response. These tests are also more sensitive than CF and so can be used to assess otherwise-undetectable antibody rises in children or immunized military recruits. The assays used most frequently are HAI and SN. The HAI test is as highly standardized as the CF test and can be applied to other viruses as well. The SN assay remains the standard, with the 3-day test in monkey kidney cells or microneutralization preferred (35). Other serologic tests include indirect IF, CIE, LA, and RIA. Newer assays utilize genetically modified cells and fluorescent reporter molecules as surrogates for SN activity and may soon replace SN in serum surveys (69).

Overall, the insensitivity of the adenoviral IgM response and the need to demonstrate IgG seroconversion greatly limit the usefulness of serology for diagnostic purposes in individual patients. Interpretation is also problematic for immunocompromised individuals, in persistent infection, for adults due to heterotypic responses, and for children whose delayed antibody rises may coincide with other clinical problems. Despite its availability, serology should therefore be reserved for epidemiological investigations or to confirm associations between virus detection and unusual clinical outcomes.

ANTIMICROBIAL SUSCEPTIBILITIES

A variety of antivirals, including ganciclovir, vidarabine, ribavirin, and cidofovir, have been explored for treatment of adenovirus disease, especially in the immunocompromised host (46). Most reports are anecdotal or small scale and have yielded mixed results. There are still no prospective, randomized controlled trials of these drugs, nor is there a proven effective therapy. Most recent experience is with ribavirin and cidofovir.

Ribavirin is a broad-spectrum antiviral agent related to guanosine, with in vitro activity against RNA and DNA viruses, including adenovirus. It is well tolerated in the intravenous form, with reversible mild anemia the most common adverse effect. Efficacy appears best in treatment of adenovirus-associated HC, probably due to the high drug concentrations achievable in urine. Successful treatment of pneumonia, hepatitis, and enteritis in transplant recipients and severe disease in an immunocompetent neonate are described (46). Many failures and fatalities are also reported, even when the drug is used with intravenous gamma globulin. A factor perhaps contributing to this variability is an intrinsic antiviral resistance, since only species C serotypes are susceptible to ribavirin in vitro (50% inhibitory concentration, 48 to 108 μM) (52). If this limitation also occurs in vivo, the usefulness of ribavirin may be limited to treatment of a subset of adenovirus infections.

Cidofovir is an acyclic nucleoside phosphonate analogue used as a broad-spectrum antiviral agent. All adenovirus serotypes are susceptible in vitro in a narrow dose range (50% inhibitory concentration, 17 to 81 μM). Resistance can develop with serial passage (27, 52). Despite its significant side effects (nephrotoxicity, myelosuppression, and uveitis), cidofovir use has increased, especially for immunocompromised patients. Improvements were noted in 31 of 45 (69%) BMT patients with various clinical presentations and 10 of 14 (71%) BMT patients with HC (47, 53). Some investigators have suggested that surveillance of high-risk BMT patients by monitoring viral load kinetics and early preemptive treatment with cidofovir will be more effective than treatment after symptoms develop. An early trial of this approach was associated with good outcomes in five of eight immunocompromised patients, and plasma viral load predicted the clinical response (42). Some episodes of viremia, however, can spontaneously resolve without treatment, so other early indicators of clinical response may be needed (75).

Other potential treatments include reduction of immunosuppression or immunotherapy using donor lymphocyte infusion (DLI). Both approaches, with or without concomitantly administered antivirals, have improved the outcomes for BMT recipients with severe disease (8, 38). To avoid inducing graft-versus-host disease with DLI, virus-specific cytotoxic lymphocytes (CTL) have been produced in vitro. Most CTL clones have broad cross-reactivity, so serotyping of virus in individual cases may not be required (31). These strategies remain promising.

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

Clinical diagnosis of adenovirus infection is rarely accurate, so laboratory evaluation is usually required. Selection of tests should be guided by the patient's symptoms and immune status, the interval between disease onset and specimen collection, and laboratory expertise. Most infections can be detected within hours or several days of sampling by direct antigen tests, nucleic acid assays, or CC. Measurement of an

IgM response is infrequently productive, and tube cultures and IgG serology rarely provide results in time for clinical decision-making (64).

Interpretation of positive results is more challenging than test selection. Asymptomatic, persistent, or recurrent infections can occur, so detection of virus or a serologic response can be a coincidental finding. Accurate interpretation must take into account patient and specimen factors, the test method, and, in some circumstances, the viral serotype and quantity detected. This requires close communication between the laboratory and the clinician. In general, detection of adenovirus from an involved organ or large quantities of virus from a related specimen in a patient with an illness epidemiologically associated with adenovirus is valid evidence that the virus is the actual cause of the disease.

Respiratory tract infections due to adenovirus are often diagnosed by IF, which is typically more sensitive in children because they shed virus longer and in greater quantity than adults. The clinical and financial benefits of providing rapid IF results have been well demonstrated (6). Negative results do not rule out infection, so culture of the following IF-negative specimens is recommended: samples from patients hospitalized for lengthy periods (e.g., patients in intensive care), lower respiratory tract specimens such as BAL samples or lung tissue, samples from high-risk patients (e.g., neonates and transplant patients), and specimens from patients with especially severe or unusual presentations. A promising alternative to IF is PCR, but interpretation of positive PCR results in respiratory tract specimens is still uncertain (43, 65). Detection of viral DNA in blood by PCR, however, may become a helpful adjunct to diagnose severe respiratory tract disease in immunocompetent children (1, 65).

Adenoviral gastroenteritis in immunocompetent children is typically diagnosed by serotype 40- or 41-specific EIA of stool. Interpretation is usually straightforward because these infections are usually mild and self-limited, with virus infrequently shed after the symptomatic period. In contrast, nonenteric adenoviruses can be detected in stools of asymptomatic healthy or immunocompromised patients for months to years, with severe or fatal gastrointestinal disease resulting in the latter group. Detection of nonenteric adenoviruses in stool is readily performed by generic EIA, generic PCR, or culture. The major problem is interpretation of positive results, particularly for transplant patients, who can have concomitant graft-versus-host disease and adenovirus infection.

Recovery of adenoviruses from other sites can be technically challenging but somewhat easier to interpret because asymptomatic shedding is rare. Ocular adenovirus infections can be detected by EIA, but culture, PCR, and even serology are sometimes needed to make the diagnosis. PCR of urine is more sensitive than culture for diagnosis of adenovirus-associated HC (16). Adenovirus encephalitis and meningitis occur infrequently, so studies comparing traditional to newer methods of detection are lacking, but PCR of cerebrospinal fluid (CSF) is likely to be more sensitive than viral culture.

Diagnosis of adenovirus disease in immunocompromised patients is especially problematic due to their many copathogens, high rates of asymptomatic virus shedding, and protean manifestations of disease. Solid-organ transplant and BMT recipients are at highest risk of severe disease and are the usual focus of testing. Evaluation can include surveillance of throat, stool, or urine specimens for culture or PCR. Involvement is typically classified as infection, probable disease, or definite disease depending on the number of virus-positive sites and symptoms (11). A rapid and noninvasive alternative to culture is detection of adenovirus viremia by PCR of serum or plasma from high-risk BMT or solid-organ transplant patients. A reproducibly high positive result obtained by this method can now be recommended as an indicator of severe adenovirus disease in these patients, although caution is warranted because some viremic episodes resolve spontaneously (17, 32, 44, 61, 75). Other applications of PCR remain investigational. These include use of PCR for preemptive treatment of adenovirus disease, to monitor treatment, and for diagnosis of disease in immunocompetent patients. Studies are in progress to standardize PCR protocols and to further evaluate these potentially useful applications. Results are eagerly awaited.

Human Papillomaviruses*

BRUCE K. PATTERSON

106

TAXONOMY AND DESCRIPTION OF THE AGENT

Papillomaviruses are ubiquitous viruses that infect many animal species including humans. Over 118 papillomavirus types have been identified in a classification that is continuously adding new types. The papillomaviruses are now considered to be in a distinct taxonomic family, *Papillomaviridae,* and unrelated to the polyomaviruses (16). The taxonomic criteria for types, subtypes, and variants are based on L1 capsid gene sequence differences. A sequence difference of 10% constitutes a type, a difference of 2 to 10% constitutes a subtype, and a difference of >2% constitutes a variant (16). These double-stranded, supercoiled, circular DNA viruses have an icosahedral capsid consisting of 72 capsomeres ranging from 45 to 55 nm in diameter. Human papillomavirus (HPV) contains a double-stranded circular DNA genome that encodes eight open reading frames, which are transcribed as polycistronic messages (21). The gene products of HPV include the early (E) and the late (L) genes. There are eight early genes designated E1 to E8 and two late genes designated L1 and L2. E1 and E2 are responsible for DNA replication (55), while E2 has also been demonstrated to exert repressor activity on early viral promoters ultimately responsible for the expression of the E6 and E7 oncogenes (17, 51, 79). E4 has been implicated in the alteration of the cytoskeleton, and E5 encodes a membrane protein with weak transforming activity (12, 45, 50). The amino-terminal 21 amino acids of E8E2C represent a novel, transferable DNA replication repressor domain that controls the viral copy number during persistent infection (88). Little is known about the gene function of E3, although some groups are performing high-risk genotyping out of this region. L1 and L2 encode viral capsid proteins. In addition, the L1 gene contains the sequence heterogeneity used to type HPV. L1 is the major gene detected by molecular diagnostic assays, as is discussed below.

EPIDEMIOLOGY AND TRANSMISSION

HPV-related cervical cancer constitutes about 12% of cancers worldwide. Epidemiological studies over the past 30 years have led many to the conclusion that persistent infection with oncogenic types of HPV followed by HPV DNA integration into the cellular genome is a required precursor in the pathway leading to cervical neoplasia (7, 8, 9, 14, 15, 34, 35, 80, 81, 86). A worldwide multicenter epidemiologic study compared the presence and type of HPV in 1,918 cervical cancer patients and 1,928 matched control women without cancer (61). The prevalence of HPV in the cancer group was 90.7%, and the prevalence of HPV in the control group was 13.4%. Detection and typing of HPV were performed for all women, and the HPV types were categorized as high, intermediate (probable high risk), and low risk (Table 1). Cofactors previously thought to contribute to cervical cancer such as smoking, contraceptive use, and age of first menstrual cycle were not found to contribute to cervical cancer in this multicenter trial. Genetic factors, such as have been inferred by studies with twins, have yet to be identified (49).

Transmission of HPV from males to females occurs via virus shedding in the male followed by the infection of cervical epithelial basal cells by way of microabrasions. HPV is unique in its necessity to infect cells that are capable of proliferation. The HPV life cycle depends on the maturation of epithelial basal cells (21). Following infection of the basal epithelial layer, HPV establishes a nuclear episome with approximately 50 copies per cell. HPV episomes replicate with cellular DNA replication so that during cell division infected daughter cells migrate from the basal layer to the suprabasal layer, where the cells differentiate. After reaching the suprabasal layer, HPV-infected cells enter into S phase and produce hundreds to thousands of copies of HPV DNA per cell (40). Following viral DNA synthesis, viral proteins including capsid protein are produced and complete viral particles are released into the female genital tract as epithelium is shed. A schematic of lateral expansion and vertical differentiation of epithelial cells is shown in Fig. 1. HPV DNA replication and particle release accompany vertical differentiation.

CLINICAL SIGNIFICANCE

Cutaneous Infections

HPV infects epithelial tissues throughout the body including skin, larynx, and anogenital tissues. Cutaneous HPV infections affect both immunocompetent and immunocompromised individuals and can lead to both benign and malignant lesions (Table 1). Common warts, plantar warts, and Butcher's warts are caused by HPV and are exclusively

* This chapter contains information presented in chapter 99 by Qinghua Feng and Nancy B. Kiviat in the eighth edition of this Manual.

TABLE 1 Clinical conditions associated with various HPV types

Clinical significance	HPV type(s)
Skin	
Common warts	2, 4, 26, 27, 29, 57
Plantar warts	1, 2, 4
Flat warts	3, 10, 28, 49
Butcher's warts	7
Epidermodysplasia verruciformis[a]	2, 3, 5, 8, 9, 10, 12, 14, 15, 17, 19, 20, 25, 36, 37, 46, 47, 50
Nongenital mucosa	
Oral mucosa	13, 32
Recurrent respiratory papillomatosis	6, 11
Head and neck cancer	2, 6, 11, 16, 18, 30
Genital mucosa	
Genital warts (condyloma accuminata)	6, 11, 42, 43, 44, 54
Low-risk HPV	6, 11, 40, 42, 43, 44, 54, 61, 70, 72, 81, CP6108
Intermediate risk	26, 53, 66
High-risk HPV	16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 68, 73, 82

[a] Inherited disorder of cell-mediated immunity.

benign in behavior. In addition to those conditions listed in Table 1, large cell acanthomas have been associated with HPV 6. Actinic keratosis is associated with a higher HPV DNA load of HPV types 5, 8, 15, 20, 24, or 36 than nonpigmented skin cancers (6, 97). HPV types belonging to the high-risk group were demonstrated in extragenital Bowen's disease, in melanoma, and in dysplastic nevi (107). HPV types associated with epidermoplasia verriciformis have also been recently demonstrated in cutaneous squamous cell carcinomas from both immunocompetent and immunocompromised individuals (70). Verrucous carcinoma of the scalp, a low-grade, well-differentiated form of squamous cell carcinoma, has also been associated with the high-risk HPV type 33 (62). In summary, evidence that supports a role for HPV in nonanogenital cancers is increasing (26).

Although HPV has been associated with nonanogenital forms of cancer, laboratory diagnosis of HPV is largely confined to genital HPV and its association with cervical cancer.

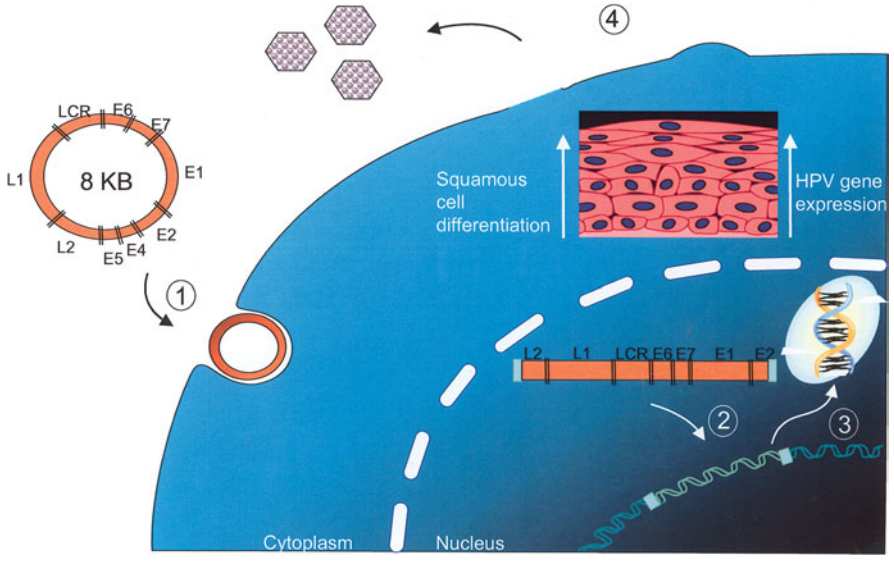

FIGURE 1 Schematic representation of HPV integration. This figure illustrates the events that most commonly lead to the transformation of cells infected by high-risk types of HPV. (1) HPV infection of epithelial cells. (2) HPV integration into the host chromosome; portions of E2 and L2 are deleted during this process. (3) Cell cycle dysregulation and cell proliferation. (4) Cell shedding and virus release. (Inset) Relationship between squamous cell differentiation and HPV gene expression (reviewed in references 21 and 109).

TABLE 2 Diagnostic terminology for cervical cytology and histology[a]

Cytologic diagnosis	Histologic diagnosis
WNL (within normal limits)	Normal (no abnormalities)
ASCUS (atypical squamous cells of undetermined significance)	Koilocytic change[b] (HPV-infected cells)
AGUS (atypical glandular cells of undetermined significance)	CIN 1 (cervical intraepithelial neoplasia—mild)
LSIL (low-grade squamous intraepithelial lesion)	CIN 2 (cervical intraepithelial neoplasia—moderate)
HSIL (high-grade squamous intraepithelial lesion)	CIN 3 (cervical intraepithelial neoplasia—severe)
SqCA (squamous cell carcinoma)	SCC (squamous cell carcinoma)

[a] Table based on the Bethesda system (105).
[b] Koilocytes represent HPV-infected cells with typical perinuclear halos.

During the past 50 years it has been well established that squamous cell cancers of the cervix arise as preinvasive squamous intraepithelial lesions (9, 18, 53, 54). A minority of these precursor lesions collectively referred to as cervical dysplasia progress over a number of years via one or more pathways to increasing states of cell cycle dysregulation, resulting in invasive cervical carcinoma. Other lesions may remain in the precursor state or, as for the majority of preneoplastic lesions, spontaneously regress as a result of immune control (31). The Bethesda system was established in the mid-1990s and revised in 2001 to classify cervical cancer precursor lesions into clearly defined cytological groups correlating with risk of progression to invasive disease as determined by histology (13, 78, 79, 105). Table 2 summarizes the terminology for cervical cytology specimens and cervical histology specimens and provides a context for the discussion of the role of HPV diagnostics in the cervical cancer screening algorithm (Fig. 2). Low-grade squamous intraepithelial lesions (LSIL) result from an infection by HPV, and ultimately, 80% of LSILs regress to within normal limits (WNL) cytology without any treatment (109). High-grade squamous intraepithelial lesions (HSIL) represent true cervical cancer precursors, and most untreated HSILs progress to invasive cancer over a period of years (109).

Pathogenesis

As previously mentioned, more than 99% of cervical squamous cell carcinomas are due to infection of squamous cells by oncogenic types of human papillomavirus (19, 108). Studies have also implicated HPV in the pathogenesis of adenocarcinoma of the uterine cervix (36). In high-risk HPV-associated lesions, transcriptional activity is always present (39, 41, 42, 92). The E6 and E7 oncoproteins as well as certain host factors are clearly involved in the transformation of cells and ultimate development of cervical cancer. The E6 protein causes degradation of p53 and BAK and activation of SRC family kinases in addition to the activation of telomerase. Similarly and synergistically, the E7 protein degrades the retinoblastoma protein (Rb) releasing the transcription factor E2F from inhibition and upregulating the cellular protein $p16^{INK4A}$ (4, 11, 32, 46, 52, 56, 57, 59, 60, 75, 76, 77, 84, 85, 98, 99). Further evidence supporting the role of E6 and E7 in the pathogenesis of cervical cancer comes from studies demonstrating that suppression of the E6/E7 promoter or inhibition of E6/E7 expression abrogates the proliferation of cancer cells in vitro (24, 72, 94). Integration of the HPV episome into the host chromosome commonly disrupts portions of the E2 gene, a negative regulator of E6/E7 expression, resulting in high levels of E6/E7 mRNA expression (17, 33,

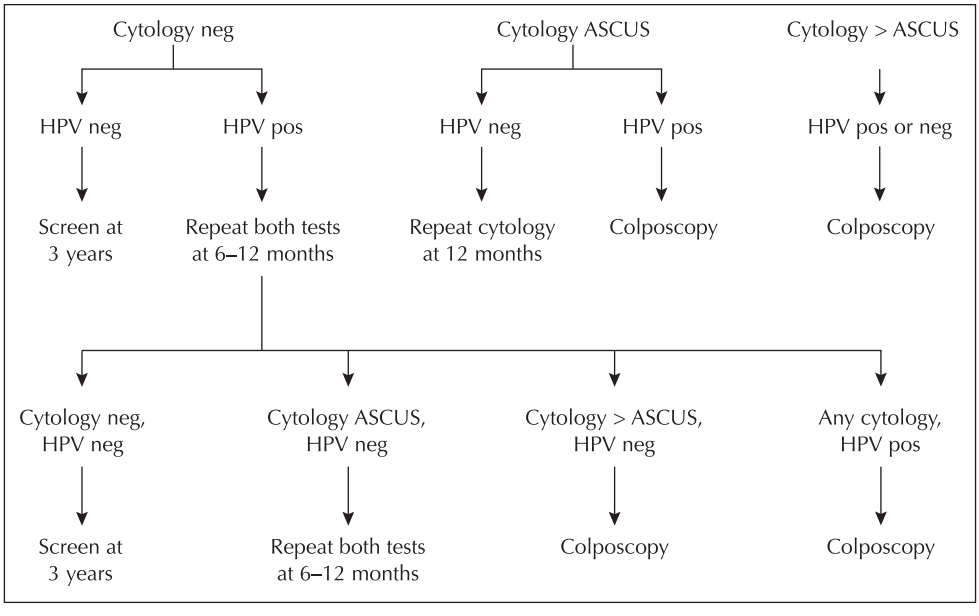

FIGURE 2 Cervical cancer screening algorithm (modified from reference 103). Neg, negative; pos, positive.

51, 73). From a diagnostic standpoint, the pattern of E6 and E7 gene expression also changes with the severity of the lesion; the level of E6 and E7 gene expression is increased in high-grade lesions compared to low-grade lesions, making the level of E6 and E7 gene expression potentially a functional discriminator between high-risk and low-risk HPV infections (58, 89). Similarly, the cellular marker $p16^{INK4A}$ is strongly associated with cancer and its precursors and serves as a diagnostic tool to screen for cervical cancer (37).

Data suggest that the HPV gene E5 also has cell-transforming capabilities (22, 25, 35, 68, 90). Expression of HPV-16 E5 protein in cultured keratinocytes resulted in an increase in the epidermal growth factor receptor on the cell surface (87). Receptor degradation is inhibited in cells expressing E5, resulting in increased recycling of receptors to the cell surface (87). Studies have indicated that anchorage-independent cell growth indicative of the transformed cell phenotype is induced in E5-transfected cells (43, 70). E5-transfected cells also demonstrated the ability to form tumors in nude mice while epidermal growth factor was capable of cooperating with the E5 gene to increase colony size (43). Of particular interest, the E5 protein from HPV-16 is expressed in LSIL, HSIL, and invasive cervical carcinoma epithelium (10).

HPV Vaccines

Much excitement is surrounding the publications of HPV vaccine trial results. HPV vaccines using L1 virus capsid-like particles (VLPs) and vaccines targeting cells expressing the HPV oncogenes (E6 and E7) have been extremely promising. Studies suggest that these VLP vaccines produce high anti-HPV antibody titers and HPV-specific T-cell responses (29, 69). Most importantly, an HPV-16 VLP vaccine demonstrated 100% protection from HPV-16 infection and related cervical intraepithelial neoplasia (CIN) in a study of 2,392 women (38). All of the nine cases of HPV-16-related cervical epithelial neoplasia in this study occurred in the placebo group (38). In another study involving a quadrivalent HPV vaccine directed against HPV 6, 11, 16, and 18 L1 genes, the study found a 90% decrease in the incidence of persistent infection or cervical abnormalities (93). Though promising, the duration of protection and infection by high-risk HPV types other than types 16 and 18 still remain as questions to be answered. Monitoring the efficacy of these vaccines has been performed using diagnostics directed against HPV L1 DNA.

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

In the mid-1990s, new technologies were introduced that allowed the cervical cytology sample to be obtained using a brush that was then placed in a liquid preservative. These liquid preservatives are alcohol based and in general contain compounds that dissolve mucus and allow the cells to disaggregate in solution. Common to the different technologies that exist today is the creation of a slide that contains a monolayer of representative cells from the ecto and endocervix. One of the technologies (SurePath; TriPath Imaging Inc., Burlington, N.C.) for creating these cells involves moving the cell suspensions through the small orifice of a syringe which disaggregates cell clusters. Interfering debris and inflammatory cells are partially removed from the disaggregated sample by centrifugal sedimentation through the density reagent. After centrifugation, the centrifuge tubes containing cell pellets are placed on the PrepStain System. The other common technology (Thin Prep; Cytyc, Marlborough, Mass.) involves the mechanical application of a filter through the cell suspension until a monolayer is created on the filter paper. The filter is then pressed onto a treated slide and stained. Both of these technologies have improved the quality and uniformity of slides and reduced but not eliminated unsatisfactory slides (12, 100). As is discussed in subsequent sections, liquid-based cervical cytology has significantly aided the use of automated screening devices and the automation of advanced molecular and proteomic assays. Some studies suggest that liquid cytology preservatives can preserve RNA for up to 12 months (91). This has led to the use of liquid-based cervical cytology samples as well as swabs for HPV diagnostics (RNA and DNA). Detailed descriptions of the cytology process are included in this section to illustrate the potential pitfalls of molecular testing from these specimens. Sample carryover is a concern for both hybridization- and amplification-based HPV diagnostics when performed from these sample types.

DIRECT DETECTION

Microscopy

As molecular biology has advanced over the past 20 years, morphologic assessment of HPV infection has become inadequate for use in cervical cancer screening. Molecular diagnostics allowed laboratorians to detect HPV infection prior to morphologic changes, and most importantly, molecular biology allowed researchers to determine the direct role of HPV in the transformation of cells and the progression to cervical cancer. Recent advances in molecular technology have allowed the growing clinical use of these techniques to determine molecular changes that signal cellular transformation and later events that lead to cervical cancer.

Some clinicians advocate the utility of cervicography especially in low-resource settings (23). Cervicoscopy involves the use of directly applied 3 to 5% acetic acid solution or in some instances fluorescent dyes. Visualization of the cervix is then performed using a colposcope. Cross-sectional studies indicate that the sensitivity of visual inspection to detect high-grade lesions ranged from 66 to 96% with a specificity of 64 to 98%. Consequently, the positive predictive value ranged from 10 to 20% and the negative predictive value ranged from 92 to 97%. The conclusions of these studies suggested that the sensitivity of visual inspection was similar to that of cytology; however, the specificity was consistently lower than that of cytology (103, 104).

Antigen Detection

Detection of cervical biomarkers has been used more extensively in the clinical laboratory than the detection of HPV antigens. This typically involves the detection of host proteins that are dysregulated by HPV-mediated cellular transformation. Cellular transformation is driven by increasing expression of E6 and E7 and consequent inactivation of the tumor suppressor RB and p53 genes. These tumor suppressor genes interact with various cell cycle-regulating proteins. E7 inactivates RB, a negative regulator of the cyclin-dependent kinase inhibitor gene $p16^{INK4A}$. Increased expression of $p16^{INK4A}$ is a marker of dysplastic cervical cells (Fig. 3). The p16 marker is used clinically on both cells and tissues, though more frequently in the latter. This protein marker has a sensitivity of 82% and a specificity of 84% for the detection of atypical cervical lesions from LSIL to invasive cervical cancer (1, 28, 37). Other markers including proliferation antigens such as Ki-67, proliferating cell nuclear antigen, and the cell cycle (DNA replication)-dependent antigens cdc2, cdc6, and Mcm are being investigated but are not in widespread

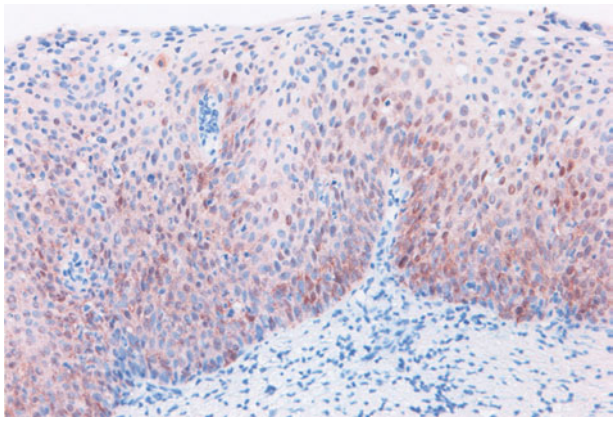

FIGURE 3 Photomicrograph of a high-grade cervical biopsy specimen demonstrating staining with the $p16^{INK4A}$ antibody (dark staining). Courtesy of Christina Kong, Stanford University School of Medicine.

clinical use (2, 52, 101). The MN transmembrane glycoprotein antigen has been studied extensively, and although the specificity of this marker was high, the sensitivity for abnormal cells was relatively low (44, 66). Epidermal growth factor receptor, transferrin receptor, and platelet-derived growth factor receptor are growth factor receptors thought to be involved in epithelial cell transformation (35). These receptors have been linked to the expression of HPV E5 protein (22, 35, 50, 71, 90). Other biomarkers predictive of HPV-driven cervical abnormalities are the focus of intense research at this time.

In Situ Hybridization for HPV L1 DNA

There are several automated platforms that perform in situ hybridization for HPV DNA on slides. The Ventana BenchMark Staining System combines immunohistochemistry and fluorescent/chromogenic in situ hybridization (Fig. 4). The INFORM HPV (Ventana Medical Systems, Inc., Tucson, Ariz.) assay detects high-risk HPV types 16, 18, 31, 33, 35, 45, 51, 56, 58, 59, 68, and 70 and low-risk HPV types

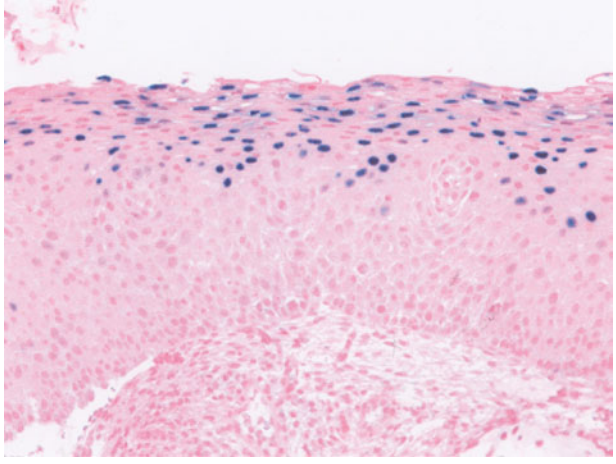

FIGURE 4 Photomicrograph of in situ hybridization performed in the clinical laboratory for high-risk HPV L1 DNA in a high-grade biopsy specimen. Courtesy of Christina Kong, Stanford University School of Medicine.

6, 11, 42, 43, and 44. The assay can be performed on both liquid-based Pap specimens and tissue biopsy specimens in less than 6 h. The sensitivity of the assay is 25 HPV copies per cell, and the localization of chromophore and the pattern of staining (homogeneous or punctate) may be indicative of either episomal or integrated forms of HPV DNA, respectively. Several studies have demonstrated that the assay has a positive predictive value of 60% for high-grade cervical lesions and a negative predictive value of 97% based on reported sensitivities of 86% and specificities of 90% (30).

Similarly, the GenPoint System (Dako, Glostrup, Denmark) uses a tyramide-based signal amplification strategy to detect biotinylated hybridization probes directed against HPV 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, and 68. One of the advantages of this system is the ability of the kit to detect HPV in formalin-fixed, paraffin-embedded tissue sections or in a variety of cell preparations. Other studies report good specificity (>95%), although the sensitivity for CIN 2 or above is relatively poor (75%) (30). Newer instrumentation has improved on a very tedious manual staining procedure.

In Situ Hybridization for HPV E6 and E7 mRNA

Most HPV assays such as type-specific PCR and Hybrid Capture II (HCII) detect the presence of L1 DNA from oncogenic genotypes despite the fact that only a minority of women infected with oncogenic types of HPV progress to cancer (83). The pattern of E6 and E7 gene expression changes with the severity of the lesion. Namely, the level of E6 and E7 gene expression increases in high-grade lesions compared to low-grade lesions, making the level of E6 and E7 gene expression a functional discriminator between normal and neoplastic cells. The HPV OncoTect (Invirion Diagnostics, LLC) assay detects increased expression of E6 and E7 mRNA on a cell-by-cell basis with quantification by flow cytometry (Fig. 5). Cell-by-cell quantification eliminates the averaging of E6 and E7 mRNA gene copies on the total number of input cells that is the hallmark of solution-based detection such as PCR. The performance of this assay has been reported to be better than HPV DNA genotyping (HCII and type-specific PCR) for the detection of high-grade lesions (63).

Nucleic Acid

As described in this chapter, HPV nucleic acid (DNA) testing has been accepted in the cervical cancer screening algorithm (interim guidance, Fig. 2). Testing for HPV and/or biomarkers associated with HPV transformation of cells is the focus of intense investigation in the basic science and molecular diagnostics arenas. Testing for HPV presents a number of challenges discussed in this section.

The female genital tract contains a complex mixture of cells that provide a structural and functional barrier to a variety of infectious agents. The female genital tract is lined with epithelial cells, with stratified squamous epithelial cells in the vagina and ectocervix, changing to columnar epithelial cells in the endocervical canal, with the transition occurring in what is called the transformation zone (T-zone). The cervical and vaginal mucosa also contains T and B lymphocytes, macrophages, dendritic cells, Langerhans' cells, and polymorphonuclear neutrophils. In this complex mixture of cells, HPV is known to infect squamous cells of the vagina and ectocervix as well as columnar cells of the endocervix.

Detection of HPV nucleic acids, in particular the L1 gene (DNA), is the most common method employed today as part of the cervical cancer screening algorithm (Table 3). Methods include liquid hybridization, which is a signal amplification

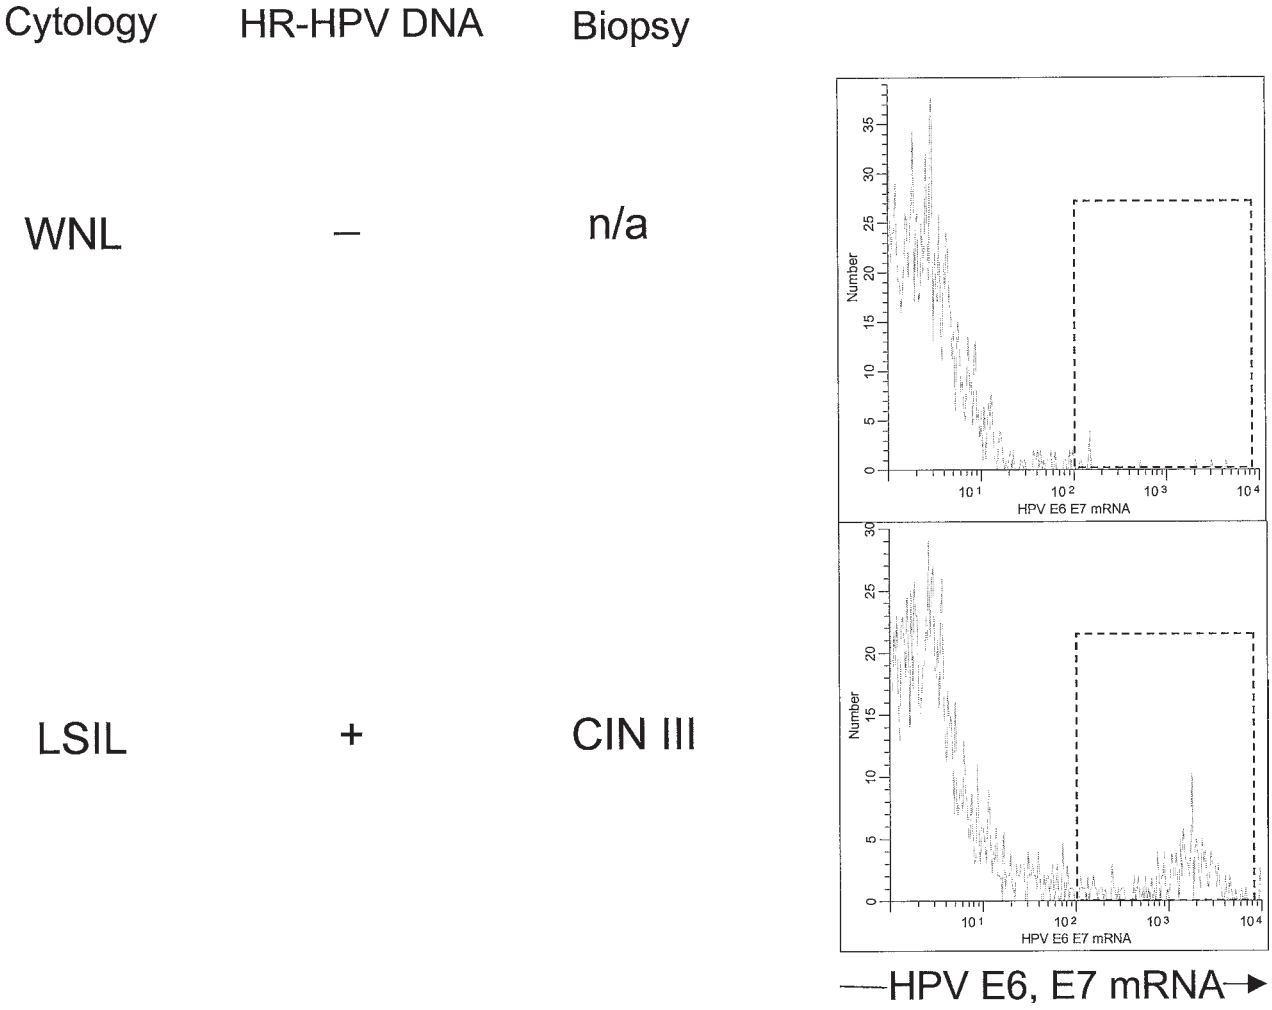

FIGURE 5 Representative histograms gated on light scatter (27) demonstrating HPV OncoTect (Invirion Diagnostics, LLC) staining of E6/E7 mRNA-expressing cells in liquid-based cervical cytology specimens (63). Samples were run on a personal capillary cytometer (PCA; Guava Technologies, Hayward, Calif.).

hybridization technology that involves the purification of DNA from cervical cytology specimens followed by hybridization to a complimentary RNA probe to form a DNA-RNA hybrid (47, 48). The Hybrid Capture Assay (HCII; Digene, Gaithersburg, Md.) High Risk probe detects high-risk HPV types 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, and 68 (61). Studies have demonstrated that the assay is extremely sensitive (93%), resulting in a high negative predictive value (99%) (48). However, the positive predictive value of the assay for CIN 2, CIN 3, or invasive cancer in the general population has been reported to be low (17 to 33%) due to the transient nature of most HPV infections (28). Cross-reactivity of the high-risk probe has been reported with some low-risk HPV types, and equivocal values contribute to indeterminate results in 5 to 10% of samples. The advantage of this assay is that it is FDA approved and there exists a large

TABLE 3 Assay types and target genes of commercially available HPV molecular diagnostic tests

Target type	Test name	Gene(s)	Format	Platform	Manufacturer
DNA	Hybrid Capture II	L1	Solution	Liquid hybridization	Digene Corporation, Gaithersburg, Md.
		L1	Solution	PCR	Roche Diagnostics, Indianapolis, Ind.
	INFORM HPV	L1	In situ	In situ hybridization	Ventana Medical Systems, Tucson, Ariz.
	GENPOINT HPV	L1	In situ	In situ hybridization	Dako USA, Carpinteria, Calif.

	HPV OncoTect	E6, E7	In situ	In situ hybridization	Invirion Diagnostics, LLC, Oak Brook, Ill.

database of clinical studies supporting the assay's use in cervical cancer screening (5, 47, 48, 82, 83). The disadvantages of this assay are the large quantities of DNA that are required to increase the analytical sensitivity in addition to the relatively low specificity.

PCR has been classically used for HPV detection in the research laboratories employing the consensus PCR primers MYB09 and MYB11. Type-specific PCR assays based on the sequence heterogeneity in the L1 gene are currently in clinical trials for use in the diagnostic algorithm for cervical cancer screening. Commercially available PCR assays for HPV utilize two different formats for the detection of HPV types (Roche Diagnostics, Pleasanton, Calif.). One iteration of this assay is the microwell plate format that detects high-risk HPV types 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, and 68 and the line blot assay or linear array assays that detect high-risk HPV types 16, 18, 26, 31, 33, 35, 39, 45, 51, 52, 53, 56, 66, 67, 69, 70, 73, and 82 as well as low-risk types 6, 11, 40, 42, 54, 55, 57, 61, 62, 64, 71, 72, 81, 83, and 84. DNA is extracted from cervical cytology samples followed by PCR amplification using biotin-labeled primers targeting the L1 region of the HPV genome. The advantages of type-specific PCR are the sensitivity (10 to 20 HPV DNA copies) and the ability to report specific types (e.g., HPV 16 and HPV 18) rather than high-risk HPV positive. Recent studies have indicated that reporting specific HPV types such as HPV 16 may increase the positive predictive value for high-grade lesions on biopsy specimens.

HPV RNA Detection

The PreTect HPV-Proofer assay (NorChip) detects HPV types by targeting E6/E7 mRNA expression from five of the most common high-risk HPV types, i.e., 16, 18, 31, 33, and 45. The PreTect HPV-Proofer is a real-time detection strategy based on the nucleic acid sequence-based amplification technology. The five HPV types are detected using molecular beacons specific for genotypic sequence differences contained within the E6 and E7 genes. In a recent study, HC II (Digene) was positive in 95% of histologically determined high-grade lesions, and the HPV Proofer mRNA test was positive in 77% of the histologically confirmed high-grade lesions. HC II was more often positive in benign and low-grade lesions, at a statistically significant level, than HPV E6, E7 mRNA (45). Of particular interest in this study, high-grade histology was detected in 83% of women with normal cytology and positive mRNA test.

SEROLOGIC TESTS

Serologic diagnosis of exposure to HPV has, in general, been used infrequently in the clinical management of HPV infection. Humoral immune responses against HPV include both immunoglobulin G (IgG) and IgA responses. In general, IgG responses have been identified as markers of lifetime exposure to HPV while IgA responses have been proposed as a marker of persistent HPV infection (96). Other studies have demonstrated a decrease in IgA responses in women with precancerous and cancerous lesions (64). Cellular immune responses against HPV are detected late in the progression of HPV to cervical cancer. These immune responses consist of CD8-positive cytotoxic T cells directed against epitopes in the E7 protein. In addition to being detected late in disease, HPV-directed cytotoxic T cells vary widely from patient to patient with cervical cancer, and their potential as a marker of disease is poor given how late they appear in the disease process (20).

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

To understand the clinical utility of HPV testing, one must also have an understanding of cytological and histological diagnoses of the uterine cervix given that, to date, HPV testing has not been approved for primary cervical cancer screening. Table 2 summarizes the terminology used for cytological and histological diagnoses of cervical cells and biopsy specimens, respectively. One of the most compelling and quoted statistics relating to the clinical significance of HPV testing is that >99% of cervical cancer is associated with the detection of HPV nucleic acids in the tumor specimen (95). Although this statistic strongly suggests that HPV is directly involved in cervical cancer, clinicians and laboratorians manage disease in the opposite direction. Accordingly clinicians and laboratorians are faced with a test that, for example, detects high-risk HPV in a patient. For a screening assay, the question arises "what are the chances that a woman with a high-risk type will develop a high-grade lesion or cancer?" In a large prospective study, the incidence of women with laboratory diagnosis of high-risk HPV who had CIN 3 or cancer was 4.4% after 45 months of follow-up. Conversely, women who were HPV high-risk DNA negative had an incidence of CIN 3 or cancer of 0.24% at 45 months and 0.87% at 10 years (83). Although these data support the use of HPV DNA testing, they also demonstrate that a large number of women who are high-risk HPV DNA positive do not develop cervical cancer or cervical cancer precursor lesions (CIN 2 or 3). Assays with the potential to improve the positive predictive value of HPV testing for the development of cervical cancer or cervical cancer precursor lesions are discussed below.

Over the past decade, HPV testing has been integrated into the cervical cancer screening algorithm. For this reason, HPV testing was incorporated into the new Bethesda System recommendations and integrated into current patient management recommendations (Fig. 3) (13, 105, 106). The recommendations were based on the combined use of cervical cytology and HPV DNA testing in large international studies of women over 30 years of age. In general, these studies demonstrated a sensitivity (for CIN 2 or higher) of 92% and a specificity of at least 95% (for CIN 2 or higher) (3, 5, 67, 74, 106). The two currently approved methods for using HPV testing are for the triage of samples diagnosed as ASCUS (abnormal squamous cells of unknown significance) and as an adjunct to the Pap smear. The goal of including HPV testing in this context is to triage or minimize the number of women who need further evaluation by colposcopy and biopsy, for example. HPV testing alone as performed today is not highly predictive of which women will definitely have a high-grade lesion considered to be CIN 2, CIN 3, or squamous cell carcinoma by biopsy. The sensitivity and specificity or more importantly the positive and negative predictive values are the most important determinants of how HPV testing is used in the cervical cancer screening algorithm.

In summary, the understanding of HPV pathogenesis and the role of HPV in cervical cancer has led to new diagnostic approaches to cervical cancer screening that should improve upon the long-standing success of the Papanicolaou smear. Cervical cancer screening in developing countries will also benefit from the many advances in HPV testing, albeit with a few modifications (102) and a focus on low cost and compatibility with instrumentation already in the field.

Human Polyomaviruses*

EUGENE O. MAJOR, CAROLINE RYSCHKEWITSCH, ALEXANDRA VALSAMAKIS, AND JEAN HOU

107

TAXONOMY

JC virus (JCV), BK virus (BKV), and simian virus 40 (SV40) are members of the family *Polyomaviridae* based on virion physical properties (icosahedral virion, 40 nm in diameter) and genome structure (5.1-kb DNA genome with closed, circular, supercoiled conformation). A number of human diseases have been associated with SV40; however, definitive causality has not yet been demonstrated. This chapter therefore focuses on JCV and BKV, the two viruses that have been demonstrated to unequivocally cause human illness. The initials of the patients from whom isolations were first made were used to name these viruses. JCV was cultured from autopsy brain tissue of a Hodgkin's lymphoma patient with cerebral white-matter lesions characteristic of the demyelinating disease progressive multifocal leukoencephalopathy (PML), and BKV was isolated from the urine of a renal transplant recipient (42, 83). The formal names applied to these viruses are *Polyomavirus hominis 1* (BKV) and *Polyomavirus hominis 2* (JCV).

DESCRIPTION OF THE AGENT

JCV and BKV have an icosahedral capsid made up of the three structural proteins VP1, VP2, and VP3. The outer shell of the capsid is made up of 72 capsomeres, each of which contains five VP1 molecules arranged symmetrically around either VP2 or VP3. The VP2 and VP3 structural proteins are believed to assist in transport of VP1 from the cytoplasm to the nucleus and further assist in virion assembly by ionic bonding to genomic nucleotides of the respective viruses (26). Electron microscopy studies showed that cloned VP1 molecules spontaneously aggregate to form virus-like particles with the icosahedral morphology of empty polyomavirus capsids (44, 98). JCV and BKV virus-like particles formed in this manner have been used as effective enzyme immunoassay antigens (111). The epitopes responsible for JCV and BKV neutralization and hemagglutination inhibition are located exclusively on the VP-l structural proteins and appear to be virus specific (46, 109).

The cell surface receptor for JCV and BKV is an α-2-6-linked sialic acid, and viral entry into cells occurs by clathrin-dependent, receptor-mediated endocytosis (37, 67, 85). Recently, a coreceptor for JCV binding has been described, the 5HT2A serotonin receptor (37). Both viruses are assembled within the nucleus.

DNA sequence analysis of BKV and JCV revealed approximately 75% homology at the DNA level and 68% homology at the amino acid level (40). The most significant genomic differences are in the noncoding nucleotides of their regulatory regions (RRs). RRs are located between the multifunctional nonstructural T protein and the agnoprotein coding regions. RRs have a number of different functions including regulation of transcription, genome replication, and host/tissue tropism including human glial, tonsillar stromal cells, and hematopoietic cells for JCV (12, 38, 104) and human tonsillar, pancreatic islet, kidney, and hematopoietic stem cells for BKV. RRs can contain single or tandemly repeated sequences, and they may contain sequence insertions. The mechanisms by which the singular and repeat structures arise are not fully understood but are believed to result from deletion and duplication of promoter/enhancer sequences during replication in the host (40, 71). The JCV RR contains several binding sites for the NF-1 family of transcription factors (40) that have been implicated in regulating cellular susceptibility to JCV infection (5, 75). JCV strains with RRs containing tandem repeats have been associated with PML and therefore appear to be more pathogenic (56, 71). The JCV regulatory region variant responsible for initiating primary infections in humans has not been definitively identified. After reactivation of latent infection in immunosuppressed hosts, JCV regulatory region nucleotide sequences apparently undergo rearrangements to produce variants that can be isolated from different tissues of the body (32, 40, 71). This also appears to be true of BKV, in which rearranged sequences were thought to have emerged from an archetype sequence (24). These viral variants have been associated with dissemination from urogenital organs or lymphoid tissue to other regions of the body, including lung, brain, and cerebrospinal fluid (CSF) (58, 100).

EPIDEMIOLOGY AND TRANSMISSION

Serological studies have confirmed the susceptibility of the majority of the human population to JCV and BKV infection. Seroconversion occurs in approximately 70% of the worldwide population between the ages of 5 and 8 (20, 61, 83). Many individuals maintain lifelong antibody titers to BKV and JCV. However, persistent, high levels of antibody to both viruses are uncommon. This observation suggests that JCV and BKV circulate independently.

* This chapter contains information presented in chapter 100 by Eugene O. Major, Maneth Gravell, and Jean Hou in the eighth edition of this Manual.

The primary route of JCV and BKV transmission is considered to be through respiratory inhalation or other readily accessible portals of viral entry, although supporting evidence is largely epidemiological or circumstantial (31, 101). Other possible routes of JCV or BKV transmission include transplacental passage and exposure to body fluids such as urine, blood, or oral secretions (31, 76, 86, 101).

CLINICAL SIGNIFICANCE

Following inhalation, the initial site of JCV infection has been proposed to be tonsillar stromal cells, due to their demonstrated susceptibility to infection (in vitro and in vivo) and to their anatomic location in the upper respiratory tract (73, 74). Although a specific correlation has not yet been made, BKV has also been demonstrated in tonsillar tissues of children suffering from upper respiratory tract infections (45) as well as in nasopharyngeal aspirates (101), suggesting respiratory inhalation as the initial viral entry point. B-lymphocytes have also been implicated as an initial target site of both JCV and BKV infection; however, they appear to be less susceptible than tonsillar stromal cells (73).

In individuals with normal immunity, primary infections are thought to be mild and usually asymptomatic, although fever and nonspecific upper respiratory symptoms may occur (45, 68). After acute infection, healthy individuals become latently infected and remain asymptomatic throughout life (14, 31, 68).

Evidence suggests that JCV and BKV may remain latent in a number of sites, notably in the kidney and cells of the lymphoid system (10, 30, 54, 73, 76). Recent evidence has also suggested a potential latent site for JCV in the colon (92). During periods of relative or absolute cellular immunodeficiency, JCV and BKV may reactivate in some latently infected individuals, producing asymptomatic viruria and in some instances severe or fatal disease (17, 31).

BKV causes cystitis (nonhemorrhagic or hemorrhagic) and ureteral stenosis in bone marrow and solid organ transplant recipients (7, 16, 27, 108). It also causes nephropathy (polyomavirus-associated nephropathy [PVAN]) in renal transplant recipients (19, 55, 91). The incidence of PVAN has increased from 1 to 5% in the era of intensive immunosuppression to suppress allograft rejection (22, 88). The prevalence of disease varies among centers from 1 to 10% (49). Most cases occur in the first year after transplantation, although approximately 25% of cases occur later (50). Rates of allograft loss range from 10 to 80% (49). Disease appears to result from reactivation of BK infection from the donor allograft (16).

In the correct clinical context, BK detection in urine can be suggestive of BK-induced hemorrhagic cystitis or ureteral stenosis (Table 1). BK replication is the primary risk factor associated with PVAN; therefore, detection of BK replication may be a useful screening measure to identify renal allograft patients at risk of disease (Table 1). Urine screening every 3 months in the first 2 years and annually thereafter up until 5 years posttransplant has been recommended (49) because BK viruria precedes viremia by 4 weeks and PVAN by a median of 12 weeks (50). Although nucleic acid detection in urine is more sensitive than cytology (49, 90), either method can be used for screening. Quantification of BK viral load in plasma or urine has been advocated to establish a presumptive diagnosis of PVAN (49).

PML usually presents as a triad of symptoms including motor dysfunction, visual deficits, and cognitive impairment. These can be manifested as hemiparesis, cortical blindness, hemianopsia, and progressive dementia (8, 68). Viruses resembling polyomaviruses had historically been visualized in white-matter lesions of PML patients; however, JCV was firmly established as the etiologic agent of this disease only after virus was consistently isolated from brain tissue of afflicted patients (81, 84, 93, 115).

PML is considered to be an opportunistic infection (14). It was a relatively rare disease before the AIDS pandemic, occurring initially in immunocompromised individuals with lymphoproliferative malignancies such as lymphoma and leukemia and later in solid organ transplant recipients receiving immunosuppressive therapy. The AIDS pandemic has caused a large increase in PML, and this disease is now seen in about 5% of all AIDS cases (15).

Histopathology results from lytic infection of oligodendrocytes that produces focal or multifocal demyelination in brain white matter (Fig. 1). In biopsy or autopsy tissues from PML patients, JCV antigens and DNA are consistently found in the demyelinated lesions by using immunohistochemistry or in situ DNA hybridization (3, 33).

Patient history, physical exam, and neuroradiology test results suggest the diagnosis of PML. The minimally invasive test of choice for confirmation of diagnosis is detection of

TABLE 1 Diagnostic tests for polyomavirus diseases

Virus	Disease	Specimen	Diagnostic test[a]	Comment
BKV	Hemorrhagic cystitis	Urine	Cytology	Decoy cells indicate polyomavirus replication
			NAAT	Qualitative PCR adequate; role for quantification unproven; negative predictive value is high
	PVAN	Urine	Cytology	Less sensitive than NAAT
			NAAT	Qualitative or quantitative format for screening; quantitative tests for presumptive diagnosis
		Plasma	NAAT	Quantitative tests for presumptive diagnosis
		Renal biopsy specimen	Histology, IHC	Definitive diagnostic tests
JCV	PML	CSF	NAAT	Qualitative PCR adequate; quantitative tests may be indicative of disease course
		Brain biopsy specimen	Histology, IHC, ISH, EM	Less invasive NAAT of CSF currently preferred over biopsy analyses, although biopsies are the most accurate

[a] Abbreviations: NAAT, nucleic acid amplification test; IHC, immunohistochemistry; ISH, in situ hybridization; EM, electron microscopy.

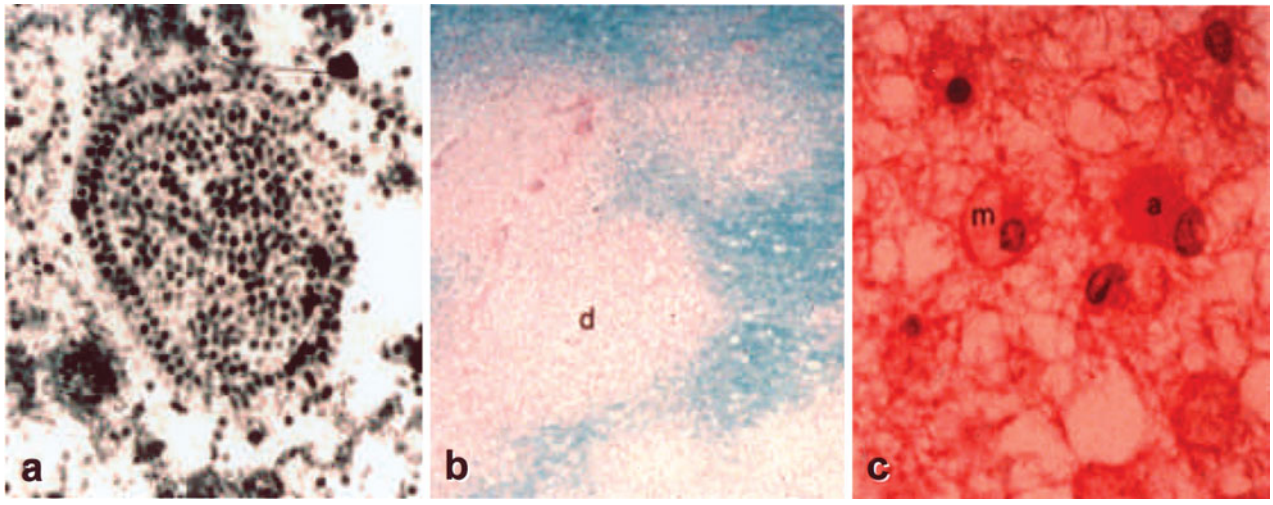

FIGURE 1 Representation of the major elements in the pathogenesis of PML. (a) Electron micrograph of brain tissue from a PML patient showing the assembly of JC virion particles in the nucleus of an infected oligodendrocyte. (b) Luxol fast blue stain of the white matter with demyelinated(d) plaque lesions in a patient with PML. (c) Hematoxylin stain of lesion showing the presence of a macrophage (m) and an astrocyte (smaller a).

JCV nucleic acids in CSF through DNA amplification methods such as PCR (Table 1) (43, 105). Electron microscopy, immunohistochemistry, and in situ hybridization (ISH) on biopsy specimens are used less commonly to establish the diagnosis.

The role of BKV and JCV as causative agents of human malignancies is controversial, at best. Detection of DNA sequences from both viruses in tumors has been variable, and currently there is insufficient evidence to unequivocally prove that these viruses are tumorigenic in humans.

SPECIMEN COLLECTION, TRANSPORT, AND STORAGE

Urine and blood can be tested for BKV. Collection methods for these specimens are reviewed in chapter 80. For nucleic acid detection by PCR amplification, urine can be tested without further processing. If virus is to be isolated, cellular debris is removed by low-speed centrifugation (1,500 × *g* for 15 min). The supernatant medium is then passed through a 0.2-μm-pore-size Nalgene filter (Nalge Co., Rochester, N.Y.), and the virus in the filtered supernatant medium is pelleted by ultracentrifugation (105,000 × *g* for 90 min). JCV or BKV pellets are resuspended and layered onto continuous 25 to 60% Optiprep (Life Technologies, Gaithersburg, Md.) gradients and banded by density gradient ultracentrifugation (160,000 × *g* for 16 h). Gradients are fractionated, and fractions are monitored for levels of JCV or BKV by hemagglutination of human type O erythrocytes. Urine can be stored for long periods at −80°C and used for future testing. Quantification of BKV in blood is performed using serum or plasma. There are currently no data on the effect of specimen type (serum versus plasma) on BKV load. Whole blood can be stored at 4°C prior to separation of serum or plasma. Serum and plasma can be stored at −80°C for extended periods of time. If isolation of BKV from peripheral blood is required, peripheral blood mononuclear cells should be isolated using suitable separation media (reviewed in chapter 80) and cocultured with susceptible cell lines as described below.

CSF can be tested for JCV nucleotide sequences. Collection methods for this specimen are reviewed in chapter 80. CSF samples can be frozen and stored for an extended period at –80°C.

Though invasive, biopsies can be useful in establishing the diagnosis of polyomavirus-induced disease. Prior to the advent of molecular detection, brain biopsy was used as the initial test, to demonstrate the characteristic histopathology of PML. The presence of JCV in affected brains was demonstrated by electron microscopy, immunohistochemistry, and ISH. These methods are still currently useful when the diagnosis is unclear (e.g., when clinical suspicion is high but CSF is negative for JCV DNA by PCR) or at autopsy. The diagnosis of PVAN is established unequivocally by examining renal biopsy specimens for histologic evidence of nephropathy and virus cytopathic effect. Immunohistochemistry is also routinely performed to definitively demonstrate the presence of polyomavirus antigens. Commercially available gelatin or sialinate-treated slides can improve adherence of tissues for use in ISH and immunocytochemistry (53, 54).

DIRECT DETECTION

Microscopy

A presumptive diagnosis of PML can be made based on histopathologic evidence of polyomavirus-infected oligodendrocytes. These cells are enlarged two- to threefold; their nuclei are also enlarged and contain large basophilic inclusions that displace chromatin. Associated histologic changes include perivascular mononuclear cell inflammation, enlarged irregular astrocytes with pleiomorphic nuclei, and foamy macrophages engulfing myelin debris (2, 9).

The diagnosis of PVAN is made by demonstrating viral cytopathic effect in renal tubular epithelium and urothelium. Enlarged basophilic inclusions and displaced chromatin are observed in infected epithelial cells. Tubular necrosis, atrophy, and fibrosis are observed (23, 35). The presence of infected epithelial cells or decoy cells in urine is suggestive of

polyomavirus infection of urinary epithelium. These cells have characteristic basophilic ground-glass nuclear inclusions (90).

Antigen Detection

There are currently no commercially available monoclonal antibodies that do not cross-react with JCV or BKV. However, a polyclonal antibody specific for JCV Vp1 has been developed by an independent laboratory and used to successfully identify JCV in PML brain tissue (57). Similarly, another laboratory-developed monoclonal antibody, Pab2003, has been used to identify JCV early protein, Large T, in the brain of PML patients (77). Polyclonal sera against BKV have been utilized to identify BKV antigens (Vp1 and agnoprotein) in human immunodeficiency virus-associated nephritis (19). Monoclonal antibodies against BKV Large T antigen have been used to detect virus in renal biopsy specimens (102). Unfortunately, there is a current lack of commercially available, specific monoclonal antibodies for diagnostic testing.

Nucleic Acid Detection

ISH

ISH can be used to detect polyomavirus DNA in tissue (Fig. 2) (53). It is used more commonly to diagnose JC syndromes (primarily PML) than diseases caused by BKV. ISH detects active viral DNA replication, an earlier event in the JCV or BKV life cycle than virion capsid formation. Cells undergoing latent infection by JCV or BKV may not produce sufficient viral antigen to be detected by immunocytochemical techniques. However, if sufficient viral DNA were present in these cells, it would still be detectable by ISH (21). Several reports have discussed the specificity and sensitivity advantages of using ISH over antigen detection by immunocytochemistry (3, 25, 95). Due to varying levels of viral transcription and protein synthesis occurring at different stages during infection, it is evident that ISH is a more sensitive method for viral detection than immunocytochemistry. Furthermore, the use of a specific DNA probe for BKV or JCV during DNA hybridization raises the level of specificity, with no cross-reactivity observed between viruses. Biotin-labeled DNA probes used in ISH assays are readily available commercially (Enzo Diagnostics, Inc., Farmingdale, N.Y.). Although biotin-labeled probes are not as sensitive as radiolabeled probes in detecting very low copy numbers of JCV DNA, they do detect as few as 100 copies of viral genomic DNA, an acceptable value for diagnostic use with patient samples.

Nucleic Acid Amplification Tests

Template Extraction

The method of nucleic acid extraction preceding PCR can affect the level of detection sensitivity. The utility of extraction lies mainly in the removal of any inhibitors in the clinical sample. CSF and urine may contain inhibitors of thermostable polymerases; although the CSF inhibitors remain unknown, some urine inhibitors have been identified (13). Furthermore, extraction increases the potential for better sensitivity by concentrating the target.

Manual extraction of urine is typically accomplished with chaotropic salt/silica membrane methods in commercially available kits such as QIAamp (QIAGEN, Valencia, Calif.), described for adenoviruses (36). This method is now widely used for extraction of other viruses in urine, including BKV (72, 80). The QIAamp Viral RNA kit (QIAGEN), which coextracts viral DNA, can be used to manually extract polyomaviruses from CSF. Automated extraction instruments (NucliSens and NucliSens MiniMag [BioMerieux, Durham, N.C.]; MagNAPure compact [Roche Diagnostics Corporation, Indianapolis, Ind.]; and BioRobot EZ1, QIAGEN) have the advantages of saving labor and potentially increasing throughput and can be used to extract BKV from urine (99, 103). Automated extraction of JCV from CSF has also been reported (MagnaPure; Roche Diagnostics Corporation). However, manual extraction appears to be 1 order of magnitude more sensitive than the automated method for JCV DNA extraction from CSF (113).

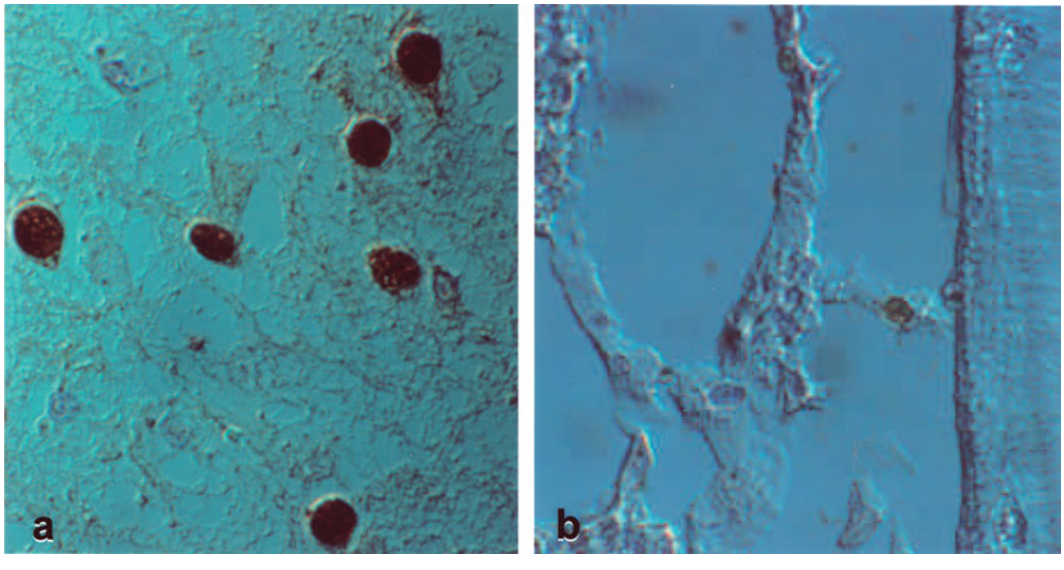

FIGURE 2 Photomicrographs of (a) brain and (b) bone marrow biopsy tissue and B lymphocytes with positive signals following in situ DNA hybridization using a JCV DNA biotin-labeled probe.

Internal Controls

Internal controls are important to identify failed amplification reactions. This is particularly important in urine specimen testing due to the possibility of residual inhibitors postextraction. In general, the internal controls are highly generalizable for JCV and BKV. Targets to ensure the presence of amplifiable DNA include RNaseP (72) and β-actin (103).

Standards

There are no commercially available assays or standards for polyomavirus detection and quantification. Laboratories must do their own internal verification studies to establish assay performance parameters. Independently developed standards are used for quality control and quality assurance once assays have been verified and implemented. Furthermore, they are critical as positive controls and as source material for proficiency testing. Collaborative efforts to develop internationally sanctioned and universally available standards for these purposes are underway.

Preparations of extracted BKV and JCV DNA from purified virus are commercially available (Advanced Biotechnologies, Inc., Columbia, Md.). Given the lack of "gold standard" methodology for polyomavirus quantification, laboratories should consider verifying concentrations of purchased nominal standards.

PCR Methods

PCR-based, qualitative BKV DNA detection assays can be useful in the diagnosis of hemorrhagic cystitis; quantitative assays are currently employed for PVAN screening (Table 1). Qualitative detection of JCV DNA in CSF by PCR has been a very useful, less invasive surrogate for biopsy (Table 1). The utility and predictive value of JCV DNA quantification are still under investigation. Some reports suggest that JCV loads in CSF correlate inversely with survival in patients who are not on antiretroviral therapy (18).

BKV and JCV DNA can be detected qualitatively with conventional or real-time PCR assays. PCR assay design for the polyomaviruses is complicated by the high degree of homology between their genome sequences. Regions within large T antigen and VP1 genes have been used as targets in a number of reported conventional (6, 94) and real-time (66, 94, 106) PCR assays since these sequences are sufficiently variable among different polyomaviruses.

After conventional PCR, products can be detected by electrophoresis through agarose gels containing ethidium bromide. Southern hybridization with radiolabeled DNA probes can also be performed (6, 94). This method has distinct advantages over simple electrophoresis including increased sensitivity and specificity.

In some studies, real-time PCR and conventional PCR-Southern detection have comparable sensitivities for the detection of polyomaviruses (94); in others it is reported to be 10- to 100-fold more sensitive than conventional PCR (72). Decreased labor intensiveness and increased throughput are additional advantages that have motivated many laboratories to switch detection methodologies. Finally, real-time PCR is currently the method of choice for polyomavirus DNA quantification due to its simplicity. Linear ranges of ≥ 7 $\log_{10}$ virus copies have been reported with these methods (97). For BKV, such high concentrations in plasma are uncommon; however, viral loads in urine frequently reach or exceed these levels.

A number of different approaches for the specific detection and quantification of different polyomavirus species have been reported including combinations of species-specific primers and probes (65, 72, 99, 106), genus-specific primers and species-specific probes (66), genus-specific primers followed by melting curve analysis to distinguish amplicons from different species (11), and species-specific primers and SYBR green (a nonspecific, fluorescent DNA intercalator) (89, 97). Most of the species-specific primer/probe strategies utilize TaqMan chemistry (described more fully in chapter 16). Published assays have used real-time PCR instruments with 96-well plate (Prism Sequence Detection System Models 7000, 7700, and 7900; Applied Biosystems, Foster City, Calif.) (48, 65, 72, 106) or capillary configurations (Light Cycler; Roche Diagnostics Corporation) (11, 90, 97). Excellent correlation of BKV quantification in analytical and clinical samples has been reported for the two types of instruments (1).

ISOLATION AND CULTURE PROCEDURES

JCV and BKV are not routinely isolated from clinical specimens because they have rather long growth cycles and a somewhat restricted host cell range. Permanent cell lines that support JCV and/or BKV replication have been developed; these cells can be used for isolation of these viruses from patient samples. Primary cultures derived from human embryonic tissues are also available. JCV grows best in cell cultures derived from human brain; virus replicates in astrocyte and precursor oligodendroglial cells. A permanent cell line, SVG, established from human fetal brain cells, can be used as an equivalent substitute for primary cultures derived from human fetal brain cells (69). The SVG cell line is highly susceptible to JCV infection and has been used for virus isolation and propagation. JCV does not infect human neurons in situ or neurons cultured in vitro. Even under optimum culture conditions and sufficient viral inoculum, JCV growth takes weeks, and multiple passages are sometimes required before progeny virus can be detected. Cytopathic effects in JCV-infected cultures are not easily recognized. They present as translucent cells with large nuclei that are ultimately shed from infected monolayers. JCV remains largely cell associated. Treatment of JCV-infected cell pellets with the nonionic detergent sodium deoxycholate releases JCV from cell association and negates inhibitors of JCV hemagglutination (78, 82).

BKV grows well and forms plaques in monolayers of primary cell cultures (human embryonic kidney, pancreatic islet, and human foreskin cells) and continuous cell lines (HeLa and Vero). BKV cytopathic effect includes nuclear enlargement and the gradual, continual peeling of cells from the monolayer. In infected cultures, BKV remains primarily cell associated; small amounts of virus are shed into the culture medium. Freeze-thaw cycles assist in releasing cell-associated BKV. Titers of JCV or BKV in harvests can be quickly determined by hemagglutination of human type "O" erythrocytes (78, 82).

SEROLOGIC TESTS

The majority of the world population is asymptomatically infected by JCV or BKV during early childhood. An immunoglobulin M antibody response is likely elicited upon initial infection by these viruses. However, due to the early age and the mild, nonspecific nature of JCV and BKV infections, serological assays have not been used to monitor their occurrence. Nor have serological assays been used to monitor the roles of recurrent infections or reactivation of latent infections in maintaining antibody titers in the adult population, or the class-specific antibody responses that may result from these infections. There is little evidence that recurrent infections occur and contribute significantly to maintenance

of antibody titers. Serology, however, has played an important role in understanding the epidemiology of human polyomaviruses and has contributed information on their worldwide distribution (20, 82).

Due to greater sensitivity and reproducibility, enzyme immunoassays have now largely replaced hemagglutination inhibition assays as the means of detecting antibodies to JCV and BKV. Two major developments have facilitated this change: the cloning of JCV and BKV VP1 proteins and the creation of a hybrid strain of JCV, JCV-SVE (Δ), with improved growth characteristics and expanded host cell range (41, 104). These two developments have made it much easier to obtain the antigen concentrations needed to perform enzyme immunoassays and other procedures requiring high antigen concentrations. Enzyme immunoassays to detect JCV- or BKV-specific IgM antibodies have been developed (62, 63). Despite 79% amino acid homology between JCV and BKV capsid proteins, a high degree of antibody cross-reactivity is not observed and independent infection by both viruses has been demonstrated serologically (46, 107).

ANTIVIRAL SUSCEPTIBILITIES

A number of drugs exhibit antiviral activity to JCV or BKV in vitro, including cytarabine, prednisone, vidarabine, fludarabine, topoisomerase inhibitors, camptothecin and alpha interferon. Only cytarabine has been examined as a potential treatment for PML in a multicenter clinical trial (45a). Although there did not appear to be an effect of ara-c on the progression of PML, subsequent analysis (112a) did correlate lower JCV viral loads in the CSF with longer survival times. Randomized controlled trials with other agents have not been performed, and accepted regimens for treatment of patients are not currently available (51). Furthermore, some severe side effects have been associated with their use. Treatment of polyomavirus-induced disease has therefore focused on modulation of immunosuppression, the underlying cause of polyomavirus reactivation.

The recently recommended BKV testing algorithm in renal transplant recipients is aimed at detecting PVAN at an early stage (49). The algorithm is based on the assumption that abrogation of BKV replication will more effectively preserve allograft function if intervention is initiated before significant renal destruction has occurred. Variable efficacy (<10 to >80% graft survival) has been observed after early reduction in immunosuppression using a number of different protocols (49). Low doses of the cytidine analog cidofovir and leflunomide, agents with in vitro antiviral activity, have been demonstrated to have some efficacy against PVAN (59, 60, 64, 106, 112). Decreased immunosuppression is contraindicated in patients with concomitant acute rejection; cidofovir combined with leflunomide is the only available treatment option for these patients. In case reports, cidofovir has also been used to treat BKV-induced hemorrhagic cystitis (47). Cidofovir has not been shown to be effective against replication of JCV in cell culture models (52).

Use of highly active antiretroviral therapy (HAART), including protease inhibitors, has been reported to prolong survival and significantly improve the health of some AIDS patients with PML (4, 29). This likely results from partial restoration of immunological function rather than from their specific action against JCV (109). Prolonged survival of HAART-treated PML patients has been shown to coincide with JCV clearance from the CSF, most likely due to partially restored intrathecal humoral responses (110). PML can progress in some AIDS patients despite effective HAART therapy (14). Inclusion of cidofovir in the drug regimen when HAART alone did not restore immune function has shown benefit to some PML patients (28, 96, 114).

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

Using BKV detection as the sole criterion for establishing the diagnosis of hemorrhagic cystitis is complicated by the fact that polyomaviruses have been detected in the urine of individuals without apparent disease (39, 70) including 10% of pregnant women, 30% of patients with renal tumors, bone marrow transplants, or renal transplants, 40 to 70% of the elderly, and many patients with human immunodeficiency virus type 1. These findings also preclude the use of viruria as a means of diagnosing acute polyomavirus infection (10, 12, 38). Recently, however, quantification of urine BKV concentrations has demonstrated that patients with hemorrhagic cystitis have greater viral loads in urine than asymptomatic patients, suggesting that optimal assay performance (sensitivity, specificity, positive predictive value, and negative predictive value) might be achieved through the application of quantitative cutoffs (65, 87).

Urine testing for BKV has been quite useful in the setting of PVAN following renal transplantation. The high negative predictive value of detection (>99%) allows effective exclusion of disease in appropriate patients (34, 35, 79). Positive urine test results require careful interpretation. Transient viruria has been observed following renal transplant; therefore, a single positive screening result is of little diagnostic value. Additional screening at regular intervals or confirmation by viral load measurement in peripheral blood or urine within 4 weeks has been recommended (49). Viral load assays (in urine or plasma) have been advocated to establish the presumptive diagnosis of PVAN. The positive predictive value of BK viral load testing is >90% when quantitative cutoffs are used (10^7 and 10^4 copies/ml in urine and plasma, respectively). However, since BKV quantification assays have not been standardized, individual laboratories need to establish and validate their own cutoffs. Renal biopsy should be performed after viral load measurement to establish a definitive diagnosis of PVAN (49).

Detection of JCV nucleotide sequences or virion particles in lesioned sites of the brain remains the definitive diagnostic indicator of PML. However, due to the invasive nature of biopsy, PCR assays of CSF have become the most frequently used alternative diagnostic tool. To date, JCV has been detected in the CSF of many individuals with PML (with or without AIDS), but not in the CSF of non-PML patients (105, 111). The ease, sensitivity, and specificity of JCV detection by PCR have alleviated the many difficulties of conventional virologic detection methods such as culture or serology.

Human Parvoviruses*

JEANNE A. JORDAN

108

TAXONOMY

The *Parvoviridae* family includes the *Parvovirinae*, members of which infect vertebrates, and the *Densovirinae*, members of which infect insects. The *Parvoviridae* family consists of small, nonenveloped, single-stranded DNA viruses. The current classification of parvoviruses is based upon their host range and dependence on other viruses for their replication. The *Parvovirinae* subfamily has recently been subdivided into five genera: *Erythrovirus*, *Dependovirus*, *Parvovirus, Amdovirus,* and *Bocavirus* (3, 29, 87). *Bocavirus* has recently been identified as a cause of lower respiratory tract infections. However, this chapter focuses solely on the genus *Erythrovirus*, whose members replicate autonomously in erythroid progenitor cells, with a major emphasis on human parvovirus B19 (prototype strain, Au) (genotype 1). Cossart and colleagues first reported their discovery of B19 in 1975 after screening sera of blood donors for hepatitis B surface antigen using an Ouchterlony immunodiffusion technique (affected serum; number 19 in panel B) (25). Subsequent evaluation of this blood unit, using immune electron microscopy, revealed viral particles consistent in size and morphology with parvovirus. B19 is the predominant parvovirus pathogen in humans. The other, less common, and more recently described erythroviruses infecting humans include genotype 2 (prototype strain, LaLi) and genotype 3 (prototype strain, V9). Among B19 virus isolates, genetic diversity is low (<2%) at the DNA level. In contrast, there is significantly greater nucleotide divergence between genotype 1 (B19) and either genotype 2 or 3 (>11%), with slightly less divergence between genotypes 2 and 3 (~8%) (37, 73, 85). There is much less known about the transmission and epidemiology of genotypes 2 and 3 than for genotype 1.

DESCRIPTION OF THE AGENT

Many important observations regarding the B19 virion have been made using electron microscopy and X-ray crystallography (2, 21, 51). The structure of recombinant B19-like particles has been studied at ~3.5-Å resolution using the latter technology; the major virus capsid protein, VP2, has a structure like a jelly roll with a β barrel motif similar to that present in other icosahedral viruses (51). The diameter of the virus is approximately 26 nm. The complete virion has a molecular mass between 5.5×10^6 and 6.2×10^6 Da and a buoyant density in cesium chloride between 1.39 and 1.42 g/cm^3. The viral particle lacks an envelope, which contributes to the virus' tenacity to resist heat and solvent and detergent treatments, an important consideration when approaching the issue of virus inactivation in blood or blood products (22). The virion does not contain lipids or carbohydrates but does contain phospholipase A_2-like activity, which is required during host cell entry (19, 104).

The B19 capsid is comprised of two structural proteins, VP1 (the minor capsid protein [83 kDa]) and VP2 (the major capsid protein [58 kDa]), representing about 4 and 96% of the capsid, respectively (74). The major nonstructural protein is NS1 (71 kDa), a DNA binding protein involved in viral replication. The NS1 protein transactivates P_6, the single promoter present on the genome (79), and induces cellular apoptosis and activates the gene for the inflammatory cytokine interleukin-6 (62, 63, 65).

The B19 genome consists of a single-stranded 5.6-kb DNA genome; the 5′ and 3′ ends contain identical 365-nucleotide repeats (90), and there exist two large and two small open reading frames (ORFs) (86) (Fig. 1). The major left-hand ORF is translated into NS1, an early viral protein, while the major right-hand ORF is translated into the VP1 and VP2 structural proteins that are expressed later in infection. The antigenic domains of NS1 are located at its carboxy terminus (96). The VP1 and VP2 capsid proteins originate from the same ORF and are identical in sequence, except for an additional 227 amino acids at the amino terminus of VP1. Structurally, this unique region of VP1 is located on the exterior of the virion capsid and contains several neutralizing epitopes, most of which are linear in nature (69). In contrast, most neutralizing epitopes of VP2 are conformational (82). During replication, equal numbers of the plus and minus strands of DNA are packaged into separate virion particles, so that during DNA extraction, under the appropriate salt concentration, the complementary strands hybridize to form a double-stranded DNA structure (9). Zhi and colleagues have constructed an infectious clone of B19 (106).

B19 has an extremely limited cell tropism, replicating only in the nuclei of erythroid progenitor cells of the burst-forming unit and colony-forming unit (24, 89). B19 infection can have a profound effect on an individual, resulting in reticulocytopenia and an abnormally low hematocrit. The cellular receptor

*This chapter contains information presented in chapter 101 by Marialuisa Zerbini and Monica Musiani in the eighth edition of this Manual.

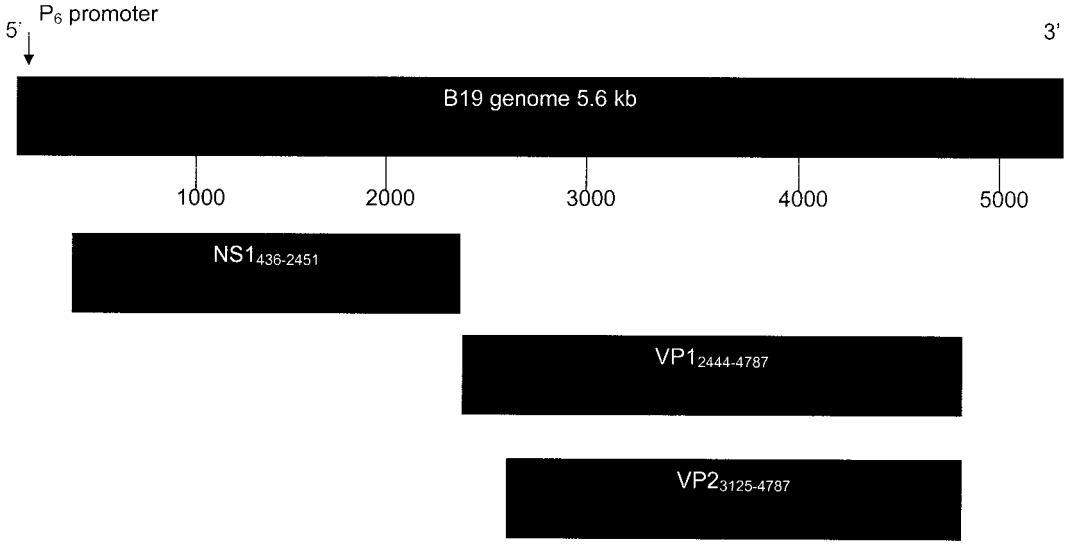

FIGURE 1 Schematic representation of human parvovirus B19 genome and transcription map (86), with the unique region of VP1 comprising bp 2444 to 3124.

that B19 binds to is the blood group P antigen, or globoside (11). Resistance in individuals to B19 infection can be attributed to a lack of the P antigen receptor on erythroid cells (13). The globoside receptor can also be found on other cell types, including cardiac myocytes, white blood cells, platelets, and trophoblasts, and may play a role in pathogenesis in these cell types (46, 97). A coreceptor has been identified that is necessary for virus entry into target cells, a process mediated by $\alpha5\beta1$ integrins (99). A permissive erythroid progenitor cell expresses high levels of both globoside and $\alpha5\beta1$ integrins, while the nonpermissive mature erythrocyte contains only globoside, lacking both $\alpha5\beta1$ integrins and a nucleus. Therefore, although globoside is necessary for infection, it is not sufficient for a cell to be permissive for B19 infection (98). Another key molecule required for B19 infectivity is phospholipase A_2, which is present in the VP1 unique region (19, 104). The enzyme cleaves phospholipids into arachidonic acid, a molecule used to synthesize both prostaglandins and leukotrienes, which play important roles in the inflammatory process.

EPIDEMIOLOGY AND TRANSMISSION

B19 is a common viral infection present worldwide. In temperate climates, epidemic manifestations occur more commonly in late winter, spring, or early summer. Epidemic peaks of B19 infection occur in cycles every 3 to 5 years. B19 infection is most common in young children and manifests itself as erythema infectiosum (EI) (fifth disease or slapped cheek syndrome) (6). In individuals who have disorders that shorten their red cell half-life, B19 infection results in transient aplastic crisis (TAC). Both EI and TAC manifestations are usually self-limiting illnesses. The incubation period for B19 infection is approximately 6 to 10 days.

B19 transmission most often occurs by the respiratory route through respiratory secretions and saliva that are expelled or released when an infected individual sneezes or coughs. Transmission is much more likely to occur among individuals in a household, day care, or crowded environment; this scenario places women with young children at high risk for acquiring infection, which can be problematic for the susceptible woman who becomes infected with B19 while pregnant. Vertical transmission of B19 occurs at a rate of approximately 30% and can result in transmission of the virus to her developing fetus. In the general population, the seroprevalence of B19-specific immunoglobulin G (IgG) rises steadily from 37% in children ages 1 to 5 years to 87% in individuals who are greater than 50 years (20). Between 50 and 60% of women in their reproductive years have circulating B19 IgG, leaving a significant percentage who do not (43).

B19 can also be transmitted parenterally from blood or blood products obtained from viremic donors (41, 81). The incidence of B19 in the blood of healthy donors ranges from 1 in 20,000 to 1 in 50,000 donors (41, 61). The risk of transmission is greater when the blood components are made from pooled units than with those made from single units, placing those individuals requiring repeated doses of any of these blood products at risk of becoming infected with B19 over time, including hemophiliacs, who require lifelong administration of clotting factor concentrate (15, 55, 81). Using nucleic acid amplification testing (NAAT), B19 DNA has been detected in numerous batches of albumin, factor VIII, factor IX, clotting factor concentrates, and immunoglobulin (10, 55). Recent observations in healthy volunteers suggest that acute B19 infection can occur from administration of blood components that contain $\geq 10^7$ genome equivalents/ml (geq/ml) of B19 DNA. In contrast, patients receiving $<10^4$ geq/ml have not shown evidence of virus transmission (15, 100). The presence of neutralizing activity in all of these pools may help to explain the lack of infectivity in pools with lower viral loads (15, 41).

CLINICAL SIGNIFICANCE

Symptoms associated with B19 infection can vary considerably, from asymptomatic to life threatening. In the immunocompetent individual, B19 infection is usually an acute self-limiting disease, while in those who are immunocompromised or who

have red cells with shortened half-lives, B19 infection can become chronic.

Much of what we first learned about B19 infection in the immunocompetent individual came from two studies out of the United Kingdom that were conducted using healthy adult volunteers (4, 78). These volunteers were infected intranasally with sera known to contain B19 particles. The infection in the B19-seronegative volunteers had two distinct phases, a nonspecific phase occurring at the end of the first week postinoculation and consisting of fever, headache, myalgia, chills, and/or itching, and a more specific phase occurring around day 17 or 18 postinoculation with symptoms including the absence of reticulocytes, followed by a significant drop in hemoglobin, along with a transient decrease in neutrophil, lymphocyte, and/or platelet counts. Viremia became detectable 6 days postinoculation, peaking on days 8 and 9. Viral levels rose to approximately 10^{10} to 10^{12} genome copies/ml of blood. B19-specific IgM antibodies became detectable 2 weeks postinoculation, while IgG antibodies appeared within days of detectable IgM antibodies (Fig. 2).

Anderson and colleagues first described EI in 1983 during an outbreak in a primary school in London, England (5). EI has a mean incubation period of approximately 17 to 19 days. Prodromal symptoms may include low-grade fever, headache, and one or more of the following: conjunctivitis, upper respiratory tract complaints, cough, myalgia, nausea, and/or diarrhea. The specific rash associated with B19 infection first appears on the face as a confluent maculopapular erythema on the cheeks, with relative perioral pallor. This manifestation provides the characteristic slapped-cheek appearance on the individual. The rash may appear next in a bilaterally symmetric fashion on the arms, legs, and trunk. Rarely are the palms of the hands and soles of the feet involved. The rash can wax and wane for an extended period, up to 3 weeks; a rise in body temperature, caused by fever, heat, exercise, or exposure to sunlight, can induce its reappearance.

TAC is an acute, self-limited cessation of the regenerative process within the erythropoietic cell lineage and is characterized by the abrupt onset of severe anemia that is associated with a dramatic decline in circulating reticulocytes. TAC was first described in 1981 as a clinical manifestation associated with B19 infection in children with sickle cell anemia and since then has been described to occur in a wide range of patients with underlying chronic hemolytic anemia or shortened red blood cell half-lives (14, 75).

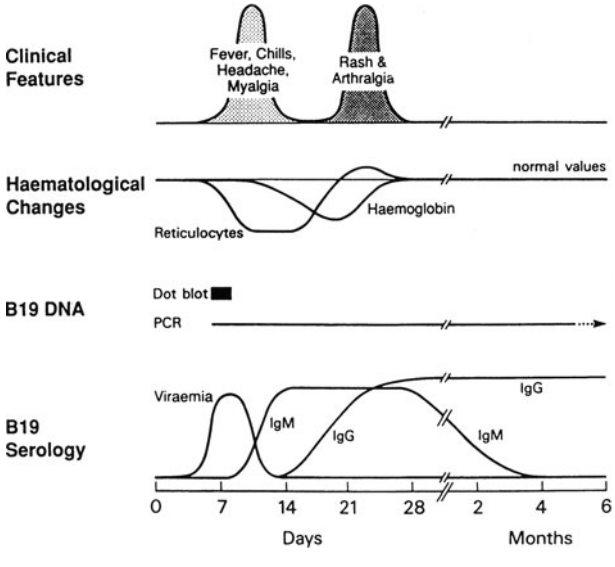

FIGURE 2 Clinical features, hematologic changes, B19 DNA presence, and serologic findings associated with B19 infection in a healthy individual (reprinted from reference 14).

One of the most important complications of B19 infection is its association with pregnancy loss (27, 94). Brown and colleagues first reported on the association of intrauterine B19 infection and fetal demise in 1984 (16). In a susceptible woman, infection with B19 during pregnancy can result in spontaneous abortion, stillbirth, severe fetal anemia, nonimmune hydrops fetalis, transfusion-dependent congenital anemia, hepatomegaly, or fetal death (12, 92). An inflammatory immune response and trophoblast apoptosis have been reported to occur in placentas from pregnancies with poor outcome due to B19 infection (45, 48). Although the rate of viral transmission across the placenta is relatively high, between 24 and 51% (102), the risk of fetal death is relatively low, between 1 and 10%, with the greatest risk being associated with infection occurring in or before the 20th week of gestation. B19 is responsible for 16 to 18% of all cases of idiopathic nonimmune hydrops fetalis (42). Although most cases of B19-induced fetal hydrops resolve spontaneously, the presentation can occur rapidly, within a few days, and result in fetal death. Weekly fetal ultrasonography monitoring for hydrops, for up to 14 weeks, is recommended for women who seroconvert to B19 positivity during pregnancy. The fetus is particularly vulnerable to B19 infection and developing hydrops during the second trimester, as this time correlates to the rapid expansion of red blood cells, including the erythrocyte precursor cell, the target cell for B19 infection.

B19 infection can be problematic for the immunocompromised patient, one with congenital or acquired immunodeficiency syndrome, a recipient of a solid-organ or bone marrow transplant, or a patient with a lymphoproliferative disorder or other malignancy, especially when receiving chemotherapy (33, 54). B19 is the leading cause of pure red cell aplasia in AIDS patients. An immunocompromised patient can present with acute B19 infection that does not resolve but becomes chronic; low- to medium-level viremia can persist for several months or even years, which can lead to selective aplasia of red blood cell precursors within the bone marrow, and occasionally to pancytopenia (71). Chronic infection can lead to persistent and severe anemia, due most likely to the patient's inability to mount an adequate immune response to clear the viremia. In these patients, clinical response to intravenous immunoglobulin (IVIg) is usually quite effective in eliminating the viremia (67).

In 1985, results from two large-scale studies were published describing the association between B19 infection and arthropathy (80, 101). A symmetric, polyarticular involvement of the joints can occur as a consequence of B19 infection in the presence or absence of the specific skin rash. Joint symptoms can occur in up to 33% of adults, being found more commonly in women than in men. Joint involvement is uncommon in children, occurring less than 10% of the time. The involved joints include the proximal interphalangeal joints of the hands and feet and, less frequently, the wrists, elbows, knees, and ankles. Swelling, warmth, redness, and stiffness can accompany the joint pain. These symptoms are usually self-limiting, remaining for a few weeks, but can persist for months or even years (72). The role of B19 in the etiopathogenesis of rheumatoid arthritis and chronic juvenile arthritis remains the subject of disagreement (18, 52).

The role of B19 has been firmly established for EI, TAC, nonimmune hydrops fetalis, chronic pure red cell aplasia, and arthropathy syndromes. However, less commonly recognized clinical manifestations have also been associated with B19, including glomerulonephritis, vasculitis, neurologic disease, myocarditis, hepatobiliary disease, rheumatic disease, hematologic disorders, and cutaneous eruptions apart from EI (93). The mechanism(s) for these various atypical clinical manifestations remains unknown, but has become a priority to elucidate.

Treatment and Prevention

Infection with B19 is usually a mild, self-limiting febrile illness and as such does not require specific therapy or treatment. Nonsteroidal anti-inflammatory drugs can provide relief to the symptomatic individual with arthritis or arthropathy. In cases where B19 infection is life threatening, treatment will vary with the clinical manifestations presented and the immune status of the patient (103). For instance, blood transfusion therapy can be used to provide temporary relief in patients with acute anemia. Severe fetal anemia, as a result of B19 infection, can be treated with one or more intrauterine transfusions of packed red blood cells. However, this treatment is not without its risks. Determining fetal anemia can now be accomplished noninvasively using Doppler measurements, which obviates funicentesis, fetal transfusion, and their associated risks if anemia is found to be absent (26, 66). IVIg therapy is generally limited to those patients suffering with chronic anemia due to B19 and has been used with much success in relieving anemia in these patients (67). Success with IVIg therapy has also been reported for treatment of juvenile polyarticular arthritis (95). However, it should be noted that as a pooled blood product, IVIg can contain B19 and therefore puts the susceptible patient at risk for acquiring B19 infection (28, 32, 35, 83).

Vaccine

Currently, preventing B19 infection is best accomplished through the use of good infection control practices to interrupt transmission, although developing a vaccine against B19 would be desirable. The most effective vaccine would contain both VP1 and VP2 antigens (8). Although VP1 comprises just 4% of the capsid, it contains important epitopes that illicit strong neutralizing antibody activity against the virus. Ideally, a vaccine should elicit both neutralizing-antibody production and a T-cell response (31, 91).

A recombinant human parvovirus B19 vaccine, composed of both VP1 and VP2 proteins that self-assemble into empty capsids resembling virus particles, was evaluated in a randomized, double-blind, phase 1 trial (7). The vaccine was given to 24 seronegative adults in a series of three doses over 6 months. The vaccine, formulated with MF59C.1 adjuvant, was found to be safe, well tolerated, and highly immunogenic. All 24 participants developed neutralizing antibodies (7). The results from this trial are promising for developing a vaccine that could protect against B19 infection and its associated risks.

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

Serum from whole blood, collected in a sterile tube lacking anticoagulant, is most suitable for serologic testing, although plasma, containing either EDTA or sodium citrate, can also be used. Whole-blood samples being transported to the laboratory should be maintained at 2 to 8°C; temperatures at or below freezing should be avoided during transport and storage to minimize red cell lysis. Serum or plasma, once separated from the cellular components of whole blood, can be stored for short periods at 2 to 8°C, or at −20 or −70°C for much more extended periods, before testing is performed.

Bone marrow aspirates, cord blood, amniotic fluid, and biopsy specimens of placenta and/or fetal tissues (liver, lung, and heart) are suitable for B19 DNA detection using in situ hybridization or NAAT, or for antigen detection using immunocytochemistry or immunohistochemistry. Bone marrow and cord blood samples should be collected in sterile tubes containing EDTA or sodium citrate. Heparin should be avoided for NAAT because of its inhibitory effect on the *Taq* polymerase unless DNA purification is included in the sample processing protocol. Amniotic fluid should be collected in a sterile tube lacking anticoagulant. Placental and fetal tissues can be placed directly into viral transport media or fixed using 10% buffered formalin. Cellular and fresh tissue samples should be maintained at 2 to 8°C for transport to the laboratory. Once again, freezing temperatures should be avoided for transport or storage prior to sample processing.

DIRECT DETECTION

Microscopic

Immune electron microscopy can be used to visualize the virus. However, this approach is not used routinely in the clinical laboratory for diagnosis.

Antigen

Immunocytochemical or Immunohistochemical Analyses

Cytospin preparations of bone marrow aspirates, cord blood, or amniotic fluid specimens can be analyzed by immunocytochemistry for the presence of B19-specific capsid antigen(s) using commercially available antibodies (49). These antibodies can also be used in an immunohistochemical analysis of formalin-fixed, paraffin-embedded placental or fetal tissues for viral antigens (49). However, these procedures are usually performed in an anatomical pathology laboratory or research laboratory, but not a clinical pathology laboratory.

Nucleic Acid

DNA In Situ Hybridization

The specimen types analyzed by immunocytochemistry or immunohistochemistry for viral antigen can be analyzed by in situ hybridization for B19 DNA (42). The DNA probes used for in situ hybridization consist of either short stretches of B19-specific oligonucleotides or a cloned plasmid containing a nearly full-length genome. Probes are most often labeled with either biotin or digoxigenin to avoid using a radioisotope. A colorimetric substrate is commonly used in conjunction with either alkaline phosphatase or peroxidase, whose products can be visualized using a light microscope. Increased analytical sensitivity can be achieved using a chemiluminescent substrate, but this strategy requires a high-performance luminometer and computer to be used in conjunction with an optical microscope.

NAAT

At present, NAAT is the most sensitive choice for detecting B19-specific DNA within a specimen, and is considered the test of choice for diagnosing infection in the immunocompromised or immunosuppressed individual, or in the fetus or

neonate, for whom using serologic tests would not be advisable. Nonhemolyzed serum or plasma samples can be analyzed for B19 DNA as a crude cell lysate without the need for DNA extraction and purification. However, DNA extraction and purification are recommended when analyzing hemolyzed serum or plasma, or highly cellular samples (bone marrow aspirates, cord blood, or amniotic fluid) or tissue specimens (fresh or formalin fixed) (105).

Numerous PCR-based primer and probe sets have been described for detecting B19-specific DNA (47, 68). It is important to note that most of these targets were designed to detect genotype 1, not genotype 2 or 3 necessarily. The earliest detection platforms consisted of agarose gel electrophoresis and Southern blot hybridization, or dot blot hybridization techniques, or enzyme immunoassay (EIA). More recently, numerous real-time PCR platforms have been developed in conjunction with fluorescence-labeled probes such as TaqMan, Molecular Beacons, or FRET probes (1, 34). This approach has many benefits, including speed, reduced risk of contamination, and ease of estimating viral load. Real-time PCR is readily adapted to either qualitative (endpoint analysis) or quantitative (viral load) detection. A quantitative assay for B19 DNA must demonstrate linearity over a wide range, as viral load can reach levels of 10^{12} geq/ml of blood during the acute phase of infection, but rapidly declines with the onset of a robust antibody production (70).

A U.S. Food and Drug Administration (FDA)-cleared NAAT assay is not currently available, although several manufacturers offer analyte-specific reagents for detecting B19 DNA. The LightCycler-Parvovirus B19 quantification kit (Roche Diagnostics, Indianapolis, Ind.) is highly sensitive for genotype 1 but is not suitable for detecting genotype 2 or one of the genotype 3 strains (39). In contrast, the RealArt Parvo B19 LC PCR (Roche Diagnostics) is suitable for detection, quantification, and differentiation of all three genotypes, albeit with lower sensitivity for certain strains (39). Because serology is insufficient for diagnosing B19 infection in the immunocompromised patient, it is imperative to assess the NAAT assay's performance for detecting the three genotypes. Investigator-designed real-time PCR assays targeting the NS1 gene or VP1 unique region have been successful in detecting genotypes 1 to 3 at similar sensitivities; these approaches use either consensus primer-based PCR followed by restriction fragment length polymorphism analysis or DNA sequencing, nested PCR, or multiplex PCR using genotype-specific primers and probes (39, 56, 84, 85).

ISOLATION PROCEDURES

Successful replication of B19 requires infection of an undifferentiated, actively replicating erythroid cell. Although freshly harvested bone marrow or fetal cord blood samples have been used successfully to propagate B19, it is impractical to use this approach routinely to culture B19 in the clinical laboratory.

IDENTIFICATION

This virus is not identified in the conventional sense using tissue culture but through molecular techniques that detect specific DNA sequences and by immunologic methods using antibodies that recognize specific viral capsid proteins.

TYPING SYSTEMS

DNA sequence analysis of the VP1 unique region or the NS1 gene can be used to differentiate among genotypes (39, 56, 84, 85).

SEROLOGIC TESTING

Serologic testing to detect B19-specific antibodies to viral capsid antigen remains the cornerstone in determining the immune status in immunocompetent individuals. In the practice of obstetrics, it is considered standard care for the physician to request B19-specific IgM and IgG serologic testing in the case of a pregnant woman with a history of exposure to a B19-infected individual. However, this approach would not be chosen when attempting to diagnose B19 infection in an immunocompromised individual, or in a fetus or neonate, due to the patient's limited ability to produce antibodies; instead, NAAT should be chosen for this purpose.

Most B19-specific serologic assays incorporate viral antigen(s) generated from recombinant expression vectors due to the limited availability of native B19 capsids. Both prokaryotic and eukaryotic expression systems have been used to produce viral capsid protein(s) (64) or self-assembled empty viral capsids (50). Most B19-specific serologic testing performed in the United States is done using one of two commercially available assays (17, 23). Biotrin International (Dublin, Ireland) manufactures B19-specific IgM and IgG EIAs for sale and distribution that have been cleared by the FDA; these kits use a μ capture EIA for B19-specific IgM antibody and a baculovirus-expressed conformational VP2 antigen for the B19-specific IgG EIA. The μ capture format is designed to minimize false-negative IgM results; microtiter wells are coated with anti-human IgM antisera, a process that allows for the binding of total IgM antibody in serum or plasma to the solid phase and thus reduces competition from IgG antibodies that can occur due to differences in concentration.

Focus Diagnostics Laboratory (Cypress, Calif.) is the other manufacturer of B19-specific IgM and IgG serologic tests, which are proprietary in nature but are known to incorporate only a linear (denatured) VP1 antigen purified from an *Escherichia coli* expression vector; these B19-specific IgM and IgG assays have not been FDA cleared.

It is well established that for better accuracy the B19-specific IgG EIA should incorporate a conformational capsid antigen (43, 53, 60). This is based on the fact that circulating IgG antibodies directed against linear epitopes of VP1 and VP2 gradually decline postinfection but that the IgG directed against conformational epitopes of those antigens are maintained long term.

EIAs measuring IgG avidity have also been developed. These assays are helpful in discriminating between primary and secondary infection but are not yet commercially available (77, 88). Standardizing B19 IgG results among laboratories and test systems can be achieved using an international standard (The 2nd International Standard, 2003; code 01/602; 77 IU per ampoule) (30). No such standard is available for B19 IgM determinations.

Commercially available indirect fluorescent-antibody (IFA) and Western blot assays can also be used to detect B19-specific IgM or IgG antibodies (59, 76). In the former, the antigen consists of a conformational VP1 protein expressed in insect cells using a recombinant baculovirus expression vector. Sera for IFA B19-specific IgM antibody testing should be pretreated with a suitable adsorbent reagent to prevent interference from rheumatoid factors (which generates a false-positive result) and reduce IgG competition (which produces a false-negative result). These assays can be used as a confirmatory assay in conjunction with an EIA that utilizes the linear, denatured VP1 antigen. In the latter assay, VP1, VP2, and NS1 antigens are used (38). However, this approach has its limitations, as the antigens are denatured, which may limit their diagnostic value.

In summary, unlike the significant variation in genomic sequence that exists among the three genotypes of *Erythrovirus*, there is a high degree of homology in the VP2 capsid protein for these three genotypes (85). This is expected to result in a high level of immunologic cross-reactivity of IgM and IgG. Therefore, choosing an EIA that incorporates a conformational VP2 antigen would be desirable for detecting all three genotypes of *Erythrovirus*.

ANTIVIRAL SUSCEPTIBILITIES

To date, there is no antiviral agent described for treatment of B19 infection.

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

Laboratory tests are essential when attempting to diagnose B19 infection due to its wide range of clinical presentations and patients affected. Determining whether to use serologic tests and/or NAAT is largely dependent upon the patient's immune status. Serologic tests should be used in diagnosing infection of or assessing immune status in the immunocompetent individual. In contrast, NAAT is the test of choice for screening the immunocompromised or immunosuppressed individual or diagnosing congenital or neonatal infections, as serologic screening would be unreliable.

Unlike serologic testing, where only serum or plasma samples are acceptable, NAAT for B19 DNA can be performed using a wide range of specimen types. The choice of specimen(s) is largely dependent upon the clinical manifestations of the patient, with each specimen type requiring validation before testing can be implemented clinically.

Assay design and antigen type(s) incorporated into a kit are important features to note when evaluating a commercial assay (44, 57). Capture EIAs employing native or recombinant antigens are excellent choices for detecting B19-specific immunoglobulin (43). Systems consisting of either *E. coli*-expressed or baculovirus-expressed B19 capsid antigens or both in combination have been described. Capture EIAs incorporating conformational antigens (nondenatured) only, or in combination with linear antigens (denatured), are superior to those utilizing denatured, linear antigens (denatured) alone (53). Several studies have demonstrated differences in B19 IgM and IgG reactivity against conformational and linear epitopes of VP1 and VP2 (53, 58, 60). Accurate B19 serologic diagnosis requires the presence of nondenatured, conformational antigens. Recombinant B19 nonstructural protein NS1 can also be expressed using either a prokaryotic or eukaryotic expression system. The presence of antibodies to NS1 is associated with persistent B19 infection and chronic arthritis (40).

Testing sera for the presence of B19-specific IgM antibodies is the most common approach for diagnosing acute infection in the immunocompetent individual (36). Detectable levels of B19-specific IgM can be found within 7 to 10 days of exposure to the virus; IgM antibodies remain measurable for 2 to 3 months before diminishing. Occasionally, IgM antibodies can persist for longer periods, 6 months or more. Therefore, their presence, especially at low levels for an extended period, is suggestive but not conclusive proof of recent infection. Acute infection can also be diagnosed by demonstrating a fourfold or greater rise in B19-specific IgG antibody titer in a patient's sera. However, this procedure requires two separate time points for sample collection and is considered impractical in most clinical situations.

Testing sera for the presence of B19-specific IgG antibodies can determine past or previous infection in the immunocompetent individual. Detecting the presence of IgG antibody, without IgM antibody, implies immunity in the patient. The antibody response to linear or denatured viral capsid proteins diminishes with time. In contrast, the antibody response to conformational capsid proteins persists for years.

Poxviruses*

INGER K. DAMON

109

Interest in poxviruses has undergone a resurgence in part because of bioterrorism response concerns (6, 35, 76) and because of the use of recombinant poxviruses for basic research, clinical therapeutics, and vaccines (38, 39, 43, 44, 61, 83, 85, 86). In preparing for the threat of smallpox, the U.S. government has developed a coordinated national response plan to refurbish relevant components of the public health infrastructure (6, 35, 47, 76, 83), including replenishing the vaccine and vaccinia immunoglobulin stockpiles, revitalizing poxvirus health education and epidemiologic training, developing antivirals and new diagnostics, and stimulating basic and recombinant poxvirus research. Additionally, periodic introductions of enzootic poxviruses continue to pose a risk to human health (2, 5, 7, 8, 15, 37, 40), as evidenced by the introduction of monkeypox into the United States in 2003 (74) and the ongoing apparent increased incidence of human monkeypox in the Democratic Republic of Congo (DRC, formerly Zaire) (5, 7, 8, 40, 62, 68) and other Congo Basin countries (46), as well as recurrences of vaccinia-like viruses infecting agricultural workers in Brazil (52, 63, 93).

TAXONOMY

All poxviruses described in this chapter belong to the family *Poxviridae* and subfamily *Chordopoxviridae* (61). The taxonomic structure of the family *Poxviridae* has been reviewed previously (59). The genuses and species of the viruses discussed in this chapter are shown in Table 1. DNA-based assays, including DNA sequencing, are the most precise methods for poxvirus genus, species, strain, and variant identification and differentiation (20, 23, 25, 27, 28, 44, 55). The G+C contents of orthopoxviruses, yatapoxviruses, *Molluscum contagiosum virus* (MCV), and parapoxviruses are ~33, ~32, ~60, and ~63%, respectively.

EPIDEMIOLOGY AND TRANSMISSION

All current, naturally occurring poxviruses that infect humans are sporadic zoonotic agents except the *Molluscipoxvirus*, MCV (71, 73, 94), which is transmitted strictly between humans. The zoonotic poxviruses include members of the genera *Orthopoxvirus* (monkeypox virus [40, 85], cowpox virus [4], and the vaccinia virus subspecies, including buffalopox virus [20, 53]), *Parapoxvirus* (Orf, milker's nodule, sealpox, and papulosa stomatitis viruses [11, 71, 75]), and *Yatapoxvirus* (tanapox virus [TPV], Yaba monkey tumor virus [YMTV], and Yaba-like disease virus [YLDV] [16, 39, 44, 79]). Orf virus and MCV infections are the most common poxvirus infections worldwide. These dermatologic lesions often can be readily identified, and laboratory confirmation of clinical diagnosis is often not utilized (22, 71, 72, 75).

Orthopoxviruses

Variola Virus

Variola virus, the cause of smallpox, has a strict human host range and no animal reservoir. The virus was most often transmitted between humans by large-droplet respiratory particles inhaled by susceptible persons who had close, face-to-face contact with an infectious person. It was spread less commonly by aerosol contact or by direct contact with the rash lesion contact or by sloughed crust material from the scab (30).

Monkeypox Virus

Human monkeypox was first reported in 1970 in the DRC. Since 1970, the disease has been seen in Liberia, the Ivory Coast, Sierra Leone, Nigeria, Benin, Cameroon, and Gabon, but most cases have been in the DRC. In the 1980s, serosurveys and virologic investigations in the DRC by the World Health Organization (WHO) indicated that (i) monkeys are sporadically infected, as are humans; (ii) three-fourths of cases, mainly those in children under 15 years of age, were from animal contact; (iii) the protective efficacy of vaccinia vaccination is about 85%; (iv) monkeypox virus has a broad host range, including squirrels (*Funisciurus* spp. and *Heliosciurus* spp.); and (v) human monkeypox has a secondary attack rate of 9% among unvaccinated contacts within households (i.e., it is much less transmissible than smallpox). In a recent outbreak in the DRC, about 250 serosubstantiated cases of monkeypox occurred among 0.5 million people in 78 villages from February 1996 to October 1997. Unlike those in the earlier outbreak, about three-fourths of the cases appeared to result from human-to-human transmission; however, the secondary attack rate of 8% among unvaccinated contacts within households appeared to be about the same as that found in the 1981-to-1986 surveillance (5, 7, 8, 37).

* This chapter contains information presented in chapter 105 by Inger K. Damon and Joseph J. Esposito in the eighth edition of this Manual.

TABLE 1 Taxonomy of poxviruses that infect humans

Genus	Species
Orthopoxvirus	Variola virus, vaccinia virus, cowpox virus, monkeypox virus
Parapoxvirus	Orf virus, milker's nodule virus, papulosa stomatitis virus
Yatapoxvirus	Tanapox virus, Yaba-like disease virus, Yaba monkey tumor virus
Molluscipoxvirus	Molluscum contagiosum virus

More recent case series have been reported from the DRC (54), and disease with a sustained chain of human-to-human transmission was reported in the Republic of Congo in 2003 (46).

The emergence of monkeypox in the United States provides another example of the ability of this zoonotic disease to exploit new ecologic niches. The North American prairie dog, diseased after exposure to an infected African rodent(s), subsequently infected and caused illness in U.S. human populations (9). The characterization of human disease in the United States, and its comparison with that classically described in the Congo Basin in the 1980s, enabled clinical and epidemiologic descriptions of distinct viral diseases.

Vaccinia Virus

Certain strains of vaccinia virus were used for human vaccination to globally eradicate smallpox (19, 22, 30, 32, 59). Since the early 1980s, vaccinia and certain other poxviruses have been used as recombinant vectors for the expression of a variety of proteins, including vaccine immunogens (38, 39, 43, 44, 61, 83, 85, 86). Infection can be transmitted to laboratory workers by accidental exposure, and significant pathology has been observed in unvaccinated individuals (48). Vaccination is therefore currently recommended for personnel working with live, replicative orthopoxviruses including vaccinia virus.

The origin of vaccinia virus is uncertain (59). Vaccinia virus infections are not generally regarded as naturally occurring, although vaccinee-to-cattle and cattle-to-human transmissions occurred on farms during the smallpox eradication campaign. Sporadic outbreaks of infection caused by the vaccinia virus subspecies buffalopox virus that involve transmission between milking buffalo, cattle, and people have been reported, mainly in India but also in Egypt, Bangladesh, Pakistan, and Indonesia. Vaccinia-like lesions have been observed on the animals' teats and the milkers' hands; milk is infectious. Biological data and limited DNA analyses of isolates from an outbreak in India in 1985 suggest that buffalopox virus may be derived from vaccinia virus strains transmitted from humans to livestock during the smallpox vaccination era (20, 53).

Quite interestingly, multiple distinct vaccinia viruses, possibly related to the vaccine strain used during smallpox eradication in Brazil, were recently found in cattle and their farm worker handlers in rural Rio de Janeiro (15, 81) as well as various locales within the Minas Gerais state (15, 52, 63, 93). Historic collections, when reevaluated with additional techniques, suggest that vaccinia-like viruses were previously isolated in the 1960s and 1970s (14). Inadvertent exposure to a vaccinia virus-vectored recombinant rabies virus vaccine dispersed to control rabies in wildlife has resulted in at least one instance of human infection; the bait was carried home by the family dog (80).

Cowpox Virus

Cowpox, sometimes a rare occupational infection of humans, can be acquired by contact with infected cows. Other animals, e.g., infected rats, pet cats, and zoo and circus elephants, have more often been sources of the disease. Cowpox virus is a rather diverse species and has been isolated from humans and a variety of animals in Europe and adjoining regions of Asia (2, 4). A serosurvey of wild animals in Great Britain found orthopoxvirus antibodies in a portion of bank and field voles and wood mice, which is consistent with small rodents' being reservoir hosts (3).

Yatapoxviruses

The epidemiology and natural history of yatapoxviruses are poorly understood. YMTV and YLDV infections have occurred in animal handlers (79); however, TPV is the main naturally occurring human pathogen in the *Yatapoxvirus* genus (31). Tanapox is an endemic zoonosis of equatorial Africa that is thought to be transmitted mechanically to humans by biting insects, especially during the rainy season (39). Recent reports have demonstrated that travelers to regions where the disease in endemic can be infected (16, 90).

Parapoxviruses

Three different parapoxvirus diseases occur in humans (31, 75), generally as occupational infections: milker's nodule (in dairy cattle, the disease is termed pseudocowpox or paravaccinia), Orf (in sheep and goats, the disease has been referred to as Orf, contagious ecthyma, contagious pustular dermatitis, contagious pustular stomatitis, and sore mouth), and papulosa stomatitis (in calves and beef cattle, the disease is termed bovine papular stomatitis). Parapoxvirus infections are transmitted to humans by direct contact with infected livestock through abraded skin on the hands and fingers, and ocular autoinoculation sometimes occurs (31, 71).

Molluscipoxvirus

MCV is the sole member of the genus *Molluscipoxvirus.* MCV appears to have a human-restricted host range, and it does not grow readily in culture. Molluscum contagiosum occurs worldwide. In children it is transmitted by direct skin contact, and sexual transmission occurs in adults (31, 71).

DESCRIPTION OF THE AGENTS

Virions are large and brick shaped (orthopoxviruses, yatapoxviruses, and molluscipoxvirus) or ovoid (parapoxviruses). Virions range in length from 220 to 450 nm and in width and depth from 140 to 260 nm. The appearances of virions under an electron microscope vary somewhat with sample preparation. By cryoelectron microscopy, in unstained, unfixed vitrified specimens, vaccinia virus appears as smooth, rounded rectangles; a uniform core is surrounded by a 30-nm-thick membrane. In conventional negatively stained thin sections, the core appears dumbbell shaped and is surrounded by a complex series of membranes. Lateral bodies of undefined function occupy the space between the outer membrane and the bar of the dumbbell. This feature may be a dehydration effect of negative staining.

Virus particles contain about half of the approximately 200 potential virus genome-encoded proteins. Virions consist of structural proteins and enzymes, including a virtually complete RNA polymerase system for primary transcription of viral genes (59). The genome is a 130- to 375-kbp (depending upon the genus) double-stranded DNA molecule that is

encapsidated in a nucleoprotein complex (nucleosome) inside the core. The genome is covalently closed at each end, and its ends are hairpin-like telomeres. Complete genome DNA sequences have been reported for several different poxviruses. GenBank entries are compiled at a dedicated website (http://www.poxvirus.org).

During virus replication (59), virion morphogenesis begins in the cytoplasm in areas known as cytoplasmic factories, where cellular organelles are largely absent. Thin-section electron microscopy observations of cells early after infection show crescent-shaped membrane structures, which progress to ovoid structures, called immature virions, which enclose a dense nucleoprotein complex. Primary transcription precedes the production of the crescents (cup-shaped in three dimensions) and the immature virons. Brick-shaped, membrane-covered mature virions (MVs; also known as intracellular mature virions [IMVs]) form as the viral core condenses.

A small portion of MVs may be further transported on microtubules from the viral factory and processed to acquire a bilayer tegument (envelope) of Golgi intermediate compartment membrane that contains specific viral proteins. The intracellular enveloped MV then moves along cellular microtubules to the cell surface, where the outermost membrane fuses with the cellular membrane to reveal a cell-associated enveloped virus on the cell surface. The cell-associated enveloped virus can prompt actin polymerization behind the virion, which may facilitate cell-to-cell infection with virus. Enveloped virions can also exit the cell to spread more distantly.

A virus receptor has not been identified. Enveloped and nonenveloped forms attach to cells differently; however, recent studies suggest that the nonenveloped particle (IMV) is the particle which enters, via fusion, into the host cell. A complex of viral proteins is believed to act as a fusion complex. The common result of entry is uncoating of the particle, release of viral contents into the cell, and initiation of virus-controlled transcription of early-class proteins. Recent reviews of virion entry, morphogenesis, and exiting processes have been published (60, 86–88).

CLINICAL SIGNIFICANCE

Orthopoxviruses

A global commission of the WHO declared smallpox eradicated in December 1979, and the declaration was sanctioned by the World Health Assembly in May 1980 (30). Human monkeypox, an emerging zoonotic smallpox-like disease caused by monkeypox virus, with recurrent (and likely endemic) disease in the Congo Basin countries of Africa, is now regarded as the most serious naturally occurring human poxvirus infection (5, 37, 40, 54). The emergence of monkeypox virus as a human pathogen in the United States in 2003 is a classic example of a pathogen's exploiting new ecologic niches and hosts. Ectromelia (also known as mousepox) virus is an orthopoxvirus that has been implicated in various human infections (97); however, such reports are not well founded because the virus can be a notorious contaminant of laboratory mice (17) used to produce reagents for diagnostics.

Variola Virus

Variola major virus strains produced a severe prodrome, fever, prostration, and a rash. Toxemia or other forms of systemic shock led to case fatality rates of up to 30%, with secondary attack rates of 30 to 80% among unvaccinated contacts within households. Variola minor virus strains (alastrim, amass, and kaffir viruses) produced less severe infection and case fatality rates of less than 1%, although secondary attack rates among unvaccinated contacts within households still ranged from 30 to 80%. DNA and biological data have indicated that alastrim variola minor viruses obtained from Europe and South America are similar to each other but distinct from the so-called African variola minor viruses, which appear to be variola major virus variants (19). The last naturally occurring smallpox case occurred in Somalia in October 1977, although a fatal laboratory-associated infection with variola major virus occurred at the University of Birmingham, Birmingham, England, in August 1978 (30).

Naturally acquired variola virus infection caused a systemic febrile rash illness. For ordinary smallpox, the most common clinical presentation, after an asymptomatic incubation period of 10 to 14 days (range, 7 to 17 days), was fever, quickly rising to about 103°F, sometimes with dermal petechiae. Associated constitutional symptoms included backache, headache, vomiting, and prostration. Within a day or two after incubation, a systemic rash appeared that was characteristically centrifugally distributed (i.e., lesions were present in greater numbers on the oral mucosa, face, and extremities than on the trunk). Initially, the rash lesions appeared macular, then papular, enlarging and progressing to a vesicle by day 4 to 5 and a pustule by day 7; lesions were encrusted and scabby by day 14 and sloughed off. Skin lesions were deep seated and were in the same stage of development on any one area of the body. Milder and more severe forms of the rash were also documented. Less severe manifestations (modified smallpox, or variola sine eruptione) occurred in some vaccinated individuals, whereas hemorrhagic or flat-pox types of smallpox occurred in patients with impaired immune responses.

Variola major smallpox was differentiated into four main clinical types: (i) ordinary smallpox (~90% of cases) produced viremia, fever, prostration, and rash; (ii) modified smallpox (5% of cases) produced a mild prodrome with few skin lesions in previously vaccinated people; (iii) flat smallpox (5% of cases) produced slowly developing focal lesions with generalized infection and an ~50% fatality rate; and (iv) hemorrhagic smallpox (<1% of cases) induced bleeding into the skin and the mucous membranes and was invariably fatal within a week of onset. A discrete type of the ordinary form resulted from alastrim variola minor infection (30).

Prior to its eradication, smallpox as a clinical entity was relatively easy to recognize, but other exanthematous illnesses were mistaken for this disease (30). For example, the rash of severe chickenpox, caused by varicella-zoster virus, was often misdiagnosed as that of smallpox. However, chickenpox produces a centripetally distributed rash and rarely appears on the palms and soles. In addition, in the case of chickenpox, prodromal fever and systemic manifestations are mild, if present at all. Chickenpox are superficial in nature, and lesions in different developmental stages may be present on the same area of the body. Other diseases confused with vesicular-stage smallpox included monkeypox, generalized vaccinia, disseminated herpes zoster, disseminated herpes simplex virus infection, drug reactions (eruptions), erythema multiforme, enteroviral infections, scabies, insect bites, impetigo, and molluscum contagiosum. Diseases confused with hemorrhagic smallpox included acute leukemia, meningococcemia, and idiopathic thrombocytopenic purpura. The Centers for Disease Control and Prevention (CDC), in collaboration with numerous professional organizations, has developed an algorithm for evaluating patients for smallpox. The algorithm

and additional information are available at http://www.cdc.gov/nip/smallpox and at www.bt.cdc.gov/EmContact/index.asp. Experience with the algorithm has been summarized previously (83).

Monkeypox Virus

Reviews of human monkeypox infection are available (5, 40). Monkeypox was first recognized by Von Magnus in Copenhagen in 1958 as an exanthem of primates in captivity. Later, the disease was seen in other captive animals, including primates in zoos and animal import centers.

The clinical appearance of human monkeypox, typified by the Congo Basin variant, is much like that of smallpox, with fever, a centrifugally distributed vesiculopustular rash (appearing also on the palms and soles), respiratory distress, and in some cases, death from systemic shock. Like variola virus, monkeypox virus appears to enter through skin abrasions or the mucosa of the upper respiratory tract, where it produces an enanthem and cough. During the primary viremia, the virus then migrates to regional lymph nodes, and during secondary viremia, it is disseminated throughout the body and the skin rash appears. During the prodrome, lymphadenopathy (generally inguinal) with fever and headache is common. Individual skin lesions develop through stages of macule, papule, vesicle, and pustule. Sequelae involve secondary infections, permanent scarring and pitting at the sites of the lesions, and sometimes alopecia and corneal opacities. Acute illness in the United States in 2003, caused by the "West African" variant, appeared generally more mild (49). Additional information on clinical manifestations of disease (36) is also available.

Vaccinia Virus

Humans have historically encountered vaccinia virus most commonly in the form of smallpox vaccine (now called vaccinia vaccine), a live-virus preparation that is cross-protective against other orthopoxvirus infections. The most recent recommendations of the Advisory Committee on Immunization Practices (ACIP) on vaccinia vaccination are available at http://www.cdc.gov/mmwr//preview/mmwrhtml/rr5010a1.htm (10). The ACIP recommends vaccination as a safeguard for laboratory and health care workers who are at high risk of orthopoxvirus infection. In the United States, the CDC Drug Service provides the vaccine after CDC approval of a formal request for this purpose by the administering physician. Vaccinia immunoglobulin is available to treat possible postvaccination complications, which can be severe. Although both products were previously licensed by the Food and Drug Administration, their use currently requires execution of an investigational new drug application because of changes in vaccine diluent formulation and a discoloration of the immunoglobulin.

Vaccination is done by using a multiple puncture technique that causes a local lesion, which develops and recedes in a distinctive manner in primary vaccinees during a 3-week period. At the site of percutaneous vaccination, a papule forms within 2 to 5 days, and the lesion reaches maximum size (about 1 cm in diameter) by 8 to 10 days postvaccination after evolving through vesicle and pustule stages; an areola may encircle the site. The pustule dries into a scab, which usually separates by 14 to 21 days after vaccination. In some vaccinated children, fevers with temperatures as high as about 100°F have occurred but have been uncommon in adults, and a regional lymphadenopathy has been observed.

Because of an increased risk for serious adverse events, such as eczema vaccinatum or vaccinia necrosum, the ACIP has stated that the vaccine is contraindicated for persons with eczema or immunocompromising conditions. The possible complications of vaccinia vaccination are described in the ACIP report (10). Despite attempts to prescreen potential vaccinees for contraindications, instances of generalized vaccinia rash, which may arise 10 to 14 days postvaccination, continue to be reported (42). On a clinical basis alone, it is often difficult to distinguish between generalized vaccinia, which represents virus presumably spread hematogenously, and a form of erythema multiforme, which may be immunologically mediated. Laboratory identification of virus within the disseminated rash may differentiate these conditions (42).

Cowpox Virus

In humans, cowpox lesions occur mainly on the fingers, with reddening and swelling. Autoinoculation of other parts of the body may occur, and severe systemic infections have been reported. Skin lesions are likened to those from a primary vaccinia virus vaccination. The site becomes papular, and a vesicle develops in 4 to 5 days. Healing takes about 3 weeks (2, 22, 31, 32).

Yatapoxviruses

The three members of the genus *Yatapoxvirus*, TPV, YLDV of monkeys, and YMTV, are serologically related (79). DNA maps of TPV and YLDV are extremely similar, suggesting that they are the same agent. However, these DNA maps are markedly different from YMTV DNA maps, even though the DNA from the three viruses cross hybridizes extensively (44).

TPV and YLDV infections in humans consist of a brief fever, followed by development of firm, elevated, round, maculopapular nodules which become necrotic and are distinct from the vesiculopustular lesions of orthopoxvirus infections. Generally, few lesions develop, and these occur primarily on the skin of the upper arms, face, neck, or trunk (39). Symptoms that occur prior to the appearance of lesions include fever, backache, and headache. Lesions umbilicate without pustulation during recovery from infection. They usually heal in 2 to 4 weeks. YMTV produces epidermal histiocytomas, tumor-like masses of histiocytic polygonal mononuclear cell infiltrates that advance to suppurative inflammation.

Parapoxviruses

Milker's nodule occurs as a reddened hemispheric papule that matures into a purplish, smooth, firm nodule varying up to 2 cm in diameter. The lesions usually are not painful and can persist for about 6 weeks. Human Orf virus infection is usually found on the fingers, hands, and arms but may also be found on the face and neck. Fever and swelling of draining lymph nodes may be present, and the lesions often ulcerate and are painful. Autoinoculation of the eye may lead to serious sequelae (71). Contact with (e.g., skinning of) certain wild animals, including deer, reindeer, chamois, and Japanese serow, has also been a source of human parapoxvirus infection. Technicians handling gray seals have contracted sealpox virus (11, 75).

Molluscipoxvirus

In children and teenagers, molluscum contagiosum lesions generally appear on the trunk, limbs (except the palms and soles), and face, where there may be ocular involvement. Infection is usually transmitted by direct skin contact. When MCV infection is transmitted sexually among teenagers and adults, the lesions are mostly on the lower abdomen, pubis, inner thighs, and genitalia. Lesions are pearly, flesh-colored,

raised, firm, umbilicated nodules, about 5 mm in diameter. The lesions tend to disseminate by autoinoculation. Prior to highly active antiretroviral therapy, MCV was an opportunistic pathogen in approximately 15% of AIDS patients in the United States. Restriction endonuclease mapping of isolates suggests that there are at least three MCV subtypes (73). Two predominant MCV subtypes, MCVI and MCVII, have been detected in a limited number of samples examined by restriction pattern and base sequence analyses, but no correlation of subtype with disease syndrome or geographic distribution has been confirmed (71–73). A rapid PCR and restriction fragment length polymorphism analysis using skin lesion material has been described previously for differentiating the MCV subtypes (69).

Clinical Utility of Laboratory Tests for Poxvirus Diagnosis

Poxvirus infections can often be distinguished by the appearances of rashes and associated dermatopathologies (18, 58). In addition, multiple different clinical laboratory tests can be useful for identifying and differentiating poxviruses, including electron microscopy, antigenic testing, nucleic acid detection, determination of virus growth features, and serology (12, 19, 20, 23, 31, 39, 44, 53, 95, 96). The utility of these test methods for the diagnosis of poxvirus infections is shown in Table 2.

COLLECTION, HANDLING, AND STORAGE OF SPECIMENS

A suspected case of smallpox should be immediately reported to the appropriate local or state health department. After review by the health department, the case should be immediately reported to the CDC if the diagnosis of smallpox is still suspected. Current international recommendations advise that work with variola virus be done using WHO-sanctioned biosafety level 4 laboratories. Two WHO collaborating centers (WHOCC) currently have the capability to handle smallpox specimens: one at the CDC in Atlanta, the other at the State Center for Virology and Biotechnology, Koltsovo, Russia. The WHOCC at the CDC also has containment facilities appropriate to work with monkeypox virus and other exotic poxviruses (e.g., TPV). Generally, clinical specimens suspected of containing other poxviruses (e.g., parapoxviruses and MCV) can be tested by experienced local staff using biosafety level 2 containment facilities and equipment.

Suitable specimens for laboratory testing of most suspected poxvirus infections are at least two to four scabs and/or material from vesicular lesions. Scabs can be separated from the underlying intact skin with a scalpel or a 26-gauge needle, and each specimen should be stored in separate containers to avoid cross-contamination. Coexistent infectious rash illnesses, including simultaneous chickenpox and monkeypox infections, have been noted (37).

Lesions should be sampled so that both the vesicle fluid and the overlying skin are collected. Once the overlying skin is lifted off and placed in a specimen container, the base of the vesicle should be vigorously swabbed with a wooden applicator or polyester or cotton swab. The viscous material can be applied onto a clean glass microscope slide and air dried. A "touch prep" can be prepared by pressing a clean slide onto the opened lesion by using a gradual pressing motion. If available, three electron microscope grids can be applied in succession (shiny side to the unroofed vesicle) to the lesion by using minimal, moderate, and moderate pressure. The glass slides and electron microscope grids should be allowed to air dry for about 10 min and then placed in a slide holder or a grid carrier box for transport to a laboratory.

Alternative lesion sampling processes, including storing material on appropriate filter paper types, are being evaluated. Sample storage in transport medium (as done, for example, with herpesviruses) is discouraged, since specimen dilution decreases the sensitivity of direct evaluation by electron microscopy. Specific recommendations for electron microscopy sampling and specimen processing can be found on the Internet (http://www.bt.cdc.gov/agent/smallpox/lab-testing/pdf/em-rash-protocol.pdf). Biopsy of lesions may also provide material suitable for direct viral evaluation or immunohistochemistry. A 3- to 4-mm-punch biopsy specimen can be made, and the specimen can be bisected, with half placed in formalin for immunohistochemical testing and the remainder placed in a specimen collection container. Blood and throat swabs obtained from suspected smallpox patients during the prodromal febrile phase and early in the rash phase were also a potential source of virus during the smallpox era (66).

Patient serum can also be obtained for serology to substantiate viral infection diagnoses or to infer a retrospective diagnosis. Paired acute- and convalescent-phase serum specimens can be of great value for diagnosis of infection. In this case, serum should be obtained as early as possible in the disease course and then 3 to 4 weeks later.

Most virus-containing specimens should be stored frozen at –20°C or on dry ice until samples reach their transport destination. Storage at standard refrigerator temperatures is acceptable for less than 7 days. Electron microscopy grids and formalin-fixed tissues should be kept at room temperature.

DIRECT DETECTION

Microscopy

Electron microscopy is a first-line method for laboratory diagnosis of poxvirus infections. Negative-stain electron microscopy of lesion samples was widely used during the

TABLE 2 Diagnostic tests for poxviruses[a]

Virus(es)	HP	EM	HA	NAT	Isolation	Serology
Orthopoxviruses	X	X	X	X	X[b]	X
Parapoxviruses	X	X		X	X[c]	X
Yatapoxviruses	X	X			X[c]	X
MCV	X	X		X		

[a] Abbreviations: HP, histopathology; EM, electron microscopy; HA, hemagglutination; NAT, nucleic acid test. X's indicate the utility of the tests for the specified viruses.
[b] Pock formation on CAM and tissue culture isolation are useful.
[c] Isolation in tissue culture only; viruses do not produce pocks on CAM.

smallpox eradication era. Because the clinical diagnosis of poxvirus infection is now infrequent, electron microscopy observations may provide one of the first clues into the cause of an unknown rash illness. Although electron microscopy can distinguish between orthopoxvirus and parapoxvirus morphologies, it cannot differentiate between species; selected serologic, biologic, and DNA-based assays must be used.

Orthopoxviruses have a distinctive brick-shaped, knobby morphology when examined with sodium phosphotungstate or other heavy-metal negative stains. Parapoxviruses appear ovoid with a spiraling criss-cross surface. The relative sensitivity of the negative-stain method was about 95% for detecting variola virus in smallpox lesions and about 75% for detecting vaccinia virus (66). Recent reports suggest that the sensitivity of such methods can be improved by directly pressing a prepared grid into the base of an unroofed skin lesion, as described above (33). Descriptions of methods for negative-stain evaluation and pictures of negative-stained particles are available on the Internet (http://www.bt.cdc.gov/agent/smallpox/lab-testing/pdf/em-rash-protocol.pdf) and elsewhere (22, 50, 66).

Poxviruses produce inclusions that have characteristic appearances when stained with May-Grunwald Giemsa and hematoxylin-eosin. Perinuclear basophilic or B-type cytoplasmic inclusions (virus factories or viroplasm) represent sites of virus replication. Certain species (e.g., the orthopoxvirus cowpox virus) produce acidophilic inclusions or A-type inclusions. Depending on the strain, A-type inclusions may (V^+) or may not (V^-) contain virions.

Antigen Detection

Orthopoxvirus is the only genus whose members produce a hemagglutinin (HA) antigen, which is detectable by hemadsorption or hemagglutination assays using chicken erythrocytes that are pretested to be suitable for such tests. Inhibition of hemagglutination and hemadsorption by patient serum is an indicator of orthopoxvirus infection (24, 26, 64–67); such antibodies may persist for 1 to 5 years after infection.

Nucleic Acid Detection

PCR analysis is used by the WHOCC at the CDC to detect orthopoxvirus DNA in samples. Single-gene PCR, followed by restriction fragment length polymorphism analysis or sequence analysis of the amplicon, permits species identification of orthopoxviruses. A number of different targets are used, including the HA gene which is unique for the genus *Orthopoxvirus*, the gene for the B cytokine response modifier (CrmB, one of several different tumor necrosis factor receptor homologs produced by orthopoxviruses), and the gene for the A-type inclusion body protein. In these assays, DNA that is present in any orthopoxvirus is amplified. The amplicon is digested with the appropriate restriction endonuclease, and digested fragments are electrophoresed. Fragment sizes are compared to reference restriction fragment length polymorphism profiles to discriminate species.

Perhaps the best-described locus for PCR detection and differentiation of orthopoxviruses is the HA DNA segment (77). This PCR method is based on the use of previously described primers EACP1 and EACP2 (for Old World orthopoxviruses) or NACP1 and NACP2 (for New World orthopoxviruses) with an ~900- or ~600-bp HA DNA amplicon to establish if the isolate is an orthopoxvirus. Subsequently, TaqI or RsaI digestion fragment analysis enables species identification.

Orthopoxviruses contain either a full-length or a truncated gene for the CrmB tumor necrosis factor receptor homolog. After the region is amplified with consensus primers (51), the amplicon size can be used to differentiate vaccinia virus (which contains a deletion in CrmB) from the other orthopoxviruses that infect humans. Primers VL2N and VL33, described by Loparev et al. (51), can be used for the amplification. Vaccinia viruses, including the subspecies buffalopox virus, show an ~1,200-bp amplicon, and monkeypox, variola, and cowpox viruses show an ~1300-bp amplicon. Restriction endonuclease digestion of the amplicon with NlaIII can be used to differentiate monkeypox, cowpox, and variola viruses; however, some isolates show more or less heterogeneous profiles by NlaIII digestion. Depending on the isolate, four to six fragments may be noted, but the sizes of the fragments can clearly differentiate species and may be adequately sensitive to distinguish strains and variants.

Amplification of the gene region for the A-type inclusion body protein is another useful technique to differentiate orthopoxviruses. Meyer et al. (56, 57) describe primers ATI-low-1 and ATI-up-1 to amplify 1,500- to 1,700-bp amplicons from the DNA of vaccinia, cowpox, or monkeypox viruses. In this method, amplicon identity is verified by using BglII or XbaI restriction fragment profiles.

Other poxvirus PCR diagnostic approaches include standard PCR methods to identify the parapoxvirus Orf virus (91). A random amplified polymorphic DNA fragment length polymorphism approach to orthopoxvirus species and strain discrimination is reported by Stemmler et al. (89). More recently described (45) is a method to discern PCR-amplified, fluorescence-labeled DNA fragments by hybridization to orthopoxvirus species-specific DNA immobilized on a microchip.

The high sensitivity of and rapid results from real-time PCR assays make them attractive for laboratory clinical diagnostic use (29). In the United States, many national reference laboratories, as well as the Laboratory Response Network laboratories, use this format of nucleic acid testing for rapid response to diagnose suspected orthopoxvirus infections and/or to rule out smallpox infections. The use of a probe or probes in this type of assay allows for the specificity; however, the extreme sensitivity of the assays can lead to false-positive contaminants from specimen carryover. Many of these methods for detection of orthopoxviruses (1, 29, 70, 84) and yatapoxviruses (98) have been described previously. Others are available at specific reference centers, including the CDC Poxvirus Program/WHOCC for Smallpox and Other Poxvirus Infections.

ISOLATION

Orthopoxviruses can be grown in a variety of established cell culture lines, including Vero, BS-C-1, CV-1, LLCMK-2 monkey kidney cells, human embryonic lung fibroblast cells, HeLa cells, chicken embryo fibroblast cells, and MRC-5 human diploid fibroblast cells, a line approved by the Food and Drug Administration for vaccine production (25). Methods for growing and discriminating the morphologies of orthopoxviruses on the chorioallantoic membranes (CAMs) of 12-day-old chicken embryos have been described previously (61, 66, 96). Orthopoxviruses are the only human poxviruses that produce pocks (95, 96) on the CAMs of fertile chicken eggs; pock morphology is useful for biologic species and variant differentiation. Parapoxviruses, yatapoxviruses, and MCV do not form pocks on the CAM, although avipoxviruses, leporipoxviruses, and capripoxviruses do so.

SEROLOGIC TESTS

Orthopoxviruses

When virus-containing clinical specimens are not available, antibody detection may be the only way to define the etiology of the disease. Serologic methods currently used to detect antibodies against human orthopoxviruses include enzyme-linked immunosorbent assays (ELISAs), the virus neutralization test (NT), Western blotting, and hemagglutination inhibition. Various protocols for poxvirus serologic testing used at the CDC are detailed elsewhere (12, 13, 24, 25, 31, 64–67, 78).

The recent description of an orthopoxvirus immunoglobulin M (IgM) assay offers great promise to enhance investigations of orthopoxvirus infection outbreaks, often semiretrospective in nature (41). This technique offers the advantage that it measures recent infection or illness with an orthopoxvirus. It is useful for evaluating disease incidence in epidemiologic surveillance studies. For example, during the 2003 U.S. monkeypox outbreak, the IgM capture assay demonstrated ~95% sensitivity and ~95% specificity for epidemiologically linked and laboratory test-confirmed patients when sera were obtained between days 4 and 56 post-rash onset. A low-grade response, termed "equivocal," awaits further research. This assay was also used to detect anti-orthopoxvirus IgM in the cerebrospinal fluid of an encephalitic patient with monkeypox (82). A recently reported peptide-based ELISA appears to show promise for specific identification of monkeypox virus-specific antibodies, perhaps even in the background of previous vaccination with vaccinia (34). This work awaits more extensive analysis.

Poxvirus genera can usually be identified and differentiated by NT with hyperimmune reference sera (12, 24, 26, 64–67). However, it can be difficult to identify the infecting species since poxviruses are antigenically closely related within a given genus. In the current state of bioterrorism response awareness, tests to evaluate residual protection from previous vaccination are being requested. It is important to note that there is no one routine immunologic test that defines a person's degree of protection against a poxvirus infection. Protection is genetically defined and requires a concert of cell-mediated and humoral immune responses. Recent work (21) suggests that humoral responses may be the critical component of recovery from and survival of a systemic orthopoxvirus infection. The presence of neutralizing antibodies generally indicates recovery from an infection, not always protracted protection from future infection. Neutralizing antibodies against variola, monkeypox, cowpox, or vaccinia viruses may be detectable as early as 6 days after infection or vaccination; the efficacy of the NT using sera of infected animals or humans may range from 50 to 95%. Neutralizing antibodies have been detected as long as 20 years after vaccinia vaccination or natural infection with other human orthopoxviruses.

In the NT, a fourfold rise in antibody titer between serum samples drawn during the acute and convalescent phases is usually considered diagnostic of poxvirus infection. When only one serum specimen is available from one phase of infection, confirmation of a clinical diagnosis may be difficult to impossible. Because orthopoxviruses are closely related, serum cross-absorption tests, such as those performed in immunofluorescent-antibody or immunodiffusion methods, have been used with variable success with patient and animal sera. Orthopoxvirus antigen cross-absorption assays have been performed using hyperimmune animal sera and have been utilized in serosurveys for animal or human monkeypox infection (40, 65, 67). False-positive results should be ruled out by using appropriate control sets of sera of known provenance.

The Western blot assay is performed essentially as described by Towbin et al. (92) and uses various antigens, including purified virus and sometimes the concentrate of culture fluid from infected cells maintained under medium that contains 1% or no serum supplement. Few laboratories are using this method, as reliable standardization has not been achieved.

Milker's Nodule, Orf, Tanapox, and Contagiosum Viruses

Serologic methods used at the CDC to help confirm parapoxvirus infections (milker's nodule and Orf) have included ELISAs (13) and Western blot assays that use various antigen preparations. Serologic testing for TPV infection by standard ELISA (13) with antigens obtained from concentrates of infected cell culture, by an indirect immunofluorescent-antibody test, and by NT has been moderately effective. Optimally, sera should be collected at the time of actual disease and 3 to 5 weeks or later after the presumed onset date. Because MCV cannot be readily grown in culture, no routine serologic test is available. Molluscum contagiosum is readily diagnosed clinically, often with the aid of electron microscopy and histopathologic testing performed by a local diagnostic facility.

Hepatitis B and D Viruses

REBECCA T. HORVAT AND GARY E. TEGTMEIER

110

Viral hepatitis is an ancient disease that was first described in the fifth century B.C. Since that time, epidemics of jaundice have been described, with the earliest recognized blood-borne outbreak of hepatitis occurring in Bremen, Germany, in 1883 among shipyard workers who received the smallpox vaccine. In 1947, MacCallum and Bauer (79) introduced the terms hepatitis A for infectious hepatitis and hepatitis B for "serum" hepatitis. It was recognized that the epidemiologies of the two diseases differed. The terms hepatitis A and hepatitis B were then adopted by the World Health Organization (WHO) in 1973 to distinguish the two distinct infectious agents of hepatitis. After the discovery of the Australia antigen in serum by Blumberg and colleagues (13–15) in 1965, the hepatitis B virus (HBV) was identified and characterized. The Australia antigen is now designated the hepatitis B surface antigen (HBsAg) and is associated with both acute and chronic hepatitis B infection. These and other discoveries in the late 20th century have led to explosive growth of information about HBV. Specific and sensitive serologic tests are now available for HBV which have led to a deeper understanding of the natural history of hepatitis B. This information also has aided the study of the pathogenesis and epidemiology of HBV, which eventually has led to the development of safe and effective vaccines for the prevention of HBV infection. In addition, this body of scientific work has fostered the development of antiviral therapies for treatment of patients with chronic HBV infection. It also became clear that not all posttransfusion hepatitis is associated with HBV infection. An additional agent(s) (hepatitis C virus) is responsible for nearly all of the remaining cases of posttransfusion hepatitis.

In 1977, a new viral antigen was recognized in hepatocytes from patients with chronic HBV infections (101). This new antigen was detected in the nuclei of hepatocytes but was antigenically distinct from HBsAg; however, it was always associated with HBV infection. Patients with this antigen responded to it with specific antibodies (102). Since it was an antigenically distinct protein, it was given the name delta antigen. In the 1980s, this protein was found to be associated with a novel, viruslike particle that was unable to replicate autonomously and formed viral particles only in the presence of HBV (116). This viruslike particle was named hepatitis deltavirus (HDV). It was then found that HDV "borrowed" HBsAg to form intact virions. Thus, without the presence of HBV, HDV cannot be packaged into viral particles. The incidence of HBV-HDV coinfection is high in certain parts of the Middle East, the Mediterranean, Africa, South America, and some South Pacific islands (64). Because HDV infection occurs only in people infected with HBV, measures taken to prevent HBV infection, such as immunization and avoidance of direct exposure to contaminated blood or needles, are also effective for the prevention of HDV infection.

HEPATITIS B VIRUS

Taxonomy

HBV, a partially double-stranded, enveloped DNA virus, is the prototype agent of the *Hepadnaviridae*. It is a member of group VII, which consists of DNA reverse-transcribing viruses. Viruses in the *Hepadnaviridae* have been isolated from woodchucks, ground squirrels, ducks, and herons (12, 126, 127). All viruses in this family are enveloped with circular, partially duplex DNA. They all have virion-associated polymerases with reverse transcriptase activities. All agents in the *Hepadnaviridae* have narrow host ranges, and to date, the mammalian hepadnaviruses have been difficult to grow in cell cultures (49, 93, 126).

HBV is an orthohepadnavirus along with the hepadnaviruses found in the ground squirrel and the woodchuck (127). The duck and heron HPVs are avihepadnaviruses (127).

Description of the Agent

Ultrastructural examination of the sera of HBV-infected patients reveals three distinct morphologic structures in various proportions (Fig. 1). The most numerous forms (by a factor of 10^4 to 10^6) are the small, pleomorphic, spherical, noninfectious particles measuring 17 to 25 nm in diameter. Particle counts of 10^{13}/ml have been detected in some sera. Tubular or filamentous forms of various lengths are also observed. A third particle, the HBV virion, has a lipid-containing outer envelope consisting of HBsAg that surrounds a nucleocapsid or core. The inner core of HBV contains a single molecule of partially double-stranded DNA, hepatitis B core antigen (HBcAg), hepatitis B e antigen (HBeAg), and DNA-dependent RNA polymerase (35). The sera of infected patients may contain as many as 10^{10} infectious virions per ml. The 17- to 25-nm-diameter spherical particles are composed entirely of HBsAg. The low buoyant densities of these

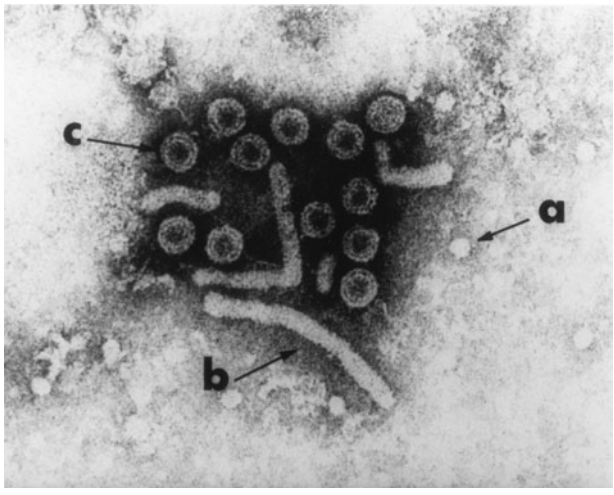

FIGURE 1 Electron micrograph of serum showing the presence of three distinct morphologic entities: 17- to 25-nm-diameter pleomorphic, spherical particles (a); tubular or filamentous forms with diameters similar to those of the small particles (b); and 42- to 47-nm-diameter double-shelled spherical particles representing the hepatitis B virion (Dane particle) (c). Magnification, ×85,008.

particles reflect the presence of lipids, which are presumably of cell membrane origin (47, 48). The tubular forms also consist of HBsAg.

HBV has a partially double-stranded, circular DNA genome that contains between 3,020 and 3,320 nucleotides. Neither of the circular strands is covalently closed. The genome is uniquely organized in that it contains overlapping genes. The genome has four open reading frames in the complete or minus-strand DNA. The genes encode structural proteins such as HBsAg and HBcAg, replicative proteins (polymerase and X protein), and regulatory elements. The genome is compact, and most of the genomic sequences are essential for productive infection. This compact organization restricts the development of mutations because changes are likely to result in a misreading of the code of an essential protein. However, recent studies have shown that there are genetic differences within the HBV genomes, creating at least eight different genotypes, some with subgenotypes (45, 91, 105).

After binding to hepatocytes, the HBV virion is taken up and uncoated. The partially double-stranded, relaxed circular DNA genome is converted into a covalently closed, circular DNA (cccDNA) template that takes a supercoiled form (Fig. 2). This cccDNA form serves as a template for transcription of the pregenomic RNA (pgRNA) and mRNA (72, 107). Within 24 h of infection, cccDNA can be detected in the liver (107). Interestingly, cccDNA accumulates only in the nucleus and is necessary for the successful initiation of

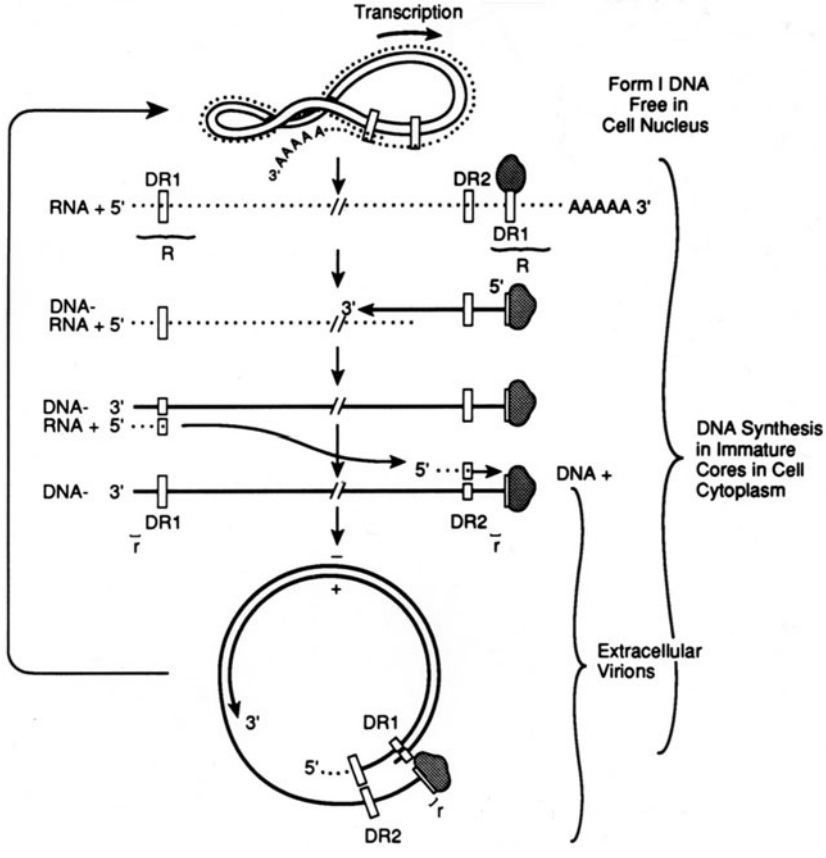

FIGURE 2 Scheme of HBV replication. Note the generation of the positive (+) and negative (−) DNA strands from an RNA intermediate. DR1, direct repeat sequence 1; DR2, direct repeat sequence 2; R, redundancy; r, 5′ and 3′ redundancy sequence. (Reprinted from reference 103 with permission of the publisher.)

HBV replication. The pgRNA that is transcribed from the cccDNA in the nucleus locates to the cytoplasm of the infected cell. In the cytoplasm, pgRNA serves as the template for the reverse transcription enzyme (polymerase) and for the HBcAg. The polymerase then converts the pgRNA into a new circular DNA molecule. Early in infection, some newly synthesized genomes from the cytoplasm circulate back to the nucleus to build up and maintain the pool of cccDNA.

Every nucleotide of the HBV genome is in a coding region, and more than half of the genome is translated in more than one open reading frame. Four viral mRNA transcripts are involved in the translation of HBV proteins. These viral mRNAs are transcribed from various promoter regions on the cccDNA template (Fig. 2). The longest is 3.5 kb and acts as the template for genome replication (pgRNA), as well as translates precore (HBeAg), HBcAg, and polymerase proteins. The 2.4-kb transcript encodes the pre-S1 protein (39 kDa), pre-S2 protein (33 kDa), and S protein (24 kDa; also known as HBsAg). A third transcript (2.1 kb) encodes the pre-S2 protein and the S protein. The final mRNA (0.7 kb) codes for the X protein that is responsible for transactivating transcription. Mature virions are produced by reverse transcription of RNA into a circular DNA molecule. The long RNA transcript (3.5 kb) and the polymerase protein are packaged into mature core particles, and the reverse transcriptase enzyme (polymerase) synthesizes a new viral DNA genome. These particles are then packed into the surface proteins in the endoplasmic reticulum and exported from the cell. The HBV surface proteins such as HBsAg are also released from infected cells as spherical and filamentous particles devoid of HBV genome and core proteins. HBV DNA replication through an intermediate reverse transcription step is unique for human DNA viruses. However, this mechanism is also found in nonprimate hepadnaviruses and the cauliflower mosaic virus.

HBcAg and HBeAg differ antigenically from each other. As noted previously, HBsAg is produced in copious amounts and circulates in the blood of infected individuals as spherical and tubular particles. HBsAg can be detected in serum 30 to 60 days after initial exposure to HBV and may persist for variable periods (39, 81). The HBcAg is a polypeptide with a molecular size of 22,000 Da. The HBeAg is approximately 16,000 Da and is derived by the proteolytic cleavage of the larger, 24,000-Da precore/core protein. Host cellular proteases cleave the protein during passage through the Golgi complex and subsequently secrete the HBeAg into the bloodstream. HBeAg appears to lack the viral DNA-binding domain. HBeAg either circulates freely in the blood as a soluble protein or is bound to albumin, α-1-antitrypsin, or immunoglobulin. It is a reliable marker for the presence of intact virions and thus for infectivity. A mutation at the end of the precore region leading to a translational stop codon yields a variant that is unable to produce HBeAg: such precore mutants may contribute to the pathogenesis of chronic hepatitis B and fulminant hepatitis (52, 105). Other HBV gene mutations have been observed in the core, core promoter, envelope, and polymerase regions. The envelope protein variants may become relevant if they are able to escape vaccine-induced antibodies to HBsAg (anti-HBs) or lead to failure of hepatitis B immune globulin (HBIG) therapy after transplantation. Likewise, the mutations in the polymerase regions may lead to resistance to antiviral agents.

HBV infection in humans is diagnosed by detecting anti-HBs, antibodies to HBcAg (anti-HBc), and antibodies to HBeAg (anti-HBe) as well as the various HBV antigens. The terminology used to describe the various antigens and antibodies associated with HBV is given in Table 1.

Epidemiology and Transmission

Hepatitis B infection is a global public health problem and is one of the most common infectious diseases in the world. The WHO estimates that more than one-third of the world population has been infected with HBV, with the majority of HBV carriers living in Asia or Africa (http://www.who.int/gpv-surv/graphics/htmls/hepbprev.htm). The WHO estimates that these infections cause more than 1 million deaths per year. Figure 3 shows the prevalence of HBV infection in different parts of the world. Almost half of the world's population resides in Asia and Africa, where the prevalence of chronic HBV infection is high (>8%). In North America, western parts of South America, Australia, and Western Europe, the prevalence of chronic HBV infection is lower (<2%). Thus, much of the burden of HBV infection is carried by the developing world.

The only natural host for HBV is humans. The major modes of HBV transmission are vertical transmission (mother to child perinatally), sexual activity (both heterosexual and male homosexual), injection drug use, and other types of physical contact with infected bodily fluids (occupational exposure, exposure to contaminated blood products,

TABLE 1 Nomenclature for hepatitis B virus

Term	Abbreviation(s)	Description
Hepatitis B virus	HBV	42-nm-diam double-shelled particle that consists of a 7-nm-diam outer shell and a 27-nm-diam inner core. Core contains a small, circular, partially double-stranded DNA molecule and DNA polymerase activity. Originally called the Dane particle. This is the prototype for the family *Hepadnaviridae*.
Hepatitis B surface antigen	HBsAg	Complex antigen found on the surface of HBV and on 20-nm-diam particles and tubular forms. Formerly designated Australia (Au) antigen or hepatitis-associated antigen (HAA).
Hepatitis B core antigen	HBcAg	Antigen associated with 27-nm-diam core of HBV.
Hepatitis B e antigen	HBeAg	Protein that results from the proteolytic cleavage of the precore/core protein by cellular proteases and is secreted as soluble protein in serum.
Antibodies to HBsAg, HBcAg, and HBeAg	Anti-HBs, anti-HBc, and anti-HBe, respectively	Specific antibodies produced in response to their respective antigens.

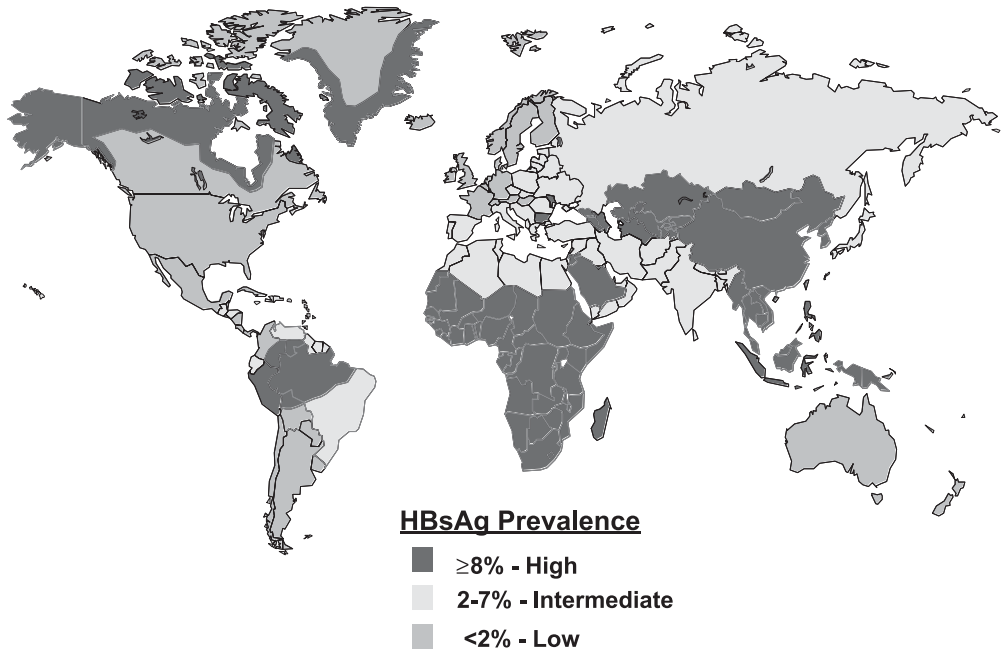

FIGURE 3 Worldwide prevalence of HBsAg-positive individuals. Data are from the CDC, 2005. (CDC website: http://www.cdc.gov/ncidod/diseases/hepatitis/slideset/hep_b/9.)

and person-to-person contact). HBV is not transmitted by aerosols, feces, or contaminated food, water, or insects. HBV can survive in the environment for prolonged periods of time outside the body. Individuals who are HBeAg positive have large numbers of virions in their blood ($>10^7$/ml) and can contaminate the environment from open sores or cuts (17, 99). Thus, transmission can occur through close person-to-person contact, most likely through open sores (84, 99). This type of transmission may occur more often in children in areas where the virus is hyperendemic and is the basis for using standard precautions in the health care setting (7, 18).

The HBV carrier rate is related to the age at which infection occurs. In some Asian and African countries, the HBV carrier rate is as high as 20% because most of the infections occur at birth or during early childhood, when the risk of chronic infection is greatest. In the United States, more than 1.25 million people are thought to be chronically infected with HBV (http://www.cdc.gov/ncidod/diseases/hepatitis/b/fact.htm). The number of new infections per year in the United States has declined from an estimated 260,000 in the 1980s to 73,000 in 2003. The greatest decline has occurred in children and adolescents and seems to be due to the increased use of hepatitis B vaccination (26, 70, 71, 85). The highest rate of disease occurs in 20- to 49-year-olds.

In the United States the lifetime risk of HBV infection is approximately 5%, with most infections occurring among well-defined risk groups. The high-risk groups historically include intravenous drug users, persons who have sexual relations with multiple partners (heterosexuals and homosexual males), hemophiliacs, hemodialysis patients and staff, inmates of correctional facilities, individuals with occupational and household exposure to infected body fluids, and institutionalized patients with developmental disabilities (80, 81). In the past, approximately one-third of the chronic infections in the United States were acquired through perinatal exposure (23). In 1994, the Centers for Disease Control and Prevention (CDC) estimated that 22,000 infants were born in the United States each year to chronically infected mothers (23); however, by 2003 the CDC showed that 92.4% of all children aged 19 to 35 months had received three or more doses of the hepatitis B vaccine (27). This reported vaccination rate should continue to reduce the number of hepatitis B infections. In 1995, the CDC expanded the hepatitis B vaccination program to include all adolescents aged 11 to 12 years (25). In 1999, the CDC included all children of less than 18 years of age who had not been vaccinated previously (25). Over the next 10 years, this comprehensive vaccination program should lead to a dramatic reduction in the number of individuals with hepatitis B infection (26, 27, 125).

Based on serologic data, the WHO has estimated that more than 2 billion people have been infected with HBV (56). Worldwide, 350 million people are estimated to be chronically infected with HBV and therefore at risk for cirrhosis and liver cancer. Annual deaths worldwide related to HBV infection are estimated to range from 500,000 to 700,000. Thus, the consequences of acute and chronic HBV infection are a major public health problem. Reports of HBV infections to public health authorities are mandatory in most countries, but unfortunately underreporting has seriously affected the efforts to raise awareness of the massive global burden of HBV infections (http://www.who.int/health-topics/hepatitis.htm). Public health education, infection control policies in hospitals and clinics, and, most important, the availability of an effective vaccine have already led to a dramatically expanded use of the hepatitis B vaccine.

Clinical Significance

Hepatitis B is a viral infection of the liver that can have variable clinical features. Symptoms may range from mild and transient to severe and prolonged. Patients may recover completely from infection, be overwhelmed by fulminant hepatitis that leads to mortality (<1.5% of hospitalized patients), or develop a chronic infection that may evolve into cirrhosis.

HBV infection can be divided into four stages that vary in duration (33, 67). The first stage (stage I) occurs during active viral replication when no immune response is detectable. The second stage (stage II) occurs when an immunologic response to the virus leads to inflammation and hepatic tissue damage, often detected as symptomatic hepatitis. At times patients with an inflammatory infection can be asymptomatic. During the third stage (stage III), the virus-infected cells are cleared and the HBeAg is no longer detected. However, HBsAg will still be present. In the fourth stage (stage IV), full immunity to HBV has developed and HBsAg has been cleared. Infected patients who do not progress beyond stage I or II become chronic HBV carriers and thus are at higher risk for the development of cirrhosis and/or hepatocellular carcinoma (HCC) (77).

Acute Hepatitis B

The incubation period for acute hepatitis B ranges from 6 weeks to 6 months. This period corresponds to stage I of the disease. The incubation period may be shortened when a patient is exposed to a large viral inoculum or infected by the percutaneous route. The administration of high-titer antibody specific for HBsAg (hepatitis B immune globulin [HBIG]) shortly after exposure prolongs the incubation period and may prevent infection. The clinical manifestations of acute HBV infection are highly age dependent. Nearly all infected newborns are asymptomatic. In children 1 to 5 years of age, only 5 to 15% have clinical manifestations. Approximately 10 to 30% of older children and adults become symptomatic (70, 74).

The clinical symptoms of acute HBV infection are flulike. Some patients experience physical signs such as jaundice, dark urine, clay-colored stools, and hepatomegaly (103). The prodromal, preicteric phase of hepatitis B tends to be more insidious and prolonged than that of hepatitis A, lasting from 1 to 2 weeks in most patients. This phase is stage II and is characterized by malaise, low-grade fever (<39.5°C), fatigue, myalgia, anorexia, nausea, and vomiting. Some patients experience weight loss and right-upper-quadrant pain associated with hepatomegaly.

The icteric phase of acute viral hepatitis is often accompanied by the appearance of dark urine followed by the development of clinical jaundice. With the emergence of jaundice, symptoms improve and fever usually subsides. The icteric phase lasts, on average, about 1 month. In 10 to 20% of HBV-infected patients, extrahepatic manifestations of the disease develop, most likely mediated by virus-specific immune complex injury. They include a serum sickness-like syndrome, acute necrotizing vasculitis (polyarteritis nodosa), and membranous glomerulonephritis.

The clinical diagnosis of acute hepatitis B is based on the results of liver enzyme testing and the detection of viral antigens, antibodies, and nucleic acid. The total bilirubin concentration during acute hepatitis B is usually <10 mg/dl (normal range, 0.20 to 1.50 mg/dl) but may occasionally exceed 20 mg/dl. Prolongation of the prothrombin time may reflect early and potentially serious derangements of liver function which may signify the development of fulminant hepatic failure. Fulminant hepatic failure occurs in <1% of patients who develop symptomatic, acute HBV infection. Evidence suggests that these patients have an overexuberant immune response to the HBV infection, resulting in massive necrosis of infected hepatocytes. The immune response to HBcAg (immunoglobulin M [IgM] anti-HBc) is almost always positive; however, HBsAg and HBeAg are not usually detectable. Mortality associated with fulminant hepatic failure is high without liver transplantation. After liver transplantation, HBV reinfection of the new liver is universal, resulting in significant HBV-induced liver injury in a number of patients (94). HBIG or antiviral therapy appears to modulate these outcomes.

Pathologic features of acute hepatitis B include both degenerative and regenerative parenchymal changes that lead to lobular disarray. HLA class I- and II-restricted cytotoxic T lymphocytes (CTLs) appear to play a major role in facilitating viral clearance during acute HBV infection. On the other hand, they are also the agents of hepatocellular injury by recognizing HBV nucleocapsid epitopes expressed on the surfaces of infected hepatocytes (10, 29, 30).

Chronic Hepatitis

Patients who remain HBsAg positive for at least 6 months are considered to have chronic HBV infection (70, 77). These patients are likely to remain positive indefinitely and thus remain at stage II of the infection. The consensus definition for chronic hepatitis B is found in the practice guidelines published by the American Association for the Study of Liver Diseases (77). Symptoms of chronic hepatitis B are generally vague and nonspecific. Patients may have some elevation in serum aminotransferase levels. In addition, HBV virions, DNA polymerase activity, and HBV DNA can be detected in blood, indicating active viral replication. A liver biopsy shows active inflammation with hepatocellular necrosis and may show fibrosis. Symptoms generally become more pronounced when cirrhosis develops. HCC develops in 12 to 55% of patients with chronic HBV infection and cirrhosis (43).

Studies from Japan have shown that 29% of HBsAg-positive patients will spontaneously revert to being HBsAg negative after approximately 12 years (59). This reversion was seen more frequently in patients 40 years old or older. The HBV DNA was detected in the sera of only 6% of the patients who reverted to an HBsAg-negative status, indicating a reduction in viral replication. The factors that determine resolution or chronicity remain largely unknown. In general, those infected early in life (<3 years) are more likely to become chronic carriers than older individuals. Individuals infected in the perinatal period have high serum HBV DNA levels but normal alanine aminotransferase (ALT) levels. HBeAg persists longer in these younger persons (74). Interestingly, the majority of these individuals (~90%) have a chronic infection without symptoms. In contrast, the potential for chronicity in immunocompetent older children and adults ranges from 6 to 10%. These patients usually have symptoms during the acute infection.

Histologic examination of liver tissue is useful to differentiate acute viral hepatitis from chronic hepatitis and cirrhosis. Chronic hepatitis B is associated with HCC, especially in males living in Asia and Africa. The incidence of death from liver cancer and cirrhosis increases as a direct function of age; however, cirrhosis is not always a requirement for the development of HCC due to HBV infection (43).

Pathogenesis

Both acute and chronic HBV infections are associated with hepatocellular necrosis as well as inflammatory and regenerative responses. Some evidence suggests that HBV may not be directly cytopathic to hepatocytes and that the host's cellular immune response to infected cells correlates with the severity of clinical disease (30). In most patients with acute HBV infection, recovery is dependent on a B-cell response that leads to production of antibodies to pre-S and S antigens. These patients also have a vigorous CTL response that is reactive to multiple epitopes in the HBV envelope, nucleocapsid, and

polymerase proteins (89). The HBV-related liver damage is attributable to this CTL response directed against HBV-infected hepatocytes. Patients who develop fulminant hepatitis due to HBV infection frequently have no evidence of HBV replication. The disease course is thought to be due to the rapid and aggressive immune clearance of HBV-infected hepatocytes (74). Patients with chronic HBV infection usually are deficient in CTLs directed against HBV proteins (30). Individuals with perinatally acquired HBV infection appear to have immune tolerance to HBV antigens, which may account for the high rate of chronic infection in the group. They do not seem to have severe liver disease in spite of the presence of high levels of virus (73, 77).

There is a strong etiologic association between chronic HBV infection and the development of HCC (43, 75). Currently, the mechanism by which HBV is oncogenic is still under investigation. Multiple factors are likely to contribute to the development of HCC. The majority of patients (80 to 90%) with HBV infection and HCC have integrated HBV DNA in hepatocytes. This integrated viral DNA may activate cellular proto-oncogenes or suppress growth regulation genes (43). Some of the gene products of HBV, such as the X protein and the truncated pre-S/S protein, seem to be potent transactivators of host cellular genes (19, 78). Recent studies have shown that the HBV DNA from HCC tissue has a high rate of mutations in the X gene (44). These mutations were noted to induce functional alteration that affects the transactivating ability of the X protein. Future studies are needed to determine whether diagnostic tests can be used to detect these mutations and predict the occurrence of HCC. In addition to these expressed HBV products, other factors are associated with HCC, such as smoking, consumption of alcohol, other hepatotropic viruses (e.g., hepatitis C virus), and mycotoxins (aflatoxin) (43). Thus, it seems that, like that of other human cancers, the development of HCC is likely to be multifactorial, involving several mutagenic events and HBV infection.

Collection, Transport, and Storage of Specimens

Except for HBV DNA, the stability of serologic markers that develop following HBV infection eliminates the need for extraordinary collection and storage procedures. Serum or plasma should be separated from blood samples within 24 h and stored at 2 to 8°C if testing is to take place within 5 days. Should longer delays be anticipated, the processed specimens must be frozen. Because heparinized or severely hemolyzed blood may occasionally cause false-positive enzyme immunoassay (EIA) responses, such samples should be avoided. Although HBV serologic markers are stable for years at −70°C, repetitive freezing and thawing may lead to substantial losses in concentration.

For nucleic acid analyses, specimens should be processed within 6 h and either tested within 24 h or stored at −70°C or lower. Plasma recovered from blood collected in tubes containing EDTA (lavender-top tubes) or in tubes containing anticoagulant citrate dextrose (yellow-top tubes) is preferred for genome amplification techniques (e.g., PCR). Conversely, heparinized plasma is considered unacceptable, because heparin interferes with some enzymes involved in amplification of the nucleic acid (6, 55), causing false-negative results. Heparin also inhibits reverse transcription (119). The above-described recommendations are general, conservative guidelines that may not conform to those specified by reference laboratories offering HBV testing. Manufacturers' recommendations for specimen type and handling should be followed for all serologic and molecular testing.

Laboratory personnel should regard all specimens collected from hepatitis B patients as potentially dangerous. As shown in several studies, the HBV is stable for prolonged periods outside the human host. Additionally, patients who are HBeAg positive will have a high viral load (10^7 to 10^9) that can contaminate the laboratory environment (7, 16, 17). Frequent disinfection of laboratory benches is important to prevent this type of exposure and to prevent cross-contamination of samples and/or equipment. The Occupational Safety and Health Administration standards for occupational exposure to blood-borne pathogens (6a) are designed to protect employees exposed to blood and other potentially infectious materials. Compliance is mandatory. At the core of the standard is the concept of standard precautions which mandate that all human blood and certain human body fluids be treated as if they are known to be infectious. The Occupational Safety and Health Administration requires that all employees who have occupational exposure be offered the hepatitis B vaccine at no cost.

Direct Detection

Detection of HBV Antigens

Currently, two HBV antigens are used to diagnose HBV infections. HBsAg can be detected in the sera of both patients with acute and those with chronic infections. It can also be detected for a short period of time after hepatitis B vaccination, which sometimes complicates the interpretation of HBV serology results. The other HBV antigen detectable in serum is HBeAg, which is commonly used as a marker for active viral proliferation and infectivity (70). A recent long-term follow-up study shows that chronic carriers with both HBsAg and HBeAg have a significantly greater risk for HCC than patients who have HBsAg alone or who are negative for HBV antigens (121). The test methodologies are similar in detail and are discussed in "Serological Tests" below.

Nucleic Acid Detection Techniques

HBV DNA is a marker for viral replication. Consequently, its detection plays an important role in the evaluation and therapeutic monitoring of HBV infection (8, 11, 22, 77). HBV DNA assays have been shown to be useful in clinical staging, monitoring of therapy, and detection of relapses after and during therapy. However, HBV DNA testing should be limited to those patients with chronic HBV infection being considered for treatment and to evaluation of response to treatment. Testing for HBV DNA is not recommended in the work-ups of all HBsAg-positive patients (77). A value of $>10^5$ genomic equivalents was established as a diagnostic criterion for chronic hepatitis B (76). The difficulty with this threshold has been the lack of standardization among the various commercial assays used for HBV DNA quantitation. Moreover, some chronic carrier patients will have fluctuating HBV DNA levels. These issues have confounded attempts to determine the impact of HBV DNA levels on the progression of liver disease (77).

Dot Blot Hybridization

The analysis of HBV DNA sequences was first performed using dot blot hybridization with human serum and tissue samples (88, 123). However, this method has been replaced with more sensitive methods such as amplification of HBV DNA. The dot blot hybridization technique is capable of detecting 0.1 to 1.0 pg (28,000 to 280,000 genomic equivalents) of HBV DNA/ml after 5 days of autoradiography, and

TABLE 2 Molecular assays used to detect HBV nucleic acid in human specimens

Assay name	Method	Detection signal	Target HBV gene(s)	Range of detection (genome copies/ml)	Minimum vol (μl) of specimen
Digene Hybrid Capture II	RNA probe binds to target DNA; captured on solid phase by antibody	Chemiluminescence	Specific for HBV *ad* and *ay* subtypes; uses entire genome probe	2×10^5–2×10^9	30
Digene Hybrid Capture Ultra-Sensitive	RNA probe binds to target DNA; captured on solid phase by antibody	Chemiluminescence	Specific for HBV *ad* and *ay* subtypes	5×10^3–6×10^7	1,000 (concentrated by ultracentrifugation)
Quantitative HBV Amplicor	Amplification by PCR with biotin-labeled primers	Absorbance of enzymatic activity	Precore/core region	200–>2×10^5	100 (processed and used as an equivalent of 50)
Versant HBV DNA3.0	Binding of target to solid-phase probe; amplification of probe by binding of branched DNA chains	Chemiluminescence	Capture and extender probes throughout entire HBV genome	2×10^3–1×10^8	50
Home-brew PCR	Amplification of target by using real-time or traditional PCR	Enzymatic activity, chemiluminescence, or fluorescence	Varies	Varies	10–2,000

the amplification methods can detect levels as low as 0.001 pg (200 to 400 genomic equivalents) of HBV DNA/ml within a few hours (77). Thus, due to the length of the procedure, the long turnaround time, and the method's lower sensitivity, dot blot hybridization is not the preferred molecular method to detect HBV DNA in patient specimens. It has been replaced by the quantitative methods listed in Table 2.

Commercial Assays

Several commercial assays have been developed to detect HBV DNA in serum. HBV DNA can be detected by amplifying a target gene or by capturing the target DNA and amplifying the specific probe that detects the target. Currently, several techniques are available to detect and/or quantify HBV DNA in patient specimens (Table 2). As of late 2005, only one HBV DNA assay had been approved by the Food and Drug Administration (FDA), namely, the COBAS Ampliscreen HBV test, a qualitative test approved only for screening of blood donors.

The assays used for the quantitative evaluation of HBV DNA include the target amplification techniques such as PCR (COBAS Amplicor HBV Monitor test [Roche Diagnostics, Indianapolis, Ind.] and HBV SuperQuant [LabCorp, Burlington, N.C.]), liquid-phase hybridization (Digene Hybrid Capture II, distributed by Abbott Laboratories, Abbott Park, Ill.), and a signal amplification, branched-DNA assay (Versant HBV DNA [Bayer HealthCare, Tarrytown, N.Y.]) (34, 53, 54). A number of other assays are being developed such as the LCx HBV DNA quantitative assay (Abbott Laboratories), a transcription-mediated amplification assay for HBV DNA (Bayer HealthCare), molecular beacons (Abbott Laboratories), and a microarray method (2, 54, 60, 124).

The commercial assays currently available for quantitation are for research use only and have not been approved by the FDA for use in diagnosis. However, all of the quantitative assays for HBV DNA have been used to monitor the status of HBV infection before and after antiviral treatment and show promising results (8, 11, 66, 70, 95, 109).

Roche Diagnostics has a target amplification assay with the trade name COBAS Amplicor HBV Monitor test. The sensitivity of this test is claimed to be 60 IU of HBV/ml, and the linear dynamic range is 60 to 38,000 IU of HBV/ml. This assay can reproducibly detect the HBV viral load in patient serum or plasma (Table 2) (34, 62, 108). The assay uses synthetic biotin-labeled oligonucleotide primers that are complementary to a conserved sequence within the precore/core gene. The HBV DNA from patient serum is amplified by using the typical cycles of PCR, and quantitation is accomplished by comparison to standards incorporated into each patient sample. The standard is carried through all steps of the assay. The PCR amplicons are detected colorimetrically after hybridization to specific probes bound to microparticles. The automated COBAS Amplicor analyzer performs all the amplification, hybridization, and detection steps for this assay. The instrument calculates the level of HBV DNA in the patient's sample by comparing it to the quantitative standard of known copy number. Another PCR assay used to quantitate HBV DNA has been developed using the LightCycler (Roche Diagnostics). This assay can quantitate HBV DNA from serum over a wide viral load range (10 to 110,000,000 IU of HBV/ml). Results are rapid since the amplification and detection can be completed simultaneously in as little as 2.5 h (54, 66).

A third assay for quantitating HBV DNA by PCR is the HBV NGI SuperQuant, available only from LabCorp. This PCR assay was originally developed by the National Genetics Institute and has a broad dynamic range from 100 to 5×10^9 genome copies/ml.

Another assay, the Digene Hybrid Capture, uses liquid-phase hybridization for the quantitation of HBV DNA. The first step is the covalent binding of a full-length RNA probe to denatured HBV DNA. Then the RNA-DNA hybrid is captured on a solid phase by using antibody specific for RNA-DNA hybrids. Another anti-RNA-DNA antibody conjugated to alkaline phosphatase is used to generate a chemiluminescent signal. The Digene Hybrid Capture assay

is designed to quantitate HBV DNA concentrations ranging from 1.42×10^5 to 1.7×10^9 copies/ml. The Digene Hybrid Capture II is an ultra-sensitive assay that will quantitate HBV DNA concentrations ranging from 4.7×10^3 to 5.6×10^7 copies/ml. This increased sensitivity is gained by concentrating 1 ml of serum by ultracentrifugation (53, 62, 108).

A commercial assay that uses the signal amplification technique is the Bayer Quantiplex/Versant HBV DNA assay which uses branched-DNA technology (53, 62, 108). In this assay, synthetic oligodeoxyribonucleotides containing unique primary segments designed to hybridize to the minus-sense strand of HBV DNA are covalently attached to a secondary fragment through branch points. These target probes hybridize to HBV DNA and to complementary synthetic fragments bound to a solid phase. On another level, the secondary fragments of the target probe direct the binding of multiple copies of synthetic branched DNA amplifier molecules that contain repeated nucleotide sequences that hybridize with alkaline phosphatase-labeled probes. The detection scheme relies on chemiluminescence emission catalyzed by alkaline phosphatase from a dioxetane substrate. This assay will detect as few as 700,000 HBV DNA copies/ml and up to 5×10^9 copies/ml (53, 62, 108).

Several other assays for the quantitation of HBV DNA are being developed but are not on the market. Abbott Laboratories is developing a ligase chain reaction (LCx HBV DNA quantitative assay)-based assay. A transcription-mediated amplification assay has been developed by Bayer HealthCare. An intriguing new technology that is being applied to the quantitation of HBV DNA is the use of microarray technology (60). This technique may be useful for quantitation of HBV DNA and simultaneous genotyping of the virus and detection of mutations associated with antiviral resistance. However, the routine use of microarray technology will require automation of the assay and thus new instrumentation. Another new test under evaluation will rapidly detect mutations in HBV associated with antiviral resistance. The line probe assay (INNO-LiPA HBV DR) is manufactured by Innogenetics, N.V., in Gent, Belgium. This assay uses numerous specific probes designed to detect known mutations associated with antiviral resistance in the HBV polymerase gene (1, 111). The probes are applied to nitrocellulose membranes and then incubated with biotinylated PCR products generated from the HBV in patients' sera. The HBV PCR product specifically hybridizes to the probes by reverse hybridization. The hybridized product is detected by color development after addition of streptavidin-alkaline phosphatase. This assay provides a relatively rapid analysis of HBV mutations in a mixed population that is developing mutations associated with resistance. The assay is easy to use and permits the detection of known HBV mutations. However, it is unable to detect new mutations associated with antiviral resistance.

A previously mentioned concern with the quantitation of HBV DNA is the poor interassay standardization among the commercial assays. Thus, results from quantification of HBV DNA by different assays can vary even when the same specimen is tested (53, 62, 66). Intra-assay variation also exists such that repeat testing of the same sample may result in differences depending on the methodology. Thus, the WHO has established international standards for HBV quantitation units (104). All commercial assays for HBV DNA should be evaluated by the manufacturers by using the WHO HBV International Standard 97/746 that can be serially diluted in HBV-negative human plasma as part of the validation process. The goal of the WHO is to have all commercial HBV DNA quantitative assay results reported as international units of HBV DNA (104). At the current time, it is important for laboratories to use consistent methodologies for all patient samples. Variations in HBV DNA levels that are less than threefold (i.e., half a log) can be related to the intrinsic variability of the assays and must not be taken into account. In contrast, variations of more than threefold can reliably be considered as reflecting significant changes in HBV load.

Isolation Procedures

Cell Cultures and Animal Models

Despite evidence for the growth of HBV in primary cultures of healthy adult or fetal human hepatocytes (49, 93), serial propagation over a prolonged period has not been accomplished. Thus, culture of HBV as a diagnostic test is not available.

Animal models have played an essential role in studies of viral inactivation, vaccine safety and efficacy, disinfection kinetics, infectivity determinations, and immunopathology and in seroepidemiologic investigations. Most have used chimpanzees and other high-order primates since they are highly susceptible to experimental infection with hepatitis B. The pattern of infection is similar to that observed in humans except that the disease is clinically milder.

Identification

Culture methods for HBV are not used in the clinical laboratory for diagnostic purposes. Thus, identification of HBV is based on serologic and molecular methods.

Typing Systems

HBV has been grouped into eight genotypes designated A through H (61, 91). These genotypes have been associated with clinical and serologic variation in patients infected with HBV (61, 91, 105). The first typing of HBV used serologic analysis to distinguish antigenic heterogeneity of the HBsAg. Nine HBsAg subtypes have been designated: *ayw1, ayw2, ayw3, ayw4, ayr, adw2, adw4q*$^-$, *adrq*$^+$, and *adrq*$^-$ (91). These antigenic differences led to the genetic typing and eventually to the genotyping of HBV isolates into eight distinct groups that differ by more than 8% from one another (91, 92). Subsequent reports have segregated the genotypes into subgroups with distinct geographical origins (5, 63, 91). The strains in genotype A derive primarily from Europe, India, Africa, and North America. There are two subgenotypes within genotype A, designated A1 and A2, which are found primarily in South Africa. Genotype B occurs mainly in China, Japan, and southeast Asia. There are four subgenotypes in this group, designated B1 through B4. The B1 subgenotype is found primarily in Japan, whereas in China the major subgenotype is B2. Subgenotype B3 was identified in Indonesia, and subgenotype B4 is detected primarily in Vietnam. Both genotype A and B isolates have primarily the *adw2* epitope, with a few exceptions such as B4 and some A1 isolates that have the *ayw1* epitope. At this time, the genotype C has four subgenotypes, C1 through C4, which are found primarily in Asia, Polynesia, Australia, and the Pacific Islands. The C1 subgenotype was detected in isolates from Japan, Korea, and China. The C2 subgenotype is found in China and southeast Asia. The C3 subgenotype was isolated from a very specific population of aboriginals from New Zealand to Polynesia. The C4 subgenotype comprises only two strains from aborigines in northeast Australia. Genotype D is widespread across Europe, Asia, and Africa and has been divided into four subgenotypes. This genotype is not restricted to a specific geographic region; rather, it is found

worldwide. Most isolates from the Middle East are of the D1 subgenotype, and HBV isolates from South Africa and Alaska are primarily D3. Genotype E is found only in West Africa and currently has no subgenotypes. All the HBV strains that are genotype E have the *ayw4* antigen. Genotype F strains are divided into two subgenotypes, called F1 and F2. F1 strains are found primarily in Central America, and F2 strains are primarily from South America. Genotypes G and H are not subgenotyped. G strains originate from the United States, Mexico, and Europe, and H strains are from Central America and California.

Genotyping of HBV may become important in disease management. Recent studies have evaluated the epidemiology of HBV genotypes and their association with progression to liver disease and HCC (31, 32, 38, 96, 97, 112, 122). Most of the studies have been conducted in Asian countries because of the large number of patients in these countries with chronic HBV infection. A number of studies have shown that patients infected with HBV genotype C are HBeAg positive for a longer period of time, have more active liver disease, and progress to cirrhosis more rapidly than patients infected with HBV genotype B (31, 32, 38, 96). Additional studies have shown that HBV-infected patients treated with pegylated interferon have a better response if they are infected with genotype A than if they are infected with HBV genotype D (4, 40). However, these preliminary studies on the impact of HBV genotypes and antiviral therapy need to be expanded before definitive conclusions can be made.

Serologic Tests

Detection of HBV Antigens and Antibodies

Serologic assays with high levels of sensitivity, specificity, and reproducibility have been developed to detect HBV antigens and antibodies. Table 3 lists the manufacturers of commercially available assays, the detection method used in each assay, and the amount of specimen needed. Some of the assays have been licensed or cleared by the FDA, and others are available outside the United States. The FDA website (http://www.fda.gov) can be checked to determine which assays are approved for use in the United States. EIAs dominate the diagnostic marketplace because the introduction of EIA kits some 20 years ago obviated the need to handle radioisotopes and provided kits with significantly longer outdates than their radioimmunoassay (RIA) counterparts. These solid-phase assays use either the sandwich principle or competitive binding. Originally, the solid phase was either a polystyrene bead or a microtiter well. More recently, microparticles have begun to replace beads in many assays, and wells of different compositions and sizes are now being used with automated platforms.

Antigen or antibody capture and detection reagents have also evolved over time. Early assays used hyperimmune animal sera or human immune sera which were later replaced by mouse monoclonal antibodies exclusively or by a combination of hyperimmune sera and monoclonal antibodies. Likewise, native, purified antigens have given way to recombinant antigens in some assays. Whereas detector antigens or antibodies labeled with horseradish peroxidase and colorimetric endpoints are still available in some assays, other detection systems such as fluorescence polarization, chemiluminescence, and now electrochemiluminescence are replacing colorimetric detection.

In some assays, testing of reactive samples must be repeated in duplicate in an independent run to confirm the results. If one or both of the duplicate results are reactive, the sample is said to be repeatably reactive. According to the manufacturers' package inserts, samples repeatably reactive for HBsAg should be subjected to specificity testing with the confirmatory kit provided by the manufacturer of the screening test that identified the reactive samples. All confirmatory assays are based on the principle of specific antibody neutralization. All of the assays utilize human anti-HBs and normal human plasma devoid of anti-HBs. Repeatably reactive samples are incubated in duplicate in the presence of human anti-HBs and in duplicate in the presence of the anti-HBs-negative human plasma. If HBsAg is present in the sample, the anti-HBs-containing reagent binds to it, blocks its binding to the anti-HBs capture antibody on the solid phase, and yields a negative result in the confirmatory test. Conversely, since no anti-HBs is present in the normal human serum, HBsAg will bind to the capture antibody on the solid phase and yield a positive test result. By using the detection values given by the sample in the presence and absence of anti-HBs, the amount of signal reduction can be calculated. If the percent reduction reaches a level defined by the test manufacturer, usually >50%, the sample is considered to be positive for HBsAg. In the diagnostic setting where the panel testing is performed, confirmatory testing for HBsAg-reactive, IgM anti-HBc-positive samples is often not done.

The older assays (bead or well based) can detect HBsAg in the range of 0.25 to 0.5 ng/ml. Newer assays are capable of detecting subnanogram amounts of HBsAg with no trade-off in specificity. For most diagnostic applications, the increased sensitivity does not result in a significant increase in detectability because of the copious amounts of HBsAg present in the blood of individuals who are either acutely or chronically infected with HBV. However, some of the newer automated assays have a reduced time for detection and require less technical personnel time.

At present, 10 commercial assays are available for detecting HBsAg (Table 3). All are solid-phase tests based on the sandwich principle. Four are EIAs (AUSZYME monoclonal EIA [Abbott Laboratories], Genetic Systems HBsAg EIA 3.0 [Bio-Rad Laboratories], ETI-MAK-2 PLUS [DiaSorin], and Ortho HBsAg System 3 [Ortho-Clinical Diagnostics]), four are chemiluminescent EIAs (CEIAs; PRISM HBsAg [Abbott Laboratories], ADVIA Centaur HBsAg total assay [Bayer HealthCare], Immulite 2000 HBsAg, [Diagnostic Products Corporation], and VITROS HBsAg assay [Ortho-Clinical Diagnostics]), one is an enzyme-linked fluorescent assay (ELFA; AxSYM HBsAg [Abbott Laboratories]), and one is an electrochemiluminescence EIA (ECL-EIA; Elecsys HBsAg [Roche Diagnostics]). Not all of the assays listed in Table 3 are approved for diagnostic use in the United States, and only four (Abbott AUSZYME, Abbott PRISM HBsAg, Genetic Systems HBsAg EIA 3.0, and Ortho HBsAg System 3) are approved for blood screening.

In all of the assays to detect anti-HBs, purified human HBsAg is bound to a solid phase to capture anti-HBs present in the test specimen. The DiaSorin test uses recombinant HBsAg as the solid-phase antigen with a human-sourced HBsAg as the labeled probe. All of the other anti-HBs tests currently licensed for use in the United States use HBsAg purified from human plasma. Newer tests, soon to be licensed, e.g., Abbott AxSYM and Architect, will use recombinant HBsAg in lieu of human-sourced material. After capture, the human antibody is then detected by using a variety of detection systems listed in Table 3. Both the *ad* and *ay* subtypes of human HBsAg are represented in the detection steps of all the assays.

TABLE 3 U.S. commercial systems for serologic testing of HBV

Marker and manufacturer	Name of assay	Detection method	Minimum vol (μl) of specimen
HBsAg			
Abbott Laboratories	AUSZYME monoclonal EIA	EIA	200
	AxSYM HBsAg	ELFA	100
	PRISM HBsAg	CEIA	400
Bayer HealthCare	ADVIA Centaur HBsAg total assay	CEIA	100
Bio-Rad Laboratories	Genetic Systems HBsAg EIA 3.0	EIA	100
Diagnostic Products Corporation	Immulite 2000 HBsAg	CEIA	100
DiaSorin	ETI-MAK-2 PLUS (HBsAg) ELISA	EIA	100
Ortho-Clinical Diagnostics	VITROS HBsAg assay	CEIA	80
Ortho	HBsAg System B	EIA	150
Roche Diagnostics	Elecsys HBsAg	ECL-EIA	50
Anti-HBs			
Abbott Laboratories	AUSAB EIA	EIA	200
Bayer HealthCare	ADVIA Centaur anti-HBs assay	CEIA	100
Diagnostic Products Corporation	Immulite 2000 anti-HBs	CEIA	50
DiaSorin	ETI-AB-AUK PLUS (anti-HBs) ELISA	EIA	100
Ortho-Clinical Diagnostics	VITROS anti-HBs assay (quantitative)	CEIA	80
Roche Diagnostics	Elecsys anti-HBs	ECL-EIA	40
Anti-HBc			
Abbott Laboratories	CORZYME EIA	EIA	100
	PRISM HBcore	CEIA	400
Bayer HealthCare	ADVIA Centaur HBc total assay	CEIA	50
Diagnostic Products Corporation	Immulite 2000 anti-HBc	CEIA	50
DiaSorin	ETI-AB-COREK PLUS (anti-HBc) ELISA	EIA	50
Ortho-Clinical Diagnostics	Ortho HBc ELISA test system	EIA	10
	VITROS anti-HBc assay	CEIA	50
IgM anti-HBc			
Abbott Laboratories	CORZYME-M (recombinant protein)	EIA	
	IMx CORE-M MEIA	EIA	150
Bayer HealthCare	ADVIA Centaur HBc IgM assay	CEIA	15
Diagnostic Products Corporation	Immulite 2000 anti-HBc IgM	CEIA	10
DiaSorin	ETI-CORE-IgMK PLUS (IgM anti-HBc) ELISA	EIA	100
Ortho-Clinical Diagnostics	VITROS anti-HBc IgM assay	CEIA	10
Anti-HBe			
DiaSorin	ETI-AB-EBK PLUS (anti-HBe) ELISA	EIA	50
Roche Diagnostics	Elecsys anti-HBe	ECL-EIA	35
HBeAg			
DiaSorin	ETI-EBK PLUS (HBeAg) ELISA	EIA	100
Roche Diagnostics	Elecsys HBeAg	ECL-EIA	35

As hepatitis B vaccination has become more widespread, the use of anti-HBs to monitor vaccine success rates has increased. Both the WHO and the CDC recognize a level of anti-HBs at 10 mIU/ml as being protective. The CDC recommends postvaccination testing for anti-HBs for health care workers who have blood or patient contact (24). Although the cutoffs of some currently available anti-HBs tests are near this level of detection, others detect anti-HBs at lower concentrations. Hence, a positive test does not necessarily indicate immunity according to WHO and CDC criteria. Anti-HBs levels decline over time, and approximately 60% of individuals who respond to vaccination lose detectable levels of antibodies over 10 to 12 years (110). Studies have demonstrated that vaccine-induced immunity continues to prevent clinical disease despite declining levels of antibody. As a result, the CDC states that "periodic serologic testing to monitor antibody concentrations after completion of the three-dose series is not recommended" (24).

Six commercial anti-HBc kits are available (Table 3). Three are EIAs (CORZYME, [Abbott], ETI-AB-COREK PLUS [DiaSorin], and Ortho HBc ELISA test system [Ortho-Clinical Diagnostics]), and three are CEIAs (ADVIA Centaur HBc total assay [Bayer HealthCare], Immulite 2000 anti-HBc [Diagnostic Products Corporation], and VITROS anti-HBc assay [Ortho-Clinical Diagnostics]). Some tests to detect anti-HBc are based on competitive binding, and all use recombinant HBcAg. In some of the assays, binding of the patient's anti-HBc is in competition with that of a monoclonal anti-HBc. In other assays, recombinant HBcAg is labeled with two different detectors to assess competitive anti-HBc binding. In

most assays, the specimens containing anti-HBc lead to signal suppression that is proportional to the amount of anti-HBc present. Other assays use the traditional sandwich EIA. The sandwich-based EIA for anti-HBc is carried out in HBcAg-coated microtiter wells to which patient anti-HBc binds. After residual sample is washed away, bound anti-HBc is detected by enzyme-labeled murine monoclonals with specificities for IgG and IgM. Values generated by positive and negative controls are used to calculate the assay cutoff and to establish run validity.

Some anti-HBc kits have testing algorithms similar to the ones required by HBsAg and anti-HBs tests. That is, duplicates of an initially reactive sample must be tested in a second, independent run. If one or both duplicates are reactive, the sample is repeatably reactive, or positive. However, results generated by recently approved automated assays do not require repeat testing unless results fall into a gray zone around the test cutoff value. In addition to their use for the diagnosis of prior or ongoing HBV infection, Abbott CORZYME and Ortho HBc ELISA test system kits may be used for blood donor screening. The Abbott PRISM anti-HBc is primarily a blood donor screening test; however, it can also be used for patient diagnosis. The other anti-HBc assays are not approved for blood donor screening.

Table 3 also gives details on six commercial kits available for the detection of IgM anti-HBc, three EIAs (CORZYME-M and IMx CORE-M MEIA [Abbott] and ETI-CORE-IgMK PLUS [DiaSorin]) and three CEIAs (ADVIA Centaur HBc IgM assay, [Bayer HealthCare], Immulite 2000 anti-HBc IgM [Diagnostic Products Corporation], and VITROS anti-HBc IgM assay [Ortho-Clinical Diagnostics]. Anti-human IgM is bound to the solid phase and used to capture IgM class antibody in the patient's serum, including IgM anti-HBc if present. Recombinant HBcAg is then added and binds to IgM anti-HBc. Enzyme-conjugated human anti-HBc is then added and in turn binds to HBcAg to complete the multilayer sandwich. The signal from the conjugated human anti-HBc is detected and evaluated. Both negative and positive controls contribute to the cutoff calculation in the bead-based CORZYME-M EIA, whereas a calibrator(s) establishes the cutoff in the other assays. Run validity is established with negative and positive controls.

Two HBeAg and two anti-HBe assays are available from two manufacturers (ETI-AB-EBK PLUS [anti-HBe] ELISA and ETI-EBK PLUS [HBeAg] ELISA [DiaSorin] and Elecsys anti-HBe and Elecsys HBeAg [Roche Diagnostics]). Both manufacturers use direct sandwich assays to detect HBeAg where anti-HBe bound to the solid phase captures HBeAg in the patient's specimen. Detection of bound antigen is accomplished by using enzyme-labeled human anti-HBe. All the assays establish run validity through the use of both positive and negative controls.

Competitive binding assays serve as the basis for anti-HBe detection in each of the available assays. The solid-phase anti-HBe reagents are the same ones described above for the detection of HBeAg. To detect anti-HBe, the patient sample and a measured amount of labeled recombinant HBeAg are added simultaneously to the solid phase. If anti-HBe is present in the patient's sample, it competes with solid-phase anti-HBe for the limited number of binding sites on the added HBeAg. Positive and negative control values are used in cutoff and run validity calculations. As with other competitive assays, and in contrast to direct sandwich assays, samples containing anti-HBe yield low detection outputs, i.e., below the respective assay cutoffs. The HBeAg and anti-HBe tests may be used for diagnosis and monitoring.

Antiviral Susceptibilities

At the current time, no specific treatment is available to patients with acute HBV infection except for supportive and symptomatic care (46, 70). However, the treatment of chronic HBV infection has changed in the last few years from bed rest to effective antiviral therapies. The major goal of treating chronic HBV infection is to suppress viral replication and halt the progression of liver damage before it leads to cirrhosis and/or HCC (36, 75, 77, 98). Although numerous antiviral and immunomodulatory therapies have been investigated in the last 30 years, only three approved therapies are available in the United States. These are alpha interferon (IFN-α); lamivudine (Epivir HBV), a nucleoside analogue; and adefovir dipivoxil, an adenosine monophosphate nucleotide analogue (36, 77, 98). Interferon was the first therapy approved for chronic HBV infection; thus, more information regarding the outcome of this treatment is available. The long-term outcome of IFN-α treatment is promising in that, of the HBeAg-positive patients who respond to this therapy, 80 to 90% remain negative for HBeAg after 4 to 8 years (3, 77, 98). However, HBV DNA is still detected in most of the patients when tested by PCR. Several studies have shown that 77% of patients receiving lamivudine therapy are HBeAg negative after 3 years (37, 106). Unfortunately, resistance to lamivudine has been detected in patients given this drug (9, 58). Resistance is manifested as the reappearance of HBV DNA in serum as detected by using a nonamplification assay. Of great interest are the studies showing that adefovir dipivoxil treatment results in a greater than 3 $\log_{10}$ reduction in HBV DNA levels after 2 years regardless of HBeAg status (51, 83). However, there have been reports of adefovir dipivoxil resistance developing in a small percentage of patients treated with this drug (51, 69, 82). A number of other antiviral agents, such as famciclovir, entecavir, emtricitabine, telbivudine, clevudine, and tenofovir, as well as various combinations of antiviral drugs, are currently being tested for possible use in the treatment of chronic HBV infection (21, 82).

Evaluation, Interpretation, and Reporting of Results

As shown in Fig. 4 and 5 and summarized in Table 4, the presence of HBsAg in serum indicates either acute or chronic active HBV infection. In a typical acute HBV infection,

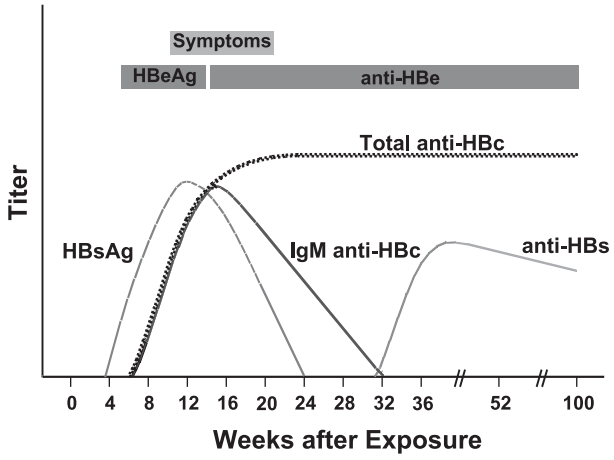

FIGURE 4 Typical sequence of serologic markers in patients with acute hepatitis B with resolution of symptoms (CDC website: http://www.cdc.gov/ncidod/diseases/hepatitis/slideset/hep_b/slide_3.htm.)

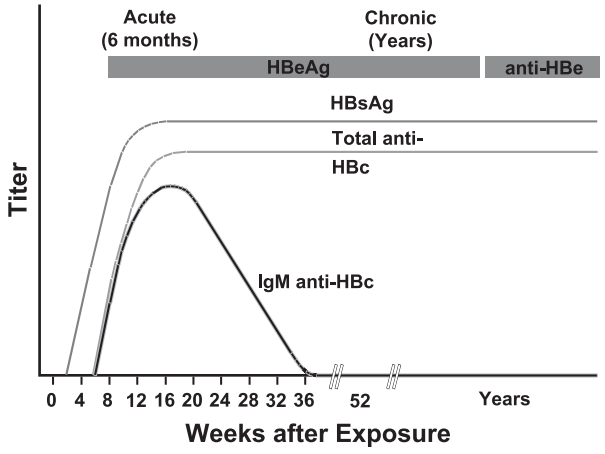

FIGURE 5 Typical sequence of serologic markers in patients with hepatitis B that progresses to a chronic course. In patients with chronic HBV infection, both HBsAg and IgG anti-HBc remain persistently detectable, generally for life. HBeAg is variably present in these patients. (CDC website: http://www.cdc.gov/ncidod/diseases/hepatitis/slideset/hep_b/slide_4.htm.)

HBsAg will be detected 2 to 4 weeks before the ALT level becomes abnormal and 3 to 5 weeks before symptoms or jaundice develops. The presence of HBV DNA precedes the appearance of HBsAg in the serum by 3 to 4 weeks. Anti-HBc, primarily of the IgM class, usually appears when the ALT level begins to increase. The presence of IgM-specific anti-HBc at a relatively high titer (>1:1,000) is evidence of an acute infection. These elevated IgM titers decline regardless of whether the clinical disease resolves or becomes chronic. Figure 5 illustrates the typical serologic pattern that occurs in a patient who becomes chronically infected. Sera from 5 to 15% of chronic hepatitis B patients may be positive by the IgM anti-HBc assay during reactivation of their disease; however, the IgM-specific anti-HBc levels are generally low, e.g., near the cutoff level for the test.

Because the total anti-HBc test is invariably positive when HBsAg is present in a clinically ill patient, this test can be used to validate the HBsAg reaction. In perhaps 5 to 10% of patients with acute hepatitis B (especially those with fulminant disease) and more frequently during early convalescence, HBsAg may be undetectable in sera.

One diagnostic dilemma is the patient with only anti-HBc detected over time without detectable anti-HBs and HBsAg. A recent workshop addressed this situation and found that in geographic areas where HBV endemicity is low, the rate of patients with only anti-HBc is 10 to 20% of all patients with HBV markers (50). About 10% of these patients had detectable HBV DNA when tested by using a PCR assay. Patients with only anti-HBc may be individuals in the "window" period and may be resolving acute HBV infection. In other patients, this result may reflect past infection that resolved or may represent an unresolved, low-grade HBV chronic infection. A recent case report has shown that a patient with only the anti-HBc marker reactivated HBV infection during immunosuppression due to human immunodeficiency virus disease (28). Therefore, it is important to consider that infections in some individuals with only anti-HBc as a marker for HBV infection may reactivate during immunosuppression. Moreover, these individuals should not be considered as blood donors.

The presence of anti-HBc alone is plausible evidence for an active or past HBV infection. Some individuals who have recovered from hepatitis B with the development of anti-HBs and anti-HBc may eventually lose their anti-HBs, resulting in a solitary anti-HBc response. Challenging a patient displaying this profile with hepatitis B vaccine leads to an anamnestic response 2 weeks later (anti-HBs level, >20 mIU/ml), whereas an HBsAg-negative carrier fails to respond in this time interval. The detection of anti-HBc alone may also represent a false-positive test result. Thus, it may be prudent to repeat the test with a newly acquired specimen.

An additional consideration in a patient with only anti-HBc as a specific serologic marker of HBV infection is the presence of a mutant HBV. A number of reports have described HBV mutant strains that resulted in conformational changes in the HBsAg or the HBeAg (117, 118). These mutants are usually not detected by commercial HBsAg or HBeAg kits. Thus, patients with unusual serologic patterns such as (i) anti-HBc reactivity only, (ii) a positive HBeAg result but a negative HBsAg result, and (iii) positive anti-HBc and anti-HBs results but a negative HBsAg result (similar to the serologic pattern that is observed in patients with a past infection) may be considered to be potentially infected with a mutant HBV. In these circumstances, the

TABLE 4 HBV markers in different stages of infections and convalescence[a]

Stage of infection	HBV DNA	HBsAg	HBeAg	Anti-HBc		Anti-HBe	Anti-HBs
				Total	IgM		
Early incubation	+	−	−	−	−	−	−
Late incubation	+	+	+ or −	−	−	−	−
Acute infection	+	+	+	+	+	−	−
HBsAg-negative acute infection	−	−	−	+	+	−	−
Chronic infection	+	+	+	++	+ or −	−	−
Healthy HBsAg carrier	−	+	−	++	+ or −	+	−
Recent infection[b]	+ or −	−	−	++	+	+	+ or ++
Remote infection[c]	−	−	−	+	−	−	+ or −
Vaccination response	−	−	−	−	−	−	+

[a] Modified from reference 103. ++, marker almost always present; +, generally present; −, typically not present.
[b] This description can be applied to early convalescence and to individuals who remain HBV DNA positive for prolonged periods in the absence of HBsAg.
[c] This description can be applied to individuals with anti-HBc in the absence of other serologic markers, including DNA. These patients may or may not have anti-HBs. There is evidence that these patients may reactivate HBV infection during immunosuppression (28).

detection of a high number of HBV DNA copies in plasma will help resolve this serologic interpretation. In the absence of anti-HBc and HBsAg, past or present hepatitis B disease can almost always be excluded. However, in rare cases HBV DNA has been detected in the sera and/or livers of some HBsAg-negative patients with or without other HBV serologic markers (20). Finally, due to the increased sensitivity of PCR, HBV DNA can be detected in the livers of some patients who have recovered completely from their infections and thus may be able to reactivate the disease during immunosuppression (20).

Anti-HBs usually becomes detectable immediately after the disappearance of HBsAg. Some patients have become anti-HBs positive several weeks after the loss of HBsAg. Anti-HBs is produced much earlier but is not observed because of the formation of immune complexes in the presence of excess HBsAg (113). Anti-HBs, with or without anti-HBc, signifies immunity to reinfection and indicates adequate protection after hepatitis B vaccination. Anti-HBs without anti-HBc develops in persons who receive the hepatitis B vaccine (which contains only HBsAg), and levels of ≥10 IU/ml are considered protective. However, many of the commercial assays can detect levels much lower than 10 IU/ml. It has been proposed that detection of anti-HBc, not detection of anti-HBs, be used as a screening test to determine susceptibility to HBV for the purpose of recommending hepatitis B vaccination. Depending on the circumstances, passive transfer of anti-HBs or anti-HBc may be observed in patients receiving clotting factor concentrates derived from human plasma, in patients after immunoglobulin administration, and in neonates of mothers with current or past hepatitis B. Since blood donations are pretested for HBsAg and total anti-HBc, passive transfer of antibodies following transfusions of blood is unlikely unless the donor has been vaccinated (donors are not tested for anti-HBs). Recognition of these possibilities will avoid an erroneous determination of HBV exposure or infection, because passive antibodies disappear gradually over 3 to 6 months, whereas actively produced antibodies are remarkably stable over many years.

Patients with chronic HBV infection should be tested for HBeAg, anti-HBe, or HBV DNA to determine their level of HBV replication and their potential for infectivity. HBeAg-positive specimens usually contain high concentrations of HBV DNA in contrast to anti-HBe-positive samples, in which the number of hepatitis B virions is markedly reduced. Patients who are HBeAg positive are more likely to transmit hepatitis B sexually, percutaneously, or perinatally. Seroconversion of a patient with HBeAg to an anti-HBe status with loss of HBV DNA is a favorable prognostic sign either after treatment with antiviral agents or when it occurs spontaneously.

HEPATITIS D VIRUS

Taxonomy

HDV is an unclassified, roughly spherical particle which is smaller than HBV, with a diameter ranging from 36 to 43 nm (103). The genome of HDV was sequenced in 1986 and found to comprise single-stranded RNA (116). The HBV genome is not homologous with the HBV genome and is not organized like a hepadnavirus genome. HDV is classified as a deltavirus (64, 87).

Description of the Agent

HDV is considered a satellite virus of HBV but biologically has no resemblance to HBV and is in a separate genus (64, 87). HDV contains a circular RNA genome that has substantial internal complementarity resulting in an unbranched, rodlike structure reminiscent of viroids or plant RNA satellite viruses. The genome is replicated by the host RNA polymerase II rather than by an HDV-encoded RNA polymerase. Replication of HDV RNA involves a rolling circle mechanism with self-cleavage. The HDV RNA is surrounded by a unique nucleocapsid protein of 68,000 Da called the HDV antigen (HDAg), which itself is surrounded by an envelope consisting of HBsAg. The HDAg, a nonglycosylated phosphoprotein, is the only product of the HDV genome. It consists of two proteins, a 195-amino-acid, 24-kDa protein and a larger, 214-amino-acid, 27-kDa protein, that play a role in the assembly of the virus (114, 115).

Epidemiology and Transmission

The incidence of HDV infection is very high in the Mediterranean Basin, the Middle East, Central Asia, West Africa, parts of South America, and some South Pacific islands (64). In the United States, most cases of HDV infection are observed in populations frequently exposed to blood-contaminated needles and blood products, such as injection drug users and hemophiliacs. Because hemophiliacs are now effectively vaccinated against hepatitis B and recombinant clotting factor concentrates are replacing plasma-derived products, hemophiliacs are no longer at risk for HDV infection. Secondary cases have been recorded in sexual partners of drug users, and such cases can amplify the spread of HDV infection within population groups other than those recognized as being at high risk for HDV infection. Person-to-person spread, including spread through household contact, is an important mode of transmission in Mediterranean countries. In South American populations with high HBV carrier rates, recurring epidemics of clinically severe acute hepatitis D have been observed (Fig. 3 and 6) (87).

Clinical Significance

Because HDV infection can become established only in persons with HBV infection, acute HDV infection can occur simultaneously with acute HBV infection (coinfection) or HDV infection can become superimposed upon an already established chronic HBV infection (superinfection).

HDV and HBV Coinfection

Coinfection with HBV and HDV usually causes an acute illness indistinguishable from acute HBV infection alone. The likelihood of fulminant hepatitis can be as high as 5% in coinfected patients. A biphasic course is sometimes observed during coinfection. HDV infection does not increase the rate of chronic hepatitis B carriers. Acute HDV infection generally occurs after a 3- to 7-week incubation period. The initial symptoms are fatigue, anorexia, and nausea that occur for 3 to 7 days. During this phase, liver enzymes become abnormal, which then leads to the typical appearance of jaundice and the onset of the icteric phase. Fatigue and nausea persist, with clay-colored stools and dark urine. In patients with acute, self-limited infection, convalescence begins with the disappearance of clinical symptoms. Fatigue may persist for longer periods of time (46, 87).

HDV Superinfection

HDV superinfection occurs when an HBV carrier is infected with HDV. Superinfection with HDV most often leads to severe, acute hepatitis with a short incubation period. Acquiring HDV in this fashion leads to chronic hepatitis D in up to 80% of cases. Chronic hepatitis D from superinfections

FIGURE 6 Worldwide prevalence of HDV-positive individuals. Data are from the CDC, 2005. (CDC website: http://www.cdc.gov/ncidod/diseases/hepatitis/slideset/hep_d/slide_6.htm.)

can lead to cirrhosis or to fulminant hepatitis (100). Fulminant hepatitis occurs more frequently after HDV superinfection than after other types of viral hepatitis. During acute HDV infection, the production of HBsAg and HBV DNA is inhibited.

Fulminant HDV infection is characterized by a serious clinical presentation resulting from encephalopathy. This complication can lead to confusion, changes in personality, problems with sleep, difficulty concentrating, and loss of consciousness. The mortality rate of fulminant hepatitis D can be as high as 80% (100). Patients with hepatitis D who have hepatic decompensation are candidates for liver transplantation, the outcome of which is better than that for patients with chronic hepatitis B alone (46).

A large percentage of patients with chronic HDV infection (60 to 70%) develop cirrhosis, usually after 5 to 10 years. However, in some patients cirrhosis can appear as early as 2 years after the onset of infection. Mortality due to hepatic failure is high among these patients. HCC develops with the same frequency in chronically infected HDV patients as in patients with HBV infection alone. The overall mortality rate for HDV infections is between 2 and 20%, which is 10 times higher than that for HBV infection alone.

Some success has been achieved in treating chronically HDV-infected patients with IFN-α. High-dose, long-term therapy is required, but relapses are common after therapy is stopped (41, 42). Recently, lamivudine has been used in patients with chronic hepatitis D (90).

Collection, Transport, and Storage of Specimens

The recommendations for the collection of specimens are similar to those for HBV. Serum or plasma should be separated and stored at 2 to 8°C, and testing should be performed within 5 days. Severely hemolyzed blood should be avoided due to the possibility of false-positive results. Repetitive freezing and thawing of specimens may lead to a loss in accurate detection. Specimens for nucleic acid analyses should be processed within 6 h, and if not tested within 24 h, they can be stored at −70°C or lower. The above-described recommendations are general, conservative guidelines that may not conform to those specified by reference laboratories offering HDV testing.

Direct Detection

Microscopy

HDAg can be detected directly in biopsy material by using microscopy to visualize specific staining using antibody specific for HDV antigen. Immunohistochemical staining of liver biopsy material for intrahepatic HDAg is a reliable way to demonstrate ongoing HDV replication. However, this method does not lend itself to simple, rapid diagnostic testing and requires that a liver biopsy be done. The anti-HDV is conjugated to fluorescein or peroxidase. Anti-HDV is derived from serum or plasma containing a high titer of anti-HDV accompanied by a low level of anti-HBc. The latter can be reduced or eliminated by dilution. An anti-HDV-negative, anti-HBc-positive control probe must be used in parallel with the anti-HDV probe to validate the anti-HDV specificity of staining. Cryostat sections are the optimum specimens. However, HDAg is stable for formalin fixation and paraffin embedding and therefore can be studied in stored paraffin-embedded tissue after digestion of the section with trypsin or pronase (57).

Antigen Tests

In the United States, commercial kits to detect HDAg in peripheral blood samples have never come to the market because of limited demand for this test. HDAg EIA services are available from a few clinical reference laboratories.

HDVAg can also be detected by Western blotting. More sensitive than EIA, Western blotting is reactive for more than 70% of patients with chronic hepatitis D. Because of its technical difficulty, Western blotting has not been used as a diagnostic test; rather, it remains a technique confined to a limited number of research laboratories. Methods used to detect HDV antibody in serum are described below in "Serologic Tests for HDV."

Nucleic Acid Detection Techniques

HDV RNA can be detected in peripheral blood samples by using real-time, reverse transcription-PCR (42, 86, 120). This technique has provided a more precise understanding of HDV infections. The levels of HDV RNA in the sera of patients with chronic hepatitis tend to be higher than the levels in asymptomatic carriers (120). Levels of HDV RNA are reduced in patients treated with IFN-α (42, 68). These reductions in HDV RNA levels are associated with improvements in liver fibrosis. Thus, the reverse transcription-PCR assay can be used to monitor response to antiviral therapy. In the United States, the assay is performed by a few reference laboratories.

SEROLOGIC TESTS FOR HDV

Antibody Tests

Tests for anti-HDV require a source of HDAg. Previously, HDAg has been obtained from HDAg-positive human (postmortem) or chimpanzee livers or serum. A more reliable source is now available from the livers of HDAg-positive woodchucks.

Commercial kits to detect IgM anti-HDV are unavailable in the United States, but testing can be accessed through a limited number of reference laboratories in the form of IgM antibody capture EIAs.

Commercial kits to detect total anti-HDV appeared in the United States in the early 1980s, first as an RIA and then as an EIA which supplanted the RIA. Because demand for anti-HDV testing has been historically low, the EIA kit was withdrawn from the U.S. market. However, testing for total anti-HDV can be obtained from the same reference laboratories offering tests for HDAg and IgM and anti-HDV.

Evaluation, Interpretation, and Reporting of Results

Any individual who is positive for HBsAg may have HDV infection, especially if the patient is from an area in which HDV infections are prevalent (Fig. 6). The diagnosis of both acute and chronic HDV infections uses the detection of HDV-specific antibodies and antigen as well as the detection of HDV RNA (86, 87, 120). The detection of total anti-HDV is sufficient for making the diagnosis of HDV infection. Anti-HDV serology should be considered when the patient is HBsAg positive, has elevated transaminase levels, and is from a country where HDV infection is prevalent. However, anti-HDV disappears shortly after an acute infection (coinfection with HBV) and may not be a consistent marker to indicate past infection (Fig. 7). Only those patients that have positive serology results for HDAg or anti-HDV should be tested for the presence of HDV RNA.

The interpretation of HDV infection diagnostic tests and their correlation with disease conditions are discussed below. The majority of this material has been adapted from the WHO website (http://www.who.int/csr/disease/hepatitis/whocdscsrncs20011/en/index3.html).

The molecular and serologic natural history of acute HBV-HDV coinfection is graphically depicted in Fig. 7. During a coinfection, HBsAg and HBV DNA can be detected in serum during the incubation period. At the onset of clinical disease, anti-HBc, HDV IgM, and HDAg (not shown due to its transient and low level if present) can be detected in serum. Late in the acute phase, anti-HDV antibodies develop and then decline to subdetectable levels when clinical symptoms resolve. With the appearance of anti-HDV, HDAg disappears. During early convalescence,

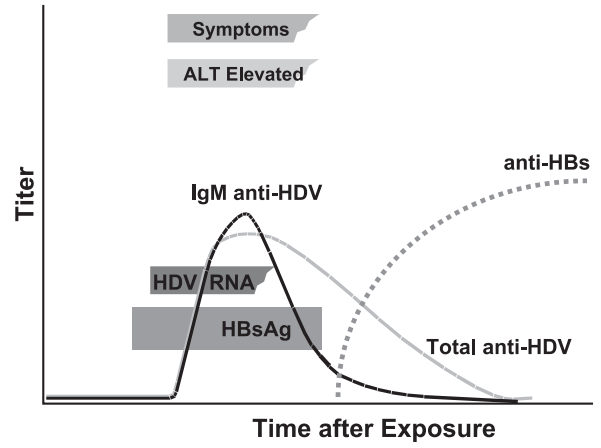

FIGURE 7 Serologic course of HDV infection when the virus is acquired as a coinfection with HBV. (CDC website: http://www.cdc.gov/ncidod/diseases/hepatitis/slideset/hep_d/slide_4.htm.)

viral replication (HDV RNA) cannot be detected and the level of anti-HDV begins to decline. The serologic markers of HDV infection usually disappear within months after recovery from acute disease. Since antibodies to HDV do not always persist after the acute infection is cleared, detection of past HDV infection is not easy to confirm. In contrast, when an HBsAg carrier acquires a superinfection with HDV, there is a loss of IgM anti-HBc and anti-HDV (IgM and total) is detected. The molecular and serologic history of HBV-HDV superinfection is graphically depicted in Fig. 8. Both HBsAg and HDV RNA appear in serum early during the infection. Chronic HDV infection is associated with the ongoing detection of HDV RNA, IgM anti-HDV, and total anti-HDV, and these markers persist indefinitely. The usual outcome of an HDV superinfection is a persistent, chronic infection. The detection of HDV RNA levels in serum can assist in evaluating the stage of HDV infection and the response to therapy.

Considerable progress has been made in the understanding of HDV epidemiology. Additionally, there is more information on the molecular characteristics of this satellite virus and its association with HBV (64, 86). The evolution of knowledge about the clinical consequences of HDV-HBV

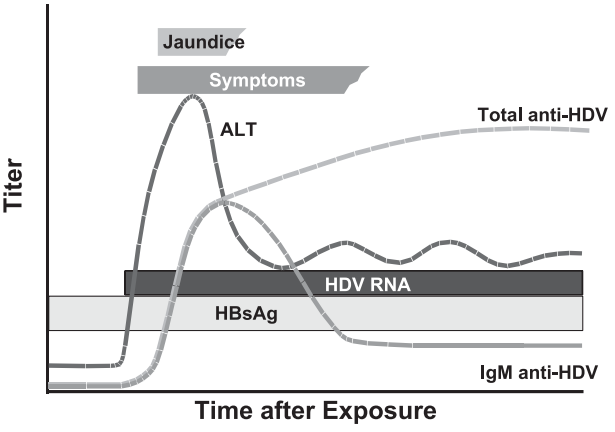

FIGURE 8 Typical serologic course of HDV superinfection in patients with chronic HBV infection. (CDC website: http://www.cdc.gov/ncidod/diseases/hepatitis/slideset/hep_d/slide_5.htm.)

coinfections and HDV superinfection of HBV carriers coupled with novel rapid technologies will inevitably lead to the development of new assays that will facilitate the diagnosis and monitoring of HDV infections.

Transmissible Spongiform Encephalopathies*

ADRIANO AGUZZI AND MARKUS GLATZEL

111

TAXONOMY

The "Protein-Only" Hypothesis

The most widely accepted hypothesis on the nature of the infectious agent causing transmissible spongiform encephalopathies (TSEs), which was termed prion by Stanley B. Prusiner (35), predicates that it consists essentially of a scrapie-like prion protein (PrP^{Sc}), an abnormally folded, protease-resistant, beta-sheet-rich isoform of a normal cellular prion protein (PrP^{C}). According to this theory, the prion does not contain any informational nucleic acids, and its infectivity propagates simply by recruitment and "autocatalytic" conformational conversion of cellular prion protein into disease-associated PrP^{Sc} (5).

A large body of experimental and epidemiological evidence is compatible with the protein-only hypothesis, and very stringently designed experiments have failed to disprove it. It would go well beyond the scope of this chapter to review all efforts that have been undertaken to this effect. Perhaps most impressively, knockout mice carrying a homozygous deletion of the murine *Prnp* gene, which encodes PrP^{C} (*Prnp*$^{0/0}$ mice), fail to develop disease upon inoculation with infectious brain homogenate (10), and their brains do not carry prion infectivity (39). Reintroduction of *Prnp* by transgenesis—even in a shortened, redacted form—restores infectibility and prion replication in *Prnp*$^{0/0}$ mice (14, 15, 40, 41). In addition, all familial cases of human TSEs are characterized by mutations in the human PrP^{C} gene (designated *PRNP*) (4, 36). Two recent studies go a long way toward settling the score as to the nature of the infectious agent, by demonstrating that prions may be synthesized in cell-free systems (11, 26).

DESCRIPTION OF THE AGENT

According to the protein-only hypothesis, the abnormal form of PrP^{C}, PrP^{Sc}, represents the infectious agent. Even if the protein-only hypothesis has not formally been proven, all studies agree that PrP^{Sc} represents an essential component of prion infectivity. The three-dimensional structure of PrP^{C} has been solved by nuclear magnetic resonance spectroscopy; similar analyses have not been possible for PrP^{Sc} (23, 37). Studies employing Fourier transform infrared spectroscopy have demonstrated that PrP^{Sc} contains more beta-sheets (about 40%) and fewer alpha-helical structures (about 30%) than PrP^{C} (30).

EPIDEMIOLOGY AND TRANSMISSION

Human prion diseases manifest as sporadic, genetic, and acquired disorders. They are referred to as sporadic Creutzfeld-Jakob disease (sCJD), familial or genetic CJD (gCJD), iatrogenic CJD (iCJD), and variant CJD (vCJD).

sCJD

sCJD is a rapidly progressive dementia, usually leading to death within 6 months of disease onset (16). The cause of sCJD remains enigmatic. To date no obvious risk factors have been identified. Because of the short mean duration of this disease, incidence and mortality rates for sCJD are similar; thus, mortality rates are routinely used to describe the epidemiology of this disease. The overall annual mortality rate from sCJD in a panel of European and non-European countries, including Australia and Canada, is 1.39 cases per million for the period between 1999 and 2002 (25). Mortality rates are fairly constant, both over time and between countries, ranging from 0.41 cases per million in 1994 in Spain to 2.63 cases per million in 2002 in Switzerland (18). Unlike other dementia-causing diseases such as Alzheimer's and Parkinson's diseases, in which incidence rises with age, the peak incidence is between 55 and 65 years of age (18).

gCJD

gCJD can be subdivided into three phenotypes: familial CJD, Gerstmann-Sträussler-Scheinker syndrome (GSS), and fatal familial insomnia (FFI). The mode of inheritance in all of these diseases, which cosegregate with mutations in *PRNP,* is autosomal dominant (19). The overall annual mortality rate for gCJD in a panel of European and non-European countries, including Australia and Canada, is 0.17 case per million for the time period 1999 to 2002. Between 1999 and 2002, mortality rates for gCJD were markedly different in various countries, ranging from 0.02 in The Netherlands to 1.07 in Slovakia (25).

* This chapter contains information presented in chapter 106 by David M. Asher in the eighth edition of this Manual.

iCJD

iCJD is caused by prion exposure during neurosurgical procedures such as implantation of human dura mater, corneal graft implantation, or treatment with human cadaveric pituitary extracts (7). iCJD is rare, with fewer than 300 published cases. The majority of cases were caused by implantation of dura mater and injection of pituitary growth hormone (7). Recent epidemiological data confirm the observation that iCJD mainly affects individuals younger than 39 years (25).

vCJD

vCJD, a relatively new member of the human prion diseases, was first reported in 1996 (46). Biochemical, neuropathological, and transmission studies have substantiated the concern that vCJD represents transmission of bovine spongiform encephalopathy (BSE) prions to humans (1, 3, 8, 21). The incidence of vCJD in the United Kingdom rose each year from 1996 to 2001, evoking fears of a large upcoming epidemic. Since 2001, however, the incidence of vCJD in the United Kingdom has appeared to be stabilizing, and only a small number of other countries have seen isolated cases. Although predictions on the future of the vCJD epidemic are still flawed with imprecision, there is growing evidence that the total number of vCJD victims will be limited (45). vCJD has a distinct clinicopathological profile, including age of onset. vCJD victims are much younger than sCJD patients (median age at death: 29 years) (25).

CLINICAL SIGNIFICANCE

Initial symptoms of sCJD include cognitive deficits, sleep disturbances, and behavioral abnormalities. As the disease progresses, other clinical features such as extrapyramidal and pyramidal symptoms, ataxia, and visual disturbances become obvious and the patients usually develop myoclonus (16). Terminally affected sCJD patients typically develop a state of akinetic mutism prior to death. The disease course is usually short, the mean duration of the illness being 4 to 5 months (Table 1).

The clinical presentation of gCJD varies with the underlying mutation. Some mutations present with a clinical picture that is similar to that of sCJD. The age at onset tends to be younger and the disease duration longer than for sCJD. FFI and GSS represent exceptions. FFI has a unique clinical course which is characterized by profound disruption of the normal sleep-wake cycle, insomnia, and sympathetic overactivity (29), whereas GSS presents with a progressive cerebellar ataxia.

In iCJD, the site of prion exposure seems to dictate the time between exposure and onset of prion disease-related symptoms. Direct intracerebral exposure to prions and implantation of prion-contaminated dura, for example, are associated with short incubation periods (16 to 28 months), whereas exposure to prions at sites outside the central nervous system (CNS) results in long incubation times, ranging from 5 to 30 years (13). Furthermore, there is evidence that the route of prion exposure influences the clinical presentation. Dura mater or growth hormone-related cases of iCJD present with a predominantly ataxic phenotype, whereas dementia was the initial symptom in cases in which prions were directly introduced into the CNS.

The fact that vCJD carries a distinct clinical profile has facilitated the formulation of diagnostic criteria. As stated above, vCJD victims are much younger than sCJD patients. Furthermore, initial features and illness duration are relatively specific, with initial psychiatric symptoms and a median illness duration of 14 months (Table 1). It has been hard to estimate incubation times for vCJD due to the fact that the exact time points of prion exposure are not defined.

The diagnosis of human prion diseases is based on the appraisal of clinical signs and symptoms (described below) and a number of auxiliary examinations (13). Electroencephalography (EEG) has historically been used to substantiate the diagnosis of a human prion disease. The usefulness of EEG has been questioned due to its limited sensitivity (49). Recent advances in neuroimaging, especially in magnetic resonance imaging (MRI), have revealed that different human prion diseases have specific patterns (44). For vCJD, the "pulvinar sign," a high T2 MRI signal in the posterior thalamus, seems to be unique and is present in about 75% of patients with vCJD (48). For sCJD, fluid-attenuated inversion recovery and diffusion-weighted MRI sequences are associated with high sensitivity and specificity and may represent a relatively noninvasive method to corroborate the diagnosis of a human prion disease (38).

An impressive wealth of molecules have been proposed as potential antiprion compounds based on in vitro data

TABLE 1 Human prion diseases: clinical features

Human prion disease	Clinical features		
	Age (yr) at onset (mean)	Disease duration (mean)	Leading clinical symptoms
sCJD	60–70	6 mo (1–35 mo)	Progressive dementia and neurological signs, e.g., myoclonus, cerebellar ataxia, visual problems, extrapyramidal symptoms
Inherited CJD			
gCJD	50–60	6 mo (2–41 mo)	Clinical symptoms similar to sCJD
GSS	50–60	5–6 yr (3 mo–13 yr)	Cerebellar dysfunction (ataxia, nystagmus, dysarthria)
FFI	50 (20–63)	13–15 mo (6–42 mo)	Insomnia Autonomic dysfunction
Acquired CJD			
vCJD	26 (12–74)	14 mo (6–24 mo)	Early psychiatric symptoms (depression, anxiety, social withdrawal), dysesthesia; later neurological deficits and cognitive decline
iCJD	—[a]	Similar to sCJD	Clinical symptoms similar to sCJD

[a] —, age at onset depending on iatrogenic exposure: incubation period, 1 to 30 yr.

(12, 33, 34, 42). Disappointingly, none of these compounds have been effective for actual therapy of prion disease in vivo. Transgenic expression of an immunoglobulin Fcγ domain fused to PrP^{C} drastically delays prion disease onset after peripheral and intracerebral prion challenge (27), raising the possibility that soluble prion protein mutants may be potential prionostatic compounds. Immunotherapy with anti-PrP antibodies has been shown to be effective in model systems (20) and may represent an alternative therapeutic approach.

COLLECTION, STORAGE, AND TRANSPORT OF SPECIMENS

General Considerations

PrP^{Sc}, the form of the infectious agent that causes prion diseases, is present in an oligomeric or polymeric form. The tight association of PrP^{Sc} molecules in aggregates may be responsible for the extreme stability of PrP^{Sc}. Prion infectivity is thus resistant to a number of techniques customarily used for decontamination of conventional infectious agents. In clinical laboratories, personal protective clothing such as disposable gowns, gloves, and barrier protection for mucous membranes (eye protection or full-face visor) is recommended when working with potentially contaminated specimens. In addition, strict adherence to standard working procedures aimed at minimizing the chance of penetrating injuries is essential. Handling of potentially infectious material requires certain additional precautions as described below.

Laboratory Handling of Potentially Contaminated Specimens

The highest titers of prion infectivity can be found in CNS tissues (brain, spinal cord, and cranial nerves), but nonneural tissues such as lymphatic tissue or muscle may contain infectious prions. Prions are not inactivated by formalin. A procedure recommended by the College of American Pathologists (http://www.cap.org) for safe handling of tissues is formalin fixation for at least 10 days, followed by formic acid treatment (50 to 100 ml of 95 to 100% [vol/vol]) for 1 h, and formalin fixation for 2 days. Tissues can then be embedded. Formic acid inactivates formalin-treated prions but has minimal effect on the quality of histology. Disposable histologic equipment should be used whenever possible.

Blood and bone marrow are presumed to contain low levels of infectivity (http://www.advisorybodies.doh.gov.uk/acdp/tseguidance/). These specimens can be handled safely under biosafety level 2 conditions by adhering to universal precautions for prevention of transmission of blood-borne pathogens. These specimens can be tested in automated analyzers found throughout clinical laboratories if instruments are enclosed, if they can contain spillage, and if waste can be disposed of safely. Maintenance and emergency procedures that protect the user from exposure should be outlined in laboratory standard operating procedures and implemented. Manual processing (specimen decanting, for example) should be performed inside a negative-pressure laminar-flow hood in a contained environment.

Prions can be substantially but not completely inactivated by physical exposure to steam or dry heat at high temperatures. Disposable laboratory equipment should be used whenever possible. Potentially contaminated laboratory waste should be autoclaved (134 to 137°C, 20 min) and then incinerated (http://www.advisorybodies.doh.gov.uk/acdp/tseguidance/). Chemical exposure to high concentrations of either sodium hypochlorite (>5.25% solution, freshly prepared) or sodium hydroxide (1 N solution) for 1 h is effective against prions and can be used to disinfect spills. Reusable laboratory material should be immersed in a freshly prepared >5.25% solution of sodium hypochlorite, or a 1 N solution of sodium hydroxide for 1 h, and then rinsed with water before being packaged for autoclave sterilization at 134°C for at least 20 min (http://www.advisorybodies.doh.gov.uk/acdp/tseguidance/).

Collection of Samples

Whole blood may be used for isolation of DNA for genetic analysis (exclusion of gCJD and detection of the *PRNP* codon 129 status). Blood should be shipped in a chilled container. Currently, an approved blood-based screening test for human prion diseases is not available. Cerebrospinal fluid (CSF) is routinely used to monitor elevation of nonspecific neuronal injury markers. CSF should be shipped at 4°C. Tissue may be used for histopathology and biochemical examination. Brain biopsies can be recommended only in order to exclude the diagnosis of diseases for which therapeutic options are available. Nonneural tissues (lymphatic tissue or muscle) may be useful in order to confirm the suspicion of vCJD. Tissue should be fixed in formalin for histologic assessment as described above and snap-frozen for Western blotting. Formalin-fixed material may be shipped at room temperature, whereas snap-frozen material must be shipped on dry ice.

Transport of Samples

Shipping of infectious material via water, land (road or train), and air must comply with the "Recommendations of the United Nations Committee of Experts on the Transport of Dangerous Goods." In these guidelines, human prions are listed in category 6 (Toxic and Infectious Substances), division 2 (Infectious Substances). The code numbers UN 2900 apply for this type of pathogen. Certified shipping containers must be used.

DIRECT DETECTION

Microscopy

Although it is not routinely recommended for the diagnosis of human prion diseases, histologic examination of CNS tissue can be diagnostically helpful premortem. Routine hematoxylin-eosin stains are used to interpret the vacuolization patterns, whereas immunohistochemical demonstration of PrP is necessary in order to determine PrP deposition patterns (Fig. 1). Postmortem, defined regions within the CNS (cerebellum and thalamus) and nonneuronal tissues can be sampled to demonstrate distinct PrP deposition patterns (9). Histologically, prion diseases are characterized by spongiform changes, astrogliosis, and neuronal loss. These changes are most evident in the cerebral cortex and in the cerebellum. The prominent cerebellar involvement is typical for prion diseases and clearly separates this group of diseases from other dementia-causing illnesses such as Alzheimer's disease or diffuse Lewy body disease. White-matter changes, which may be present in some cases, are thought to constitute secondary changes. In vCJD and in about 10 to 20% of sCJD patients, prion plaques are a prominent feature and may be demonstrated by Congo red staining or immunohistochemistry. Birefringence under polarized light, usually a characteristic feature of amyloid plaques, may be absent due to harsh pretreatment of fixed tissue.

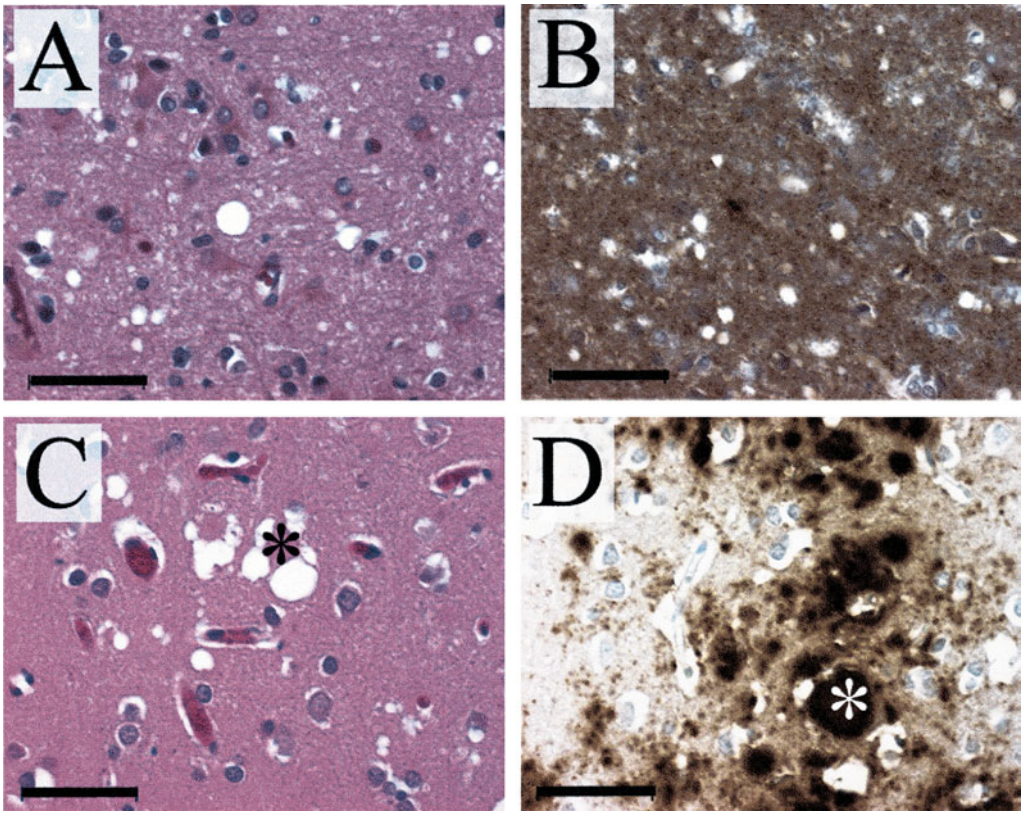

FIGURE 1 Histological features of prion diseases. The panels depict CNS parenchyma of sCJD (A and B) and vCJD (C and D) showing astrogliosis and widespread spongiform changes. PrP depositions are synaptic (A and B) and in the form of florid plaques (asterisk, C and D). Panels A and C are hematoxylin-eosin stains, and panels B and D are immunohistochemical stainings for PrP (scale bar = 50 μm).

Antigen Detection of PrP^{Sc} by Western Blotting

Western blotting is routinely performed on unfixed tissue originating from the CNS. Generally, this test is undertaken in a postmortem setting. In rare cases where a brain biopsy is justified, a biopsy specimen may be used.

The basis of biochemical characterization of PrP^{Sc} resides in its relative resistance to proteolytic degradation. Whereas PrP^{C} is entirely digested by proteinase K, identical treatment of PrP^{Sc} leads to removal of a variable number of N-terminal amino acids. Western blotting of digested PrP^{Sc} reveals three distinct bands, corresponding to di-, mono-, and unglycosylated forms (31). The molecular classification of PrP^{Sc} takes two parameters into account: the molecular weight of unglycosylated PrP^{Sc} and the relative amounts of PrP^{Sc} di-, mono-, and unglycosylated forms. The resulting information is then used to establish the "type" of PrP^{Sc} according to proposed schemes (22, 32) (Fig. 2). Depending on the exact conditions under which the protease digestion and the Western blotting procedure are performed, between three and six different PrP^{Sc} types can be distinguished (22, 28). Distinct PrP^{Sc} types are thought to represent the molecular correlates of distinct prion strains. The fact that the PrP^{Sc} types found in vCJD patients and in BSE-diseased cattle are identical is one of the main arguments supporting the theory that BSE prions are responsible for the vCJD epidemic in humans (21). It is unknown how glycotype ratios can be faithfully maintained during prion replication; however, experiments with yeast prions indicate that this occurs in a synthetic prion replication system (24, 43). This phenomenon may be related to the quaternary structure of prion aggregates (2).

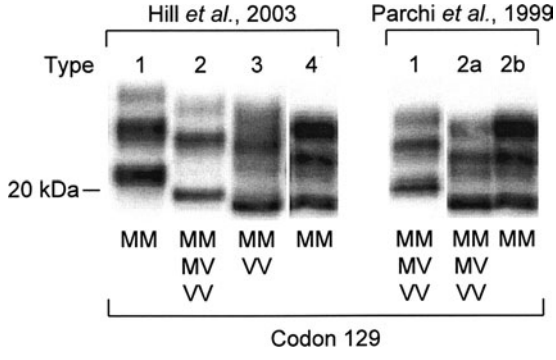

FIGURE 2 Western blot analysis of PrP^{Sc}. Depicted are PrP^{Sc} types according to two proposed schemes which discriminate PrP^{Sc} types based on the mobility of the unglycosylated band of PrP^{Sc} and the signal intensity of the PrP^{Sc} di-, mono-, and unglycosylated forms. One scheme (22) differentiates four principal PrP^{Sc} types (1 to 4) (22). Three principal PrP^{Sc} types (1, 2a, and 2b) are proposed in the second scheme (32).

Nucleic Acid: Genetic Testing

For genetic testing, DNA is extracted from whole blood using routine methods. The entire open reading frame may be amplified for sequencing using PCR (17). Sequencing of *PRNP* allows for the exclusion of gCJD (47). More than 29 disease-causing insertional or point mutations in *PRNP* have been identified to date (Table 2). In addition, there are several *PRNP* polymorphisms, one of which (codon 129M/V) may have a disease-modifying function. Homozygosity for methionine at codon 129 may constitute a risk factor for the development of prion disease (6): methionine homozygotes are clearly overrepresented among sCJD patients, and all individuals affected by vCJD are homozygous for methionine at codon 129. In addition, this polymorphism has a considerable effect on the clinical, biochemical, and neuropathological presentation of prion-diseased individuals (6).

SEROLOGIC TESTS

To date there are no serologic screening or confirmatory tests for prion diseases. Rather, several studies had evaluated the usefulness of surrogate markers, such as the 14-3-3 and tau proteins, that are found in CSF as a consequence of neuronal death. These proteins are ubiquitously expressed. 14-3-3 participates in protein kinase signaling and is involved in neuronal migration. Tau is a phosphoprotein that promotes the assembly and stability of neuronal axons by binding to microtubules. Elevation of these proteins is relatively nonspecific and can be seen in other conditions such as encephalitis, cerebral infarction, and paraneoplastic neurological disorders. Satisfactory sensitivity and specificity (over 90%) can be achieved only in selected cohorts (49). Results from these tests, in combination with clinical data, may help at best to strengthen the diagnosis of a probable human prion disease. While 14-3-3 is routinely tested using a Western blot, tau may be measured in an enzyme-linked immunosorbent assay format (49).

TABLE 2 Disease causing mutations in *PRNP*

Mutations that cause GSS	Mutations that cause a disease that is clinically similar to sCJD	Mutations that cause FFI

TABLE 3 Useful diagnostic tests for TSEs

Disorder[a,b]	Useful supplemental diagnostic tests and specimens[a]
sCJD	Histology, Western blotting, genetic testing for exclusion of gCJD, auxiliary tests such as determination of 14-3-3 or tau protein in the CSF
gCJD	Genetic testing, histology, Western blotting, auxiliary tests such as determination of 14-3-3 or tau protein in the CSF
vCJD	Histology, Western blotting (lymphoid tissue and CNS tissue), genetic testing for exclusion of gCJD, auxiliary tests such as determination of 14-3-3 or tau protein in the CSF

[a] Clinical presentation is of primary diagnostic importance.
[b] Neuroimaging studies yield distinct results and can be useful.

EVALUATION, REPORTING, AND INTERPRETATION OF RESULTS

The diagnosis of human prion disorders can be difficult to establish but is best approached through careful consideration of clinical presentation and other clinical studies such as neuroimaging. Brain biopsy and histologic assessment can be performed to rule out treatable disorders. Detection of spongiform changes and deposition of PrP^{Sc} in affected areas can help establish the diagnosis of prion disorders. The absence of these changes (for example, due to sampling bias) is not helpful in the exclusion of these disorders. Less invasive tests such as detection of surrogate markers (tau and 14-3-3) in CSF can be helpful when considered in the context of available clinical neuroimaging information. Genetic testing can be performed to establish the diagnosis of genetic prion disorders. The constellation of tests that can be helpful in the diagnosis of each of these disorders is shown in Table 3. All testing other than neuropathology and sequencing of *PRNP* is usually performed on a research basis.

Antiviral Agents*

NELL S. LURAIN AND KENNETH D. THOMPSON

112

The use of antiviral agents for the treatment of viral diseases continues to expand. Most of the agents currently approved by the Food and Drug Administration (FDA) are active against one or more of the following viruses: human immunodeficiency virus types 1 and 2 (HIV-1 and HIV-2), hepatitis viruses B and C (HBV and HCV), the human herpesviruses, and influenza viruses A and B. This chapter is organized according to these virus groups with cross-referencing for agents with activity against more than one group of viruses. The major targets of these agents are viral replication enzymes, proteases, and entry and exit pathways (27, 31, 39, 93, 112).

AGENTS ACTIVE AGAINST HUMAN IMMUNODEFICIENCY VIRUS TYPES 1 AND 2

There are now four classes of antiviral agents for the treatment of HIV-1 infection: (i) nucleoside and nucleotide reverse transcriptase inhibitors (NRTIs and NtRTIs), (ii) non-nucleoside reverse transcriptase inhibitors (NNRTIs), (iii) protease inhibitors (PIs), and (iv) entry or fusion inhibitors. Current information on each drug is available through the AIDSinfo website (http://AIDSinfo.nih.gov), which has separate guidelines for the use of approved antiretroviral agents in (i) adolescents and adults, (ii) pediatric patients, and (iii) pregnant HIV-1-infected women (33, 61, 107). These guidelines describe the agents along with dosages, adverse effects, and drug interactions. Working groups for each of these patient populations regularly update the guidelines. Additional prescribing information can be obtained from the individual pharmaceutical company websites. Changes in recommended drug doses, as well as observed adverse effects and drug interactions, occur frequently, making it necessary to consult the most up-to-date sources.

Antiretroviral agents are administered in combinations of different drug classes termed highly active antiretroviral therapy (HAART) to maximize efficacy and to minimize the induction of drug resistance. Initially, HAART was defined as two NRTIs and a PI; however, HAART is now generally regarded as any combination regimen designed to achieve the goal of complete virus suppression. These regimens comprise a minimum of three drugs and are usually either NNRTI-based (two NRTIs or NtRTIs plus one NNRTI) or PI-based (two NRTIs or NtRTIs plus one or more PIs). Monotherapy is restricted to the prevention of perinatal transmission of HIV. The drugs most often used for this purpose are zidovudine (ZDV or AZT) and nevirapine (NVP) (33).

There are currently 21 approved antiretroviral drugs with numerous possible combinations for treatment regimens. Recommended regimens for adults and adolescents are given in the guidelines (33) for treatment-naïve and treatment-experienced patients. The large number of drugs creates a tremendous potential for drug interactions among the different classes as well as interactions with other types of drugs prescribed for conditions associated with HIV infection. Close monitoring of these complex interactions is required to avoid detrimental changes in drug levels and/or toxicity.

Table 1 summarizes the structures, mechanisms of action, and major adverse effects of the individual drugs and drug combinations approved by the FDA. Drug interactions described below for each drug are only highlights of potential interactions. Frequent updates and more comprehensive information can be obtained from the AIDSinfo website listed above.

Nucleoside and Nucleotide Reverse Transcriptase Inhibitors

NRTIs and NtRTIs are not active as administered but must be phosphorylated by cellular kinases into the nucleoside triphosphate form, which lacks a 3-prime hydroxyl group for DNA chain elongation (3). These compounds act as competitive inhibitors of the viral reverse transcriptase (RT), which results in chain termination. The NRTIs require triphosphorylation, while the NtRTIs require only diphosphorylation.

These drugs are active against both the HIV-1 and HIV-2 RTs (133), and they are used in combination regimens with either NNRTIs or PIs. Several of them also are active against the HBV DNA polymerase, which has RT activity (see "Agents Active against Hepatitis B Virus" below) (127, 137). Lactic acidosis with hepatic steatosis is a rare but very serious adverse effect associated with all members of this class. These toxic effects of NRTIs and NtRTIs appear to be the result of inhibition of the mitochondrial DNA polymerase γ (14, 26).

*This chapter contains information presented in chapter 107 by Ella M. Swierkosz in the eighth edition of this Manual.

TABLE 1 Antiviral agents for HIV

Antiviral agent (abbreviation)	Trade name, pharmaceutical company[a]	Structure	Mechanism of action	Major adverse effects
NRTIs and NtRTIs				
Zidovudine (ZDV or AZT)	Retrovir, GSK	3′-Azido-2′,3′- dideoxythymidine	Converted to triphosphate analogue of dTTP by cellular kinases; competitive inhibitor of RT viral DNA chain termination	Bone marrow suppression, GI symptoms,[b] headache, insomnia, lactic acidosis and severe hepatosplenomegaly with steatosis
Didanosine (ddI)	Videx, BMS	2′,3′-Dideoxyinosine (adenosine analogue)	Converted to dideoxytriphosphate analogue of dATP by cellular kinases; activity similar to that of ZDV	Pancreatitis, peripheral neuropathy, nausea, diarrhea, lactic acidosis and severe hepatosplenomegaly with steatosis
Zalcitabine (ddC)	Hivid, Roche	2′,3′-Dideoxycytidine	Converted to ddCTP analogue of dCTP by cellular kinases; activity similar to that of ZDV	Peripheral neuropathy, pancreatitis, stomatitis, lactic acidosis and severe hepatosplenomegaly with steatosis
Stavudine (d4T)	Zerit, BMS	2′,3′-Didehydro-2′,3′-dideoxythymidine	Converted to triphosphate analogue of dTTP by cellular kinases; activity similar to that of ZDV	Peripheral neuropathy, lipodystrophy, motor weakness, lactic acidosis and severe hepatosplenomegaly with steatosis
Lamivudine (3TC)	Epivir, GSK	Dideoxycytidine analogue	Converted to triphosphate analogue of dCTP by cellular kinases; activity similar to that of ZDV	Minimal toxicity, lactic acidosis and severe hepatosplenomegaly with steatosis posttreatment exacerbation of hepatitis B coinfection
Abacavir (ABC)	Ziagen, GSK	Carbocyclic guanosine analogue	Converted to triphosphate analogue of dGTP by cellular kinases; activity similar to that of ZDV	Hypersensitivity reaction, lactic acidosis and severe hepatosplenomegaly with steatosis
Emtricitabine (FTC)	Emtriva, Gilead	Thio-5-fluorocytosine analogue	Converted to triphosphate analogue of dCTP by cellular kinases; activity similar to that of ZDV	Minimal toxicity, lactic acidosis and severe hepatosplenomegaly with steatosis, posttreatment exacerbation of hepatitis B coinfection
Tenofovir (TDF)	Viread, Gilead	Acyclic diester prodrug tenofovir disoproxil fumarate; acyclic analogue of adenosine monophosphate	Diester hydrolysis required for conversion to tenofovir; monophosphate analogue requires diphosphorylation by cellular kinases; activity similar to that of ZDV	Asthenia, headache, GI symptoms, lactic acidosis and severe hepatosplenomegaly with steatosis, posttreatment exacerbation of hepatitis B coinfection
Zidovidine-lamivudine	Combivir, GSK	Combination of ZDV and 3TC	See individual descriptions above	See individual descriptions above
Abacavir-lamivudine	Epzicom, GSK	Combination of ABC and 3TC	See individual descriptions above	See individual descriptions above
Abacavir- zidovudine-lamivudine	Trizivir, GSK	Combination of ABC, ZDV, and 3TC	See individual descriptions above	See individual descriptions above
Tenofovir-emtricitabine	Truvada, Gilead	Combination of TDF and FTC	See individual descriptions above	See individual descriptions above
NNTRIs				
Delavirdine (DLV)	Rescriptor, Pfizer	Nonnucleoside inhibitor of HIV-1 RT	Noncompetitive inhibitor binds to HIV-1 RT; blocks RNA-dependent and DNA-dependent DNA polymerase activity by disruption of catalytic site	Skin rash (Stevens-Johnson syndrome), headache, elevated transaminase levels

Efavirenz (EFV)	Sustiva, BMS	Similar to DLV but structurally unrelated	Activity similar to that of DLV	Skin rash (Stevens-Johnson syndrome), psychiatric symptoms, nervous system symptoms, elevated transaminase levels, teratogenic effects
Nevirapine (NVP)	Viramune, BI	Similar to DLV but structurally unrelated	Activity similar to that of DLV	Severe hepatotoxicity, skin rashes (Stevens-Johnson syndrome)
Protease inhibitors				
Indinavir (IDV)	Crixivan, Merck	Peptidomimetic substrate analogue of HIV-1 and HIV-2 proteases	Binds competitively to active site of HIV protease; prevents cleavage of viral polyprotein precursors; produces immature, noninfectious viral particles	Nephrolithiasis, urolithiasis, hemolytic anemia, headache, hyperglycemia, GI symptoms, fat redistribution, hyperlipidemia, increased bleeding episodes in hemophiliacs
Saquinavir (SQV)	Fortovase, Roche	Similar to IDV; soft-gel formulation	Activity similar to that of IDV	Hyperlipidemia, fat redistribution, GI symptoms, hyperglycemia, hyperlipidemia, elevated transaminase levels, headache, increased bleeding episodes in hemophiliacs
	Invirase	Hard-gel formulation	Activity similar to that of IDV (not interchangeable with Fortovase)	Similar to those of Fortovase
Ritonavir (RTV)	Norvir, Abbott	Similar to IDV	Activity similar to that of IDV	GI symptoms, circumoral paresthesias, hyperlipidemia, hepatitis, asthenia, taste perversion, hyperglycemia, fat redistribution, increased bleeding episodes in hemophiliacs
Lopinavir (LPV)-ritonavir	Kaletra, Abbott	Coformulation of LPV and RTV, 4:1 ratio; similar to IDV	Activity similar to that of IDV	GI symptoms, asthenia, hyperlipidemia, elevated transaminase levels, hyperglycemia, fat redistribution, increased bleeding episodes in hemophiliacs
Amprenavir (APV)	Agenerase, GSK	N,N-Disubstituted hydroxyethylamino sulfonamide	Activity similar to that of IDV	GI symptoms, rash, oral paresthesias, hyperlipidemia, elevated transaminase levels, hyperglycemia, fat redistribution, increased bleeding episodes in hemophiliacs
Fosamprenavir (f-APV)	Lexiva, GSK	Phosphorylated prodrug of APV	Converted to amprenavir by cellular phosphatases; activity similar to that of IDV	Skin rash; GI symptoms, headache, hyperlipidemia, fat redistribution, elevated transaminase levels, hyperglycemia, increased bleeding episodes in hemophiliacs
Atazanavir (ATV)	Reyataz, BMS	Azapeptide aspartyl substrate analogue similar to IDV	Activity similar to that of IDV	Indirect hyperbilirubinemia, prolonged PR interval, hyperglycemia, fat redistribution, increased bleeding episodes in hemophiliacs
Nelfinavir (NFV)	Viracept, Pfizer	Monomethane sulfonate salt of protease substrate analogue similar to IDV	Activity similar to that of IDV	Diarrhea, hyperlipidemia, hyperglycemia, fat redistribution, elevated transaminase levels, increased bleeding episodes in hemophiliacs

(Continued on next page)

TABLE 1 Antiviral agents for HIV (*Continued*)

Antiviral agent (abbreviation)	Trade name, pharmaceutical company[a]	Structure	Mechanism of action	Major adverse effects
Tipranavir (TPV)	Aptivus, BI	Nonpeptidic protease inhibitor; coadministered with RTV	Activity similar to that of IDV	Hepatotoxicity, hyperglycemia, sulfa allergy, rash, hyperlipidemia, fat redistribution, increased bleeding episodes in hemophiliacs
Entry inhibitors				
Enfuvirtide (T20)	Fuzeon, Roche	36-Amino-acid synthetic peptide (residues 127–162 of gp41); N terminus acetylated; C-terminus carboxamide	Binds to first heptad repeat in gp41; prevents conformational changes required for fusion of viral and cellular membranes; administered by injection	Local injection site reactions, pneumonia, hypersensitivity reactions

[a] Pharmaceutical companies: Abbott Laboratories, North Chicago, Ill.; BI, Boehringer Ingelheim Pharmaceuticals, Ridgefield, Conn.; BMS, Bristol-Myers Squibb, Princeton, N.J.; Gilead Sciences, Foster City, Calif.; GSK, GlaxoSmithKline, Research Triangle Park, N.C.; Merck & Co., Whitehouse Station, N.J.; Pfizer, New York, N.Y.; Roche Pharmaceuticals, Nutley, N.J.
[b] GI symptoms include nausea, vomiting, and diarrhea.

Zidovudine

Pharmacology and Therapeutic Regimens

ZDV was the first agent used in antiretroviral therapy (41). The oral bioavailability is 60%, the half-life in serum is 1.1 h, and the intracellular half-life is 7 h. ZDV can be administered without regard to meals. It is metabolized to the glucuronide, which is excreted by the kidneys.

ZDV crosses the blood-brain barrier to achieve effective concentrations in the central nervous system (CNS) and also crosses the placenta (107). It can be given as standard monotherapy that is administered intravenously (i.v.) to pregnant women during labor to prevent maternal-fetal transmission and can be administered orally to the child at birth (24, 107). As alternative intrapartum and postpartum therapy, ZDV can be given orally in combination with lamivudine (3TC) to both mother and neonate. For adults and adolescents, ZDV is recommended as one of the two NRTIs or NtRTIs in preferred or alternative NNRTI-based and PI-based regimens (33).

Drug Interactions

ZDV inhibits the phosphorylation of stavudine (d4T) by thymidine kinase (TK) (56). Ribavirin inhibits the phosphorylation of ZDV (104). Ganciclovir (GCV) and alpha interferon (IFN-α) may enhance the hematologic toxicity associated with ZDV (19, 23).

Didanosine

Pharmacology and Therapeutic Regimens

The oral bioavailability of didanosine (ddI) is 30 to 40%. The half-life in serum is 1.5 h, and the intracellular half-life is >20 h. ddI should be administered without food. However, ddI is unstable at acidic pHs and therefore requires an enteric formulation, antacids, or buffering agents. Half of the drug is excreted by the kidneys. There is limited penetration of the CNS, but ddI has been shown to cross the human placenta (107). ddI is recommended only as alternative therapy with another NRTI or NtRTI in either NNRTI-based or PI-based drug regimens (33).

Drug Interactions

The combination of ddI with either d4T or zalcitabine (ddC) can increase the rates and severities of toxicities associated with each individual drug. Tenofovir (TDF), ganciclovir (GCV), and valganciclovir (val-GCV) increase ddI exposure, leading to increased ddI toxicity (106, 110). Ribavirin may increase the active metabolite of ddI, producing increased toxicity (33).

Zalcitabine

Pharmacology and Therapeutic Regimens

The oral bioavailability of ddC is 85%. The half-life in serum is 1.2 h, and the intracellular half-life is undetermined. ddC can be administered with or without food; however, there is a reduced absorption rate when the drug is taken with meals. Seventy percent of the drug is eliminated unmetabolized by renal excretion. There is limited penetration of the CNS. In animal studies, ddC has been shown to cross the placenta (107). It is recommended as alternative therapy with another NRTI or NtRTI in NNRTI- or PI-based combination therapy (33).

Drug Interactions

The combination of ddC with either ddI or d4T can increase the rates and severities of toxicities associated with each individual drug (33). There is overlapping resistance between ddC and ddI. ddC inhibits the phosphorylation of 3TC.

Stavudine

Pharmacology and Therapeutic Regimens

The oral bioavailability of d4T is 86%. The half-life in serum is 1.0 h, and the intracellular half-life is 7.5 h. d4T can be administered with or without food. Fifty percent of the drug is excreted by the kidneys. Placental passage occurs in animals, and d4T penetrates into the cerebrospinal fluid (CSF) (44, 107). d4T is recommended as an alternative drug in dual NRTI-NtRTI backbones in combination with an NNRTI or PIs (33).

Drug Interactions

d4T combined with either ddI or ddC can increase the rates and severities of toxicities associated with each individual drug. ZDV and ribavirin inhibit the phosphorylation of d4T (56, 63, 104).

Lamivudine

Pharmacology and Therapeutic Regimens

The oral bioavailability of 3TC is 86% in adolescents and adults and 66% in children. The half-life in serum is 5 to 7 h, and the intracellular half-life is 18 to 22 h. 3TC can be administered with or without food. Seventy-one percent of the drug is excreted by the kidneys by active organic cationic secretion. The drug crosses the human placenta (107). 3TC is recommended as part of a preferred therapy regimen in combination with another NRTI or NtRTI and either an NNRTI or PIs for treatment-naïve patients (33).

Drug Interactions

3TC and ddC each inhibit the phosphorylation of the other (33).

Abacavir

Pharmacology and Therapeutic Regimens

The oral bioavailability of abacavir (ABC) is 83%. The half-life in plasma is 1.5 h, and the intracellular half-life is 12 to 26 h. ABC can be administered with or without food. It is metabolized by alcohol dehydrogenase and glucuronyl transferase, and 82% of the metabolites are excreted by the kidneys. Ingestion of ethanol decreases the metabolism and elimination of the drug. Placental passage has been demonstrated in animal studies (107). ABC penetration of the CNS is adequate to inhibit HIV replication (16). It is recommended as an alternative drug in dual NRTI-NtRTI backbones in combination with an NNRTI or PIs (32, 33). Combination formulations of two and three NRTIs or NtRTIs including ABC are commercially available (Table 1).

Drug Interactions

ABC decreases the level of methadone. Alcohol increases the concentration of ABC in plasma through the common metabolic pathways of alcohol and ABC (33).

Emtricitabine

Pharmacology and Therapeutic Regimens

The oral bioavailability of emtricitabine (FTC) is 93%. The half-life in plasma is 10 h, and the intracellular half-life is >20 h. FTC can be administered with or without food. It is excreted mostly unchanged (86%) by the kidneys, and 14% is eliminated in the feces. It is not known whether FTC crosses the placenta (107) or if there is penetration of cells of the CNS (88). FTC is recommended as a preferred drug in combination with another NRTI or NtRTI in either NNRTI-based or PI-based regimens for treatment-naïve patients (33).

Drug Interactions

No significant interactions with other antiretroviral agents have been reported (33, 88).

Tenofovir

Pharmacology and Therapeutic Regimens

The oral bioavailability of tenofovir (TDF) from the prodrug tenofovir disoproxil fumarate is 25% in fasting patients and 39% in patients taking it with a high-fat meal, although the drug is administered without regard to meals. The half-life in plasma is 17 h, and the intracellular half-life is >60 h. The drug is excreted mostly unchanged (70 to 80%) by the kidneys. TDF has been shown to cross the placenta in animal studies (107). It is less likely than other NRTIs and NtRTIs to be associated with mitochondrial toxicity (48). TDF is recommended as a preferred NRTI or NtRTI in dual combination backbones with the NNRTI efavirenz (EFV) (33).

Drug Interactions

TDF increases the concentration of ddI in plasma, leading to increased toxicity (106, 110). There may be increased toxicity associated with the coadministration of GCV, val-GCV, acyclovir (ACV), or cidofovir (CDV) (33, 48).

NRTI and NtRTI Combination Formulations

There are four fixed-dose double or triple combinations available as commercial formulations for convenience of administration: ABC-3TC-ZDV (Trizivir), ABC-3TC (Epzicom), FTC-TDF (Truvada), and 3TC-ZDV (Combivir). The triple combination ABC-3TC-ZDV is recommended only when preferred or alternative NNRTI- or PI-based regimens cannot be used for treatment-naïve patients because of potential drug interactions. Clinical trials have shown the ABC-3TC-ZDV combination to be equivalent to PI-based regimens but inferior to NNRTI-based regimens in reducing HIV RNA loads in plasma below detectable levels (33, 51, 121). The dual combinations are used as NRTI-NtRTI backbones in combination with an NNRTI or PIs in triple or quadruple drug therapy.

Nonnucleoside Reverse Transcriptase Inhibitors

Drugs in the NNRTI class do not require intracellular anabolism for activation. There is no common structure; however, they bind noncompetitively to a catalytic site on the HIV-1 RT but not the HIV-2 RT. The disruption of DNA polymerization activity leads to premature DNA chain termination (27, 31). There are currently three FDA-approved NNRTIs: NVP, delavirdine (DLV), and EFV. All are metabolized by the cytochrome P450 (CYP450) system, which also metabolizes the PIs (see below) and other drugs used to

treat conditions associated with HIV infection. Drug-drug interactions can lead to either induction or inhibition of the metabolism of other antiretroviral agents and medications for associated symptoms. NNRTIs are used as part of triple therapy regimens with two NRTIs or NtRTIs to preserve the effectiveness and delay exposure to the adverse effects of PIs. A disadvantage of the NNRTIs is the relatively low number of mutations required to confer cross-resistance to all drugs in this class (33).

Delavirdine

Pharmacology and Therapeutic Regimens

The bioavailability of DLV is 85%, and the half-life in plasma is 5.8 h. DLV can be administered with or without food. The level of plasma protein binding is 98%, and there is little CNS penetration. DLV is metabolized primarily in the liver by the CYP450 system and is an inhibitor of CYP3A4. The metabolites are excreted in the urine (51%) and eliminated in the feces (44%). Placental passage of DLV has not been determined (107). DLV is not recommended for use in combination regimens for treatment-naïve patients, because it has lower antiviral activity and requires more frequent dosing than the other NNRTIs (33).

Drug Interactions

Dose modifications or cautious use is indicated for antifungal agents ketoconazole and voriconazole, oral contraceptives, methadone, and erectile dysfunction drugs. Coadministration of the following drugs with DLV is contraindicated: lipid-lowering agents simvastatin and lovastatin; the gastrointestinal (GI) motility agent cisapride; histamine$_2$ (H2) blockers; proton pump inhibitors; anticonvulsants phenobarbitol and phenytoin; sedatives and hypnotics; ergot derivatives; antimycobacterial drugs rifampin, rifapentin, and rifabutin; the herb St. John's wort; and the PIs amprenavir (APV) and fosamprenavir (f-APV) (33, 104).

Efavirenz

Pharmacology and Therapeutic Regimens

The oral bioavailability of EFV is undetermined. The half-life in serum is 5.8 h. The levels in plasma are increased when the drug is administered with a high-fat or high-calorie meal. EFV is 99.5% protein bound in the plasma, mainly to albumin. CNS penetration is low, but EFV has been shown to cross the placenta in animals (107). EFV is metabolized by CYP3A4 and CYP2B6 and is an inducer and inhibitor of CYP3A4. Glucoronidated metabolites are excreted in the urine (14 to 34%) and eliminated in the feces (16 to 61%). EFV is the preferred NNRTI in triple regimens with two NRTIs or NtRTIs, except for pregnant women, because teratogenic effects have been observed in cynomologus monkeys during the first trimester of pregnancy (33).

Drug Interactions

Dose modifications may be necessary for potential drug interactions between EFV and the following: indinavir (IDV), lopinavir (LPV), APV, ritonavir (RTV), nelfinavir (NFV), clarithromycin, methadone, and oral contraceptives (33, 104). Contraindicated drugs are rifapentine, cisapride, sedatives and hypnotics, ergot derivatives, St. John's wort, voriconazole, and saquinavir (SQV) as the sole PI.

Nevirapine

Pharmacology and Therapeutic Regimens

The oral bioavailability of NVP is >90%, and the half-life in serum is 25 to 30 h. NVP is 60% protein bound, and the concentration in the CSF is 45% of the concentration in plasma. NVP can be administered with or without food. It is metabolized in the liver by CYP450 isoenzymes and is a CYP3A4 inducer. Glucuronidated metabolites are excreted in the urine (80%) and feces (10%). NVP is known to cross the human placenta (107). It has been used in resource-limited regions as a single agent, which can be administered orally, in an intrapartum and newborn prophylaxis regimen to prevent maternal-fetal transmission (107). NVP is recommended only as an alternative to EFV in NNRTI-based combination regimens with NRTIs and NtRTIs for adult females with $CD4^+$ T-cell counts of $\leq$250 cells/mm^3 or males with counts of $\leq$400 cells/mm^3 (33).

Drug Interactions

NVP reduces the concentrations of IDV, SQV, oral contraceptives, ketoconazole, clarithromycin, and methadone in plasma (104). Coadministration of rifampin, rifapentine, or St. John's wort with NVP is contraindicated (33).

Protease Inhibitors

The introduction of PIs in 1996 significantly improved HIV antiviral therapy by inhibiting HIV disease progression and greatly improving prognosis. This class of drugs, like the NNRTIs, requires no intracellular anabolism for antiviral activity. The target is the protease encoded by HIV-1 and HIV-2, which is required for posttranslational processing of the precursor Gag and Gag-Pol polyproteins (27, 39, 45). Competitive inhibition of the protease by PIs results in production of immature noninfectious viral particles.

PIs are commonly used in HAART regimens in combination with NRTIs and NtRTIs to achieve maximum antiretroviral activity and to minimize the development of resistance. PI-based regimens introduced initially led to treatment failure related to the limited bioavailability, frequent dosing, and toxicity. There are several characteristics of PIs that affect their bioavailability and toxicity. They are highly bound to plasma protein, mainly alpha-1 acid glycoprotein (AAG) (42, 71). The low concentration of unbound drug is responsible for the therapeutic activity as well as the toxicity. PIs are substrates for P-glycoprotein and multidrug resistance-associated protein (136). These are efflux transporters, which enhance the elimination of the drugs from cells in the intestine, liver, and kidneys (138) and reduce intracellular drug concentrations. All of the PIs are metabolized in the intestine and liver by enzymes of the CYP450 system (12), mainly CYP3A, CYP2C9, and CYP2C19. An individual PI can induce and/or inhibit specific CYP450 isoenzymes, which can enhance or reduce the PI's own metabolism or that of other PIs. As noted above, the CYP450 system metabolizes the NNRTIs and numerous other drugs that may be used for conditions associated with HIV infection. Thus, the choice of treatment regimens is complicated by multiple potential drug-drug interactions which may enhance toxicity and/or require modifications of doses of coadministered drugs (33).

Although most PIs are inhibitors of CYP3A4, RTV is the most inhibitory. For this reason, RTV is used in boosting regimens to improve the pharmacokinetic profile of a second PI (109, 138). Subtherapeutic concentrations of RTV increase the systemic exposure of a second PI by reducing the rate

of metabolism and increasing the half-life (12), which lowers dosing requirements and lessens food effects for the second drug. An example is LPV, which alone has very little bioavailability and a very short half-life but in combination with RTV is used therapeutically both for treatment-naïve patients and for salvage therapy (25). The effect of RTV on the pharmacokinetics of other PIs varies as a result of differences in interactions with components of the CYP450 system that determine bioavailability (138). Specific recommendations are described below for each drug.

Indinavir

Pharmacology and Therapeutic Regimens

The bioavailability of IDV is 65%, and the half-life in serum is 1.5 to 2.0 h. IDV should be administered with low-calorie, low-fat food. It is 60% plasma protein bound, mainly to AAG (71). IDV is an inhibitor of CYP3A4, although it is less inhibitory than RTV (see below). The majority of the drug (83%) is eliminated as metabolites in the feces. There is minimal passage of IDV across the placenta (107), but it penetrates into the CSF (64, 139).

IDV can be used in RTV-boosted regimens with two NRTIs or NtRTIs for treatment-naïve patients (33). Unboosted IDV is not recommended in PI-based regimens because of its multiple dosing and fasting requirements.

Drug Interactions

Coadministered drugs that require dose modifications or cautious use include antifungal agents, anticonvulsants, the lipid-lowering agent atorvastatin, and erectile dysfunction agents. Other drug classes that are contraindicated for coadministration with IDV include nonsedating antiarrhythmics, the lipid-lowering agents simvastatin and lovastatin, antimycobacterial drugs rifampin and rifapentine, ergot derivatives, sedatives and hypnotics, the GI motility agent cisapride, the neuroleptic pimozide, and St. John's wort. IDV should not be used with atazanavir (ATV) because of additive adverse effects of hyperbilirubinemia and jaundice (33, 104).

Saquinavir

Pharmacology and Therapeutic Regimens

The oral bioavailability of Invirase, the hard-gel capsule formulation of SQV, is approximately 4%. The bioavailability of Fortovase, the soft-gel capsule formulation, is higher but not completely determined. The half-life in serum of both formulations is 1 to 2 h. SQV is metabolized by CYP450 and is a CYP3A4 inhibitor. It is 97% bound to plasma proteins and is eliminated mainly in the feces as metabolic products (33). There is minimal passage of SQV across the placenta (107).

SQV can be used in RTV-boosted regimens with two NRTIs or NtRTIs for treatment-naïve patients. Unboosted SQV is not recommended in PI-based regimens because of low oral bioavailability, multiple dosing requirements, and a high pill burden (33).

Drug Interactions

Coadministered drugs that require dose modifications or cautious use include antifungal agents, lipid-lowering agents atorvastatin and pravastatin, anticonvulsants, methadone, and erectile dysfunction agents. Drugs that are contraindicated for coadministration with SQV include simvastatin and lovastatin, rifampin and rifabutin, cisapride, pimozide, sedatives and hypnotics, ergot derivatives, St John's wort and garlic supplements, and dexamethasone (33, 104).

Ritonavir

Pharmacology and Therapeutic Regimens

The oral bioavailability of RTV is undetermined, and the half-life in serum is 3 to 5 h. RTV needs to be administered with food. It is 98% plasma protein bound and is metabolized by CYP3A. The major metabolite is isopropylthiazole, which has the same antiviral activity as the parent drug. The route of elimination of the oxidative metabolites and unaltered drug is fecal (33). Passage across the placenta is minimal (107).

The main role of RTV in current HIV therapeutics is to enhance the pharmacokinetics of a second PI (25, 138), because RTV is such a strong inhibitor of CYP450 isoenzymes. RTV-boosted PIs are recommended in combination with two NRTIs or NtRTIs in several PI-based regimens for treatment-naïve patients. RTV is a pharmacoenhancer of IDV, APV, SQV, LPV, ATV, and to a lesser degree NFV. The use of RTV alone in PI-based regimens is not recommended because of GI intolerance (33).

Drug Interactions

In general, RTV is a very strong inhibitor of CYP3A4 that has numerous potential drug interactions requiring close monitoring (33, 104). Coadministered drugs that require dose modifications or cautious use include antifungal agents, rifampin, rifabutin, clarithromycin, atorvastatin, pravastatin, anticonvulsants, methadone, erectile dysfunction agents, desipramine, and theophylline. Drugs whose effects may be decreased by RTV coadministration include anticoagulants, anticonvulsants, and antiparasitics. Drugs that are contraindicated for coadministration with RTV include the calcium channel blocker bepridil; cardiac drugs amiodarone, flecainide, propafenone, and quinidine; simvastatin and lovastatin; rifapentine; cisapride; pimozide; sedatives and hypnotics; ergot derivatives; oral contraceptives (ethinyl estradiol); and St. John's wort.

Lopinavir-Ritonavir

Pharmacology and Therapeutic Regimens

LPV is administered only in combination with low-dose RTV (r). The bioavailability of LPV/r is undetermined, and the half-life is 5 to 6 h. It should be taken with food of moderate fat content. The level of plasma protein binding is 99%. LPV/r is metabolized by the CYP450 isoenzymes and inhibits CYP3A4 and to a lesser extent CYP2D6. It is eliminated mainly in the feces and urine as metabolites. It is not known whether LPV crosses the placenta (107). LPV/r is the preferred drug combination in PI-based regimens with two NRTIs or NtRTIs for treatment-naïve patients (33).

Drug Interactions

The interactions of LPV/r are similar to those of RTV alone (33, 104) (see above).

Amprenavir

Pharmacology and Therapeutic Regimens

The bioavailability of APV is undetermined, and the half-life in serum is 7.1 to 10.6 h. APV can be administered with or without food, but high-fat-content meals should be avoided. The level of plasma protein binding is 90%. APV is metabolized in the liver by CYP3A4, of which it is an

inhibitor and inducer (33, 40). Approximately 90% is eliminated as metabolites in the feces and urine. It is not known whether APV crosses the placenta (107).

APV either boosted or unboosted with RTV is not recommended for treatment-naïve patients because of the high pill burden (33). The oral solution contains propylene glycol, which is contraindicated for pregnant women and young children.

Drug Interactions

Drugs that require dose modifications or cautious use with APV include antifungal agents, rifabutin, atorvastatin, anticonvulsants including methadone, erectile dysfunction agents, H2 receptor antagonists, and proton pump inhibitors (33, 43). Drugs that are contraindicated for coadministration with APV include the calcium channel blocker bepridil, simvastatin and lovastatin, rifampin and rifapentine, cisapride, pimozide, sedatives and hypnotics, ergot derivatives, St. John's wort, and oral contraceptives (33, 104). The oral solution of RTV contains ethanol; therefore, it should not be used to boost the oral solution of APV, because the two solutions use the same metabolic pathway for elimination (33). APV and its prodrug f-APV should not be used together, because there is no benefit and there is potential additive toxicity. DLV is also contraindicated with APV.

Fosamprenavir

Pharmacology and Therapeutic Regimens

f-APV is a prodrug with no antiviral activity but must be converted to APV by cellular phosphatases (40) (see "Amprenavir" above). It is not known whether f-APV crosses the placenta (107). RTV-boosted f-APV is recommended in alternative PI-based regimens with two NRTIs or NtRTIs for treatment-naïve patients (33).

Drug Interactions

See "Amprenavir" above.

Atazanavir

Pharmacology and Therapeutic Regimens

ATV is an azapeptide PI that differs structurally from other peptidomimetic PIs. The bioavailability is undetermined, and the half-life in serum is 7 h. The bioavailability, however, is increased by administration with food. ATV is 86% protein bound and penetrates the CNS (99). It is metabolized in the liver by CYP3A4, and it is also an inhibitor of this enzyme. The metabolites are eliminated in the feces. It is not known whether ATV crosses the placenta (107).

ATV has the advantage of once-daily dosing and a low pill burden, and the drug exposure can be increased by boosting with RTV (55). ATV is recommended for use in alternative PI-based regimens with two NRTIs or NtRTIs (33).

Drug Interactions

ATV should not be used with IDV because of additive adverse effects of hyperbilirubinemia and jaundice. Drugs that require dose modifications or cautious use include antifungal agents; rifabutin and clarithromycin; oral contraceptives; atorvastatin; anticonvulsants carbamazepine, phenobarbital, and phenytoin; erectile dysfunction agents; H2 receptor antagonists; proton pump inhibitors; and antacids and buffered medications. Drugs that are contraindicated for coadminstration with ATV include the calcium channel blocker bepridil, simvastatin and lovastatin, rifampin and rifapentine, cisapride and proton pump inhibitors, pimozide, sedatives and hypnotics, ergot derivatives, St. John's wort, and irinotecan (33, 104).

Nelfinavir

Pharmacology and Therapeutic Regimens

The bioavailability of NFV is 20 to 80%, and the half-life in serum is 3.5 to 5 h. NFV shows the greatest accumulation in cells compared to the other PIs; however, the level of protein binding is >98% (42). It is administered with food, which increases the bioavailability. NFV is metabolized by CYP450 isoenzymes and is both an inhibitor and an inducer of CYP3A4 (40). There is minimal placental passage (107). NFV is used in alternative PI-based regimens with two NRTIs or NtRTIs for treatment-naïve patients (33).

Drug Interactions

Drugs that require dose modifications or cautious use include antifungal agents, rifabutin, atorvastatin, anticonvulsants including methadone, and erectile dysfunction agents. Drugs that are contraindicated for coadministration with NFV include simvastatin and lovastatin, rifampin and rifapentine, cisapride, pimozide, sedatives and hypnotics, ergot derivatives, St. John's wort, and oral contraceptives (33, 104).

Tipranavir

Pharmacology and Therapeutic Regimens

Tipranavir (TPV), a nonpeptidic PI (136), is the most recently approved of the PI class of drugs. The bioavailability is undetermined, and the half-life in serum is 4.8 to 6 h. The drug should be taken with food. TPV is >99.9% protein bound in plasma to both albumin and AAG. Metabolism is mainly through CYP3A4. However, most of the drug is eliminated unchanged in the feces. It is not known whether TPV crosses the placenta (107). TPV requires coadministration with RTV to reach effective levels in plasma (12, 86). The current indicated use is for patients who are highly treatment-experienced or who are infected with virus strains resistant to multiple PIs.

Drug Interactions

TPV decreases ethinyl estradiol concentrations, and therefore nonhormonal contraception methods should be used, and it also reduces methadone levels. Classes of drugs that are contraindicated include antiarrhythmics, antihistamines, ergot derivatives, cisapride, pimozide, and sedatives and hypnotics. Coadministration of APV, LPV, or SQV with RTV-boosted TPV is not recommended (12).

Fusion Inhibitors

A new class of antiretroviral agents has been developed that target the entry of HIV into the host cell. Enfuvirtide (T20) is the first member of this class to be approved. It is a linear synthetic peptide of 36 amino acids that binds to the first heptad repeat in the gp41 subunit of the HIV-1 envelope glycoprotein. The sequence of the peptide was derived from that of HIV-1(LAI), a subtype B strain. The binding prevents conformational changes that are required for fusion between the virus envelope and the cell membrane (93). Entry is inhibited, thereby preventing infection of the target cell. This is a novel antiviral mechanism, because the drug is active outside rather than inside the cell.

Enfuvirtide

Pharmacology and Therapeutic Regimens

T20 is administered by subcutaneous injection. The bioavailability is 84% (93), and the half-life in serum is 3.8 h. It is assumed that the metabolism of the drug produces the constituent amino acids, which enter the amino acid pool in the body and are recycled. It is not active against HIV-2, but there are recent data that suggest that it is active against non-B subtypes and possibly group O as well (105). It is not known whether T20 crosses the placenta (107). It is presently used for the treatment of HIV-1 infection in treatment-experienced patients (33).

Drug Interactions

There is no evidence that T20 induces or inhibits any of the CYP450 isoenzymes; therefore, it is unlikely to interact with any of the drugs that are metabolized by the CYP450 system. No significant interactions with other antiretroviral drugs have been identified (93).

AGENTS ACTIVE AGAINST HEPATITIS B VIRUS

There are two major classes of drugs available to treat HBV infection: nucleoside and nucleotide analogues and interferons. Because a large percentage of patients are coinfected with HIV, these agents can also be categorized by whether they have activity against both viruses or only HBV. Of the drugs that are specifically approved for use against HBV, IFN-α2a and IFN-α2b, pegylated IFN-α2a and IFN-α2b, adefovir (ADV), and entecavir are active only against HBV, and 3TC is active against both HBV and HIV. TDF and FTC are approved only for use against HIV but have also been shown to have activity against HBV (8, 33, 50, 73, 127). The common target for antiviral drugs active against both viruses is the RT function of the HIV and HBV replication enzymes (137).

Chronic HBV infection plays an important role in the morbidity and mortality of HIV-infected patients (119). The strategy for treating coinfected patients is to determine whether infection with only one virus or that with both viruses needs to be treated. If only HIV infection needs to be treated, drugs with activity against both HIV and HBV, such as 3TC and TDF, should be withheld. If only HBV infection needs to be treated, drugs without anti-HIV activity, such as pegylated interferon and ADV, can be used. If infection with both viruses needs to be treated, HAART regimens with NRTIs or NtRTIs such as 3TC and TDF that suppress replication of both viruses should be considered (33). 3TC monotherapy rapidly selects for HBV resistance (89, 119); therefore, combination therapy with one NRTI (3TC or FTC) and one NtRTI (TDF or ADV) may be effective (8, 119). Pegylated interferon is used to treat HBV infection, but the side effects limit the length of therapy, and the response appears to be lower in HIV-HBV-coinfected patients (119). There is also some evidence that the HBV genotypes (A through H) may affect the response to therapy. Genotype A appears to be associated with the best response (1, 11, 68, 119).

Nucleoside and Nucleotide Analogues

Lamivudine

3TC (Table 1) was the first nucleoside analogue that was approved for the treatment of chronic HBV infection. Because it has activity against both HIV and HBV, it has been effective in reducing loads of both viruses in plasma as part of HAART regimens. However, HBV-specific drug resistance mutations are selected over long-term therapy at a higher rate (20% per year) in coinfected patients than in those that are HIV negative (10). Discontinuation of 3TC by HBV-infected patients can produce severe flare-ups of liver transaminase levels, which are usually self-limited but have been fatal in a few cases. Another common problem is the rebound viremia that occurs when therapy is terminated (33). This is thought to be derived from the viral covalently closed circular DNA, which is not affected by nucleoside or nucleotide therapy and remains in the infected hepatocytes (137).

Pharmacology

See the section on HIV antiviral agents above. 3TC has activity against both HIV and HBV. The selection of HBV drug resistance mutations eventually decreases efficacy for the treatment of chronic hepatitis. Recent recommendations suggest combination dual NTRI-NtRTI therapy using TDF for coinfected patients to reduce the rate of selection of HBV 3TC-resistant strains (119).

Drug Interactions

See the section on HIV antiviral agents above.

Adefovir

Structure and Mechanism of Action

The prodrug adefovir dipivoxil (ADV) is manufactured by Gilead Sciences (Foster City, Calif.) as Hepsera. It is a diester of ADV, which is an acyclic nucleotide analogue of adenosine monophosphate. It was originally developed as an antiretroviral drug; however, the high doses required were associated with nephrotoxicity (137). A much lower dosage is effective against HBV (52). It is diphosphorylated by cellular kinases into the triphosphate form, which is a substrate for the RT activity of the HBV DNA polymerase. Incorporation of ADV into the replicating viral DNA causes chain termination.

Adverse Effects

The most frequently reported adverse reactions associated with ADV therapy are asthenia, headache, and GI symptoms. Nephrotoxicity can occur in patients with underlying renal dysfunction and those taking nephrotoxic agents such as cyclosporine, tacrolimus, aminoglycosides, vancomycin, and nonsteroidal anti-inflammatory drugs. Discontinuation of therapy can produce severe acute exacerbation of hepatitis (33).

Pharmacology

The bioavailability is 59%, and the half-life in serum is 7.5 h. ADV is administered without regard to food. It is excreted by the kidneys. There are no data for placental passage of the drug. ADV is recommended for the treatment of HBV infection in patients with 3TC-resistant virus (128).

Drug Interactions

ADV does not alter the pharmacokinetics of 3TC and TDF. The bioavailability appears to be increased by ibuprofen.

Entecavir

Structure and Mechanism of Action

Entecavir is manufactured by Bristol-Myers Squibb (Princeton, N.J.) as Baraclude and received FDA approval in

March of 2005. It is a carboxylic 2′-deoxyguanosine analogue, which inhibits three stages of HBV replication: priming, reverse transcription, and plus-strand DNA synthesis (74, 115, 137). It does not appear to affect mitochondrial DNA replication (74, 119).

Adverse Effects

Severe acute exacerbations of HBV infection may occur in patients who discontinue therapy. Common adverse effects are headache, fatigue, dizziness, and GI symptoms (74).

Pharmacology

The bioavailability is approximately 100%, and the half-life in serum is 15 h (74). Entecavir should be administered without food. It is excreted mainly as unmetabolized drug by the kidneys.

Drug Interactions

Entecavir is not a substrate, inhibitor, or inducer of any of the CYP450 isoenzymes. There is no interaction with 3TC, ADV, or TDF. It is possible that drugs that reduce renal function or compete for active tubular secretion may increase the concentration of entecavir in serum and/or that of the coadministered drug.

Tenofovir Disoproxil Fumarate

TDF (Table 1) is approved for the treatment of HIV-infected patients. It has repeatedly been shown to have activity against HBV, but it is not licensed for this purpose (127, 137). It does not show cross-resistance with HBV 3TC-resistant mutants, and it appears to have a lower potential for the selection of resistance mutations. For this reason, it is being considered as a component in combination therapy for coinfected patients to reduce the possibility of selection of HBV drug-resistant mutants (8, 119). Severe flare-ups of hepatic enzyme levels have been reported in coinfected patients who have discontinued TDF therapy (33).

Emtricitabine

FTC (Table 1) is approved for therapy of HIV-infected patients. It has activity against HBV but is not licensed for anti-HBV therapy. FTC and 3TC are biochemically similar and appear to be interchangeable for potential use in the treatment of HIV-HBV-coinfected patients (119). However, they also share the same HBV resistance mutations; therefore, combination therapy with these two drugs is not recommended (137). In addition, as with 3TC, severe acute exacerbations of HBV infection can occur once therapy is discontinued (33).

Interferons

IFN-α is a type I interferon naturally secreted by hematopoietic cells. There are multiple members of the IFN-α family, with broad biological effects including antiviral, antiproliferative, and immunomodulatory activities (116). Recombinant forms of some of these molecules have been developed as antiviral agents and approved for the treatment of HBV and HCV infection (see below).

Interferon-α2a and Interferon-α2b and Pegylated Interferon-α2a and Interferon-α2b

Structure and Mechanism of Action

The IFN-α agents are produced through recombinant DNA technology from cloned human leukocyte interferon genes expressed in *Escherichia coli*. The standard IFN-α2a (RoferonA; Roche Pharmaceuticals, Nutley, N.J.) and IFN-α2b (Intron-A; Schering-Plough) are 20,000-molecular-weight proteins. The pegylated interferons (peginterferon) are covalent conjugates of standard interferon with branched (2a) or straight (2b) polyethylene glycol (PEG) chains. The molecular masses are 31,000 (2a) and 60,000 (2b) Da. Peginterferons 2a and 2b are manufactured as Pegasys (Roche) and PEG-Intron (Schering-Plough), respectively.

Interferons bind to specific cell membrane receptors. Binding to the receptors activates an intracellular signaling cascade, which leads to the expression of a multitude of interferon-stimulated genes. There are broad biological effects resulting from the expression of these genes, which include the inhibition of viral replication in infected cells as well as decreased cell proliferation, increased apoptosis, and increased phagocytosis by macrophages (116).

Pharmacology

Interferon is administered by subcutaneous injection. Peginterferon has decreased renal clearance and a greatly extended half-life compared to standard interferon. The longer half-life allows for once-weekly dosing (122). Peginterferon is recommended for the treatment of patients with HBe antigen-negative or antigen-positive chronic hepatitis B (47, 68, 75, 84). In recent studies, combination therapy with peginterferon and 3TC did not produce a better response than therapy with peginterferon alone in these patients (75, 84), although staggered therapy with peginterferon and 3TC may improve the rate of virologic response (20). There is some evidence that HBV genotypes may affect the response to treatment (1, 68, 75).

Adverse Effects

There are a number of serious conditions induced by interferon therapy. These include life-threatening or fatal neuropsychiatric reactions (suicide, depression, and drug addiction), severe bacterial infections associated with neutropenia, bone marrow toxicity with severe cytopenias, flu-like syndrome (headache, fatigue, myalgia, and abdominal pain), GI symptoms (anorexia, diarrhea, and nausea), myocardial infarction, and stroke (68, 101, 122).

Drug Interactions

The potential for interaction of peginterferon with drugs metabolized by the CYP450 isoenzymes in patients with hepatitis is not known. Peginterferon therapy is contraindicated in patients with advanced HBV-related cirrhosis (89).

AGENTS ACTIVE AGAINST HEPATITIS C VIRUS

The only antiviral agents that have shown any activity in achieving a sustained virologic response against chronic HCV infection are standard IFN-α2a and IFN-α2b, pegylated IFN-α2a and IFN-α2b, and combinations of these interferons with ribavirin. Ribavirin monotherapy is not effective against HCV infection (126). Numerous studies have led to the current standard of care, which is combination therapy with pegylated IFN-α and ribavirin (5, 46, 83, 122, 125). There is also good evidence that the HCV genotype is predictive of the response to therapy. Of the six HCV genotypes, genotypes 2 and 3 are the most susceptible to therapy, and the rates of sustained virologic responses are lower for genotypes 1, 4, 5, and 6 (77, 82, 101, 122).

Interferons

Interferon-α2a and Interferon-α2b and Pegylated Interferon-α2a and Interferon-α2b

See the section on HBV agents above.

Other Agents

Ribavirin

Structure and Mechanism of Action

Ribavirin is a synthetic nucleoside analogue with the structure 1-beta-D-ribofuranosyl-1*H*-1,2,4-triazole-3-carboxamide. It is manufactured as Rebetol by Schering-Plough and as Copegus by Roche for the treatment of HCV infection. It is not known how ribavirin combined with peginterferon inhibits HCV.

Ribavirin has in vitro activity against several other RNA viruses, including respiratory syncytial virus (RSV) and Lassa fever virus (100). In cell cultures, the inhibitory activity of ribavirin for RSV is selective. Reversal of the in vitro antiviral activity by guanosine or xanthosine suggests that ribavirin may act as an analogue of these cellular metabolites, although the mode of action is unknown. However, clinical trials with ribavirin show that the drug is not effective in the treatment of RSV infections (90).

Pharmacology

The bioavailability is increased by a high-fat meal; therefore, ribavirin should be administered with food. The multiple-dose half-life of ribavirin in plasma is 12 days, and the drug may persist in other body compartments for up to 6 months. The pathway for elimination has not been determined. Ribavirin appears not to be a substrate for the CYP450 isoenzymes.

Adverse Effects

Animal studies have demonstrated teratogenic and embryocidal effects. These observations, along with the persistence of the drug, are the reasons ribavirin is strongly contraindicated during pregnancy. Major adverse effects include hemolytic anemia, aggravation of underlying cardiac disease, hepatic failure, and pulmonary symptoms (83, 122). Ribavirin is always given in combination with interferon for the treatment of HCV infection; therefore, additional adverse effects are associated with interferon therapy (see above).

Drug Interactions

HIV-HCV coinfection can be treated; however, the pill burden and potential drug interactions may affect the regimen. Cases of hepatic failure have been reported with NRTIs, in particular ddI and ZDV. ZDV plus ribavirin is linked to higher rates of anemia (33).

AGENTS ACTIVE AGAINST HERPESVIRUSES

The majority of the antiviral compounds that are active against the herpesviruses are nucleoside or nucleotide analogues, which inhibit DNA replication. Several of these compounds require phosphorylation by a viral enzyme as well as cellular kinases for activation. In most cases the ultimate target is the activity of DNA polymerase, although other enzymatic steps in DNA synthesis also may be inhibited (31). Besides the nucleoside and nucleotide analogues, the antiherpes compounds include a pyrophosphate analogue (foscarnet [PFA]) that targets the DNA polymerase directly, an antisense oligonucleotide (fomivirsen), and an entry inhibitor (docosanol). The structure, mode of action, pharmacology, and adverse effects of each drug are summarized in Table 2.

Acyclovir and Valacyclovir

The selective activity of the acyclic guanosine analogue ACV against herpes simplex virus (HSV) was first reported in 1977 (37). ACV was one of the first effective anti-HSV compounds available clinically and has been in general use for the treatment of serious HSV infections for the past 25 years. Val-ACV, the L-valyl ester, is rapidly converted to ACV (67) after administration.

ACV is phosphorylated by the viral TK (36) and then phosphorylated into the di- and triphosphate forms by cellular enzymes. ACV triphosphate competes with dGTP for the viral DNA polymerase. Incorporation of ACV into the growing DNA chain prevents further nucleotide extension of the viral DNA.

Spectrum of Activity

ACV is active against HSV-1, HSV-2, and varicella-zoster virus (VZV) (80) and is commonly used to treat serious infections caused by these viruses. ACV is also activated by the UL97 kinase of human cytomegalovirus (HCMV) (124) and is recognized by the HCMV DNA polymerase. ACV has been used for prophylactic treatment to prevent HCMV disease in patients following transplantation (7, 60, 96, 111).

Pharmacology

The pharmacokinetics of ACV after oral administration have been evaluated in healthy volunteers and in immunocompromised patients with HSV and VZV infection. The level of protein binding in plasma is from 9 to 33%, and the average bioavailability is from 10 to 20%. The elimination half-life in plasma is 2.5 to 3.3 h. ACV may be administered with or without food.

ACV is excreted by the kidneys in an amount accounting for 62 to 91% of the dose administered. The only known urinary metabolite is 9-[(carboxymethoxy)methyl] guanine. The half-life and total body clearance of ACV are dependent on renal function. A dosage adjustment is recommended for patients with reduced renal function. The half-life and total body clearance of ACV in pediatric patients over 1 year of age are similar to those in adults with normal renal function.

The oral formulation of ACV continues to be used widely. In addition, an oral prodrug of ACV, val-ACV, is available and has improved bioavailability compared to the parent compound (120).

Drug Interactions

No clinically significant interactions have been identified for ACV.

Penciclovir and Famciclovir

Penciclovir (PCV) is structurally related to ACV and is also a selective inhibitor of HSV. Famciclovir (FCV), the oral prodrug, is the diacetyl 6-deoxy analogue of PCV (129) and undergoes rapid transformation into the active compound PCV. There are differences in the anabolism of PCV compared to that of ACV. PCV has a higher affinity for the HSV TK than ACV, resulting in higher levels of PCV triphosphate in HSV-infected cells. PCV triphosphate is more stable in HSV-infected cells, resulting in a 10- to 20-fold longer half-life than that of ACV triphosphate. The HSV DNA polymerase, however, has a higher affinity for ACV

TABLE 2 Antiviral agents for herpesviruses

Antiviral agent (abbreviation)	Trade name, pharmaceutical company[a]	Structure	Mode of action and route of administration	Major adverse effects
Acyclovir (ACV)	Zovirax, GSK	2-Amino-1,9-dihydro-9-[(2-hydroxyethoxy)methyl]-6*H*-purine-6-one	Converted to monophosphate by viral TK; converted to triphosphate by cellular kinases; DNA chain terminator; available as oral or i.v. formulations	Minimal toxicity, nausea, vomiting, headache, diarrhea, precipitation in renal tubules if maximum solubility exceeded
Valacyclovir (val-ACV)	Valtrex, GSK	L-Valyl ester of acyclovir	Mode of action same as that of ACV; oral formulation results in increased bioavailability	Nausea, headache, vomiting, dizziness, abdominal pain
Penciclovir (PCV)	Denavir, Novartis	9-[4-Hydroxy-3-(hydroxymethyl)butyl] guanine	Mode of action same as that of ACV; topical formulation for treatment of herpes labialis	Headache and application site reaction no different from those with placebo
Famciclovir (FCV)	Famvir, Novartis	Diacetyl 6-deoxy analogue of PCV	Mode of action same as that of ACV; oral form of penciclovir	Headache, nausea, diarrhea
Ganciclovir (GCV)	Cytovene, Roche	9-[2-Hydroxy-1-(hydroxymethyl) ethoxy] methyl guanine	Converted to monophosphate by HCMV UL97 kinase or HSV or VZV TK; converted to triphosphate by cellular kinases; DNA chain terminator; oral and i.v. formulations	Fever, neutropenia, anemia, thrombocytopenia, impaired renal function, diarrhea
Valganciclovir (val-GCV)	Valcyte, GSK	L-Valyl ester of GCV	Mode of action same as that of GCV; oral form of ganciclovir that results in increased bioavailability	Diarrhea, neutropenia, nausea, headache, anemia
Foscarnet (PFA)	Foscovir, AstraZeneca	Trisodium phosphonoformate	Pyrophosphate analogue; interferes with pyrophosphate binding site of DNA polymerase; i.v. administration	Renal impairment, fever, nausea, anemia, diarrhea, vomiting, headache, seizures, altered electrolytes in serum
Cidofovir (CDV)	Vistide, Gilead	1-[(*S*)-3-Hydroxy-2-(phosphonomethoxy)propyl] cytosine; formerly called HPMPC	Converted to di- and triphosphate by cellular kinases; DNA chain terminator; i.v. administration with probenecid	CDV: renal toxicity, decreased intraocular pressure, neutropenia, fever; probenecid: nausea, vomiting, headache, rash
Fomivirsen	Vitravene, Novartis	Oligonucleotide complementary to IE2 transcript of HCMV	Binding of the oligonucleotide to mRNA blocks translation of IE2 gene product and virus replication; administered by ophthalmic injection	Uveitis, iritis, vitritis
Vidarabine (Ara-A)	Generic	9*H*-Purin-6-amino-9-β-D-arabinofuranosyl-monohydrate	Mode of action not well understood; appears to inhibit viral DNA synthesis; ophthalmic ointment for topical use	Lacrimation, conjunctival pain, keratitis, photophobia
Trifluridine	Viroptic, Monarch	α,α,α-Trifluorothymidine	Mode of action not well understood; appears to inhibit viral DNA synthesis; ophthalmic aqueous solution for topical use	Burning on instillation and palpebral edema, punctuate keratopathy, hypersensitivity reaction, stromal edema, keratitis sicca, hyperemia, increased ocular pressure
Docosanol	Abreva, GSK	*n*-Docosanol	Prevents HSV entry into cells by inhibition of fusion between HSV envelope and cell membrane; over-the-counter topical cream preparation	Headache, skin rash

[a] Pharmaceutical companies: AstraZeneca, Wilmington, Del.; Gilead Sciences, Foster City, Calif.; GSK, GlaxoSmithKline, Research Triangle Park, N.C.; Monarch Pharmaceutical, Bristol, Tenn.; Novartis, East Hanover, N.J.; Roche Pharmaceuticals, Nutley, N.J.

triphosphate than for PCV triphosphate. ACV is an obligate DNA chain terminator, but PCV allows limited chain elongation. The overall effect of the differences between ACV and PCV is that the two compounds have similar anti-HSV potencies (6).

Spectrum of Activity

PCV and FCV are active against HSV and VZV (35). Neither of these compounds is active against other human herpesviruses.

Pharmacology

PCV is available only as a cream for the topical treatment of herpes labialis (113). FCV was developed to improve the bioavailability of the parent compound PCV (79). Following oral administration, FCV is deacetylated and oxidized to form PCV; therefore, little or no FCV is detected in plasma or urine. The absolute bioavailability of FCV is 77% ± 8%.

FCV is eliminated as PCV in urine (108). Elimination half-life, urinary recovery, and renal clearance of PCV do not change with increasing dose. PCV displays linear pharmacokinetics in the anticipated therapeutic dose range of FCV.

Drug Interactions

No clinically significant interactions have been identified for PCV.

Ganciclovir and Valganciclovir

GCV was the first effective anti-HCMV drug developed for clinical use and in older literature is referred to as DHPG (85). GCV is an acyclic nucleoside analogue of 2′-deoxyguanosine, which requires phosphorylation to become active (123). GCV triphosphate concentrations may be 100-fold greater in HCMV-infected cells than in uninfected cells, indicating preferential phosphorylation of GCV in infected cells (28). Unlike ACV, GCV is not an absolute chain terminator, and short subgenomic fragments of HCMV continue to be synthesized (53, 54). Val-GCV, the L-valyl ester of GCV, is rapidly converted to GCV (30).

Spectrum of Activity

GCV is active against HCMV as well as HSV, VZV, Epstein-Barr virus, and human herpesvirus 6 (78).

Pharmacology

A pharmacokinetic study was performed with patients with HIV who received GCV as a single i.v. infusion over 1 h, 500 mg orally every 3 h, or 1,000 mg orally twice daily. The mean peak concentrations in serum were 8.27, 1.02, and 1.18 μg/ml, respectively, for each of these regimens. The absolute bioavailabilities of the drug in the oral regimens were 8.84 and 8.53%, respectively. The extent of GCV absorption, peak concentrations, and average concentration at steady state were not statistically different between the oral regimens. Both oral regimens resulted in concentrations in the range of the concentration that inhibits 50% of most HCMV isolates (2). Oral GCV is available for the treatment and prophylaxis of HCMV infection; however, val-GCV has increased absorption that results in increased bioavailability (103, 131). Renal excretion of unchanged drug by glomerular filtration and active tubular secretion is the major route of elimination of GCV.

Drug Interactions

Coadministration of GCV and ddI results in increased levels of ddI.

Foscarnet

PFA is an organic analogue of pyrophosphate, which exerts its antiviral activity by selective inhibition at the pyrophosphate binding site on the viral DNA polymerase at concentrations that do not affect cellular DNA polymerases (97). PFA does not require intracellular activation.

Spectrum of Activity

Although PFA is active against several herpesviruses, including HSV, HCMV, VZV, and Epstein-Barr virus, it is most commonly used to treat infections with antiviral drug-resistant HSV and HCMV.

Pharmacology

Pharmacokinetic data indicate that PFA undergoes negligible metabolism, appears to be distributed widely from the circulation, and is eliminated via the renal route. The available data, however, indicate that the pharmacokinetics of the drug vary among patients and within an individual patient, particularly with regard to plasma PFA levels (78). The PFA terminal half-life determined by urinary excretion is 87.5 ± 41.8 h, possibly due to the release of PFA from bone (22). Approximately 90% of PFA is excreted as unchanged drug in urine. Systemic clearance of PFA decreases and half-life increases with diminishing renal function. Based on these observations, it is necessary to modify the dosage of PFA for patients with renal impairment (4).

Drug Interactions

Possible drug-drug interaction between PFA and intravenous pentamidine, which results in hypocalcemia, has been described. Caution is advised for patients receiving drugs known to affect serum calcium levels. Because of the tendency for renal toxicity, the use of PFA in combination with other potentially nephrotoxic drugs should be avoided (114).

Cidofovir

CDV is a nucleotide analogue of deoxycytidine monophosphate. In earlier published literature it is referred to as HPMPC (118). CDV phosphorylation does not require a viral enzyme. For HCMV, two successive CDV molecules must be incorporated in order to affect chain termination (135).

Spectrum of Activity

CDV is active against several herpesviruses, including HCMV, HSV, and VZV (70, 118). CDV also has activity against poxviruses (81), adenovirus (95), polyomaviruses (72), and human papillomavirus (117).

Pharmacology

CDV must be administered with probenecid (29, 134). Approximately 90% of the CDV dose administered is recovered unchanged in the urine within 24 h. When CDV is administered with probenecid, the renal clearance of CDV is reduced to a level consistent with creatinine clearance, suggesting that probenecid blocks active renal tubular secretion of CDV (29). In vitro, CDV is less than 6% bound to plasma or serum proteins.

Drug Interactions

No clinically significant interactions have been identified for CDV. However, the required administration of probenecid with CDV may produce drug-drug interactions resulting from the potential block of acidic drug transport in the kidneys (29).

Fomivirsen

Fomivirsen is a phosphorothioate oligonucleotide, which is complementary (antisense) to the HCMV immediate-early (IE2) transcript with the following sequence: 5′-GCG TTT GCT CTT CTT CTT GCG-3′ (98). The target region of the mRNA encodes several proteins responsible for the regulation of viral gene expression that are essential for HCMV replication. Hybridization of the oligonucleotide with the mRNA target leads to inhibition of specific protein synthesis by mechanisms including translational arrest and degradation of the mRNA by RNase H cleavage. The end result is inhibition of virus replication. This sequence appears to be unique to HCMV and is not complementary to any known mRNA sequence in humans.

Spectrum of Activity

Fomivirsen is approved only for the treatment of retinitis caused by HCMV (66).

Pharmacology

After intravitreal injection, the long residence time in the retina and the vitreous provides a pharmacokinetic basis for the treatment intervals (76). Fomivirsen is cleared from the vitreous over the course of 7 to 10 days by a combination of tissue distribution, metabolism, and vitreal egress. In the eye, fomivirsen concentrations are greatest in the retina and iris (49).

Fomivirsen is metabolized by exonucleases in a process that sequentially removes residues from the terminal ends of the oligonucleotide, yielding shortened oligonucleotides and mononucleotide metabolites. Data with related compounds indicate that mononucleotide metabolites are further catabolized, similar to endogenous nucleotides, and are excreted as low-molecular-weight metabolites.

Vidarabine

Vidarabine (Ara-A) is a purine nucleoside analogue for the topical treatment of epithelial keratitis caused by HSV (9). It appears to interfere with the early steps in viral DNA synthesis. Ara-A is phosphorylated by cellular kinases before being incorporated into the viral DNA, resulting in the inhibition of viral DNA synthesis.

Spectrum of Activity

Ara-A was the first anti-HSV compound shown to reduce the mortality of proven HSV encephalitis (130). It has activity against HSV, VZV, HCMV, and vaccinia virus. It is approved for the topical treatment of acute keratoconjunctivitis caused by HSV.

Pharmacology

Ara-A is rapidly deaminated into arabinosylhypoxanthine, the main metabolite, which has much lower antiviral activity (9), but it may act synergistically with the parent drug to inhibit DNA replication. Because of low solubility, systemic absorption of Ara-A should not be expected to occur following ocular administration. Trace amounts of the metabolite are found in the aqueous humor.

Trifluridine

Trifluridine is a fluorinated pyrimidine nucleoside used for the topical treatment of epithelial keratitis caused by HSV (21). Trifluridine interferes with DNA synthesis in cultured mammalian cells, but its antiviral mode of action is not completely known.

Spectrum of Activity

Trifluridine has in vitro and in vivo activity against HSV-1, HSV-2, and vaccinia virus (102). Some strains of adenovirus are also inhibited in vitro by trifluridine. It is approved for the topical treatment of acute keratoconjunctivitis caused by HSV.

Pharmacology

Intraocular penetration by trifluridine occurs after topical instillation into the eye. Decreased corneal integrity or stromal or uveal inflammation may enhance the penetration of trifluridine into the aqueous humor. Systemic absorption following therapeutic dosing with trifluridine appears to be negligible (17).

n-Docosanol

n-Docosanol, also known as behenyl alcohol, is a saturated 22-carbon aliphatic alcohol (69). Docosanol works by inhibiting the fusion between the plasma membrane of human cells and the envelope of HSV. Consequently, docosanol prevents viral entry into cells and subsequent viral replication.

Spectrum of Activity

n-Docosanol exhibits in vitro activity against several lipid-enveloped viruses, including RSV, HSV-1, and HSV-2.

Pharmacology

A topical preparation of *n*-docosanol is available as a 10% cream for the treatment of HSV infection. It is available without a prescription as an over-the-counter medication.

AGENTS ACTIVE AGAINST INFLUENZA VIRUSES

There are two classes of agents for the treatment of influenza: M2 protein inhibitors and neuraminidase inhibitors. The M2 inhibitors are active only against influenza type A, and the neuraminidase inhibitors have activity against both types A and B (91).

M2 Protein Inhibitors

The viral M2 protein facilitates the hydrogen ion-mediated dissociation of the matrix protein-ribonucleoprotein (RNP) complex within the endosome and the release of the viral RNP into the cytoplasm of the host cell (94). The inhibitors block the passage of H^+ ions through the M2 ion channel, which prevents uncoating of the virus (31, 91).

Amantadine and Rimantadine

Amantadine was the first anti-influenza agent discovered, and it was licensed in 1966 for therapy and prophylaxis of influenza A virus infections (112). Rimantadine was licensed in 1993 (92). Both drugs have similar antiviral activities, but they differ in their metabolisms and adverse effects.

Structure and Mechanism of Action

Amantadine hydrochloride is designated chemically as 1-adamantanamine hydrochloride, and rimantadine is methyl-1-adamantanemethyl amine hydrochloride. Both amantidine and rimantadine inhibit the uncoating and release of viral RNA into the host cell.

Pharmacology

Both amantadine and rimantadine are water soluble and absorbed from the GI tract. Oral administration of amantadine or rimantadine shows that the maximum nasal concentrations are similar for both drugs (58). Both compounds have nearly complete oral bioavailability and have a long half-life of >12 h in plasma. Amantadine is excreted primarily unchanged in the urine by glomerular filtration and tubular secretion, and rimandatine is metabolized by the liver (91).

When these compounds are started within 48 h of the onset of influenza symptoms, there has been an associated 1-day reduction of the duration of clinical symptoms including fever, systemic complaints, and virus shedding. Efficacy rates of up to 85% have been shown for preventing influenza illness (132).

Drug Interactions

Agents with anticholinergic properties may potentiate the anticholinergic-like side effects of amantadine. The chronic use of cimetidine may reduce the clearance of rimantadine. Coadministration with acetaminophen or aspirin may reduce the peak concentration of rimantadine.

Adverse Effects

The adverse reactions reported most frequently at the recommended dose of amantadine are nausea; vomiting; dizziness; insomnia; CNS complaints such as difficulty concentrating, jitteriness, and nervousness; and exacerbation of seizure disorders. Less frequently reported adverse reactions are depression, anxiety and irritability, hallucinations, confusion, anorexia, dry mouth, constipation, ataxia, livedo reticularis, peripheral edema, orthostatic hypotension, headache, somnolence, nervousness, dream abnormality, agitation, dry nose, diarrhea, and fatigue.

The common adverse effects associated with rimantadine include nausea, vomiting, anorexia, and CNS effects including headache, insomnia, nightmares, nervousness, lightheadedness, and difficulty concentrating. There are significantly fewer side effects associated with rimantadine than with amantidine (91).

Neuraminidase Inhibitors

The influenza virus neuraminidase is an envelope glycoprotein that cleaves the terminal sialic residues, releasing the virion from the infected cell. The viral neuraminidase allows the influenza virus to spread from cell to cell. Two neuraminidase inhibitors are approved for the treatment of infections with influenza A and B viruses: oseltamivir and zanamivir (34). Both compounds are sialic acid analogues that competitively and reversibly bind to the active site of the enzyme, which results in the inhibition of virus particle release from infected cells.

Oseltamivir

Structure

Chemically, oseltamivir phosphate is (3*R*,4*R*,5*S*)-4-acetylamino-5-amino-3(1-ethylpropoxy)-1-cyclohexene-1-carboxylic acid, ethyl ester, phosphate, which is an ethyl ester prodrug requiring conversion to the active form, oseltamivir carboxylate, by enzymes in the liver, GI tract, and blood.

Spectrum of Activity

Oseltamivir is active against both influenza A and B viruses (38).

Pharmacology

Oseltamivir is readily absorbed from the GI tract after oral administration of oseltamivir phosphate and is extensively converted predominantly by hepatic esterases to oseltamivir carboxylate (62). At least 75% of an oral dose reaches the systemic circulation as oseltamivir carboxylate. The half-life in plasma is 6 to 10 h. The level of binding of oseltamivir carboxylate to plasma protein is low. Coadministration with food has no significant effect on the peak concentration of oseltamivir carboxylate in plasma.

The efficacy of oseltamivir in preventing naturally occurring influenza illness has been demonstrated in treatment and prophylaxis studies with a nursing home population (13). In a study of postexposure prophylaxis for household contacts of index cases, oseltamivir reduced the incidence of clinical influenza without the emergence of drug-resistant virus (57).

Absorbed oseltamivir is eliminated primarily by conversion to oseltamivir carboxylate. Concentrations of oseltamivir in plasma decline in most subjects after oral administration. Oseltamivir carboxylate is not further metabolized and is eliminated in the urine. The renal clearance rate exceeds the glomerular filtration rate, indicating that tubular secretion occurs in addition to glomerular filtration.

Drug Interactions

Studies of oseltamivir suggest that clinically significant drug interactions are unlikely. In vitro studies demonstrate that neither oseltamivir nor oseltamivir carboxylate is a good substrate for P450 mixed-function oxidases or for glucuronyl transferases.

Adverse Effects

The most frequently reported adverse events in clinical studies were nausea and vomiting (87), which were generally of mild to moderate degree and usually occurred on the first two days of administration.

Zanamivir

The chemical name of zanamivir is 5-(acetylamino)-4-[(aminoiminomethyl)-amino]-2,6-anhydro-3,4,5-trideoxy-D-glycero-D-galacto-non-2-enonic acid. For the treatment of influenza, zanamivir is administered to the respiratory tract by oral inhalation only by using a blister pack (65). The contents of each blister are inhaled using a specially designed breath-activated plastic device for the inhaling powder. A blister that contains the medication is pierced, and zanamivir is dispersed into the air stream created when the patient inhales through the mouthpiece.

Most studies of zanamivir have involved topical administration by inhalation of dry powder. This route rapidly provides high local concentrations at the sites of delivery. Zanamivir treatment has been shown to reduce the severity and duration of naturally occurring, uncomplicated influenza illness in adults (15).

Spectrum of Activity

Zanamivir is active against both influenza A and B viruses (59).

Pharmacology

The absolute oral bioavailability of zanamivir is low, averaging 2%. After intranasal or oral inhaled administration, a median of 10 to 20% of the dose is systemically absorbed, with maximum concentrations in serum generally reached within 1 to 2 h. The median half-life in serum ranges between 2.5 and 5.05 h, suggesting that the elimination rate

is limited by absorption. The low level of absorption of the drug after inhaled administration results in low concentrations in serum, and therefore there is modest systemic exposure to zanamivir after inhalation. Zanamivir is not metabolized, and the potential for clinically relevant drug-drug interactions is very low (18). After i.v. administration, 90% is excreted unchanged in the urine.

Drug Interactions

No clinically significant drug interactions are predicted based on data from in vitro studies (18).

Adverse Effects

The adverse effects in patients in treatment studies were similar to those in patients receiving placebos, although bronchospasm has been reported in patients with underlying asthma. Additional adverse reactions occurring in fewer than 1.5% of patients receiving zanamivir include malaise, fatigue, fever, abdominal pain, myalgia, arthralgia, and urticaria (59, 61; http://us.gsk.com/products/assets/us_relenza.pdf).

Mechanisms of Resistance to Antiviral Agents

ROBERT W. SHAFER, SHIRIT EINAV, AND SUNWEN CHOU

113

Understanding the mechanisms of viral drug resistance is critical for clinical management of individuals receiving antiviral therapy, for development of new antiviral drugs, and for drug resistance surveillance. In this chapter, we review the mechanisms of resistance to antiviral drugs used to treat seven common viral infections: those with herpes simplex virus (HSV), cytomegalovirus (CMV), varicella-zoster virus (VZV), human immunodeficiency virus types 1 and 2 (HIV-1 and HIV-2), influenza A and B viruses, hepatitis B virus (HBV), and hepatitis C virus (HCV).

Drug-resistant viruses are identified by in vitro passage experiments in which wild-type viruses are cultured in increasing concentrations of an inhibitory drug and by ex vivo analysis of virus isolates obtained from individuals receiving antiviral therapy. Measuring drug susceptibility involves culturing a fixed inoculum of virus in serial dilutions of an inhibitory drug. The drug concentrations required to inhibit virus replication by 50 or 90% are the most commonly used measures of susceptibility. Drug susceptibility assays are not designed to determine the drug concentration required to inhibit virus replication in vivo. They are instead designed to identify viruses with reduced drug susceptibilities relative to wild-type viruses. The clinical significance of reductions in drug susceptibility is determined by studying the treatment responses of individuals harboring viruses with reduced susceptibilities.

HERPESVIRUSES

All currently licensed systemic drugs for herpesvirus infections target viral DNA polymerase. Nucleoside analogs that are selectively phosphorylated by viral enzymes are commonly used as initial therapy. To improve oral bioavailability, some are formulated as prodrugs. Acyclovir, its prodrug valacyclovir, and famciclovir (the prodrug of penciclovir) have been used successfully to treat genital HSV infections, VZV infections, and mucocutaneous HSV infections in immunocompromised hosts. Ganciclovir and its prodrug valganciclovir are used to treat CMV infection. These selective nucleoside analogs are supplemented by the drugs foscarnet (phosphonoformate) and cidofovir that inhibit viral DNA polymerase without prior activation by viral enzymes. Foscarnet is a pyrophosphate analog, and cidofovir is a phosphonomethoxycytosine nucleotide analog. These are generally used as second- and third-line drugs when there is a lack of response to initial therapy.

Herpes Simplex Virus

Both acyclovir and penciclovir are initially monophosphorylated by the HSV thymidine kinase (TK) and then triphosphorylated by cellular enzymes. In their active forms, these drugs inhibit viral DNA polymerase by competing with guanosine triphosphate for incorporation into newly synthesized DNA chains, where they cause chain termination. Because the viral TK enzyme is not essential for HSV replication, a wide variety of TK mutations may decrease the phosphorylation of nucleoside analogs, and this is by far the most common mechanism of acyclovir and penciclovir resistance in HSV (61).

Most TK mutants are classified as TK negative, usually in which frameshift or stop mutations delete important functional domains, or TK partial, in which the mutation reduces the phosphorylation of both natural nucleosides and antiviral drugs (130). TK-altered mutants, which selectively reduce the phosphorylation of antiviral nucleosides while natural nucleosides are normally phosphorylated, occur less commonly. The TK mutations selected by penciclovir often differ from those selected by acyclovir, but cross-resistance is expected (159). The effect of specific substitutions on TK activity and drug susceptibility often must be defined by site-directed mutagenesis (53). Because there are so many TK mutations, phenotypic approaches to the detection of HSV resistance have been favored over genotypic approaches (101).

TK-negative HSV mutants are attenuated in mouse models with respect to virulence, latency, and reactivation potential (24). However, animal studies and clinical case reports (66, 131, 156) show that resistant viruses cause overt disease and recurrent infection. Even isolates with frameshift mutations that are predicted to be TK negative may in fact express some TK activity that enables reactivation from latency (66). Although drug-resistant HSV TK mutants can easily be selected in cell culture, recent data indicate that the frequency of isolation of acyclovir-resistant HSV in clinical practice has remained stable at about 0.3% for immunocompetent hosts and 7% for immunocompromised hosts (170).

Drug-resistant TK mutants are expected to remain susceptible to drugs that do not depend on virally mediated phosphorylation, including foscarnet, which is currently the main alternative therapy for acyclovir-resistant HSV infection, and cidofovir. DNA polymerase *(pol)* mutations are occasionally responsible for HSV resistance to acyclovir, penciclovir, foscarnet, and cidofovir. Because the viral DNA polymerase gene is essential for replication, mutations are

more selective than those affecting TK and usually consist of single-amino-acid changes in functional domains of the enzyme. The resistance and cross-resistance properties vary depending on the mutation and are best evaluated by transfer of specific mutations to control viral strains (12). These analyses show that *pol* mutations conferring acyclovir or foscarnet resistance are distributed among several conserved regions, with some clustering of mutations in regions II, VI, and III. A few mutations confer resistance to both acyclovir and foscarnet (61). Little is known about the range of cidofovir resistance mutations in clinical isolates, but available information suggests that there is no consistent cross-resistance with acyclovir or foscarnet (12).

Varicella-Zoster Virus

Because VZV also expresses a TK, the drugs used and the mechanisms of resistance are similar to those for HSV. Acyclovir is less potent against VZV than HSV, and either intravenous acyclovir or oral prodrugs (valacyclovir or famciclovir) are needed to obtain levels of reliable antiviral activity in blood (139). VZV treatment efficacy depends more on the prompt initiation of adequately bioavailable therapy than on the loss of drug susceptibility (31). The notable exceptions are AIDS patients who may develop chronic, spreading verrucous skin lesions in which prolonged viral replication selects for resistant strains (136).

Analogous to acyclovir-resistant HSV isolates, most acyclovir-resistant VZV isolates contain mutations that result in TK deficiency or substitutions that alter substrate specificity (61). A tendency for resistance mutations to cluster at certain TK gene loci has been reported (61, 132), possibly simplifying genotypic resistance testing, which may have a greater role with this virus than with HSV because of the slower growth of VZV in cell culture.

Alternative drugs for acyclovir-resistant VZV are foscarnet and cidofovir. Foscarnet resistance maps to codons corresponding to conserved functional domains II and III of the VZV DNA polymerase (61), similar to that in foscarnet-resistant HSV and CMV mutants. Some mutants selected by foscarnet in cell culture have a slow-growth phenotype indicating the potential consequence of drug resistance mutations for DNA polymerase, an essential viral gene product (184). DNA polymerase mutations conferring resistance to these drugs and to acyclovir appear to be mostly distinct, although specific information relating to foscarnet or cidofovir resistance in clinical isolates is limited and not validated by mutagenesis studies (61).

Cytomegalovirus

CMV lacks a TK enzyme but expresses a phosphotransferase (UL97) which is essential for the production of normal amounts of infectious virus in cell culture (152). Ganciclovir, the standard initial therapy for CMV disease, is monophosphorylated by UL97 and subsequently converted into the active triphosphate form in infected cells (173). Risk factors for CMV resistance are high levels of continuing viral replication, as seen in immunocompromised hosts, coupled with continuing antiviral drug exposure, usually a few months or more (62). Since the advent of combination antiretroviral therapy, there has been a marked decrease in CMV infection in HIV-1-infected persons. During the same time, however, CMV infection has been increasingly diagnosed in transplant recipients, especially those with posttransplant primary infection and lung or pancreas transplantation (62).

More than 90% of ganciclovir-resistant CMV isolates found following treatment contain UL97 mutations (29). Because of the important function of UL97 in the viral life cycle, UL97 ganciclovir resistance mutations occur at a restricted number of positions and usually preserve the UL97 gene's reading frame. Resistance mutations have been observed at codons 460, 520, and 590 to 607, with the most common being those at codons 460, 592, 594, 595, and 603 (29). Several deletion mutations conferring resistance have been observed between codons 590 and 607. Rarely in clinical practice, a *pol* mutation may cause ganciclovir resistance, without mutation in the UL97 gene (48). Genotypic testing is attractive because of the limited number of UL97 codons involved and the technical difficulty of phenotypic testing of clinical isolates. UL97 is not known to be involved in resistance to foscarnet or cidofovir.

After continued exposure to ganciclovir, mutations in the CMV DNA polymerase gene (*pol*) may be selected and contribute to an increased level of resistance to the drug (26, 169). Recombinant phenotyping confirms the high-level ganciclovir resistance conferred by a combination of UL97 gene and *pol* mutations (28). Ganciclovir and cidofovir resistance mutations have been reported at codons 301, 408 to 413, and 501 to 545, which correspond to exonuclease, IV, and δC regions of *pol*, and at codons 978 to 988 (region V) (25).

Foscarnet resistance mutations in CMV *pol* often involve conserved regions II (e.g., codons 700 and 715), III (e.g., codons 802 and 809), and VI (e.g., codon 781) and some nonconserved loci (e.g., codon 756) (62). There appears to be limited cross-resistance between foscarnet and the other current anti-CMV drugs. Some foscarnet resistance mutations in region III also appear to confer low-grade ganciclovir or cidofovir resistance of uncertain clinical significance. This region of *pol* may have a role in recognition of the incoming nucleotide triphosphate and pyrophosphate exchange. An unusual deletion mutation (codons 981 and 982) in region V confers resistance to all three drugs: ganciclovir, cidofovir, and foscarnet (28). Some CMV *pol* mutations have been associated with a slow-growth phenotype (62).

Genotypic detection of CMV *pol* resistance mutations is feasible based on extensive knowledge of natural polymorphisms associated with interstrain variation and of well-characterized drug resistance mutations. The wide distribution of known and potential resistance mutations makes it necessary to determine the *pol* sequence from codons 300 to 1,000, and interpretation of results is more complicated than that for the UL97 gene. Moreover, there continue to be reports of sequence changes in *pol* that are indeterminate for drug resistance and that require further genetic analysis (62).

Fomivirsen is a little-used antisense topical CMV antiviral. Fomivirsen resistance has not been associated with a mutation in the cognate CMV sense sequence (135). A drug that has entered early clinical trials is maribavir, a benzimidazole L-riboside that inhibits the viral UL97 phosphotransferase (13). Maribavir-resistant laboratory CMV mutants have been isolated that contain mutations in UL97 (13) or UL27 (27). Another class of drugs targets viral DNA cleavage and processing, with resistant strains showing mutations in UL56 or UL89 (46).

HUMAN IMMUNODEFICIENCY VIRUS TYPE 1

Twenty antiretroviral drugs have been approved for treatment of HIV-1 infection, including seven nucleoside and one nucleotide reverse transcriptase (RT) inhibitors (NRTIs), eight protease inhibitors (PIs), three nonnucleoside RT inhibitors (NNRTIs), and one fusion inhibitor. In previously untreated individuals with drug-susceptible HIV-1 infection,

combinations of three or four drugs from two drug classes lead to prolonged virus suppression and, in most patients, immune reconstitution. Once complete HIV-1 suppression is achieved, it usually persists indefinitely if therapy is not interrupted (149). However, because antiretroviral therapy does not inhibit proviral HIV-1 DNA, viral eradication is not possible. Recurrent viremia and immunological decline ensue whenever therapy is discontinued, regardless of the previous duration of virological suppression.

HIV-1 genetic variability results from the high rate of RT enzyme errors, the high rate of virus replication in vivo, recombination when viruses with different sequences infect the same cell, and the accumulation of proviral variants during the course of infection (30, 116). The virus population within an individual does not consist of a single genotype but is instead an ensemble of innumerable related genotypes or quasispecies. The selection of drug-resistant variants depends on the extent to which virus replication continues during incompletely suppressive therapy, the ease of acquisition of a particular mutation (or set of mutations), and the effect of drug resistance mutations on drug susceptibility and virus replication.

The presence of drug resistance before the start of a new antiretroviral treatment regimen is an independent predictor of virological response to that regimen, and clinical trials have shown that drug resistance testing, particularly genotypic testing, provides clinical benefit in selecting treatment for infected individuals (reviewed in references 82 and 160). Although drug resistance is usually acquired during therapy, it can also be transmitted between individuals. In the United States, Europe, and Brazil, about 10 to 15% of new HIV-1 infections are with strains harboring resistance to one or more of the currently approved RT inhibitors or PIs (150).

Reverse Transcriptase

The RT enzyme is responsible for RNA-dependent DNA polymerization and DNA-dependent DNA polymerization. RT is a heterodimer consisting of p66 and p51 subunits. The p66 subunit contains the DNA binding groove and the active site; the p51 subunit displays no enzymatic activity and functions as a scaffold for the enzymatically active p66 subunit. The p66 subunit has five subdomains, including the "finger," "palm," and "thumb" subdomains, which participate in polymerization, and the "connection" and RNaseH subdomains (84, 94). Most RT inhibitor resistance mutations are in the 5' polymerase-encoding regions, particularly those corresponding to the finger and palm subdomains (158).

Nucleoside and Nucleotide RT Inhibitor Resistance

The NRTIs are prodrugs that are phosphorylated by host cellular enzymes. The occurrence of triphosphorylation (or diphosphorylation in the case of tenofovir) at different rates in different cell types complicates the in vitro assessment of both NRTI activity and phenotypic resistance testing, leading to marked discordances between in vitro and in vivo NRTI potencies (59). Differences between the highly activated lymphocytes required for susceptibility testing and the wider variety of cells that are infected in vivo also provide the most likely explanation for why the NRTIs differ in their dynamic ranges and in the levels of in vitro resistance that are clinically significant (104, 122). Clinical isolates from persons failing NRTI therapy may have several-hundred-fold reductions in susceptibility to zidovudine, lamivudine, and emtricitabine but will rarely have more than fivefold reductions in susceptibility to didanosine, stavudine, and tenofovir. However, very slight reductions in susceptibility to this second category of drugs—as low as 1.5 fold—are clinically significant (193).

There are two biochemical mechanisms of NRTI resistance. One mechanism is mediated by discriminatory mutations that reduce RT affinity for an NRTI, preventing its addition to the growing DNA chain (157). Another mechanism is mediated by primer-unblocking mutations that increase the hydrolytic removal of the chain-terminating NRTIs (5, 15, 123).

M184V, a discriminatory mutation that causes high-level in vitro resistance to lamivudine and emtricitabine, is the most commonly occurring NRTI resistance mutation. M184V also causes low-level in vitro resistance to didanosine and abacavir and increased susceptibility to zidovudine, stavudine, and tenofovir (193). However, viruses with M184V replicate less well than wild-type viruses, possibly explaining why abacavir and particularly didanosine appear to be fully active against viruses with this mutation (128).

The primer-unblocking mutations M41L, D67N, K70R, L210W, T215Y/F, and K219Q/E are selected by zidovudine and stavudine and are also called thymidine analog mutations. A subset of these mutations (M41L, L210W, and T215Y) are particularly important for causing cross-resistance to didanosine, abacavir, and tenofovir (97, 124, 128). An uncommon mutation, a double-amino-acid insertion at position 69, is responsible for high-level resistance to all NRTIs when it occurs in combination with multiple thymidine analog mutations (195).

The remaining clinically significant NRTI resistance mutations include mutations at positions 65, 74, 75, 115, and 151. K65R causes resistance to all NRTIs except zidovudine and possibly stavudine (140). L74V causes resistance to didanosine and abacavir. V75T/M/A cause resistance to stavudine and possibly other NRTIs; Y115F causes resistance to abacavir; Q151M, which is usually accompanied by accessory mutations at positions 62, 75, 77, and 116, causes resistance to each of the NRTIs (161, 165).

Nonnucleoside RT Inhibitor Resistance

The NNRTIs delavirdine, efavirenz, and nevirapine inhibit HIV-1 RT allosterically by binding to a hydrophobic pocket close to the active site. This hydrophobic NNRTI binding pocket is less well conserved than the deoxynucleoside triphosphate binding site. Indeed, HIV-1 group O and HIV-2 are intrinsically resistant to most NNRTIs (197). Moreover, wild-type HIV-1 group M isolates tend to have greater interisolate variability in susceptibilities to NNRTIs than in susceptibilities to NRTIs and PIs (141).

A single mutation in the NNRTI binding pocket may result in high-level resistance to one or more NNRTIs. Resistance emerges rapidly when NNRTIs are administered as monotherapy or in the presence of incomplete virus suppression, suggesting that NNRTI resistance can be caused by the selection of rare, preexisting populations of mutant viruses within an individual. A single dose of nevirapine used to prevent mother-to-child HIV transmission can select for NNRTI-resistant mutants that are detectable for two or more months and may interfere with the subsequent response to an NNRTI-containing treatment regimen (87, 88).

The NNRTI resistance mutations are clustered between residues 98 and 108, 179 and 190, and 225 and 238. K103N, which is the most common, confers a >20-fold increase in resistance to each of the NNRTIs and appears to be sufficient to cause virological treatment failure with each of the NNRTIs. High levels of clinical cross-resistance among the NNRTIs occur because most NNRTI resistance mutations confer resistance to multiple NNRTIs (7, 167) and because

a single NNRTI often selects for multiple different NNRTI-resistant populations within a person even if only one drug-resistant population is detected during direct PCR sequencing.

There is no cross-resistance between NRTIs and NNRTIs. Indeed, several NNRTI resistance mutations increase susceptibility to certain NRTIs (98) and combinations of certain NRTI resistance mutations increase NNRTI susceptibility (166, 192).

HIV-1 Protease

The HIV-1 protease enzyme is responsible for the posttranslational processing of the viral *gag* and *gag-pol* polyproteins to yield the structural proteins and enzymes of the virus. The enzyme is an aspartic protease composed of two noncovalently associated, structurally identical monomers 99 amino acids in length. The hydrophobic substrate cleft recognizes and cleaves nine different peptide sequences to produce the matrix, capsid, nucleocapsid, and p6 proteins from the *gag* polyprotein and the protease, RT, and integrase proteins from the *gag-pol* polyprotein. In addition to the substrate cleft, a mobile flap which sits above the substrate cleft plays a major role in substrate recognition and drug resistance. The three-dimensional structures of many wild-type and mutant proteases have been cocrystallized with either inhibitors or peptide substrates.

Protease Inhibitor Resistance

There are eight Food and Drug Administration (FDA)-approved PIs: amprenavir, atazanavir, indinavir, lopinavir, nelfinavir, ritonavir, saquinavir, and tipranavir. Fosamprenavir is a prodrug of amprenavir with improved bioavailability that has also recently been approved by the FDA. With the exception of nelfinavir, each of these PIs is usually administered with subtherapeutic doses of ritonavir because ritonavir is a potent cytochrome P450 enzyme inhibitor that increases the levels of all PIs except nelfinavir in serum by 10-fold or more. Lopinavir is the only PI that is coformulated with ritonavir. Ritonavir is rarely administered by itself because of its poor tolerability when administered at therapeutic dosages.

Mutations at more than 20 protease positions are associated with drug resistance (Table 1). Most of these mutations contribute resistance to more than one PI (154, 155). Mutations in the substrate cleft cause resistance by reducing the binding affinity between the inhibitor and the mutant protease enzyme. Mutations elsewhere in the enzyme either compensate for the decreased kinetics of enzymes with active-site mutations or cause resistance by altering enzyme catalysis, dimer stability, or inhibitor binding kinetics or by reshaping the active site through long-range structural perturbations (49). Mutations at several of the protease cleavage sites are also selected during PI treatment (35, 115). Protease cleavage site mutations improve the kinetics of protease enzymes with PI resistance mutations. By themselves, they have not been shown to reduce PI susceptibility.

The requirement for multiple mutations to overcome the activity of certain PIs has been referred to as a "genetic barrier" to drug resistance (34, 90). This genetic barrier is highest in persons receiving their first PI, particularly if it is coadministered with ritonavir. Ritonavir-boosted regimens are so potent that when administered to PI-naïve individuals, failure is almost universally caused by nonadherence rather than by drug resistance (91).

Cell Entry Inhibitor Resistance

The HIV-1 envelope consists of surface (gp120) and transmembrane (gp41) glycoproteins. gp120 binds to the CD4 receptor and to one of the chemokine coreceptors (CCR5 or CXCR4) on target cells. After gp120-CD4-coreceptor binding, gp41 undergoes a conformational change that promotes fusion of viral and cellular membranes. Two heptad repeat regions (HR1 and HR2) of gp41 form a helical bundle that contains trimers belonging to HR1 and HR2. Enfuvirtide is a highly active synthetic peptide that inhibits fusion by binding to HR1 and preventing its bundling with HR2 (92). Enfuvirtide-resistant isolates contain either single or double mutations between positions 36 and 45 of gp41 HR1 (125, 168, 188). Single mutants typically have on the order of 10-fold-decreased enfuvirtide susceptibility, whereas double mutants typically have on the order of 100-fold-decreased susceptibility.

CCR5 inhibitors bind to one of the transmembrane loops of CCR5, thereby distorting the receptor and restricting HIV-1 gp120 binding. Several CCR5 inhibitors have shown potent activity in phase I and II clinical trials in treating persons that do not harbor CXCR4-tropic HIV-1 variants (44). In vitro resistance has developed slowly and incrementally through the development of multiple gp120 mutations (119). In vivo, rapid failures have occurred in persons with preexisting minor populations of CXCR4 variants that were undetected during eligibility screening (44).

Intersubtype Variation

Naturally occurring protease and RT polymorphisms differ among subtypes, but for the most part these differences are not responsible for mutations with major effects on drug susceptibility. Indeed, nearly all published in vitro and in vivo studies suggest that all subtypes are equally susceptible to current antiretroviral drugs (142). Preliminary data suggest that the drug resistance mutations observed in subtype B isolates are the most common ones observed in non-B subtypes (89). However, subtle differences in the specific mutations observed among subtypes have been reported and will continue to be identified (16, 19, 20, 67, 68, 133, 172).

INFLUENZA VIRUS

Influenza A, B, and C viruses have segmented, encapsidated, minus-strand RNA genomes, each associated with a polymerase complex. The RNA particles are located inside a shell of Matrix 1(M1) protein that lines the viral lipid membrane. Embedded in the membranes of influenza A and B viruses are three proteins: two spiked glycoproteins (hemagglutinin [HA] and neuraminidase [NA]) and the membrane channel protein M2. Influenza C virus does not have an NA but instead has a single surface glycoprotein with both HA- and NA-like activities. There are four approved anti-influenza virus drugs belonging to two mechanistic classes: M2 channel blockers (the adamantine derivatives amantadine and rimantadine) and NA inhibitors (zanamivir and oseltamivir). Peramivir is a third NA inhibitor in clinical development. M2 channel blockers are active only against influenza A virus. NA inhibitors are active against influenza A and B viruses but not influenza C virus.

M2 Channel Blockers

M2 forms an ion channel that plays a role in virus uncoating and possibly in regulating the HA activity of newly formed viruses (64). Passage of hydrogen ions through the M2 channel into the virion following endocytosis promotes the dissociation of the M1 protein from the ribonucleoprotein complexes so that the ribonucleoprotein can enter the cell nucleus and initiate replication. By controlling the pH within trans-Golgi vesicles during virus exit, the M2 protein also prevents the exposure of the acid-sensitive HA to an adversely low pH (64, 83). Amantadine and rimantadine interfere with the penetration of hydrogen ions through the M2 channel and prevent

TABLE 1 Mechanisms and mutations associated with antiviral drug resistance

Virus	Antiviral agent(s)	Mechanism(s) of resistance	Mutations
HSV	Acyclovir, valcyclovir, penciclovir, famciclovir	TK and/or DNA polymerase mutations	TK frameshift or substitution mutations causing a TK-deficient phenotype and cross-resistance among the four drugs. Less commonly, TK-altered or DNA polymerase mutations
	Foscarnet	DNA polymerase mutations	Mutations clustering in regions II, VI, and III, (probable pyrophosphate binding regions)
	Cidofovir	DNA polymerase mutations	Mutations in regions δC and II (based on limited data from laboratory strains)
VZV	Acyclovir, valcyclovir, penciclovir, famciclovir	TK and/or DNA polymerase mutations	TK frameshift or substitution mutations causing a TK-deficient phenotype and cross-resistance among the four drugs. Less commonly, TK-altered or DNA polymerase mutations
	Foscarnet	DNA polymerase mutations	Mutations clustering in regions II, VI, and III (probable pyrophosphate binding regions)
	Cidofovir	DNA polymerase mutations	No VZV-specific data are available.
CMV	Ganciclovir	UL97 phosphotransferase mutations and/or DNA polymerase mutations	Usually UL97 mutations at residues 460, 520, 592, 594, 595, and 603 as well as mutations at codons 590–607. DNA polymerase mutations (exo, IV, δC, and V regions) sometimes confer resistance, usually with UL97 mutations.
	Foscarnet	DNA polymerase mutations	Mutations in regions II, III, and VI. Some may also decrease ganciclovir susceptibility.
	Cidofovir	DNA polymerase mutations	Mutations in regions exo, IV, δC, and V, resulting in cross-resistance to ganciclovir
HIV-1	PIs[a]: amprenavir, atazanavir, indinavir, lopinavir, nelfinavir, ritonavir, saquinavir, tipranavir	Protease mutations interfere with inhibitor binding or compensate for the decreased replication associated with other mutations.	Substrate cleft mutations: D30N, V32I, G48VM, I50VL, V82AFSTLM, I84V. Flap mutations: M46IL, I47VA, F53L, I54VMTLAS. Mutations at other conserved sites: L23I, L24I, L33F, G73SCT, L76V, N88DTS, L90M. Mutations at polymorphic sites: L10IVFR, K20RMTI, M36I, L63P, A71VTI, V77I
	NRTIs: abacavir, didanosine, emtricitabine, lamivudine, stavudine, zidovudine. Nucleotide RT inhibitor: tenofovir	RT mutations that allow the enzyme to discriminate between NRTIs and naturally occurring nucleosides or that promote ATP-dependent hydrolytic removal of chain-terminating nucleotide monophosphates	M184V confers high-level resistance to lamivudine and emtricitabine. K65R confers intermediate resistance to didanosine, abacavir, tenofovir, lamivudine, and emtricitabine. L74V confers resistance to didanosine and abacavir. Q151M occurs in association with A62V, V75I, F77L, and F116Y and confers high-level resistance to all NRTIs except possibly lamivudine and emtricitabine. M41L, D67N, K70R, L210W, T215FY, and K219QE develop in isolates from persons receiving zidovudine and stavudine but confer clinically significant cross-resistance to each of the other NRTIs except possibly lamivudine and emtricitabine.
	NNRTIs: delavirdine, nevirapine, efavirenz	Mutations in the NNRTI binding pocket of RT that interfere with inhibitor binding	A98G, L100I, K101EP, K103NS, V106AM, V108I, V179DE, Y181CIV, Y188CLH, G190ASEQ, P225H, F227L, M230L, P236L, K238T. Most mutations cause resistance to each of the NNRTIs.
	Fusion inhibitor: enfuvirtide	Mutations in the first heptad repeat region (HR1) of the gp41 transmembrane protein	Enfuvirtide is a peptide mimetic of the HR2 region of gp41. Drug resistance mutations in the HR1 region interfere with the association of the HR1 and HR2 domains necessary for virus-cell fusion. Mutations occur in a highly conserved region between gp41 residues 36 and 45.
Influenza virus	M2 channel blockers: amantadine, rimantadine	M2 transmembrane domain substitutions that interfere with hydrogen ion transfer	Mutations at residues 27, 30, 31, and 34, particularly A30V and S31N
	NA inhibitors: zanamivir, oseltamivir, peramivir[b]	NA receptor binding site mutations that decrease inhibitor affinity	R152K and R292K confer high-level resistance to each of the NA inhibitors. E119GAD confers high-level zanamivir and low-level oseltamivir resistance. E119V confers high-level oseltamivir resistance but does not affect resistance to zanamivir. H274Y confers high-level oseltamivir and low-level zanamivir resistance. D198N causes intermediate resistance to oseltamivir and zanamavir but not peramivir.

(Continued on next page)

TABLE 1 Mechanisms and mutations associated with antiviral drug resistance (*Continued*)

Virus	Antiviral agent(s)	Mechanism(s) of resistance	Mutations
		HA mutations that reduce the affinity of HA for its receptor	Mutations in many different residues in or close to the HA receptor binding site cause decreased dependence on NA activity in vitro. The clinical significance of these mutations is uncertain.
HBV	Interferon	Unknown	Unknown
	Nucleoside analogs: lamivudine, adefovir, entecavir, emtricitabine,[b] tenofovir,[b] telbivudine[b]	Polymerase substitutions that interfere with nucleotide triphosphate binding. Several may also promote primer unblocking.	M204VI, L180M, V173L: lamivudine, emtricitabine, telbivudine; variable partial cross-resistance to tenofovir, entecavir. N236T, A181V: adefovir, tenofovir. A194T: tenofovir. I169T, T184G, S202I, M250V: entecavir
HCV	Interferon	Uncertain	Genotype 1 isolates respond less well to interferon than genotype 2 or 3 isolates, but the molecular basis for this phenomenon is not known. Within genotype 1 isolates, certain sequence patterns within NS5A may be associated with interferon resistance.
	Ribavirin	Uncertain	Uncertain
	Investigational drugs: PIs, RNA-dependent RNA polymerase nucleoside and nonnucleoside RNA polymerase inhibitors	PI and nonnucleoside inhibitor resistance mutations appear to interfere with binding. Nucleoside inhibitors appear to enhance polymerase discrimination.	It is too premature to list specific mutations, as clinical experience is limited.

[a]Extensive additional information on each of the PI, NRTI, and NNRTI resistance mutations can be found at http://hivdb.stanford.edu. Several additional NRTI resistance mutations appear to act through a combination of the two mechanisms described above.
[b]Investigational drugs. Emtricitabine and tenofovir, although investigational for treating HBV infection, are approved for treating HIV-1 infection.

transport of the ribonucleoprotein complex to the nucleus (64, 77).

Cross-resistance to both drugs results from single-amino-acid substitutions at position 26, 27, 30, 31, or 34 within the M2 transmembrane domain (9, 10). Some of the mutations, such as those at positions 30 and 31, inhibit M2 channel binding, whereas others, such as those at position 27, may allow binding to occur without affecting channel function (6). M2 inhibitor resistance develops rapidly during in vitro passage experiments and during treatment in about 30% of persons receiving amantadine or rimantadine (10, 78, 79, 164). Amantadine- and rimantadine-resistant variants maintain normal infectivity and virulence in animal models and cause typical disease in humans (2, 9, 78). Patients infected with drug-resistant virus have slower responses to treatment than do patients infected with wild-type virus (79).

Large surveillance studies have shown that M2 inhibitor resistance, usually caused by the S31N mutation, increased among H3N2 isolates from 1% in the 1990s to more than 50% in China and more than 90% in the United States by 2003 and 2005 to 2006, respectively (17, 18, 205). H5N1 viruses isolated from human and avian sources since 2003 also appear to usually have the S31N mutation, making them intrinsically resistant to M2 inhibitors (21, 153). M2 inhibitor resistance among H1N1 and H1N2 viruses has not increased to the same extent as that observed in H3N2 viruses.

Neuraminidase Inhibitors

HA binds to sialic (*N*-acetylneuraminic) acid-containing cellular receptors, thus initiating viral infection. NA cleaves the alpha-ketosidic bonds linking terminal sialic acid residues to adjacent oligosaccharide moieties, preventing the formation of aggregates between HA and cell surfaces sialic acids and allowing newly formed viruses to be released from the surfaces of infected cells (33, 182). NA may also promote viral spread within mucosal secretions in the respiratory tract (33, 182). Because HA binds to cellular receptors to initiate infection, whereas NA destroys cellular receptors to allow virus release from cells, a balance between these two activities is required for efficient infection (186).

NA is a homotetramer containing 470 amino acids (33, 181, 182). A hydrophobic stalk peptide at its N terminus is responsible for membrane anchoring. A globular head contains the enzyme active site, a pocket lined by a central shell of 17 conserved, predominantly charged active-site residues and 16 neighboring conserved residues (181, 182). Zanamivir and oseltamivir are sialic acid analogs that competitively inhibit NA (185).

Zanamivir and oseltamivir are active against a wide range of strains including each of the nine identified avian NA subtypes (70) as well as avian H5N1 variants isolated in 1997 and 2004 (73, 102, 103, 134). Although these drugs appear to be less active against influenza B virus in vitro, the clinical significance of this finding is uncertain (70).

NA inhibitor activity can be measured by using enzymatic assays, cell culture, and animal models (mice and ferrets). However, NA inhibitor activity in cell culture is variable because different clinical isolates have different degrees of dependence on HA activity and because the cells used for in vitro assays have different concentrations of glycoconjugate receptors (202). Indeed, there are currently no suitable cell lines that bear receptors comparable to those in the human respiratory tract (120).

The extent to which the mechanisms of resistance that emerge in vitro are clinically relevant is not always certain. For example, during in vitro passage experiments, NA inhibitor

resistance can be conferred by mutations in HA and/or NA. Drug resistance HA mutations that decrease HA affinity to its cellular receptor allow the virus to exit infected cells without the need for significant NA activity (69, 121). However, in animal models as well as in humans, viruses with HA mutations alone remain susceptible to NA inhibitors (1, 14, 71, 81).

In contrast to HA resistance mutations, NA resistance mutations emerge both in vitro and in vivo and are clinically significant (71). NA resistance mutations emerge at residues within the catalytic site (residues 152 and 292) or the surrounding structural framework (residues 119, 198, and 274). These residues are highly conserved in untreated influenza virus strains (120), and NA inhibitor-resistant variants with mutations at these residues have reduced enzymatic activity and virulence in animal models (32, 74, 80, 81, 85, 200).

Mutations in the catalytic site usually confer resistance to each of the available NA inhibitors. For example, the uncommon mutation R152K and the common mutation R292K confer resistance to zanamivir, oseltamivir, and peramivir in both influenza A and B viruses (69, 86). The framework mutations E119G/A/D cause high-level zanamivir resistance and low-level oseltamivir resistance, whereas E119V causes high-level oseltamivir resistance but does not affect zanamavir or peramivir susceptibility. H274Y reduces oseltamivir but not zanamivir susceptibility (69, 120, 121). The effect of H274Y may also be subtype dependent, as the mutation has been reported to cause markedly reduced susceptibility in several H1N1 isolates but not in one H3N2 isolate (126, 187).

Resistance to NA inhibitors develops at a much lower rate in vitro and in vivo than does resistance to M2 blockers, presumably as a consequence of the negative impact NA inhibitor resistance mutations have on NA function and virus replication. In addition, the spread of NA inhibitor-resistant virus between individuals appears so far to be rare. Oseltamivir resistance in viruses from 10 of 182 and 9 of 50 children treated with oseltamivir has been reported previously (93, 194). Oseltamivir resistance caused by the H274Y mutation in viruses from three Vietnamese children with fatal H5N1 infections has also been reported (40, 100). Oseltamivir resistance in viruses from adults is uncommon, being reported in 1 to 4% of those from treated adults (71). There has been only one case report of zanamivir resistance (72). The higher rate of oseltamivir resistance may be due to greater selective pressure resulting from oral administration or may be a function of the structure of oseltamivir, which is more dissimilar to the natural sialic acid substrate than zanamivir (70).

HEPATITIS B VIRUS

HBV is a partially double-stranded DNA virus of about 3.2 kb. Following infection, its genome localizes to the nucleus, where it is converted into a covalently closed circular DNA (cccDNA) form that serves as the template for transcription of mRNA and genomic RNA. Genomic RNA is reverse transcribed into viral DNA, and the resulting viral cores either bud into the endoplasmic reticulum and are exported from the cell or return to the nucleus for conversion back into cccDNA (58). HBV cccDNA is highly stable and can be eliminated by cell turnover but not by drug therapy (52, 189, 206). Therefore, complete cure or eradication of infection is highly unusual with current antivirals (58).

HBV replicates at a high rate, producing an estimated 10^{11} virions per day (137). In the absence of therapy, HBV DNA levels are often as high as 10^8 to 10^{10} copies/ml (8 to 10 log-copies/ml). HBV polymerase, because it has RT activity, is functionally and structurally similar to HIV-1 RT and has an error rate higher than that of most DNA virus polymerases. However, the overlapping arrangement of open reading frames in the HBV genome limits the viability of many spontaneous mutants (56). For example, the nucleotides encoding the HBV polymerase also encode the HBV envelope in a different reading frame. Therefore, the rate at which mutations become fixed is estimated to be considerably lower than that for HIV-1 (63).

Anti-HBV Drug Therapy

There are four FDA-approved drugs for the treatment of chronic HBV infection. Alpha interferon was approved in 1992, followed by three nucleoside analogs: lamivudine (1998), adefovir (2002), and entecavir (2005). Emtricitabine and tenofovir, antiretroviral drugs that are similar to lamivudine and adefovir, respectively, are also active against HBV in vitro and in vivo. Telbivudine is a drug in advanced clinical development (96).

Alpha interferon, particularly pegylated interferon, is an important treatment option, particularly in patients with HBV e antigen-negative infections in whom it is more effective than lamivudine at causing sustained decreases in virus and hepatic enzyme levels and occasional loss of HBsAg following treatment discontinuation (118).

Because of the difficulty in eradicating HBV, the goals of therapy are to substantially reduce HBV DNA levels, clear HB e antigen when it is present, and decrease hepatic inflammation. Serum HBV DNA levels are the best marker of HBV activity and the risk of clinical progression (111, 129). Much of the literature is based on assays with various sensitivities and dynamic ranges, but there has been a trend towards the use of assays with greater sensitivities. Whereas the initial assays had sensitivities of about 10^4 to 10^5 copies/ml, more recent assays have sensitivities of about 10^2 copies/ml (111).

Clinical HBV resistance is usually defined as the failure to achieve a 1.0 $\log_{10}$ decrease in the level of HBV DNA in serum by 3 months (primary failure) or as an increase in HBV DNA levels of 1.0 $\log_{10}$ compared with the viral load nadir (secondary failure). HBV susceptibility testing is difficult because of the absence of cell culture systems that allow efficient virus infection in vitro. In research settings, assessment of the phenotypic impact of genotypic changes has relied on the PCR-mediated transfer of HBV genome cassettes and on site-directed mutagenesis within replication-competent laboratory strains (45, 199). In clinical settings, the cause of resistance is assessed genotypically by directly sequencing the HBV polymerase gene or by using a point mutation assay for known drug resistance mutations (111, 112).

HBV Polymerase and Nucleoside Analog Resistance

The three-dimensional structure of HBV polymerase has not been solved because of difficulty in obtaining sufficient amounts of highly purified active protein. However, homology modeling using other polymerases, including HIV-1 RT, has provided insight into the roles of many of its residues (8, 38). These models have shown that HBV polymerase shares regions similar to the finger, palm, and thumb configuration in HIV-1, as well as seven domains that are conserved among many published polymerase enzyme sequences. In 2001, a standardized numbering system for polymerase mutations was established for the RT part of the HBV *pol* gene (171).

High-level (increased by >1,000 fold) lamivudine resistance is caused by mutations M204V/I, which are in the YMDD motif, characteristic of all RTs and analogous to the site of HIV-1 lamivudine resistance (3, 60, 110, 171, 177).

Although M204I can be detected in isolation, M204V is always accompanied by the compensatory mutations L180M and/or V173L (3, 41, 110, 138). M204V/I and V173L, but not L180M, result in HBsAg coding changes of unknown significance.

M204V/I and their accompanying mutations cause high-level cross-resistance to emtricitabine and the investigational inhibitor telbivudine but do not appear to reduce susceptibility to the acyclic nucleotides, adefovir and tenofovir (198), and both drugs retain activity in treating persons with lamivudine-resistant viruses (11, 43, 144, 146, 148, 180, 191). M204V and L180V together cause partially decreased (≥30 fold) susceptibility to entecavir (198). Nonetheless, entecavir retains significant in vitro and clinical activity against lamivudine-resistant viruses (22, 105, 163, 176). In treating lamivudine-resistant virus infections, entecavir reduces HBV levels by about 4 to 5 logs, often enough to completely suppress virus replication but less than the usual 6- to 7-log reduction observed in previously untreated persons receiving entecavir.

M204V/I occur in viruses in 15 to 30% of patients treated with lamivudine for 1 year, 40 to 50% of those treated for 3 years, and 70% of those treated for 5 years (56, 95, 96, 118). The risk of drug resistance and subsequent virological breakthrough is associated with baseline HBV DNA levels, baseline hepatic enzyme elevations, high body mass index, and duration of detectable viremia (95, 201). The risk of resistance may also depend on the number of available uninfected hepatocytes and may therefore increase post-liver transplantation (111, 145, 147). Although viruses with M204V/I replicate less well than wild-type viruses, nearly all studies suggest that this mutation is clinically significant and that a new anti-HBV drug should be substituted for lamivudine in persons with elevated hepatic enzymes or in persons who are immunocompromised (23, 42, 56, 106, 111).

Adefovir resistance emerges more slowly than lamivudine resistance, occurring in viruses in 5 to 20% of persons after 2 years of therapy (55, 75, 76, 117, 190). Two mutations, N236T (4, 75, 183) and A181V (75), both near the polymerase active site, reduce adefovir susceptibility. Although the levels of susceptibility reduction associated with these mutations, 3- to 10-fold, are much lower than the levels associated with M204V/I and lamivudine resistance, these reductions are associated with virological breakthrough (4, 54, 183, 198). The N236T mutation confers cross-resistance to tenofovir but not to lamivudine, emtricitabine, entecavir, and telbivudine (199). N236T reduces viral replication levels in vitro (199). The effect of A181V on other drugs has not been described. N236T and A181V do not cause substitutions in the envelope protein. A194T has been reported in viruses from two patients developing virological rebound after receiving tenofovir for the treatment of lamivudine-resistant HBV infections, but the effect of this mutation on tenofovir susceptibility is not well defined (162).

Entecavir resistance has been reported in viruses from about 7% of persons receiving entecavir for 48 weeks for the treatment of infections with lamivudine-resistant isolates (163, 176); it has not yet been reported in viruses from persons receiving entecavir for initial therapy. In viruses from two well-described patients, clinical entecavir resistance was associated with the development of the mutations I169T-M250V and I169T-T184G-S202I in combination with the preexisting lamivudine-associated mutations (L180M-M204V/I) (176). Site-directed mutagenesis experiments confirmed the roles of these entecavir-selected mutations in causing high-level (>1,000-fold-reduced susceptibility) entecavir resistance. T184G and S202I (but not M250V) cause HBsAg coding changes of unknown significance.

Few studies of combination therapy have been published, but preliminary data suggest that combination therapy will prolong virological suppression and decrease the rate of drug resistance (174). Although no clinical benefit of combined therapy with interferon and lamivudine has been observed, the risk of lamivudine resistance has been shown to be markedly reduced in persons receiving combined therapy (118). In patients who are already infected with lamivudine-resistant isolates, it is not yet known with certainty whether it is more advantageous to substitute adefovir for lamivudine (148) or to add adefovir.

HEPATITIS C VIRUS

HCV is a positive-sense, single-stranded enveloped virus with a genome of about 9.5 kb. The six major HCV genotypes differ from one another by up to 35% of their sequences (203). Like HIV-1, HCV exists in vivo as a complex quasispecies consisting of an ensemble of viral genomes differing from one another by 1 to >5%. During the past 2 years, major advances have been made in developing robust methods for in vitro HCV replication (109, 204) and small-molecule HCV inhibitors (39).

Interferon and Ribavirin

Pegylated alpha interferon plus ribavirin for 6 to 12 months, the standard treatment for HCV, leads to sustained virological responses in about one-half of treated persons. Alpha interferon does not directly inhibit HCV; rather, it acts by inducing interferon-stimulated genes and by upregulating antiviral T-cell responses, which create an intracellular environment that is hostile to the replication of many viruses including HCV (51). A dose-response relationship exists between ribavirin and the likelihood of virus suppression (108), but the mechanism by which ribavirin acts is not known. The leading hypotheses are that ribavirin, a nucleoside analog, either interferes with deoxynucleoside triphosphate metabolism (99), directly inhibits HCV RNA polymerase (114), or increases HCV mutagenesis (36, 37), making the HCV quasispecies within an individual less able to respond to the alpha interferon challenge.

Two findings suggest that viral factors influence the response to therapy. First, HCV genotypes 2 and 3 are more likely to respond to therapy than genotype 1. Second, therapy is much more successful in persons with acute (and probably less complex quasispecies) rather than chronic infection. Several authors have proposed that certain changes in a 40-amino-acid region of HCV NS5A (sometimes referred to as an interferon sensitivity-determining region) or in other HCV proteins (e.g., the envelope 2 protein) interfere with interferon responsiveness (47, 50, 57, 65, 143, 151, 175, 196). However, no mechanism of antiviral resistance to either interferon or ribavirin has been identified with certainty.

Investigational Targeted Inhibitors

Small-molecule inhibitors of the NS3 serine protease and the NS5B RNA-dependent RNA polymerase with both in vitro and in vivo activities have been developed and are in early clinical trials (39). These inhibitors belong to three mechanistic classes: PIs, nucleoside polymerase inhibitors, and allosteric nonnucleoside polymerase inhibitors. In vitro experiments have already shown that resistance to first-generation HCV PIs emerges rapidly (107, 113, 178, 179).

Multiple nucleoside and nonnucleoside analogs have been shown to inhibit HCV polymerase in vitro (39). Nonnucleoside inhibitors that bind to three different polymerase locations have been identified (39, 127). Mutations selected for by both types of polymerase inhibitors have already been selected in vitro (127). The number of anti-HCV small-molecule inhibitors entering clinical trials as well as the number of drug resistance mutations associated with these inhibitors is expected to increase during the next several years.
